Dienes and polyenes. Compounds with more than one carbon–carbon double bond occur widely in nature and are commercially important. The chemical properties of dienes, compounds with two C=C bonds, depend on the relative positions of the double bonds. The most important class, having alternate double and single bonds, are called conjugated dienes. Other classes have isolated double bonds (separated by two or more single bonds) or cumulative double bonds as in allenes.

Conjugated dienes

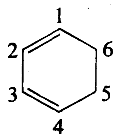
$C{=}C{-}C{=}C$	$C{=}C{-}C{-}C{=}C$	$C{=}C{=}C$
conjugated	isolated	cumulative

Nomenclature. The system for naming polyenes is the same as for alkenes, except that the positions of all double bonds must be designated by appropriate numbers. The following examples are illustrative:

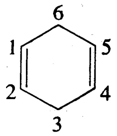
$CH_2{=}C{=}CH_2$ propadiene (allene)

$\overset{1}{C}H_2{=}\overset{2}{C}H\overset{3}{C}H{=}\overset{4}{C}H_2$ 1,3-butadiene

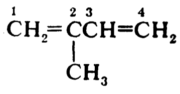
$\overset{1}{C}H_2{=}\overset{2}{C}{=}\overset{3}{C}H\overset{4}{C}H_3$ 1,2-butadiene



1,3-cyclohexadiene



1,4-cyclohexadiene



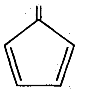
$$\overset{1}{C}H_2{=}\underset{\substack{|\\CH_3}}{\overset{2}{C}}\overset{3}{C}H{=}\overset{4}{C}H_2$$

2-methyl-1,3-butadiene (isoprene)

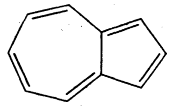
$\overset{1}{C}H_2{=}\overset{2}{C}H\overset{3}{C}H_2\overset{4}{C}H_2\overset{5}{C}H{=}\overset{6}{C}H_2$ 1,5-hexadiene

$\overset{1}{C}H_2{=}\overset{2}{C}H\overset{3}{C}H{=}\overset{4}{C}H\overset{5}{C}H{=}\overset{6}{C}H_2$ 1,3,5-hexatriene

Physical properties. The physical properties of polyenes, such as boiling point and density, are similar to those of alkanes or alkenes with an equal number of carbon atoms. The most exceptional characteristic of polyenes is the intense colour often associated with those in which the double bonds are conjugated. Some examples (with only the skeletons shown) are:



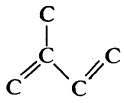
fulvene, C_6H_6 (bright yellow)



azulene, $C_{10}H_8$ (deep blue)

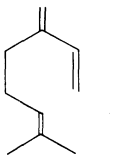
The colour depends both on the number of double bonds and on their arrangement in the molecule.

Occurrence and synthesis. A rather large number of hydrocarbons with more than one double bond occur in nature. Many of them belong to a class of compounds called isoprenoids. These substances have ten carbons or more (in multiples of five) with structures based on the linking together of isoprene units, fragments with the carbon atoms arranged as in isoprene (2-methyl-1,3-butadiene).

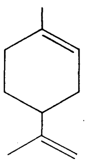


isoprene unit

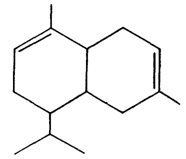
Examples of these structures, together with their common names and sources, are given below, showing only the skeleton.



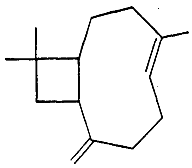
myrcene, $C_{10}H_{16}$ (bayberry)



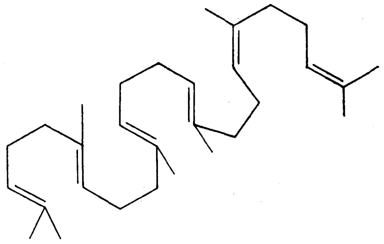
limonene, $C_{10}H_{16}$ (lemon, orange)



cadinene, $C_{15}H_{24}$ (oil of cade and of cubebs)



caryophyllene, $C_{15}H_{24}$ (oil of cloves)



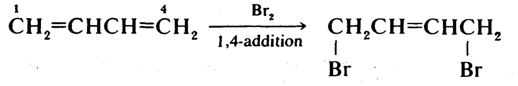
squalene, $C_{30}H_{50}$ (whale oil)

The most important commercial diene is 1,3-butadiene. It is manufactured by dehydrogenation of butenes:

$$\left.\begin{array}{l}CH_2{=}CHCH_2CH_3\\ \quad\text{and/or}\\ CH_3CH{=}CHCH_3\end{array}\right\}\xrightarrow{\text{calcium nickel phosphate, 650°}} CH_2{=}CHCH{=}CH_2 + H_2.$$

Isoprene is a product of hydrocarbon cracking, and it also can be obtained synthetically from propene, or from acetone and acetylene. Butadiene and, more recently, isoprene are used to manufacture synthetic rubber. Cyclopentadiene, a coproduct of butadiene and isoprene from cracking reactions, is the most readily available cyclic diene. Its chlorinated derivatives are used as insecticides (aldrin, dieldrin). Other dienes and polyenes can be synthesized by extensions of the reactions used to make simple alkenes.

Reactions. Dienes and polyenes undergo many of the reactions of simple alkenes. They add bromine, hydrogen, and acids; they can be converted to epoxides; and they undergo ozonolysis and polymerization. Conjugated dienes show certain special properties. In particular they show a propensity to add reagents to the ends of the conjugated system. The major product from the addition of one molecule of bromine to 1,3-butadiene, for example, is 1,4-dibromo-2-butene. The process is called 1,4-addition, in contrast to the usual addition to ordinary alkenes, which is called 1,2-addition. A double bond appears between carbons 2 and 3 in the addition product.

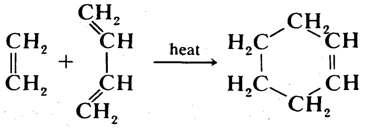


$$\overset{1}{C}H_2{=}CHCH{=}\overset{4}{C}H_2 \xrightarrow[\text{1,4-addition}]{Br_2} \underset{Br}{\underset{|}{C}}H_2CH{=}CH\underset{Br}{\underset{|}{C}}H_2$$

1,4-dibromo-2-butene

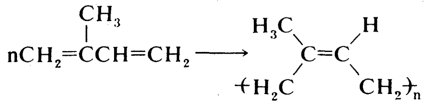
1,4-addition reactions

Conjugated dienes undergo 1,4-cycloaddition with alkenes. For example, 1,3-butadiene and ethylene give cyclohexene:



cyclohexene

The reaction is general and constitutes the most important method for making 6-membered rings. It was discovered by, and is named after, the German chemists Otto Diels and Kurt Alder (Diels–Alder reaction), who received a Nobel Prize in 1950. In the presence of certain catalysts, isoprene undergoes 1,4-polymerization to form a product indistinguishable from natural rubber, in which the isolated double bonds have the *cis* geometry.



$$nCH_2{=}\overset{CH_3}{\overset{|}{C}}CH{=}CH_2 \longrightarrow \left(\begin{array}{ccc} H_3C & & H \\ & C{=}C & \\ H_2C & & CH_2 \end{array}\right)_n$$

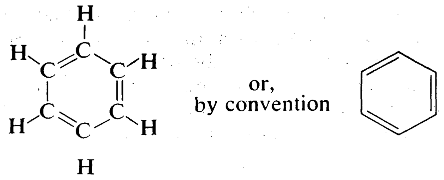
isoprene rubber

AROMATIC HYDROCARBONS

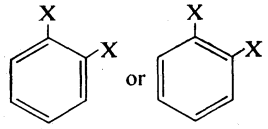
It was recognized during the first half of the 19th century that there exists a fairly large class of organic substances with distinctly different properties from the aliphatic compounds. The hydrogen–carbon ratio in the formulas of these compounds suggests unsaturation—it is often less than one, whereas in alkenes it is two, and it is even higher in alkanes. Nonetheless, these substances do not react as if they were unsaturated: they do not readily add bromine, are not easily oxidized, and mainly undergo substitution rather than addition reactions. Frequently these substances have pleasant aromas; for example, they can be obtained from the volatile oils of cloves, cinnamon, anise, wintergreen, vanilla, etc., and hence they were often called aromatic compounds. Joseph Loschmidt, an Austrian chemist, recognized in 1861 that most aromatic substances have formulas that can be derived from that of the hydrocarbon benzene, C_6H_6, by replacing one or more of the hydrogens of that substance by other atoms or groups. Following this observation the term aromatic lost its orginal, nontechnical meaning, and to the chemist came to mean any compound structurally derived from benzene. In the 1930s the concept of aromaticity was broadened considerably, and now both benzenoid and nonbenzenoid aromatic compounds are recognized. The former constitute the larger, and technically more important, class.

Origin of the term aromatic compounds

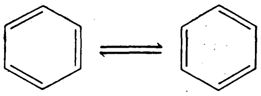
Benzenoid aromatic compounds. *Structure of benzene.* Friedrich August Kekule, the German chemist, suggested in 1865 that each carbon atom in benzene was at the corner of a regular hexagon, with one hydrogen atom attached to each carbon. To give each carbon a valence of four, Kekule inserted a conjugated system of double bonds into the ring. This formula satisfactorily explained the observation that benzene forms only one monosubstitution product (*e.g.,* one C_6H_5Cl, one C_6H_5Br, and one C_6H_5OH). All six hydrogens occupy equivalent po-



sitions in the Kekule formula. But it does not explain certain other observations; for example, benzene does not decolourize bromine rapidly at room temperature as other unsaturated molecules do. Nor does it explain why, when two adjacent hydrogens are replaced by other atoms (say X), only one compound is obtained. Kekule's formula predicts two isomers, depending on whether a double or a single bond separates the substituted carbons:

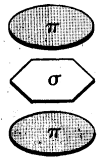


To overcome these difficulties Kekule suggested in 1872 that the positions of the double bonds were not fixed, but the two forms interconverted so rapidly that they could not be separated.



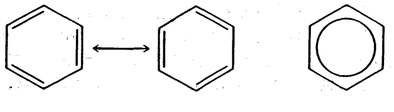
Kekule forms in equilibrium

The current view of the benzene structure differs from that of Kekule in an important conceptual way, though his formulas are still useful. Instead of two kinds of molecules in rapid equilibrium, benzene and its derivatives consist of only one kind of molecule, with a structure that can be considered a hybrid, called a resonance hybrid, of the two Kekule forms. All the carbon–carbon bonds in benzene are identical; they are neither single nor double, but of a new, hybrid type (superficially, one-and-a-half bonds). The most direct evidence for this structure comes from the molecular geometry. It has been shown that the carbon atoms in benzene are in fact at the corners of a regular hexagon, and the carbon–carbon bond distances are all identical at 1.39 Å, a value intermediate between those of the normal C—C and C═C distances (see above *Geometry of the double bond*). The hydrogen atoms of the molecule lie in the same plane as the carbons, and all angles (between carbon–hydrogens as well as between carbon–carbon bonds) are 120°. Looked at in another way, the six carbons in a benzene ring are joined by six σ bonds (six electron pairs that lie in the plane of the ring, one pair between each adjacent pair of carbon atoms); in addition, there are six π electrons (one pair for each of the three double bonds in a Kekule structure), and these lie in three π orbitals, occupying the space above and below the molecular plane. The π electrons are said to be delocalized, or spread over all six carbons.

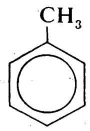


Space occupied by the
σ and π electrons in benzene

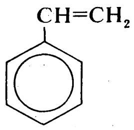
The hybrid structure of benzene is represented in various ways: one is to show a double-headed arrow between Kekule structures; another is a hexagon with a circle in the middle, to denote the delocalization of the π electrons. In the rest of this article, the latter structure is used to emphasize the delocalization of the double bonds.



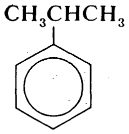
Nomenclature. Benzenoid aromatic hydrocarbons often are called arenes. Since this branch of organic chemistry developed at an early date, before aliphatic chemistry in general and before the development of systematic nomenclature, common names are used more frequently here than they are with aliphatic compounds. Some examples are:



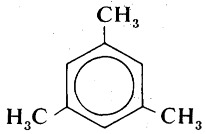
toluene
(methylbenzene)



styrene
(vinylbenzene)

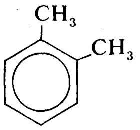


cumene
(isopropylbenzene)

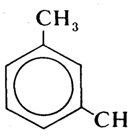


mesitylene
(1,3,5-trimethylbenzene)

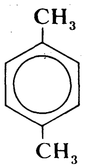
Two substituents may have three possible orientations on a benzene ring, called *ortho* (*o*), *meta* (*m*), or *para* (*p*), as illustrated with the three dimethylbenzenes, or xylenes:



o-xylene



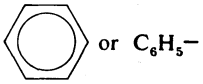
m-xylene



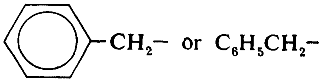
p-xylene

Two aromatic groups useful in naming compounds of this type are the phenyl and benzyl groups:

Phenyl and benzyl groups

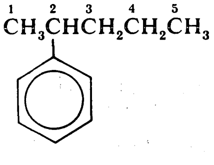


phenyl group

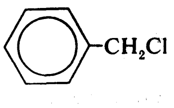


benzyl group

as in



2-phenylpentane



benzyl chloride

The benzene ring is sometimes called an aromatic nucleus, to differentiate it from a side chain or substituent that may be attached to it.

Physical properties. The smallest number of carbon atoms that an aromatic hydrocarbon can contain is six; hence none of these substances can have molecules small enough to be gases at room temperature (Table 15). Because of their symmetrical structures, benzene, *p*-xylene, durene, and hexamethylbenzene have relatively high melting points compared to those of closely related compounds that are more unsymmetrical. Toluene is used in place of mercury, which has a melting point of −38.9° C (−38° F), in low-temperature thermometers because of its low freezing point (−95° C [−139° F]) and its large coefficient of expansion (which means that large volume changes accompany small temperature changes). Aromatic hydrocarbons are better solvents for certain substances, such as lacquers, paints, and synthetic enamels, than are alkanes. Aromatic solvents need adequate ventilation, however, because even low concentrations are toxic, and prolonged exposure, especially to benzene vapours, can damage red blood cells.

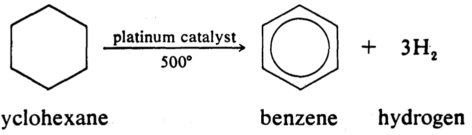
Table 15: Physical Constants of Benzene and the Methylbenzenes

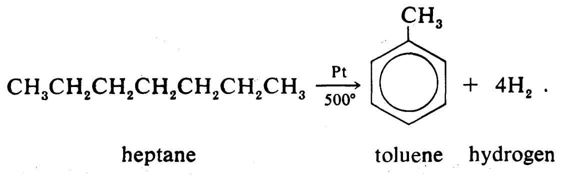
name	formula	boiling point (°C)	melting point (°C)
Benzene	C_6H_6	80.1	+5.5
Toluene	$C_6H_5CH_3$	110.6	−95
o-Xylene	1,2-$(CH_3)_2C_6H_4$	144.4	−25
m-Xylene	1,3-$(CH_3)_2C_6H_4$	139.1	−48
p-Xylene	1,4-$(CH_3)_2C_6H_4$	138.4	+13
Hemimellitene	1,2,3-$(CH_3)_3C_6H_3$	176.1	−25
Pseudocumene	1,2,4-$(CH_3)_3C_6H_3$	169.4	−44
Mesitylene	1,3,5-$(CH_3)_3C_6H_3$	164.7	−45
Prehnitene	1,2,3,4-$(CH_3)_4C_6H_2$	205	−6
Isodurene	1,2,3,5-$(CH_3)_4C_6H_2$	198	−24
Durene	1,2,4,5-$(CH_3)_4C_6H_2$	197	+80
Pentamethylbenzene	$C_6H(CH_3)_5$	232	+54
Hexamethylbenzene	$C_6(CH_3)_6$	265	+166

Source and synthesis. The chemistry of aromatic compounds was initially investigated during the last half of the 19th century, mainly in Germany and England, where illuminating gas and coke were produced by the large-scale carbonization of coal. Coal tar, a by-product of the process, contains about 25 percent by weight of aromatic hydrocarbons, together with other useful components.

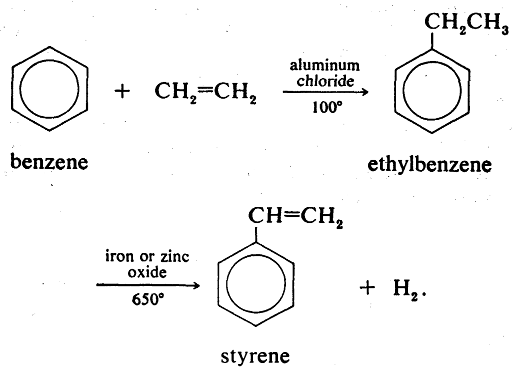
Aromatic hydrocarbons from petroleum

Currently, however, over 80 percent of aromatic hydrocarbon production is based on petroleum. Some aromatic hydrocarbons are present in crude petroleum and can be obtained directly, but most are produced by catalytic dehydrogenation of alkanes, a process called reforming:

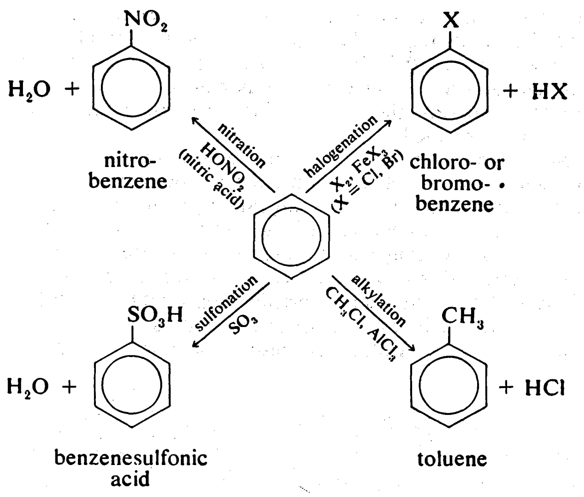




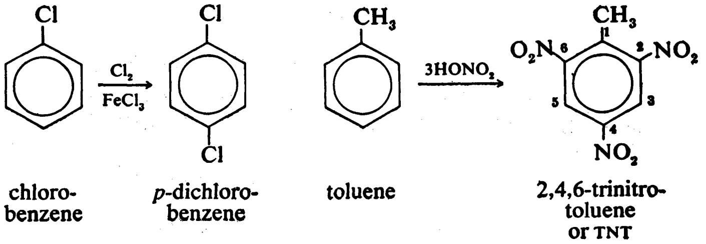
Other aromatic hydrocarbons can be obtained through synthesis, *e.g.*, ethylbenzene and styrene from benzene:



Reactions. The most characteristic reaction of aromatic hydrocarbons is substitution; *i.e.*, replacement of the aromatic hydrogens by other atoms or groups. Some of the more important substitution reactions are illustrated below:



The reaction may be repeated to replace additional hydrogens, producing di- or polysubstituted compounds, as in the chlorination of chlorobenzene and the nitration of toluene.

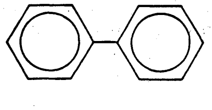


The products of these substitution reactions may be useful in their own right or as precursors of other useful materials, such as synthetic dyes, plastics, fabrics, and medicinals.

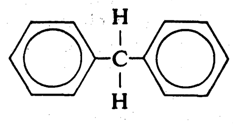
Under special conditions, aromatic hydrocarbons undergo addition reactions like those of unsaturated compounds. Thus benzene compounds can be catalytically hydrogenated to cyclohexanes, although higher temperatures and pressures are required than is the case with hydrogenation of simple alkenes. In the presence of light, benzene adds six atoms of halogens; the product from chlorine (1,2,3,4,5,6-hexachlorocyclohexane) is a widely used insecticide (Lindane).

Polycyclic aromatic hydrocarbons. Many aromatic hydrocarbons with more than one benzene ring are known. Two or more rings may be joined to one another directly through a single carbon–carbon bond, as in biphenyl, or with one or more carbon atoms between the rings, as in diphenylmethane or paracyclophanes. More important commercially are the aromatic hydrocarbons with fused or condensed rings, in which two or more carbon atoms are shared in common by several aromatic rings. Naphthalene, anthracene, phenanthrene, dibenzanthracene, and

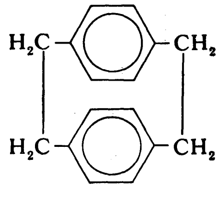
Fused ring compounds



biphenyl



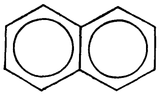
diphenylmethane



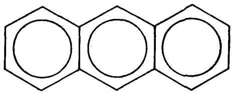
a paracyclophane

coronene are well-studied examples. As the number of fused rings increases, the carbon–hydrogen ratio also increases—from 1.0 in benzene to 2.0 in coronene. If the hexagonal network in coronene is extended indefinitely in all directions, the flat, cellular structure of graphitic carbon is obtained.

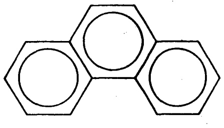
Most condensed aromatic hydrocarbons are beautifully crystalline solids. Many are present in coal tar; naphthalene is the most abundant, constituting about 10 percent of the tar, or 40 percent of the available aromatic hydrocarbons. Although most naphthalene is used to make polymeric resins and plasticizers employed in the manufacture of products made of plastics, appreciable quantities are consumed in the manufacture of dyes, insecticides, and medicinals. Anthracene, also present in coal tar, is colourless when pure; it exhibits a strong, pale-blue fluorescence when exposed to ultraviolet light. Many synthetic dyes contain the anthracene ring system. The phenanthrene ring system, especially in partially or fully hydrogenated form, is present in many natural products, such as the steroid hormones. Some fused polynuclear aromatic hydrocarbons, such as the dibenzanthracene shown, are carcinogenic—they produce skin cancers when applied locally to the skin and sarcomas (cancers of muscle, bone, or connective tissue) when injected subcutaneously in mice.



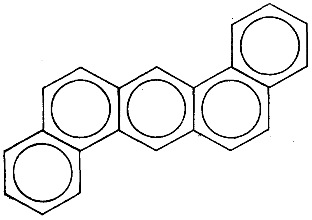
naphthalene
$C_{10}H_8$



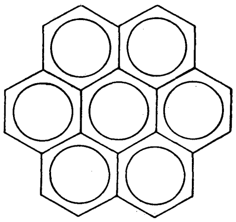
anthracene
$C_{14}H_{10}$



phenanthrene
$C_{14}H_{10}$



dibenzanthracene
$C_{22}H_{14}$

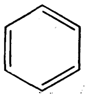


coronene
$C_{24}H_{12}$

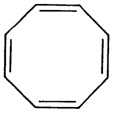
The same types of substitution reactions common with benzene also can be carried out with polynuclear compounds. Condensed ring hydrocarbons, such as naphthalene, usually react more readily than benzene does.

Nonbenzenoid aromatic compounds. Once it became clear that the aromatic properties of benzene and related compounds were due to the closed system of conjugated double bonds in the six-membered ring, it was only natural that organic chemists should attempt to synthesize both larger and smaller rings with conjugated systems of double bonds. The first targets were cyclobutadiene and cyclooctatetraene, the next lower and higher analogues of benzene. Cyclobutadiene has proved particularly elusive; most attempts to prepare it or its derivatives have failed. Cyclooctatetraene was first synthesized by Richard Willstätter, a German chemist, winner of a Nobel Prize in 1915. Although this substance is fairly stable, it does not have a planar conformation like that of benzene; rather, the molecule is tub-shaped. Cyclooctatetraene readily decolourizes bromine, undergoes addition rather than substitution reactions, and, in short, behaves like a polyene rather than an aromatic compound.

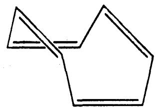
cyclobutadiene
C_4H_4



Kekule's formula of benzene
C_6H_6



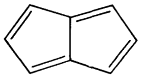
cyclooctatetraene
C_8H_8



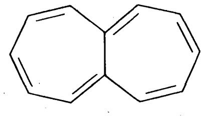
cyclooctatetraene

The Hückel rule

Some nonbenzenoid hydrocarbons with definitely aromatic properties are known, however. Erich Hückel, a German chemist, deduced theoretical reasons why cyclic, planar, conjugated systems must have $4n+2\pi$ electrons (*i.e.,* 2, 6, 10, 14 . . .) and not $4n$ π electrons (*i.e.,* 4, 8, 12 . . .), or any other number, if they are to be aromatic. Thus, cyclobutadiene, with four π electrons, and cyclooctatetraene, with eight, are not aromatic; whereas benzene, a planar molecule with six electrons, is aromatic. Other examples that conform to the Hückel rule are:

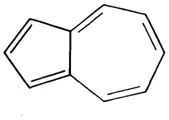


pentalene, C_8H_6
(8 π electrons, planar)



heptalene, $C_{12}H_{10}$
(12 π electrons, planar)

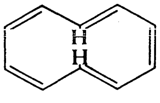
unstable, nonaromatic



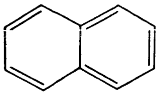
azulene $C_{10}H_8$
Kekule-type formula
(10 π electrons, planar)
stable, aromatic

Thus, azulene, a nonbenzenoid compound, isomeric with naphthalene, readily undergoes substitution reactions, a property of aromatic rather than unsaturated systems.

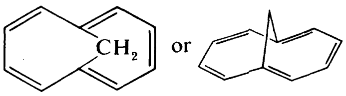
Cyclodecapentaene, with ten π electrons, also should be aromatic according to the Hückel rule. But the two hydrogens that jut into the middle of the ring make this structure difficult to synthesize. If the two hydrogens are replaced with a bond, the resulting compound is naphthalene, which of course is aromatic, but benzenoid. On the other hand, if a single carbon atom, necessarily also bearing two hydrogens, is substituted for the two hydrogens of cyclodecapentaene, the conjugated ten-π-electron system can still be nearly planar. In striking confirmation of the Hückel theory, this hydrocarbon, though nonbenzenoid, undergoes substitution reactions and has other aromatic properties.



cyclodecapentaene

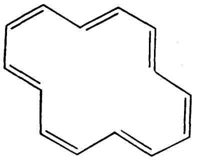


naphthalene

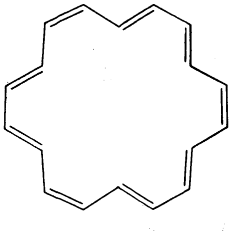


aromatic

Among the larger cyclic polyenes, called annulenes, the ones with 14 and 18 π electrons also give some evidence of being aromatic and, in accord with the Hückel rule, are more stable than those with 16 or 20 π electrons.



[14]-annulene
$C_{14}H_{14}$



[18]-annulene
$C_{18}H_{18}$

In general, it may be said of hydrocarbons that although their molecules are composed of atoms of only two elements, these atoms can be arranged in an almost infinite number of ways to give a class of organic compounds having an extraordinary variety of physical and chemical properties. (H.Ha.)

Alcohols, phenols, and ethers

The hydroxyl group

Alcohols, phenols, and ethers are organic chemical compounds—that differ from all other organic compounds in that their molecules contain at least one oxygen atom joined to a carbon atom solely by a single bond (as the connections between atoms are called). In alcohols and phenols this oxygen atom is part of a hydroxyl, or —OH, group; that is, the oxygen is joined to a hydrogen atom as well as to a carbon atom, $\equiv$C—OH. In ethers the oxygen atom is bonded to two carbon atoms, $\equiv$C—O—C$\equiv$.

Generally, the oxygen-bearing carbon atoms in alcohols, phenols, and ethers are part of hydrocarbon chains, series of carbon atoms to which hydrogen atoms are attached. Phenols differ from alcohols in that the hydrocarbons to which their oxygen atoms are joined are aromatic. Used in this sense, the word aromatic refers to certain rings of carbon atoms containing alternating single and double bonds, a system with distinctive properties.

It is instructive to compare the basic chemical structures of these compounds to the structure of the water molecule (see Table 16). Examination of these structures suggests that alcohols and phenols can be considered derivatives of water, in which a hydrocarbon chain has replaced a hydrogen atom. Experimentally, it is found that alcohols, in particular, resemble water closely, especially when the hydrocarbon group is small. In ethers, both hydrogen atoms have been replaced, and these substances do not resemble water in their behaviour at all.

Table 16: Comparison of the Structures of Water, Alcohols, Phenols, and Ethers

classification	structure*
Water	H—O—H
Alcohols	R—O—H
Phenols	Ar—O—H
Ethers	R—O—R′

*Ar = aromatic ring; R and R′ = hydrocarbon chains.

Another way of characterizing alcohols is to say that a hydroxyl (—OH) group has replaced a hydrogen atom in a hydrocarbon molecule (RH → ROH; the symbol R represents a group of atoms that remains unchanged in a reaction). The most typical alcohols are those in which a hydroxyl group is linked to a carbon atom attached to other atoms solely by single bonds. When the hydroxyl function is attached directly to an aromatic ring, as in phenols, the differences in physical and chemical properties are of such a magnitude that those compounds generally are not considered to be alcohols at all.

Alcohols are quite reactive substances chemically, and either the hydrogen of the hydroxyl group or the entire hydroxyl group can combine with or be replaced by other groups. Generally, alcohols are neutral compounds showing neither acid nor alkaline properties. Alcohols combine with inorganic compounds to form crystalline products, such as $MgCl_2 \cdot 6CH_3OH$, which are similar to common hydrate salts (inorganic compounds combined with water molecules). Primary alcohols are easily oxidized to aldehydes and to acids ($RCH_2OH \rightarrow RCHO \rightarrow RCO_2H$); secondary alcohols are oxidized to ketones ($R_2CHOH \rightarrow R_2C{=}O$); and tertiary alcohols on oxidation yield various decomposition products in which the carbon chain is broken ($R_3COH \rightarrow$ decomposition products). Alcohols generally react with carboxylic acids to produce neutral compounds called esters ($RCO_2H + R'OH \rightarrow RCO_2R' + H_2O$). Alcohols also can be converted to ethers under suitable dehydrating conditions ($2ROH \rightarrow ROR + H_2O$).

Every alcohol contains a grouping of atoms $\equiv$C—OH in which the three bonds on the carbon atom may be joined to three hydrogen atoms, three alkyl (hydrocarbon) groups, or any combination of these. Monohydric alcohols, those with single hydroxyl groups, can exist in various structural modifications. A primary alcohol contains at least two hydrogens on the carbon atom attached to the hydroxyl group; a secondary alcohol has one hydrogen on that carbon; there are no hydrogens on the hydroxyl carbon of a tertiary alcohol (see Table 17).

Table 17: Structure of Primary, Secondary, and Tertiary Alcohols

classification	examples	
	name	formula
Primary ($-CH_2OH$)	methyl alcohol	CH_3OH
Primary ($-CH_2OH$)	propyl alcohol	$CH_3CH_2CH_2OH$
Secondary ($>$CHOH)	isopropyl alcohol	$(CH_3)_2CHOH$
Tertiary ($\geq$COH)	trimethylcarbinol	$(CH_3)_3COH$

Acidic nature of phenols

Typical phenols have an acidic nature (as contrasted to alcohols and ethers, both of which are neutral, neither acidic nor basic). As acids, phenols exhibit a tendency to form salts with strong bases. Resonance structures (representations of the electronic structure of the molecule) of phenol itself and of the phenoxide ion, which is formed from phenol by loss of a proton, H^+, help explain the acidity of phenols. The resonance forms of phenol involving distribution of negative charge over the benzene ring can be produced only by a simultaneous development of positive charge on the oxygen atom. This means that separation of charges, an energy-consuming process, operates in producing these structures, and they make relatively little contribution to the overall state of the phenol molecule. With the phenoxide ion, on the other hand, no charge separation is involved; negative charge appears on all resonance structures, and those in which the charge is on the benzene ring serve to distribute charge already present. Thus, these forms make significant contributions to the structure of the ion, and it is favoured energetically over the phenol molecule. Since loss of the proton is what converts phenol to the phenoxide ion, the phenol molecule readily loses a proton or behaves in the fashion characterized as acidic.

The phenolic aromatic ring undergoes substitution reactions, such as nitration, chlorination, and sulfonation, more readily than benzene does, due to the presence of the negative charge on the ring, which serves to attract the substituting group. Because the negative charge on the ring appears only at certain locations (called the *ortho* and *para* positions: *ortho* for the ring carbon adjoining the one with the oxygen bond; *para* for the ring carbon diametrically opposite the one with the oxygen bond), it is primarily at these sites that substitution occurs. Under proper conditions, alkyl halides and olefins can react with phenols to form ethers. Esters of phenols are formed by reaction with acid chlorides or anhydrides.

Ethers are far less reactive than alcohols and phenols; they resemble hydrocarbons in that they are relatively inert at ordinary temperatures to strong bases, alkalies, and alkali metals. With strong acids, however, ethers form oxonium salts [$ROR' + HX \rightarrow (RR'OH)^+ + X^-$]. ($X^-$ stands for a negatively charged ion, such as chloride, Cl^-, or bromide, Br^-.) These react further with strong acids to produce alkyl halides and alcohols or water.

$$(RR'OH)^+X^- \xrightarrow{HX} RX + R'OH$$

$$(RR'OH)^+X^- + HX \xrightarrow{HX} RX + R'X + H_2O$$

ALCOHOLS

Nomenclature. The word alcohol is derived from the Arabic *kuḥl* (also *kohl* or *kohol*). It originally was used to mean a "very fine powder" but gradually came to connote "essence." Later the term was applied to wine spirits, which were referred to as *alcool vini,* and eventually simply alcohol.

A heterogeneous system of nomenclature has evolved for

Multiplicities of names

mono-, di-, and polyhydric alcohols, and the more important members have two or more common names. Ethanol, for example, is known as ethyl alcohol, grain alcohol, and spirits of wine. The first system of nomenclature for alcohols, which was based on the use of the term "carbinol" for methanol, was originated by a 19th-century German chemist, Hermann Kolbe. In this system, all alcohols are named as derivatives of carbinol, the various substituents being named first. Many secondary and tertiary alcohols are readily named by this system, as are aromatic and heterocyclic derivatives. Carbinol nomenclature is gradually fading out of usage, however.

The presently accepted systematic nomenclature for alcohols was adopted at a meeting of the International Union of Pure and Applied Chemistry (IUPAC), in Paris in 1957. According to the IUPAC system, the name of the alcohol is derived from the name of the parent hydrocarbon (which corresponds to the longest straight chain in the molecule incorporating the alcohol function). The final "-e" of the hydrocarbon name is replaced by "-ol" (or is followed by "-diol," "-triol," etc., for increasing numbers of alcohol functions). An arabic number before the name gives the position in the chain of the hydroxyl group, with the numbering beginning at the end of the chain that gives the hydroxyl the smallest number; *e.g.*, 2-butanol for $CH_3CH_2CHOHCH_3$. For unsaturated alcohols, the position of the hydroxyl group is given by a number before "-ol" and the number indicating the position of the double bond appears first, as 2-buten-1-ol for $CH_3CH{=}CHCH_2OH$. Certain other functional groups in the molecule, such as the carboxyl group, take precedence over the hydroxyl group in naming molecules and are given the terminal position; the prefix "hydroxy-" is used to denote the hydroxyl group. For example, 2-hydroxypropanoic acid is the systematic name for lactic acid, $CH_3CHOHCOOH$.

A frequent practice in forming common names is to indicate straight chains with a prefix "*n*-" (for normal) and certain branched chains with the prefix "iso-." The latter prefix is usually associated with those compounds containing a terminal $-CH(CH_3)_2$ group and no other branching. This prefix specifically applies to isopropyl, isobutyl, and isoamyl alcohol, but it is occasionally used in a more general sense to indicate any branched-chain structure.

Confusingly enough, the various alcohol nomenclature systems are in more or less simultaneous use. Generally, however, conversions from one form to another are made without difficulty (see Table 18).

Compounds containing two or more hydroxyl groups on separate carbons are named systematically according to the IUPAC rules as polyols, with separate numbers indicating the position of each hydroxyl. These compounds are also given common names, the diols being called glycols and the triols glycerols. Among the higher polyols are pentitols and hexitols.

Solubilities

General physical properties. Typical alcohols are colourless liquids or solids. Normal primary alcohols containing fewer than 12 carbon atoms are liquid at room temperature, whereas those with 12 or more carbons are solid at room temperature. Polyhydric alcohols usually are syrups; alcohols with complex arrangements of carbon atoms, such as the sterols (like cholesterol, which has 27 carbon atoms in its molecule), generally are solids. Lower alcohols, with up to three carbons in their molecules, are soluble in water, and all monohydroxy alcohols are soluble in organic solvents. The water solubility of alcohols decreases as the molecular weight rises, because the structure becomes relatively more hydrocarbon in nature. Conversely, the boiling points, vapour pressures, densities, and viscosities of alcohols increase with higher molecular weight. Adding hydroxyl groups to an alcohol without increasing the number of carbon atoms increases the solubility in water and decreases the solubility in ether and ethanol; at the same time the melting point, boiling point, density, and viscosity are increased. Hydrogen bonding—that is, secondary attractive forces between hydroxyl groups in adjacent molecules—is the main reason the alcohols have higher melting and boiling points than the corresponding hydrocarbons.

Additional hydroxyl groups in an alcohol enhance its sweetness. For example, ethanol, C_2H_5OH, is not sweet; propylene glycol, $C_3H_6(OH)_2$, is slightly sweet; glycerol, $C_3H_5(OH)_3$, is quite sweet; and mannitol, $C_6H_8(OH)_6$, is so sweet that it is known as a sugar alcohol. Lower alcohols have characteristic odours; alcohols with 8 to 12 carbons have roselike or lilylike odours, which find use in perfumes. The higher alcohols (with more than 12 carbons) are practically odourless. Physical properties of some common alcohols are shown in Table 19.

Occurrence in essential oils

Occurrence and preparation. Alcohols in free form are not a common occurrence in nature; they are found mainly in the essential or volatile oils obtained from the flowers, leaves, and stems of plants. Chiefly, these are a group of monohydric primary alcohols with carbon chains of 7 to 12 atoms. Their characteristic odours make them valuable ingredients for perfumes. More complex alcohols with branched structures and unsaturated linkages, such as citronellol and geraniol, both 10-carbon alcohols, are found in rose and geranium oils and are isolated from citronella oil. The fatty alcohols (primary alcohols with long, straight carbon chains), cinnamic alcohol ($C_6H_5CH{=}CHCH_2OH$), phenylpropyl alcohol ($C_6H_5CHOHC_2H_5$), and menthol and terpineol (cyclic 10-carbon alcohols) are other alcohols that occur naturally. Several sugar alcohols, containing, respectively, four and five hydroxyl groups on as many carbon atoms, are found in mosses, lichens, and yeasts. Sorbitol, a six-carbon, six-hydroxyl alcohol, occurs widely in fruits, berries, algae, and red seaweed. Mannitol, an isomer of sorbitol, is a major component of the exudate of plane, olive, and manna ash trees, and is found in pumpkin, grasses, mushrooms, marine algae, and brown seaweed. Sterols, such as cholesterol, are present in both the animal and vegetable kingdoms. They are found, for example, in bile, gallstones, brains, blood, egg yolk, and many plant products.

In nature, alcohols are many times more prevalent in combined form than as the free compounds. Fats, for instance, are esters of the trihydric alcohol, glycerol; and certain waxes and oils are esters of fatty alcohols. Many sterols occur in nature in esterified form.

Destructive distillation

Destructive distillation of hardwood was a common process in the early 1900s for producing wood alcohol as well as charcoal, acetic acid, and acetone. The major constituent of wood alcohol is methanol. It is quite difficult to purify this distillate to obtain the pure alcohol, however, so synthetic production has largely supplanted destructive distillation as the chief method used to make high-purity methanol in large quantities for industry.

Carbohydrates (sugar derivatives, such as starch) are a major group of natural compounds that can be made to yield ethyl alcohol by the biological process of fermentation. Before fermentation is begun, grain is cooked to form a starch mass; this mixture is cooled, and malt is then added to supply the enzymes that hydrolyze starch to fermentable sugar. Molasses also can be used as a starting material for fermentation. It contains enough sugar that

Table 18: Examples of Alcohol Nomenclature

formula	parent hydrocarbon	common name	carbinol name	IUPAC name*
CH_3OH	methane	methyl alcohol	carbinol	methanol
CH_3CH_2OH	ethane	ethyl alcohol	methylcarbinol	ethanol
$CH_3CHOHCH_3$	propane	isopropyl alcohol	dimethylcarbinol	2-propanol
$CH_3CH=CHCH_2OH$	2-butene	crotyl alcohol	propenylcarbinol	2-buten-1-ol
$(CH_3)_3COH$	2-methylpropane	*tert*-butyl alcohol	trimethylcarbinol	2-methyl-2-propanol

Table 19: Physical Properties of Alcohols

IUPAC name*	common name	no. of carbon atoms	formula	melting point (°C)	boiling point (°C)	density (d_4^{20})
Methanol	methyl alcohol	1	CH_3OH	−93.9	64.96	0.7914
Ethanol	ethyl alcohol	2	CH_3CH_2OH	−117.3	78.5	0.7893
1-Propanol	*n*-propyl alcohol	3	$CH_3CH_2CH_2OH$	−126.5	97.4	0.8035
2-Propanol	isopropyl alcohol	3	$(CH_3)_2CHOH$	−89.5	82.4	0.7855
2-Propen-1-ol	allyl alcohol	3	$CH_2=CHCH_2OH$	−129	97	0.8540
1-Butanol	*n*-butyl alcohol	4	$CH_3(CH_2)_2CH_2OH$	−89.53	117.25	0.8098
1-Pentanol	*n*-amyl alcohol	5	$CH_3(CH_2)_3CH_2OH$	−79	138.0	0.8144
1-Dodecanol	lauryl alcohol	12	$CH_3(CH_2)_{10}CH_2OH$	26	259	0.8309^{24}
1-Octadecanol	stearyl alcohol	18	$CH_3(CH_2)_{16}CH_2OH$	59.4	332	0.8124^{59}
9-Octadecen-1-ol	oleyl alcohol	18	$CH_3(CH_2)_7CH=CH(CH_2)_7CH_2OH$	6–7	334	0.8489
1,2-Ethanediol	glycol	2	CH_2OHCH_2OH	−11.5	198	1.1088
1,2,3-Propanetriol	glycerol	3	$CH_2OHCHOHCH_2OH$	20	290	1.2613
Phenylmethanol	benzyl alcohol	7	$C_6H_5CH_2OH$	−15.3	205.35	1.0419

*Name approved by the International Union of Pure and Applied Chemistry.

it can be fermented without preliminary hydrolysis. In either case, yeast is added to bring about the fermentation; enzymes present in the yeast convert the sugars in the natural material to ethyl alcohol and carbon dioxide.

Fermentation

The fermentation process also may be used to produce other alcohols; *n*-butyl alcohol, for example, has been obtained from sterilized molasses by fermentation with a pure culture of bacteria (a species of *Clostridium*). Treatment of glycerol with certain other bacteria yields 1,3-propanediol, as well as *n*-butyl alcohol. Fusel oil, a mixture of impurities that occurs in fermentation ethanol, contains *n*-propyl, isobutyl, isoamyl, and active amyl alcohol (the *d*-isomer of this secondary alcohol). In Europe, glycerol has been produced as a by-product of the alcohol fermentation of sugar. The substance 2,3-butanediol is an example of a glycol obtained from sugar, molasses, or wheat mash by fermentation. Because of their occurrence in nature, many alcohols can be obtained from natural products by purely physical means such as distillation or, as indicated above, they can be liberated from complex chemical structures by means of enzymes, heat, or hydrolysis.

Synthetic production. Specific alcohols, such as ethanol, methanol, and glycerol, are consumed in enormous amounts for literally thousands of applications. Generally, the alcohols produced from natural sources are expensive, difficult to purify, and somewhat unpredictable in their availability. Therefore, in order to meet the demands of industry for alcohols of many descriptions in pure form and at low cost, producers have had to develop special processes that form alcohols from readily available raw materials under carefully controlled conditions.

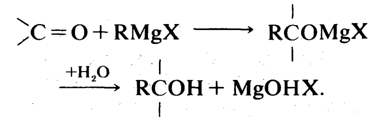
Aldol condensation. Aldehydes or ketones with a hydrogen atom on the carbon adjacent to the carbonyl group can be condensed to *β*-hydroxy aldehydes or ketones, respectively. Dehydration followed by catalytic hydrogenation then produces the alcohol; for example, acetaldehyde undergoes self-condensation to give, after dehydration, crotonaldehyde. This product then can be reduced to the alcohol 1-butanol.

$$\underset{\text{acetaldehyde}}{2CH_3CHO} \longrightarrow \underset{\text{condensation product}}{CH_3CHOHCH_2CHO}$$

$$\underset{\text{condensation product}}{CH_3CHOHCH_2CHO} \xrightarrow[-H_2O]{\text{acid}} \underset{\text{crotonaldehyde}}{CH_3CH=CHCHO}$$

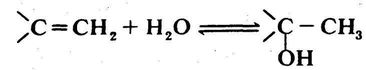
$$\xrightarrow[2H_2]{\text{reduction}} \underset{\text{1-butanol}}{CH_3(CH_2)_2CH_2OH}$$

The Grignard reaction. The Grignard reaction involves addition of an alkyl (or aryl) magnesium halide to an aldehyde, ketone, ester, or epoxide. Hydrolysis of the product produces an alcohol. In generalized terms, reaction of an alkylmagnesium halide with a carbonyl compound is as follows:



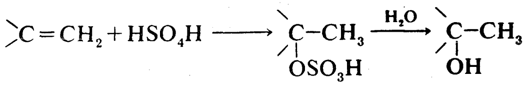
$$\rangle C=O + RMgX \longrightarrow R\overset{|}{\underset{|}{C}}OMgX \xrightarrow{+H_2O} R\overset{|}{\underset{|}{C}}OH + MgOHX.$$

Hydration of olefins (alkenes). A hydration process (addition of water to a double bond) is used industrially to produce ethanol directly from ethylene. The reaction is a general one and may be written as follows:



$$\rangle C=CH_2 + H_2O \rightleftharpoons \rangle\underset{OH}{C}-CH_3.$$

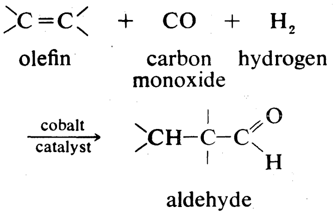
Indirect hydration may be carried out by adding the olefin to sulfuric acid, with subsequent hydrolysis of the intermediate alkyl sulfate.



$$\rangle C=CH_2 + HSO_4H \longrightarrow \rangle\underset{OSO_3H}{C}-CH_3 \xrightarrow{H_2O} \rangle\underset{OH}{C}-CH_3$$

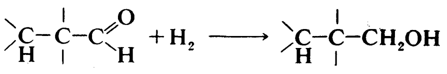
Secondary and tertiary alcohols may be produced in this manner.

Hydroformylation of olefins. Lower-molecular-weight olefins react with carbon monoxide and hydrogen in the presence of a catalyst in a reaction called hydroformylation or the oxo reaction.



$$\underset{\text{olefin}}{\rangle C=C\langle} + \underset{\text{carbon monoxide}}{CO} + \underset{\text{hydrogen}}{H_2} \xrightarrow[\text{catalyst}]{\text{cobalt}} \underset{\text{aldehyde}}{\rangle CH-\overset{|}{\underset{|}{C}}-C\genfrac{}{}{0pt}{}{\diagup\!\!\diagup O}{\diagdown H}}$$

The resulting aldehyde is subsequently hydrogenated to form an alcohol.



$$\rangle\underset{H}{C}-\overset{|}{\underset{|}{C}}-C\genfrac{}{}{0pt}{}{\diagup\!\!\diagup O}{\diagdown H} + H_2 \longrightarrow \rangle\underset{H}{C}-\overset{|}{\underset{|}{C}}-CH_2OH$$

Hydrolysis of halides and sulfates. Alkyl halides and sulfates readily undergo alkaline hydrolysis to yield alcohols.

$$RX + HOH \xrightarrow{\text{alkali}} ROH + HX$$

This general procedure produces primary and secondary alcohols. Glycerol can be synthesized from propylene by a series of reactions including hydrolysis of a halide as one step in the process. Unsaturated alcohols can be prepared by high-temperature chlorination followed by hydrolysis of the intermediate halide of an alkene. An example is the production of allyl alcohol from propylene.

$$CH_2{=}CHCH_3 + Cl_2 \longrightarrow CH_2{=}CHCH_2Cl + HCl$$

propylene chlorine allyl chloride hydrogen chloride

$$CH_2{=}CHCH_2Cl + NaOH$$

allyl chloride sodium hydroxide

$$\longrightarrow CH_2{=}CHCH_2OH + NaCl$$

allyl alcohol sodium chloride

Hydrolysis of organic esters. The hydrolysis of esters, which is catalyzed by acids and bases, at one time was of considerable importance in producing alcohols from natural esters. While not practiced commercially in the United States, it is employed in Europe and Japan.

$$R'COOR + HOH \longrightarrow R'COOH + ROH$$

Oxidation of hydrocarbons. Saturated hydrocarbons can be oxidized to alcohols in air by the use of high temperatures (260°–370° C [500°–698° F]), moderate pressures (15–50 atmospheres), and short periods of contact of the hydrocarbon with a catalyst.

Pyrolysis of fatty acids. In one particular instance the sodium salt of a hydroxyl-substituted, unsaturated fatty acid (ricinoleic acid) on pyrolysis gives an alcohol (2-octanol) among the products.

$$CH_3(CH_2)_5CHOHCH_2CH{=}CH(CH_2)_7COONa$$

$$\xrightarrow[\Delta]{NaOH} CH_3(CH_2)_5CHOHCH_3 + NaOOC(CH_2)_8COONa$$

2-octanol sodium sebacate

Reduction of carbonyl compounds. At high temperatures and pressures carbonyl compounds can be reduced in the presence of complex catalysts.

$$\rangle C{=}O + H_2 \longrightarrow \rangle CHOH$$

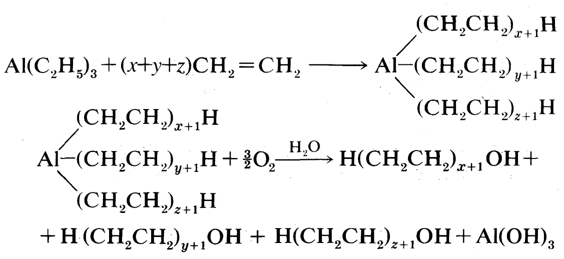
The largest application of this reaction is the production of methanol from carbon monoxide:

$$CO + 2H_2 \longrightarrow CH_3OH.$$

As carbonyl compounds, esters are reduced by alkali metals in alcohol or, in a more modern technique, by high-pressure hydrogenation over a copper oxide–chromium oxide catalyst. The process is used industrially to produce fatty alcohols from the esters of fatty acids.

$$RCOOR' + 2H_2 \longrightarrow RCH_2OH + R'OH$$

Catalytic polymerization of olefins. Since about 1955 straight-chain primary alcohols have been prepared in the petroleum industry from ethylene with the use of triethyl aluminum (Ziegler) catalysts. The course of the reaction is as follows:



$$Al(C_2H_5)_3 + (x+y+z)CH_2{=}CH_2 \longrightarrow Al\begin{cases}(CH_2CH_2)_{x+1}H\\(CH_2CH_2)_{y+1}H\\(CH_2CH_2)_{z+1}H\end{cases}$$

$$Al\begin{cases}(CH_2CH_2)_{x+1}H\\(CH_2CH_2)_{y+1}H\\(CH_2CH_2)_{z+1}H\end{cases} + \tfrac{3}{2}O_2 \xrightarrow{H_2O} H(CH_2CH_2)_{x+1}OH + H(CH_2CH_2)_{y+1}OH + H(CH_2CH_2)_{z+1}OH + Al(OH)_3$$

Principal chemical reactions. In general, the chemical reactions undergone by alcohols are essentially related to the hydroxyl groups and their position in the molecule. The nature of the hydrocarbon radical and the presence of other functional groups, however, also exert considerable influence. Alcohols are neutral compounds that do not ionize in water. Nevertheless, when they react with alkali metals, alcohols do act as acids, and when they react with strong acids they are functioning as bases. Tertiary alcohols are the most basic of the alcohols because the alkyl groups donate electrons to the carbon to which the oxygen is attached; this process increases the electron density at the oxygen atom and makes it more attractive toward a proton (*i.e.*, more basic).

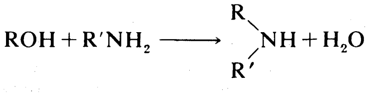
Neutrality of alcohols

Oxidation and the formation of esters and ethers (see above) are probably the most common reactions of alcohols. A number of other reactions also are encountered frequently in work with alcohols.

Ammonolysis and aminolysis. Alcohols generally react with ammonia to give amines and with amines to give further alkylation products.

$$ROH + NH_3 \longrightarrow RNH_2 + H_2O$$

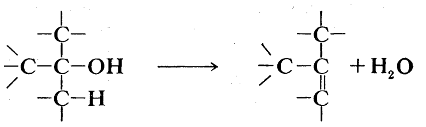
alkylamine



$$ROH + R'NH_2 \longrightarrow R(R')NH + H_2O$$

dialkylamine

Dehydration. Dehydrating agents remove water from alcohols with the production of unsaturated compounds or, if two molecules of alcohols are involved in the reaction, with formation of ethers. Tertiary alcohols tend to be dehydrated to alkenes the most easily; primary alcohols the least. For this reason, primary alcohols are converted to ethers more readily (without competition from alkene formation).



tertiary alcohol alkene

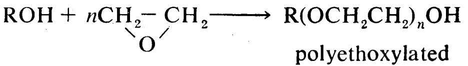
$$2ROH \longrightarrow ROR + H_2O$$

ether

Dehydrogenation. Like oxidation, dehydrogenation of primary alcohols gives aldehydes and dehydrogenation of secondary alcohols gives ketones. The high-temperature dehydrogenation of ethyl alcohol to acetaldehyde is a good example.

$$CH_3CH_2OH \xrightarrow{300° C} CH_3CHO + H_2$$

Ethoxylation. The reaction of alcohols with ethylene oxide gives polymeric products in which many units of the ethoxy group ($-CH_2CH_2O-$) are incorporated.



$$ROH + nCH_2{-}CH_2(O) \longrightarrow R(OCH_2CH_2)_nOH$$

polyethoxylated alcohol

Halogenation. Conversion of alcohols to alkyl halides can be accomplished by treatment with hydrogen halides or phosphorus trihalides.

$$ROH + HCl \longrightarrow RCl + H_2O$$

alkyl chloride water

$$3ROH + PCl_3 \longrightarrow 3RCl + P(OH)_3$$

Reaction with alkali metals. Alkali metals convert alcohols to their alkali metal alkoxides. Reaction of an alcohol with metallic sodium, for instance, produces the corresponding sodium alkoxide.

$$2ROH + 2Na \longrightarrow \underset{\text{sodium alkoxide}}{2RONa} + H_2$$

Sulfation. Treatment of alcohols with fuming sulfuric acid gives alkyl sulfates, a reaction analogous to ester formation with carboxylic acids.

$$ROH + H_2SO_4 + SO_3 \longrightarrow ROSO_3H + H_2SO_4$$

Toxicity

Biological and medical properties. With the exception of methanol, most monohydric saturated alcohols in industrial use are not hazardous as far as cumulative injury to internal organs is concerned, but some have a cumulative effect on the nervous system. The toxic effect of aliphatic alcohols on the central nervous system is a narcosis, generally increasing with the molecular weight of the alcohol. Apparently the increased effect with increasing molecular weight results from the larger hydrocarbon portion of those molecules, which favours solubility in lipids (fatty materials) of the nervous system. Physiologically, all alcohols are weaker narcotics than their parent hydrocarbons, but metabolic differences influence the degree and nature of toxicity. Ethyl alcohol, for example, is a noncumulative poison because the human body rapidly converts it to carbon dioxide and water. Methyl alcohol, by contrast, is labelled a poison because it has a slower rate of elimination and decomposes to formaldehyde and formic acid, both of which are poisonous to nervous tissue and are able to damage ocular tissues.

As the number of carbon atoms in an alcohol exceeds eight, the resultant low volatility and poor water solubility of the molecule reduces the likelihood of its ingestion or inhalation. There is a decrease of toxicity in a series of alcohols of the same number of carbon atoms in going from primary to secondary to tertiary. Unsaturation brings about a pronounced increase in toxicity, with allyl alcohol being about 30 times more toxic than *n*-propyl alcohol.

Alcohols as chemical intermediates

Industrial applications. As a group, alcohols are among the most important organic chemicals, judged by the large amounts produced. The most important industrial use of alcohols is as chemical intermediates, chiefly because alcohols can readily be converted into a large variety of other compounds by simple chemical reactions. For instance, reaction with carboxylic acids leads to fats and waxes; dehydration produces olefins and ethers; sulfonation and ethoxylation form surface active agents for use in detergents; and other syntheses yield compounds used as plasticizers, emulsifiers, lubricants, emollients, and foaming agents.

Ethyl alcohol is second in importance only to water as a solvent for drugs, lacquers, perfumes, cosmetics, detergents, and plastics. Recent applications are in aerosol and mouth-wash products, a motor fuel, and a rocket fuel.

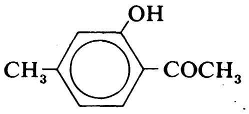
Identification and analysis. Physical methods, such as spectroscopy and chromatography, are frequently used to identify alcohols. Chemically this is done by forming a derivative that characterizes the functional hydroxyl group. An important first step is to convert the crude alcohols or more complex mixtures containing other substances to organic or inorganic esters, which can then be isolated in pure form. Additionally, if the esters are crystalline in nature with well-defined melting points, the melting points may serve for purposes of identification. Esters frequently used for the characterization of alcohols are the phthalates, benzoates, and borates. Carbamates, commonly known as urethans, are popular derivatives of primary and secondary alcohols, particularly *α*-naphthylurethan and *p*-nitrophenylurethan. Formation of complex crystalline salts with calcium chloride is another technique for isolation and purification of alcohols.

Detection of impurities

Often in analysis of an alcohol the substances of interest are the impurities rather than the alcohol itself. Hence, many analytical methods involve separation of minor components by laboratory manipulations, whereas the amount of alcohol is determined by a simple reading on an instrument. The most significant and useful determination involves the hydroxyl function; it is analyzed most frequently by acetylation, phthalation, formylation, and oxidation reactions or by the measurement of active hydrogen. Colour, odour, taste, refractive index, density, and melting and boiling points are properties that aid in identifying alcohols and their states of purity.

PHENOLS

Nomenclature. Phenol is both the specific name for monohydroxybenzene (C_6H_5OH) and the generic name for compounds containing one or more hydroxyl functions attached to an aromatic ring. As with alcohols, nomenclature has been built around trivial names, consequently such names as phenol, cresol (for methylphenols), and naphthol (for hydroxynaphthalenes) are widely used and have been adopted as part of the IUPAC rules. In systematic nomenclature for phenols with more elaborate ring systems, the name for the phenol is obtained by dropping the final "e" from the hydrocarbon name and adding "ol"; thus, the phenols formed from chrysene are termed chrysenols. Frequently, in naming phenols with many substituents, the hydroxyl group is treated as merely another substituent; in this case it is denoted by the prefix "hydroxy-" and a number to locate it on the ring as 4-methyl-2-hydroxyacetophenone for the compound.



General physical properties. Phenols are colourless liquids or white solids at room temperature. Monohydric phenols have a characteristic burning taste. The lowest member of the family, phenol, has a bland and sweetish smell, whereas higher homologues are sharp and spicy smelling. Dihydric phenols, such as resorcinol and hydroquinone, have only slight odours; and trihydric and other polyhydric phenols have essentially no odour at all. Phenols have considerably higher melting points, boiling points, and densities than the parent hydrocarbons from which they are derived (see Table 20).

Since the phenolic hydroxyl group is more strongly polarized than that of alcohols, phenols tend to form stronger hydrogen bonds than do alcohols. As a result, phenols show increased solubilities in water and higher boiling points than alcohols, and their solvency for polar organic molecules is greater. Monohydric phenols are partially soluble in water, and polyhydric phenols are much more soluble. Most phenols are readily soluble in oxygen-containing organic solvents but less so in nonpolar solvents such as the aliphatic hydrocarbons. Alkyl substitution on the benzene ring of phenols, however, enhances their solubility in nonpolar solvents.

Phenols have antiseptic and germicidal properties, which increase to a maximum as the length of an alkyl side-chain substituent reaches about six carbon atoms. The lowest member, phenol, is highly toxic and caustic, but these properties progressively diminish with the higher members of the series. Polyhydric phenols are still markedly toxic but less caustic than the monohydric compounds.

Sources of "natural" phenol

Occurrence and preparation. So-called "natural" phenol is obtained by the destructive distillation of coal or from wood tar although it also can be obtained from petroleum and from organic matter of vegetable origin. Other phenols of truly natural origin (that is, not dependent on prior chemical transformation) are found in essential oils, particularly thymol and carvacrol. Phenol itself was first obtained from coal tar in 1834 by the German chemist Friedlieb Ferdinand Runge and called carbolic acid. The French chemist Auguste Laurent in 1841 produced the pure compound from coal tar and named it phenic acid. Although coal tar represented the major source of phenol before World War I, the great use of phenol in plastics spurred the use of synthetic methods of production, with the result that by the mid-1960s over 95 percent of the phenol produced was of synthetic origin. Three general procedures are used for synthesis, each of which utilizes benzene as a starting material; the methods are: sulfonation, chlorination, and alkylation with propylene (which leads to cumene, or isopropylbenzene, as the first intermediate).

Table 20: Physical Properties of Phenols

	formula	melting point (°C)	boiling point (°C)	density (d^{20}_4)
Phenol		43	181.75	1.0576
o-Cresol		30.94	190.95	1.0273
m-Cresol		11.5	202.2	1.0336
p-Cresol		34.8	201.9	1.0178
2,3-Dimethyl-phenol		75	218	1.16
Pyrocatechol		105	245*	1.1493 (21°)
Resorcinol		111	280	1.2717
Hydroqui-none		173–174	285–287	1.328 (15°)
Pyrogallol		133	309	1.453 (4°)
2-Naphthol		123	295	1.28

*At 750 mm Hg.

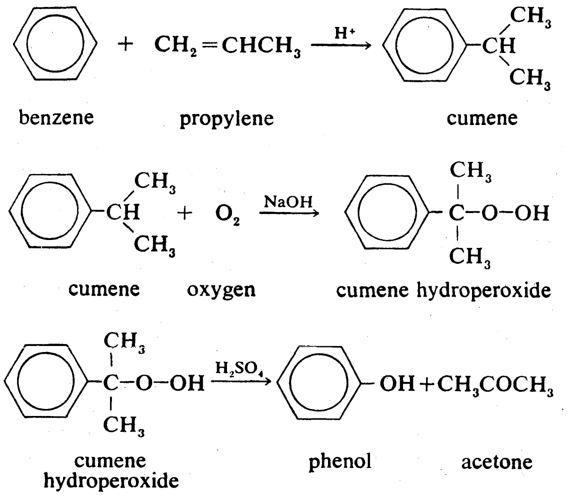
In addition to phenol itself, the cresols, xylenols, and higher phenol homologues are obtained from coal tar and other products of the destructive distillation of organic matter (usually of vegetable origin). Coal tar has been a prime source of phenols because of its extensive production in gasworks and coke-oven plants, which heat coal to produce heating gases for fuel and coke for steel manufacture. Depending on the source of the coal and the conditions used for carbonization, various complex mixtures of acidic tars are obtained along with tar bases and naphthalene. When this coal tar is distilled, a "middle oil" fraction is obtained that is rich in phenols. Further treatment with aqueous sodium hydroxide and acidification with carbon dioxide separate phenol from neutral and basic impurities and subsequent distillation yields phenol, cresols, and cresylic acids.

Phenols in free form occur in the so-called essential oils, which are derived from seeds or leaves of plants. Oils of thyme and origanum may contain from 60 percent to 80 percent of thymol or carvacrol. Thymol is also obtained in substantial quantities from Indian ajowan seed oil. Modern demand for these natural phenols has spurred synthetic processes, which are used to supplement material from natural sources. A nonvegetable source of phenols is petroleum distillates; several processes exist for isolating phenols from petroleum tars.

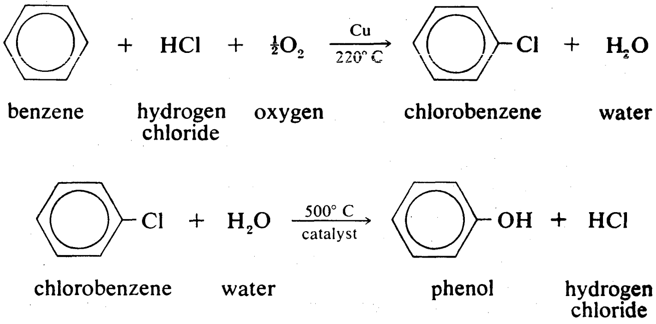
Synthetic production. The following synthetic methods are widely used to make phenol and, on a far smaller scale, certain other monohydroxybenzene derivatives.

Oxidation of cumene

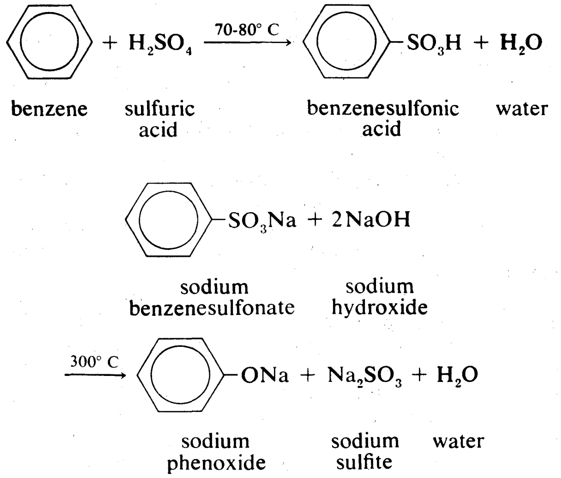
The cumene process. In the first step in this procedure, benzene is alkylated with propylene to give cumene. Cumene is then oxidized to cumene hydroperoxide by air in the presence of an alkaline catalyst, and the hydroperoxide is cleaved with an acid catalyst to phenol and acetone. This process may also be used to make cresols from toluene.



Chlorination. In a modification of the old German Raschig process, chlorination of benzene is accomplished with hydrogen chloride and oxygen. Chlorobenzene is hydrolyzed in the vapour phase over a catalyst to give phenol and regenerate hydrogen chloride.



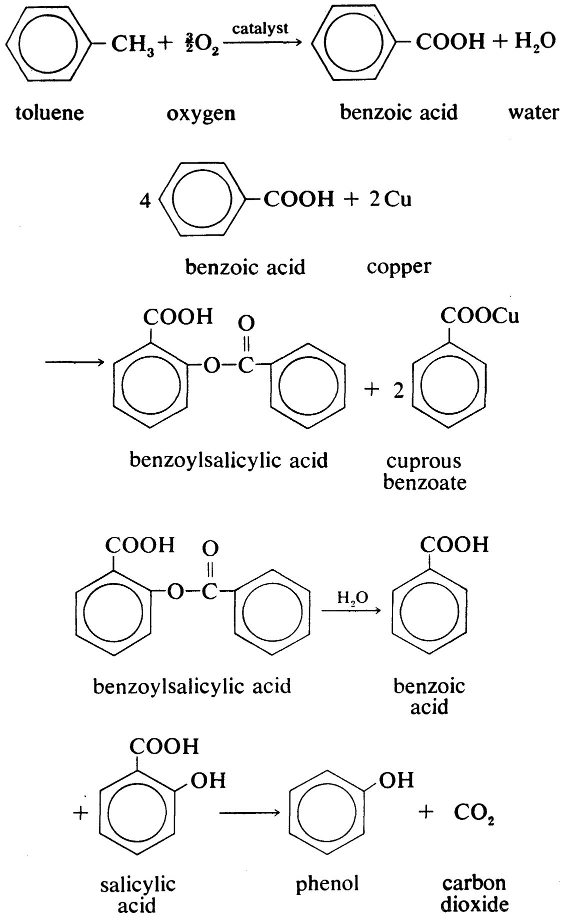
In an alternate process the intermediate chlorobenzene is purified by distillation and hydrolyzed with aqueous sodium hydroxide at high temperature and pressure. Formation of a by-product, diphenyl ether, is repressed by recycling this compound in the feed to maintain an equilibrium concentration. Sodium phenoxide is separated by



solvent extraction and acidified with hydrochloric acid to give phenol, which is purified by distillation.

Sulfonation. Benzene is sulfonated in the liquid state with sulfuric acid, and then neutralized with sodium sulfite. The resulting sodium benzenesulfonate is fused with sodium hydroxide, and the phenoxide neutralized with sulfur dioxide to phenol.

Toluene oxidation. Toluene is oxidized to benzoic acid by the use of air at 130–140° C (266–284° F) with a cobalt salt catalyst. The second step employs air, steam, and a copper–magnesium salt mixture to form an intermediate cupric benzoate, which decomposes to cuprous benzoate and benzoylsalicylic acid. Steam hydrolyzes the acid ester to benzoic and salicylic acids, and the latter compound decomposes to phenol and carbon dioxide:



Cyclohexane oxidation. Cyclohexane is oxidized with air at 130° C in the liquid phase with a cobalt naphthenate catalyst to cyclohexanol and cyclohexanone. The crude product is purified by distillation and dehydrogenated at 380° C (716° F) over a platinum catalyst. The reaction mixture is fractionated to yield phenol.

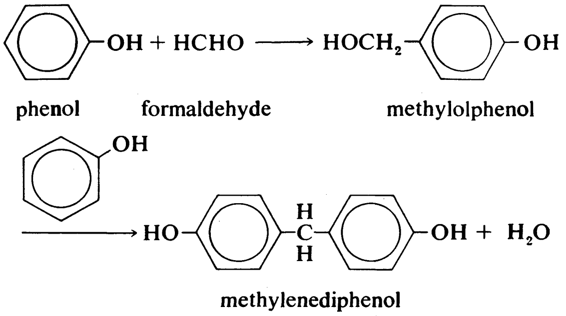
Principal chemical reactions. The chemical properties of phenols differ from those of alcohols chiefly because of the acidic character of the phenols. Because of their acidity, the phenols react with strong bases to form alkali-metal salts known as phenoxides, phenolates, or phenates. These salts are readily decomposed by acids or carbon dioxide.

Phenols alkylate more readily than their parent hydrocarbons, primarily in the *ortho* and *para* positions. Alkylation with dienes forms alkenyl phenols or cyclic compounds or both. Alkyl halides or dialkyl sulfates form phenolic ethers readily by reaction with alkali metal phenoxides. Phenol esters result from reactions of phenols with acid chlorides or anhydrides.

As a simple derivative of benzene, phenol can be readily chlorinated, nitrated, and sulfonated. It can be oxidized to give di- and trihydric phenols, derivatives of diphenols, and various decomposition products. Catalytic hydrogenation produces cyclohexanol and cyclohexane.

Phenol–formaldehyde resins

The most important reaction of phenol is its condensation with formaldehyde to form useful synthetic polymers, the phenol–formaldehyde resins, which are widely used to make articles of plastic. Under alkaline conditions, phenol reacts with formaldehyde to form methylolphenols and methylenediphenol.



Antiseptic properties

Biological and medical properties. The antiseptic activity of phenol is a property that accounts for much of its industrial utilization. In dilute solutions (of 1 to 2 percent) it also finds application as an agent for combatting itching of the skin. Undiluted phenol is highly corrosive to mucous membranes and skin, and it is considered a nerve poison. It may enter the human system by many methods, including absorption by skin, oral ingestion, and vapour inhalation. Phenol and the three cresol isomers are of about the same order of toxicity and produce identical symptoms in poisoned animals.

The lethal dose of phenol for adults has been estimated at 10 to 15 grams (0.32 to 0.48 ounces) orally and less when absorbed from body cavities or mucous membranes. Systemic toxicity of ingested phenol depends on the absolute amount consumed. Continuous exposure even to low levels may cause a chronic poisoning. A safe allowed concentration of phenol vapour in air for an eight-hour exposure is 5 parts per 1,000,000. The metabolic effects of phenol are not well known.

Industrial applications. In the 19th century, phenol was used extensively as an antiseptic, and the term "phenol coefficient" is widely used as a measure of the relative strength of disinfectants. Due to its irritating effect on humans, the use of phenol has been largely discontinued for general antisepsis. Higher-molecular-weight homologues and derivatives of phenol have supplanted phenol itself in the areas of germicidal cleaning.

World War I created a large demand for phenol as a starting material for production of a trinitro derivative, picric acid, which was used extensively as an explosive. In the 1930s the expanding plastics industry began to require large amounts of phenol for the Bakelite-type resins, and this usage expanded to the point in the 1950s where it consumed about 70 percent of total phenol production. From the 1960s onward this use fell significantly.

The chemical and pharmaceutical industries are large users of phenol for conversion to many different products. The salicylates (carboxyphenols) are starting materials for the preparation of aspirin, dyes, and flavours. Chlorophenols and their derivatives find application as fungicides, bactericides, and selective weed killers. Alkyl phenols produce an important group of synthetic detergents and are also used as oxidation inhibitors. Phenolsulfonic acid can be converted to synthetic tanning agents, and triphenyl phosphate is a plasticizer for cellulose acetate film. Large quantities of phenol are converted to cyclohexanol, which is converted eventually to nylon, and to bisphenol-A, used in the production of epoxy resins.

Identification and analysis. Natural phenol may contain small amounts of moisture, oils, tars, and naphthalene and substantial amounts of *o*-cresol; it normally assays in the range of 82 to 99 percent. Synthetic phenol, on the other hand, runs above 98 percent, with better grades assaying over 99.5 percent. The moisture content of phenol samples can be determined with a special reagent known as the Karl Fischer reagent. When a known impurity is present in phenol, depression of the freezing point provides a method of determining the amount.

Purification by means of acidity

Since phenols are weak acids, treatment with aqueous sodium hydroxide forms water-soluble phenolates, which may then be readily separated from water-insoluble compounds. Acidification regenerates phenol from the phenolate. This is a useful purification method.

Characteristic solid products result from the reaction of phenols with picric acid. The well-defined melting points of these products permit identification of the specific phenols that produce them. In the absence of other phenol compounds, a substitution reaction that yields the 2,4,6-tribromophenol can be used to determine the phenol on the basis of the amount of bromine consumed in the reaction.

Qualitative determination of phenols is readily achieved by the well-known reaction with ferric chloride, which produces highly coloured compounds with the different phenols; phenol itself and resorcinol give violet colours, cresol forms a blue colour, and catechol yields a green-coloured complex. Instrumental methods, especially gas and liquid chromatography and infrared spectrophotometry, are widely used in the detection, identification, and analysis of phenols.

ETHERS

Nomenclature. The name ether apparently was applied to diethyl ether for the first time in 1730 by F.G. Frobenius, who referred to the compound as *spiritus aethereus,* or *vini vitriolatus.* The word ether is derived from the Greek *aithēr* meaning the clear sky or air; it represents the airy or volatile nature of typical compounds of this class. As with the term phenol, ether is used both for a specific compound (diethyl ether) and as a general term; in this case, however, use of the general term in the specific sense has not been officially sanctioned and is discouraged. In common nomenclature of ethers, simple symmetrical compounds with both R groups the same are named for the parent hydrocarbon; thus, $CH_3CH_2OCH_2CH_3$ is called diethyl ether or, simply, ethyl ether. With complex ethers containing different R groups both are named, as methyl ethyl ether for $CH_3OCH_2CH_3$. Alternatively, ethers may be designated by the IUPAC system as hydrocarbon derivations; $CH_3OCH_2CH_2CH_2CH_3$, for example, is called in this system 1-methoxybutane. Trivial or unsystematic names also are used for some complex ethers, such as anisole for methyl phenyl ether ($CH_3OC_6H_5$) and phenetole for ethyl phenyl ether ($CH_3CH_2OC_6H_5$).

General physical properties. At room temperature, ethers are colourless, neutral liquids with pleasant odours. Saturated and unsaturated aliphatic ethers have densities that range from 0.7 to 0.8, whereas the densities of aromatic ethers range from 1.0 to 1.1. Compared to the corresponding alcohols, ethers are generally lower in density, less water soluble, and have lower boiling points. The boiling points of ethers tend to approximate those for hydrocarbons of the same molecular weight, from which it can be concluded that association in liquid form is not
Solubilities significant. Ethers are easily soluble in organic liquids. Dioxane, however, is unusual among ethers in that it is completely soluble in water as well. A large number of organic compounds form azeotropes (constant-distilling mixtures) with ethers. Because of these properties, ethers are extensively used for the extraction and separation of organic chemicals. Physical properties of some common ethers are shown in Table 21.

Table 21: Physical Properties of Ethers

	formula	melting point (°C)	boiling point (°C)	density (d_4^{20})
Methyl ether	$(CH_3)_2O$	−138.5	−23.0	—
Ethyl ether	$(C_2H_5)_2O$	−116.2	34.51	0.7138
Isopropyl ether	$[(CH_3)_2CH]_2O$	−85.89	68.0	0.7241
n-Butyl ether	$(n\text{-}C_4H_9)_2O$	−95.3	142.0	0.7689
Vinyl ether	$(CH_2{=}CH)_2O$	−101	28	0.773
Allyl ether	$(CH_2{=}CHCH_2)_2O$	—	94.0	0.8260
Cyclopropyl methyl ether	$\overline{CH_2CH_2C}HOCH_3$	−119	44.7	0.8100
Benzyl ether	$(C_6H_5CH_2)_2O$	3.60	298	1.0428
Diphenyl ether	$(C_6H_5)_2O$	26.84	257.93	1.0748
1,4-Dioxane		11.8	101.1	1.0353

Occurrence and synthetic production. Simple ethers are not found commonly in nature, but the ether linkage is present in such natural products as sugars, starches, and cellulose.

Dehydration. Catalytic dehydration of alcohols is the oldest and most important method of producing ethers. Sulfuric acid is the dehydration catalyst most commonly used; it remains behind when water and ether are removed by distillation.

$$ROH + H_2SO_4 \xrightarrow{\text{cold}} RHSO_4 + H_2O$$

$$RHSO_4 + ROH \xrightarrow{\text{heat}} ROR + H_2SO_4$$

Williamson ether synthesis. The reaction of alkyl halides with sodium alcoholates is generally known as the Williamson ether synthesis. Both simple and mixed ethers are made in this manner. Metallic oxides may be used in place of the alcoholate to produce symmetrical ethers.

Reaction of olefins with alcohols or phenols. In the presence of sulfuric acid, alcohols or phenols combine with olefins to produce mixed ethers.

$$(CH_3)_2C{=}CH_2 + ROH \xrightarrow{H_2SO_4} (CH_3)_3COR$$

Reaction of boron trifluoride alcoholates. Heating of boron trifluoride alcoholates under pressure yields simple ethers.

$$n\text{-}C_4H_9OH \cdot BF_3 \xrightarrow[\text{autoclave}]{\text{benzene}} \underset{\substack{\text{dibutyl}\\ \text{ether}}}{(n\text{-}C_4H_9)_2O}$$

Use of diazomethane. Methyl ethers can be made from alcohols by reaction with the methylating agent, diazomethane.

Principal chemical reactions. Ethers are relatively inert with regard to chemical reaction, and in this regard they resemble the corresponding alkanes (which carry no functional groups). Since neither alkali metals nor alkalies attack ethers at low temperatures, they may be dried over metallic sodium.

Autoxidation. In the presence of oxygen, ethers oxidize to unstable peroxides, and this reaction may create the danger of explosion in stored ethers.

Salt formation. Strong inorganic acids and Lewis acids (compounds capable of accepting electron pairs) form oxonium compounds with ethers.

Cleavage reactions. Heat decomposes ethers, especially in the presence of alumina catalysts, to form olefins and water as the principal products.

Strong acids, such as hydriodic and nitric acid, cleave one or both of the carbon–oxygen linkages to form alkyl derivatives, and, in those cases in which only one bond is cleaved, alcohols.

Complex formation. Ether is used extensively as a solvent for Grignard reagents because it forms soluble complexes with most alkylmagnesium halides. It also forms complexes with inorganic halides, boron trifluoride, lithium aluminum hydride, and lithium borohydride.

Use as an anesthetic

Biological and medical properties. Ether has a widespread use as a surgical anesthetic; it acts on the central nervous system to render the patient insensible. Administration is by inhalation, rapid absorption taking place from the lungs. Ether is not a severe skin irritant, but it may cause slight irritation when swallowed or applied rectally. Ether is rapidly excreted from the lungs; small amounts also are excreted in the urine. The compound undergoes no chemical change in the human body. Concentrations of ethyl ether of more than 400 parts per 1,000,000 in air are considered dangerous when applied by inhalation. Ingestion of more than a fluid ounce may cause death.

Isopropyl and vinyl ethers are less effective anesthetics than ethyl ether, and the isopropyl compound is 1.5 to 2.0 times more toxic than ethyl ether. *n*-Butyl ether is more toxic than isopropyl ether by inhalation but less so by oral administration. Irritation of mucous membranes by the butyl derivative is greater than by isopropyl ether.

Industrial applications. A major application of ethers is as solvents for fats, oils, waxes, perfumes, resins, dyes, gums, and hydrocarbons. Since ethers are insoluble in water, they function well as extracting agents for organic compounds in such uses as separating acetic acid from dilute solutions. The solvent properties of mixtures of ethyl ether and alcohol with respect to cellulose nitrate are enhanced, with the result that this solvent mixture is used in the manufacture of collodion films and pyroxylin plastics, both of which are based on cellulose nitrate.

Use as solvents

In the chemical laboratory and to a certain extent in the chemical industry, ethers are used as anhydrous, inert media for the preparation of organic compounds by such special reactions as the Grignard and Wurtz–Fittig reactions. By changing the alkyl group of the ether, solvents with a wide range of boiling points and densities are obtained, thereby providing materials with specific physical properties for specific uses. Special precautions to prevent fires and explosions are always necessary.

Vapours of specific ethers, such as bis(2-chloroethyl)-ether, are toxic to insects, and these substances are therefore employed as insecticides, miticides, and soil fumigants. Ethyl ether is used to denature several alcohol formulations, making the product unsuitable for human consumption. Ethyl ether also is employed as a starter for diesel engines and as an entrainment agent (a substance that carries water with it on distillation) in the dehydration of ethyl and isopropyl alcohol.

Benzyl ether is a plasticizer for cellulose nitrate and acetate, improving their properties for use as plastics. Isopropyl ether is a good solvent for antiknock compounds, and it serves as a high-octane blending agent for gasoline.

Identification and analysis. The solubility of ethers in cold concentrated sulfuric acid is used to distinguish these compounds from the paraffinic hydrocarbons and the alkyl halides. The so-called Zeisel method, which cleaves ethers with hydriodic acid, measures the methoxy and ethoxy groups when the other hydrocarbon chain of the ether is higher than ethyl and is not tertiary.

Ethyl ether is the most important member of the ether family, and many of the methods used for its analysis are applicable to other ethers.

Ethyl ether is commercially available in various specified grades: anesthetic, absolute (for use as a chemical reagent), industrial, solvent, and synthetic. Analytical methods have been developed to measure small amounts of impurities, especially peroxides. (J.A.Mo.)

Aldehydes and ketones

Industrial uses

Aldehydes and ketones are families of similar organic chemical compounds, the molecules of which contain a special grouping of atoms called the carbonyl group. Largely because of the chemical properties of this group, aldehydes and ketones have many important industrial uses. Acetone, for example, is a solvent commonly employed in vast quantities in the production of paints, lacquers, and other substances. Acetaldehyde, like many other aldehydes and ketones, is a chemical intermediate, a substance converted by chemical reactions into other compounds widely employed in the production of plastics, dyes, and pharmaceuticals. In biological systems, many important compounds, such as the sugars and certain of the steroid hormones, contain aldehyde or ketone groups.

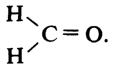
GENERAL CONSIDERATIONS AND PROPERTIES

The carbonyl group, by which aldehydes and ketones are identified, consists of a carbon atom joined by two of its four available bonds to the two available bonds of an oxygen atom, and by the remaining two bonds to other carbon or hydrogen atoms. The molecular structure of the carbonyl group is written in chemical symbols as

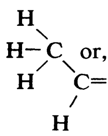
in which the letters C and O are the symbols for atoms of carbon and oxygen, respectively, and the lines represent chemical bonds between the atoms. As this partial formula indicates, the oxygen atom forms two chemical bonds (or in chemical terminology has a valence of two), and the carbon atom forms four bonds (valence, four), two of the valence bonds of carbon being utilized in forming the carbonyl bond with oxygen and two being available for joining to other atoms in the molecules of aldehydes and ketones.

Molecular structures

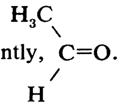
Aldehydes are distinguished from ketones in that they have at least one hydrogen atom (symbol H, valence one) joined directly to the carbon of the carbonyl group. The simplest aldehyde is formaldehyde, which is used in tanning, preserving, and embalming, and is a constituent of certain plastics. In its molecules two atoms of hydrogen are attached to the carbonyl carbon; its structural formula, therefore, is



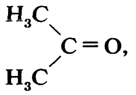
The next most complex aldehyde is acetaldehyde, in the molecule of which one carbon atom is joined to the carbonyl carbon, and the four valences of the second carbon are completed by joining three hydrogen atoms to it. The result is a molecule the structure of which can be designated by the formula



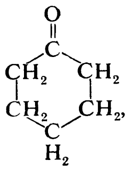
or, more conveniently,



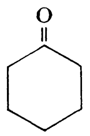
The CH_3 unit or group is called a methyl group. When two methyl groups are joined to the carbonyl carbon the result is acetone,



but acetone is a ketone, not an aldehyde, because there is no hydrogen atom attached directly to the carbonyl carbon. The compound called cyclohexanone is a cyclic ketone, its molecules consisting of a ring of six carbon atoms, one of which carries the doubly bonded oxygen of the carbonyl group. The structural formula of cyclohexanone is



or, in a notation customarily used by chemists,



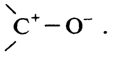
Aldehydes and ketones are so similar in their chemical and physical properties that they are generally classified together and often they are termed, collectively, carbonyl compounds, since it is the chemistry of the carbonyl group that identifies them. Each individual aldehyde or ketone has properties of its own, and all the members of both families readily undergo a wide variety of chemical reactions (a property which makes them highly suitable for use in chemical synthesis, such as the production of medicinal agents). Aldehydes generally are more chemically reactive than ketones. The simpler ones, such as formaldehyde and acetaldehyde, readily combine with themselves in repeated linkages to produce enormously long chains, containing tens of thousands of the simple molecule. Such macromolecules, known as polymers, can also be produced from the combination of aldehydes (especially formaldehyde) with other types of molecules. Many of these polymers are the familiar plastics of commerce; *e.g.,* Bakelite. Although some aldehydes and ketones occur in nature, including—in small amounts—acetone and acetaldehyde, most carbonyl compounds of commercial importance are prepared synthetically.

Function of the carbonyl group

The properties and behaviour of aldehydes and ketones are explained in large part by the nature of the carbonyl group. The addition of oxygen atoms to any element or compound is called oxidation; the removal of oxygen is called reduction. In a general definition of these reactions, oxidation means the removal of electrons from an atom or molecule, while reduction is the addition of electrons to an atom or molecule. Thus, an oxidizing agent removes electrons and, in the process of adding them to itself, becomes reduced. Similarly, a reducing agent becomes oxidized, since it donates electrons to the substance which it reduces. Actually, in many oxidation and reduction reactions, electrons are not physically removed or added but a compound is formed between the reactants. For example, if B oxidizes A some of A's electrons will also be held by B in the resulting molecule AB. An element or molecule may have more than one electron removed, either in a single oxidation process or in several steps. In the latter case, the substance will have more than one oxidation state, or number. The most completely oxidized state of the carbon atom is found in carbon dioxide, CO_2, which means that the carbon atom has all four of its valence electrons attached to the two oxygen atoms, bonding all three atoms together. The fully reduced state of carbon occurs in methane (CH_4), in which the four electrons of the hydrogen atoms are held by the carbon. The carbonyl group thus represents a partially oxidized state, and aldehydes and ketones are subject to either further oxidation or further reduction—a situation that accounts in part for their great chemical reactivity and for the wide variety of chemical reactions in which they take part.

Electronic structure of the carbonyl group. The chemical bonds that hold the nuclei of atoms together in molecular structures are the result of the motion of electrons around and between the constituent atoms. Thus, any group of atoms can be considered in terms of the electronic configuration that is associated with the bonded nuclei. Because it requires energy to disrupt any chemical bond, and because different kinds of bonds have different strengths, chemical reactions often can be predicted on the basis of known bond strengths. The electronic structure of the carbonyl group will clearly influence the physical and chemical characteristics of aldehydes and ketones. The carbonyl group may be pictured in terms of molecular orbitals that represent the "standing wave forms" of the electrons that are associated with particular bonds, in this case the carbon–oxygen double bond. The electronic structure of the carbonyl group can also be described in an alternate but chemically equivalent fashion as a resonance hybrid; *i.e.,* a combination of two structures, neither of which alone adequately depicts the molecule but which, taken together, represent its true structure. One of the resonance forms of the carbonyl group is the doubly bonded form already described:

The other is one in which a positive charge appears on the carbon atom and a negative charge on the oxygen atom:



Hybrid state

The hybrid state of the actual carbonyl group is indicated in symbols by showing both forms connected by a double-headed arrow, as

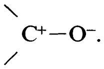
The presence of plus and minus charges in one of the resonance structures suggests that the carbonyl group is highly polar (that is, that it shows an uneven distribution of electrons that makes the oxygen electrically negative and the carbon electrically positive). In contrast to a carbon–carbon double bond

which is essentially nonpolar and weaker than should be expected from the combination of two carbon–carbon single bonds, the carbon–oxygen double bond is strongly polar, possessing more than twice the bond energy of a carbon–oxygen single bond.

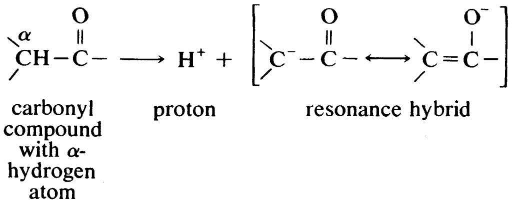
Physical properties. The polarity of the carbon–oxygen double bond is responsible for many of the physical properties of carbonyl compounds; for example, their dipole moment, which affects their behaviour in electric fields. The dipole moment of a substance is a measure of the uneven distribution of electrons that produces an asymmetry of electrical charges in the molecule. The highly polarized character of the carbonyl group introduces a certain degree of attraction between the molecules of carbonyl compounds; *i.e.,* since the oxygen of each carbonyl molecule carries more negative charge than the carbon atom, it will be attracted to the carbon end of other carbonyl molecules. This attraction in turn affects the melting points and boiling points of the compounds, both of which properties depend on the ease of separability of the molecules. Thus, the melting points of the simpler aldehydes and ketones are from 50° to 80° C (90° to 144° F) higher than those of hydrocarbons, compounds of comparable size, shape, and molecular weight but lacking these polar structural units. Although formaldehyde is a gas at ordinary temperatures, other low-molecular-weight carbonyl compounds are volatile liquids. The water solubility of simple carbonyl compounds is considerably enhanced because of the polar nature of the carbon–oxygen double bond (polar compounds generally being more water soluble than nonpolar compounds; see Table 22 for boiling points, melting points, and solubilities of common aldehydes and ketones).

Nucleophilic sources

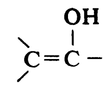
Chemical properties. The chemical properties, too, of aldehydes and ketones are largely determined by the particular electronic character of the carbonyl group. Thus, substances attracted to positive charges (called nucleophilic reagents because they contain electron-rich atoms) generally attack the carbonyl carbon, which bears a partial positive charge resulting from the contribution of the charged resonance form



Hydrogen atoms on the carbon atom immediately adjacent to the carbonyl, the so-called α-carbon, are easily removed from the molecule because the resulting negatively charged group (called an anion) is a resonance hybrid (see above) of two forms, a situation that provides extra stability to the structure.

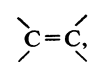


The effect of the resonance stabilization of the anion is to cause the α-hydrogen (hydrogen attached to the α-carbon) to be easily lost as a proton, that is, a transferable hydrogen nucleus represented by the symbol H^+, also called a hydrogen ion; in other words, the resonance stabilization makes the α-hydrogen acidic. A further consequence of the ease of loss of α-hydrogens is that carbonyl compounds bearing such hydrogens are easily converted to their so-called enol



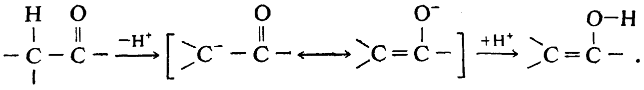
$$\overset{\text{OH}}{\overset{|}{>C=C-}}$$

forms (the name being derived from a combination of -ene, the ending for double-bond compounds,

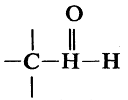


$$>C=C<,$$

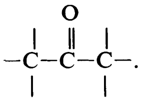
and -ol, the ending for hydroxyl compounds, —OH). The interconversion usually occurs through the resonance-stabilized anion (see above). The reaction is represented in equation form in the following manner:



Generally, aldehydes and ketones enter into a wide variety of chemical reactions involving the carbonyl group itself or the α-carbons (see below for specific examples). Aldehydes typically are more reactive than ketones, in part because the carbonyl carbon in aldehydes is more open to attacking groups because the hydrogen atom attached to it is less bulky than the carbon-containing groups attached to it in ketones, and this can be seen readily by comparing the formulas:



aldehyde



ketone

Nomenclature. The naming of organic compounds is complicated by the fact that any chain of carbon atoms may have branches or rings attached to it. When a dominant group, such as the carbonyl, is present, the basic design of the nomenclature is to chart complicated structures by reference to the dominant group. Many aldehydes and ketones are referred to by common names, and in such usage aldehydes are named by analogy with the carboxylic acids to which they are related; thus, formaldehyde from formic acid, acetaldehyde from acetic acid. Ketones, however, are commonly designated by the groups (called substituent groups) attached to the carbonyl carbon, along with the appellation ketone; *e.g.*, methyl ethyl ketone for the compound $CH_3COCH_2CH_3$, in which a methyl (CH_3) and an ethyl (C_2H_5) are the substituent groups, both being joined to the carbonyl carbon. In formal, or systematic, nomenclature of aldehydes and ketones, the longest chain carrying the carbonyl group is specified as the parent structure, and the name of the compound is derived from the name of the parent structure by use of the suffix -al if the compound is an aldehyde (propanal, CH_3CH_2CHO—common name, propionaldehyde from propionic acid) or -one if it is a ketone (propanone, CH_3COCH_3—common name, acetone). To indicate the location on the parent chain of any carbon atom, in order to specify where a substituent group may be attached, the carbon atoms are numbered, beginning with the aldehyde carbon. With the ketones, because the carbonyl atom may be anywhere in the chain, the numbering begins at that end of the chain that gives the ketone carbon the smallest possible number:

Common names and systematic names

$$\overset{4}{C}H_3\overset{3}{C}H_2\overset{2}{C}O\overset{1}{C}H_3, \text{ not } \overset{1}{C}H_3\overset{2}{C}H_2\overset{3}{C}O\overset{4}{C}H_3.$$

In common terminology, the position of substituents is indicated by Greek letters, designating the carbon immediately adjacent to the carbonyl group with the Greek letter α, the second with β, and so on. Examples of these usages are: $ClCH_2CH_2CHO$, named 3-chloropropanal, or, commonly, β-chloropropionaldehyde; and

Designation of substituents

$$CH_3\underset{\underset{CH_3}{|}}{C}HCOCH_3,$$

Table 22: Aldehydes and Ketones

carbonyl compound	common name	systematic name	C=O infrared absorption frequency (cm⁻¹)	melting point (°C)	boiling point (°C)	water solubility	industrial uses
Aliphatic aldehydes							
HCHO	formaldehyde	methanal	1743*	−92	−21	very soluble	monomer for polymers (*e.g.*, Delrin), explosives (*e.g.*, Cyclonite)
CH_3CHO	acetaldehyde	ethanal	1752*	−121	21	soluble in all proportions	synthesis of acetic acid, acetic anhydride, ethyl acetate, acrylonitrile, crotonaldehyde, 1-butanol
Cl_3CCHO	chloral	trichloroethanal	1762†	−58	98	very soluble	synthesis of DDT
Aromatic aldehydes							
C_6H_5CHO	benzaldehyde	benzaldehyde	1704†	−26	178	slightly soluble	chemical intermediate, flavouring substance
	anisaldehyde	4-methoxybenzaldehyde	1700†	0	250	slightly soluble	perfume ingredient
	vanillin	4-hydroxy-3-methoxy-benzaldehyde	1700†	77–79	285	slightly soluble	flavouring substance
Aliphatic ketones							
CH_3COCH_3	acetone	2-propanone	1742*, 1715†	−95	56	soluble in all proportions	solvent, synthesis of mesityl oxide and methyl methacrylate
$CH_3COCH_2CH(CH_3)_2$	methyl isobutyl ketone	4-methyl-2-pentanone	1720†	−85	117	slightly soluble	solvent
	cyclohexanone	cyclohexanone	1710†	−45	155	slightly soluble	synthesis of monomer for polymers (*e.g.*, Nylon-6)
Aromatic ketones							
$C_6H_5COCH_3$	acetophenone	acetophenone	1686†	21	202	insoluble	chemical intermediate, perfume ingredient
$C_6H_5COC_6H_5$	benzophenone	benzophenone	1662†	48	306	insoluble	chemical intermediate
Unsaturated aldehydes and ketones							
$C_3CH = CHCHO$	crotonaldehyde	2-butenal	1685†	−74	104–5	very soluble	synthesis of 1-butanol
$(CH_3)_2C = CHCOCH_3$	mesityl oxide	4-methyl-3-penten-2-one	1690†	−53	130	soluble	synthesis of methyl isobutyl ketone

*In vapour phase. †In solution.

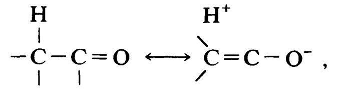
3-methyl-2-butanone or methyl isopropyl ketone. (A list of representative aldehydes and ketones of various types, with their common and systematic names, properties, and uses, is included in Table 22.)

Principal methods of synthesis. Aldehydes and ketones can be synthesized by a wide variety of methods, some being generally useful for both classes of compounds and others being more specific in their application. These methods can be generally categorized as involving: (1) oxidation with cleavage of carbon–carbon bonds, (2) oxidation without such cleavage, (3) reduction (without cleavage), and (4) formation of new carbon–carbon bonds.

PRINCIPAL CHEMICAL REACTIONS

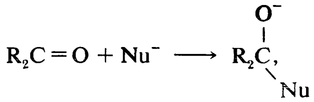
Further discussion of aldehydes and ketones requires a knowledge of electronic structure, chemical reactions, and vocabulary that cannot be provided here. The necessary background, however, can be found in detail in the articles ATOMS; CHEMICAL ELEMENTS; and CHEMICAL REACTIONS; and in the section *Organic chemical compounds.* The polarity of the carbonyl group, which reduces the electron density both at the carbonyl carbon,

and at the α-hydrogen,



Addition and displacement reactions

promotes easy reaction with nucleophilic agents (groups that attack positively charged centres) and enhances the acidity of the α-proton. Two of the characteristic reactions of aldehydes and ketones, therefore, are addition processes in which a nucleophile adds to the carbonyl carbon—



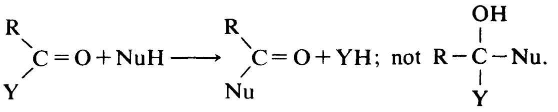
in which R is any hydrocarbon chain and Nu any nucleophilic agent—and displacement processes wherein the carbonyl compound loses an α-hydrogen and itself becomes a nucleophile—$RCH_2COR \rightleftharpoons R^-CHCOR + H^+$.

Major categories of reactions. *Addition of noncarbon nucleophiles to the carbonyl carbon.* The reactivity of nucleophiles based on atoms other than carbon (heteroatom nucleophiles) toward $R_2C{=}O$ increases according to the following sequence: halogen < oxygen < nitrogen < sulfur. Thus, the very weakly nucleophilic halide anions have virtually no tendency to become joined to aldehydes and ketones, and water molecules are added only to a few especially reactive ones. Acetone, for example, is hydrated only to a limited extent in aqueous solution, but hexafluoroacetone, strongly activated by the electron-withdrawing fluorine atoms, is almost completely converted to its hydrate under comparable conditions. Alcohols (oxygen compounds), amines (nitrogen compounds), and mercaptans (sulfur compounds), on the other hand, are added more effectively than water. The initial addition of such compounds is often followed by a dehydration step that may be either intramolecular (within the molecule) or intermolecular (between molecules). Intermolecular dehydration is observed following the acid-catalyzed addition of alcohols to ketones; the initially formed product, termed a hemiketal, reacts, via dehydration, with a second molecule of alcohol to give a second product called a ketal.

Addition of carbon nucleophiles to the carbonyl carbon. Carbon nucleophiles are especially reactive toward aldehydes and ketones, and this type of reaction forms the basis for many important synthetic methods. Among the carbon nucleophiles most frequently used for this purpose are hydrogen cyanide (HCN), Grignard reagents (RMgX, in which R is a hydrocarbon, Mg a magnesium atom, and X a halogen, usually chlorine or bromine), and other organometallic compounds, active methylene nucleophiles, including the nitroalkanes (RNO_2), and such highly polarizable substances as diazomethane (CH_2N_2) and certain ylides.

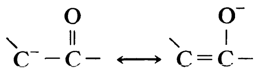
Comparison with carboxylic acid derivatives

A feature that generally differentiates aldehydes and ketones from carboxylic acid derivatives is the tendency of the latter to undergo nucleophilic displacement rather than addition; *i.e.,*



Alpha-trihalo ketones ($RCOCX_3$) and β-diketones ($RCOCH_2COR$), however, resemble carboxylic acid derivatives in this respect, the driving force for the displacement in these cases resulting from the special stability of the groups displaced, the $-CX_3$ and $-CH_2COR$ anions.

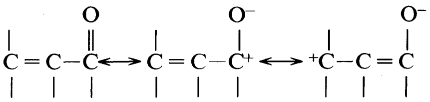
Displacement at the α-carbon. The capacity of the carbonyl group to attract and stabilize a negative charge facilitates the displacement of hydrogens attached to the α-carbon. The resulting resonance-stabilized (see above) anion



acts as a carbon nucleophile in a variety of reactions. Among others, it can react with: (1) molecular bromine, to give α-bromo compounds; (2) alkyl halides, to give α-alkylated compounds; and (3) other carbonyl compounds to give β-hydroxy compounds that may lose water to form unsaturated substances.

Conjugated systems

Conjugate addition. Electronic effects can be transmitted within organic molecules by way of conjugated systems, which are series of alternate single and double bonds between adjacent carbon atoms or between carbon atoms and atoms of other elements, such as oxygen. (Conjugated systems contain two or more directly-attached pi bonds—bonds in which the molecular orbitals are unsymmetrical around the bond axis.) Because aldehydes and ketones with a double bond between the α-carbon and the β-carbon (α–β-unsaturated carbonyl compounds) are conjugated systems, they exhibit this transmission of electronic effect. As a result, they exist as resonance hybrids (see above) in which one of the forms has a positive charge on the β-position rather than on the carbonyl carbon



$$\mathrm{C{=}C{-}\overset{O}{\overset{\|}{C}}} \longleftrightarrow \mathrm{C{=}C{-}\overset{O^-}{\overset{|}{C^+}}} \longleftrightarrow \mathrm{{}^+C{-}C{=}\overset{O^-}{\overset{|}{C}}}$$

As a result, nucleophiles may attack the β-carbon rather than the carbonyl carbon, leading to addition across the conjugated system, a process generally referred to as conjugate addition.

Oxidation–reduction reactions. Aldehydes and ketones are capable of gaining or losing electrons (*i.e.,* of undergoing, respectively, reduction or oxidation). Nucleophilic additions to aldehydes and ketones actually are examples of reduction, as is most explicitly shown when the hydride ion is the nucleophile (lithium aluminum hydride, sodium borohydride, and other metal hydrides are sources of the hydride ion) reducing aldehydes to primary alcohols ($RCHO \rightarrow RCH_2OH$) and ketones to secondary alcohols ($R_2C{=}O \rightarrow R_2CHOH$). When certain metals, such as magnesium, are used as reducing agents, the conversion of carbonyl compounds to dimeric (incorporating two molecules of the starting material) products may take place, a process called bimolecular reduction. Clemmensen reduction, one of the several methods available, employs amalgamated zinc (zinc–mercury alloys) in the presence of hydrochloric acid as the reducing medium. Another method consists of the conversion of the starting compound to a thioacetal or thioketal (sulfur-containing derivatives) followed by hydrogenolysis (cleavage with hydrogen) in the presence of a catalyst: $R_2C{=}O \rightarrow R_2C(SC_2H_5)_2 \rightarrow R_2CH_2 + 2C_2H_5SH$.

Clemmensen reduction

Aldehydes are considerably more susceptible than ketones to oxidation, since they are readily oxidized to carboxylic acids under conditions that have little effect on ketones. Under more strenuous conditions (such as heating with strong oxidizing agents), however, ketones can also be oxidized, by a process involving cleavage of carbon–carbon bonds associated with the carbonyl group. Thus, the action of hot nitric acid on cyclohexanone (see above and Table 22) cleaves the cyclohexane ring and gives the dicarboxylic acid, adipic acid, a substance used in the preparation of nylon. In the presence of strong base, an aldehyde lacking any α-hydrogen atoms (*e.g.,* HCHO, C_6H_5CHO, and R_3CCHO) undergoes a self-oxidation–reduction (the Cannizzaro reaction); treatment of benzaldehyde with strong aqueous sodium hydroxide yields a mixture of sodium benzoate, an oxidation product, and benzyl alcohol, a reduction product.

Polyfunctional aldehydes and ketones. The presence of additional functional groups within the molecule greatly influences the properties and behaviour of aldehydes and ketones. Such compounds, for example, frequently show altered infrared absorption characteristics (light absorption properties indicative of the electronic state of the carbonyl group), as shown in the Table. Conjugate addition (see above) is a direct consequence of the interaction of a carbonyl function with an α,β-unsaturated group within the molecule. Furthermore, carbonyl groups frequently are found to undergo direct chemical reaction with other functional groups within the same molecule. In many sugars, intramolecular addition of a hydroxyl group to the aldehyde or ketone function is known to occur. Glucose, for example, exists almost entirely in a cyclic, or ring, form.

Effect of one carbonyl on another

Similarly, in polycarbonyl compounds the effect of one carbonyl function upon another may frequently be observed. The enhanced reactivity of β-diketones toward substitution is a good example of such mutual influence. In some dicarbonyl compounds, an internal chemical reaction between the various portions of the molecule occurs. For example, intramolecular condensation is observed during the so-called Robinson procedure for preparing six-membered rings of carbon atoms, a method frequently employed in synthetic processes.

Synthesis with aldehydes and ketones. Because of (1) their ease of preparation by many different methods; (2) their relative stability and convenience; (3) their ability to react with protective groups, which insure their unreactivity during other chemical manipulations; and (4) their capacity for undergoing chemical reactions of almost unlimited variety, the aldehydes and ketones are nearly ideal chemical intermediates. There are, in fact, few multistep synthetic procedures that do not involve aldehydes or ketones at some stage in the process. To cite one example among many, a laboratory synthesis of longifolene—a hydrocarbon obtained from certain turpentines, involves carbonyl chemistry at nearly every stage of the process.

IDENTIFICATION AND USES

Character-ization of aldehydes

Analysis of aldehydes and ketones. Aldehydes and ketones as a group are readily characterized by their ability to form derivatives such as phenylhydrazones, oximes, and semicarbazones (see above). It was the use of phenylhydrazine to form characteristic crystalline derivatives of the sugars that permitted chemists to unravel many of the complexities of carbohydrate chemistry in the latter part of the 19th century. Characteristic, strong absorption bands in their infrared spectra (patterns of infrared light absorption) near 1720 cm^{-1} (reciprocal centimetres, a standard unit for light absorption measurements) also are useful in identifying aldehydes and ketones. Various substituents in the neighbourhood of the carbonyl group cause shifts in the absorption band that may be used to help identify the substituents. For example, as shown in the Table, aromatic and olefinic groups adjacent to the carbonyl function cause the absorption due to the carbonyl bond to move to the neighbourhood of 1680 cm^{-1}. Aldehydes are specifically characterized by their easy oxidation to carboxylic acids by such mild oxidants as silver ion (Tollens reagent) and cupric ion (Fehling reagent), neither of which has an appreciable effect on ketones. Nuclear-magnetic-resonance spectroscopy, a technique that measures the intensity of magnetic fields of atomic nuclei, also is useful in identifying aldehydes; in the spectra obtained with this technique, a characteristic band is found with aldehydes.

Physiologically active carbonyl compounds

Aldehydes and ketones of commercial, physiological, and medicinal importance. A number of aldehydes and ketones are important industrial compounds and are manufactured on a large scale, in millions of tons. These and other aldehydes and ketones (see Table 22) are useful industrially as solvents, polymer components, flavouring agents, perfume ingredients, and chemical intermediates. Many compounds with important physiological properties contain carbonyl functions. Among those possessing an aldehyde group are retinene and pyridoxal phosphate. Retinene, obtained by oxidation of vitamin A_1, combines with a protein to form a pigment called rhodopsin, or visual purple, which plays a key role in the phenomenon of human vision. Pyridoxal phosphate is a coenzyme that, in association with a variety of enzymes, catalyzes certain essential life processes. The sugars are another important class of compounds in which either an aldehyde or ketone function is present. Among the common sugars are glucose (an aldohexose) and fructose (a ketohexose). Many compounds of medicinal value contain aldehyde or ketone functions. Many natural and synthetic steroid hormones bear aldehyde or ketone groupings. Molecules of the anti-inflammatory agent cortisone have three-ketone groups, and aldosterone, a salt-retaining hormone, has two ketone groups and an aldehyde group. (C.D.G.)

Carboxylic acids and their derivatives

The carboxylic acids and their derivatives are organic chemical compounds, either prepared synthetically or found naturally in fats, vinegar, milk products, and fruit juices and flavours. They are used as solvents and in the preparation of other chemical compounds that are employed in the production of plastics, dyes, pharmaceuticals, and a large number of other products.

THE CARBOXYL GROUP

Structure

The molecules of the carboxylic acids contain a particular arrangement of carbon, oxygen, and hydrogen atoms, called a carboxyl group. It is this group that is responsible for the characteristic chemical behaviour of the carboxylic acids. In the carboxyl group, a carbon atom is joined to two oxygen atoms, one of which also is joined to a hydrogen atom. In chemical symbols, this structure of the carboxyl group is written  $-\overset{\overset{\displaystyle O}{\|}}{C}-O-H$, in which each line represents one chemical bond between the atoms. As indicated by this structure, the hydrogen atom forms only one bond (or, in chemical terminology, has a valence of 1); oxygen forms two bonds (valence, 2) and carbon four (valence, 4). In order to apportion the bonds properly, one of the oxygen atoms must be attached to the carbon by two bonds or, as it is commonly called, a double bond. The carbon atom has one unused bond left over after the carboxyl group is formed (as indicated by the line in front of the carbon symbol in the diagram above), and this bond must be used if the molecular structure is to be completed.

The simplest way that this can be done is to add a hydrogen atom, giving the simplest possible carboxylic acid, formic acid, the structure of which may be written  $H-\overset{\overset{\displaystyle O}{\|}}{C}-O-H$, or in shorter form as HCOOH or HCO_2H. Formic acid is used as a disinfectant and as an acidifying agent in textile and paper manufacturing.

Alternatively, a methyl group may be joined to the carbon of the carboxyl group to give acetic acid, with the structure  $H-\underset{\underset{\displaystyle H}{|}}{\overset{\overset{\displaystyle H}{|}}{C}}-\overset{\overset{\displaystyle O}{\|}}{C}-O-H$ or CH_3COOH. A dilute form of acetic acid is commonly known as vinegar.

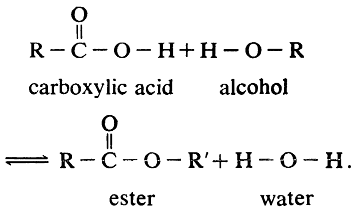
The structures of many other carboxylic acids may be made by joining other atoms to the methyl carbon in place of the hydrogen atoms. Such structures consist of chains of carbon atoms joined to one another in linear sequences, with side branches formed of other short chains and rings made when the chain doubles back and rejoins itself; each such structure represents the molecule of a different carboxylic acid. Often, for convenience, the symbol R is used to represent a general and unspecified arrangement of carbon and hydrogen atoms (a hydrocarbon unit) and the formula RCOOH is used as a general representation for all carboxylic acids.

The derivatives of the carboxylic acids all have molecular structures that contain variants of the carboxyl group. In general, these conform to the pattern $R-\overset{O}{\overset{\|}{C}}-Z$, in which R has the same meaning as above and Z is some atom other than carbon or hydrogen (*i.e.,* a heteroatom), usually oxygen, nitrogen, or a halogen (*i.e.,* one of the group of elements including fluorine, chlorine, bromine, and iodine). Often hydrogen (or other) atoms must be attached to the heteroatom to complete its valence bonds, and in these cases the Z represents a group of atoms. The carboxylic acids themselves conform to the general formula $R-\overset{O}{\overset{\|}{C}}-Z$, the Z in this case being the hydroxyl, or — OH, group.

Esters

Probably the most familiar class of carboxylic acid derivatives is the family of compounds known as esters. In esters, the heteroatom is oxygen, and a hydrocarbon unit is joined to it. In the methyl esters (the simplest of the family), the hydrocarbon unit joined to the oxygen atom is simply a methyl ($-CH_3$) group. Perhaps the most important ester of commerce is ethyl acetate, in which an ethyl ($-C_2H_5$) group is attached to the oxygen atom. Ethyl acetate is an ester of acetic acid, CH_3COOH. Its structural formula is $CH_3COOC_2H_5$. Ethyl acetate is used as a solvent, a flavouring and perfume ingredient, and a chemical intermediate (substance converted to other chemical compounds).

Esters can be formed from carboxylic acids by reaction with other organic compounds called alcohols under conditions that remove a molecule of water from the two constituents. This process is indicated in the following equation, which represents the chemical reaction that occurs:



$$\underset{\text{carboxylic acid}}{R-\overset{O}{\overset{\|}{C}}-O-H}+\underset{\text{alcohol}}{H-O-R} \rightleftharpoons \underset{\text{ester}}{R-\overset{O}{\overset{\|}{C}}-O-R'}+\underset{\text{water}}{H-O-H}.$$

In this equation, as in other chemical equations, the structural formulas of the starting materials are written to the left of the arrow and the products to the right. The double arrows indicate that the chemical reaction proceeding from left to right may be reversed, the products reacting to produce the reactants. In the structural formulas, written as above, the letters represent atoms of the various elements and the lines represent bonds between the atoms. Also, as above, R represents an unspecified hydrocarbon unit and R′ a second hydrocarbon unit, which may be the same as the first or may be different from it. As the general formula for esters, RCOOR′, suggests, this family of compounds is large, since both the R and R′ groups can be varied to include a great many kinds of hydrocarbon structures, as well as units with heteroatoms of various kinds substituted in them. Many simple esters, liquids with fruity flavours and odours, are used extensively in flavourings and perfumes. Some are naturally occurring.

Other derivatives

The other principal classes of carboxylic acid derivatives are the anhydrides, halides, peroxy acids, amides, hydrazides, and azides. The general formulas of these derivatives are given in Table 23. Each class can be considered to be formed from a carboxylic acid and a second compound by the same type of dehydration (removal of water) reaction that gives esters from carboxylic acids and alcohols. The second molecule that reacts with a carboxylic acid to give the derivative in each case is as follows: anhydride, a second molecule of carboxylic acid; halide, a halogen acid; peroxy acid, hydrogen peroxide; amide, an amine; hydrazide, hydrazine; and azide, hydrazoic acid. The preparation of the various derivatives, in actual practice, may not follow this idealized scheme since more convenient methods of synthesis have been worked out. Amides (particularly proteins) and esters are the most important carboxylic acid derivatives found in nature. Many of these derivatives, however, are synthesized for important industrial uses.

Typically, the carboxylic acids themselves are readily converted to the various classes of derivatives, and the derivatives in most cases can be converted into one another. Thus, the carboxylic acids and their derivatives comprise a family of closely related and readily interconvertible compounds. In many ways, the chemistry of each class is the chemistry of all.

THE CARBOXYLIC ACIDS AND DERIVATIVES AS A GROUP

Nomenclature. Because many of the more familiar carboxylic acids were first isolated from natural sources before the development of systematic chemical nomenclature, they are known by common names that reflect their origin. For example, it has long been known that ants secrete formic acid (Latin *formica,* "ant"), that acetic acid is present in vinegar (Latin *acetum,* "vinegar"), and that lactic acid is produced by the souring of milk (Latin *lac, lactis,* "milk"). Systematic names, which are generally preferred—except for the most common acids—because they are directly related to the chemical structure of the

Table 23: Formulas and Nomenclature of Carboxylic Acids and Their Derivatives

class	formula: $R-\overset{O}{\overset{\|}{C}}-Z$.	common name		systematic name

**E.g.,* acet-, propion-, etc. †*E.g.,* ethan-, propan-, etc. ‡Nitriles, another class of carboxylic acid derivative, may be considered to be dehydration products of amides. They have the general formula $R-C\equiv N$ and are named -onitrile.

acid, are derived from the name of the hydrocarbon with the same carbon skeleton. The name of the acid is derived by dropping the final "e" from the hydrocarbon name and replacing it with the ending "-oic acid." Thus, the name hexanoic acid is derived from that of the hydrocarbon hexane, to which it is formally related; this acid, however, usually is known by its common name, caproic acid (Latin *caper, capri,* "goat"). Systematic and common names of straight-chain saturated acids are given in Table 24.

Naming of derivatives

Methods of naming carboxylic acid derivatives vary. Suffixes or prefixes are used, or both, as indicated in Table 23, to indicate the type of derivative; the root of the acid's name gives the acid from which the compound is derived. As an example, in the naming of esters, the alcohol portion of the ester is given first, as a radical or partial molecule—such as ethyl from ethyl alcohol—followed by the root of the acid name—as acet- from acetic acid—followed by the suffix -ate. The ester formed from ethyl alcohol and acetic acid, then, is called ethyl acetate. When the systematic name of the acid (-oic) is employed, the ending used is -oate. The systematic name of ethyl acetate is ethyl ethanoate.

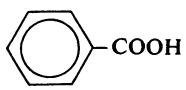
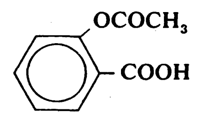
Classification. Carboxylic acids and their derivatives are classified in different ways, depending on the purpose of the classification. Many of the acids with straight carbon chains, particularly those with even numbers of carbon atoms, are constituents of fats and are commonly classed together as fatty acids. Generally the carboxylic acids are classed as aliphatic (a term that means an ordinary hydrocarbon chain) if the rest of the molecule (other than the carboxylic acid group) is aliphatic. The fatty acids, by this definition, are aliphatic; aliphatic acids frequently are classified further as saturated or unsaturated depending upon whether or not they contain unsaturation—that is, multiple bonds (double or triple) between the atoms of the carbon chain. When the carboxyl group is directly attached to an aromatic system—*e.g.,* a benzene ring—a carboxylic acid is, however, classed as an aromatic acid. Benzoic acid is the parent compound of the aromatic acids. Acetylsalicylic acid, or aspirin, the best known aromatic carboxylic acid, is derived from benzoic acid. The structural formulas of benzoic acid and acetylsalicylic acid are:



benzoic acid



acetylsalicylic acid (aspirin)

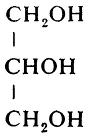
in which the hexagon containing a circle represents a benzene ring (that is, a circular structure of six carbon atoms each of which has one hydrogen atom attached to it).

Carboxylic acids are often categorized by the extra functional groups their molecules carry. Dicarboxylic and tricarboxylic acids are common. Carboxylic acids are classed as halo, keto, hydroxy, or amino acids when a halogen atom or a carbonyl, hydroxyl, or amino group is also part of the molecule.

Classification of derivatives

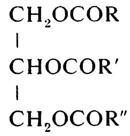
Generally carboxylic acid derivatives are placed in the same classes as the acids from which they are derived. Thus, aliphatic, aromatic, and various substituted esters, amides, and other derivatives are known. Exceptions occur when the acid-derived group makes up a relatively small part of the molecule. The derivative is then considered to be another type of substance altogether, modified by addition of the carboxylate grouping. Thus acetylsalicylic acid usually is considered a derivative of salicylic acid, not an ester of acetic acid.

Natural occurrence. Carboxylic acids occur widely in nature. In addition to acetic and formic acids, which are found in the free state, many of the fatty acids—straight-chain acids, saturated and unsaturated—occur as fats; that is, as esters of the trihydric alcohol glycerol (the term trihydric meaning that there are three hydroxyl or alcohol groups in each molecule of the substance). The structural formula of glycerol and a generalized formula of a fat derived from glycerol by the formation of ester bonds with three fatty acids are as follows:



$$\begin{array}{c} CH_2OH \\ | \\ CHOH \\ | \\ CH_2OH \end{array}$$

glycerol



$$\begin{array}{l} CH_2OCOR \\ | \\ CHOCOR' \\ | \\ CH_2OCOR'' \end{array}$$

fat (R,R′, R″ = fatty acid side chains, saturated and unsaturated)

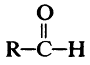
Fatty acids occur also as esters and amides of long-chain alcohols and amines. Free fatty acids are readily obtained from these sources by hydrolysis—cleavage of the ester or amide bond with addition of a single molecule of water. The free acids, however, are almost invariably obtained from such sources in the form of mixtures that are very complex and difficult to separate.

Substituted carboxylic acids also are found extensively in natural materials. Lactic acid occurs in sour-milk products and citric acid in fruits. These, other hydroxy acids, and many keto acids, are important metabolic products and exist in most living cells. Amino acids are constituents of proteins, from which they can be secured by hydrolysis. Halogen-substituted acids also occur, as do polycarboxylic acids and a number of aromatic acids.

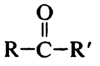
With the exception of esters and amides, few carboxylic acid derivatives appear in natural products. Esters, with their fruity and fragrant odours, are common constituents of plant flavours and essences. The carboxylic acids and their derivatives are all readily available by synthetic procedures (see below), often of such simplicity that even naturally occurring substances are prepared synthetically rather than isolated from natural sources.

General chemical and physical properties. The carboxyl group, in a sense, is a special form of the carbonyl group, the doubly bonded carbon–oxygen function characteristic of aldehydes and ketones. Structural representations of the carbonyl group and the generalized formulas of aldehydes, ketones, and carboxylic acids (and derivatives) are all given here for purposes of comparison:

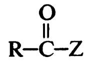
$$-\overset{\overset{O}{\|}}{C}-$$
carbonyl group



$$R-\overset{\overset{O}{\|}}{C}-H$$
aldehyde

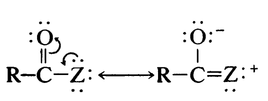


$$R-\overset{\overset{O}{\|}}{C}-R'$$
ketone



$$R-\overset{\overset{O}{\|}}{C}-Z$$
carboxylic acid and derivatives

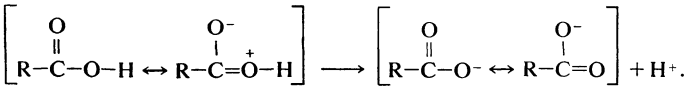
In the molecules of aldehydes and ketones, the carbonyl group is attached directly to carbon or hydrogen atoms, neither of which exerts a major influence on the chemical behaviour of that carbonyl group. In the carboxylic acids and their derivatives, however, the carbonyl carbon is joined directly to an atom with one or more pairs of electrons over and above those employed in the bond with the carbon atom. These so-called unshared pairs of electrons are able to interact with the electrons of the carbonyl group, thereby greatly modifying the chemical properties of that group and of the heteroatom as well. The nature of this interaction usually is represented in terms of the following diagrams:



In these diagrams the dots represent single electrons, situated in pairs; the curved arrows indicate a tendency for the electron pairs, or the bonds (which are equivalent to pairs of electrons), to migrate as shown; and the plus and minus signs stand for local electric charges brought about by the movement of the electrons. The double-headed arrow between the two representations implies that the complete structure of the molecule is a resonance hybrid of these two structures—that is to say, that the molecular structure incorporates aspects of both forms but duplicates neither. When such resonance forms exist for a molecule it is said to be stabilized by resonance. In this case, the most important feature of the electronic interaction represented by the resonance forms is that it gives this modified carbonyl group new chemical properties of its own, which justify classifying the group as a new and unique structure; *i.e.,* a carboxyl group.

As the name indicates, the chief characteristic of carboxylic acids is their acidity. As a class the carboxylic acids are more acidic than most other organic compounds containing hydroxyl (—OH) groups, but they are generally much weaker acids than the familiar mineral acids, such as nitric, sulfuric, and hydrochloric acids. The acidity of the carboxyl group results from the loss of a proton or hydrogen ion (that is, a hydrogen atom bearing a positive charge, as indicated by the symbol H^+), leaving behind a carboxylate anion—a negatively charged unit derived from the carboxyl group.

The carboxylate anion, like the carboxyl group, exists as resonance hybrid (see above) of several forms, two of which are shown below for each structure:



$$\left[R-\overset{\overset{O}{\|}}{C}-O-H \leftrightarrow R-\overset{\overset{O^-}{|}}{C}=\overset{+}{O}-H\right] \longrightarrow \left[R-\overset{\overset{O}{\|}}{C}-O^- \leftrightarrow R-\overset{\overset{O^-}{|}}{C}=O\right]+H^+.$$

carboxylic acid carboxylate anion

The basis for acidity of carboxylic acids

It is significant that the two resonance forms shown for the carboxylate anion are symmetrical and both carry a negative charge (as shown by the minus signs on the symbols for the oxygen atoms); this situation, which produces a structure of low energy content, means that the carboxylate anion is a relatively stable structure. In the carboxylic acid molecule itself, however, the resonance forms (as shown) are not symmetrical and one of them carries a separation of charge in its structure. This structure is less favourable (shows less resonance stabilization) than the symmetrical, equally charged structures of the carboxylate anion. As a result of this disparity in resonance stabilization, the carboxylic acid readily gives up a proton—acts as an acid—to produce the anion, which is favoured by its extra resonance energy.

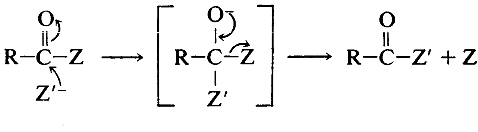
The nature of the R group of the carboxylic acid has an effect on the acidity of the carboxyl group by making it more or less easy for the proton to depart. Generally speaking, electron-attracting groups increase acidity by withdrawing electrons from the vicinity of the proton, thereby facilitating its departure; the opposite is true of electron-repelling groups. In many of the carboxylic acid derivatives, the carboxyl group has been modified, with the result that the proton in question is no longer present, and such substances are not acidic.

Chemical properties

The chemical reactions undergone by the carboxylic acids and their derivatives can be put into two broad categories. The first is a nucleophilic (positive-charge-seeking) reaction directed at the carbonyl carbon atom. The overall effect of this type of reaction is the displacement of one group, Z, which is capable of carrying a negative charge by another, Z′. The reaction is customarily represented by the following equation:

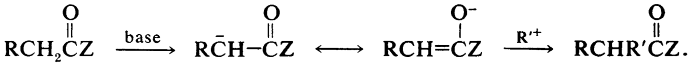
$$R-\overset{\overset{O}{\|}}{C}-Z+Z'^- \longrightarrow R-\overset{\overset{O}{\|}}{C}-Z'+Z^-.$$

The reaction proceeds, however, by way of attack on the carbonyl carbon as shown in the representation below:



in which the movement of electron pairs (or bonds) is indicated by curved arrows and the structure enclosed within brackets is an intermediate substance that is not isolated. It is by reactions of this type that carboxylic acid derivatives are interconverted, one variety being readily prepared from another under the proper chemical conditions.

Secondly, carboxyl compounds undergo the sort of reaction undergone by typical carbonyl compounds (aldehydes and ketones), in which the substituents are introduced into the so-called alpha position (the carbon atom adjacent to the carbonyl or, in this case, carboxyl group). Such reactions proceed by way of an intermediate resonance-stabilized anion (an anion being a negatively charged unit), which subsequently reacts with a positively charged unit. The latter is incorporated into the final structure. The reaction occurs as shown in the following equation:



$$RCH_2\overset{\overset{O}{\|}}{C}Z \xrightarrow{\text{base}} R\overset{-}{C}H-\overset{\overset{O}{\|}}{C}Z \longleftrightarrow RCH=\overset{\overset{O^-}{|}}{C}Z \xrightarrow{R'^+} RCHR'\overset{\overset{O}{\|}}{C}Z.$$

resonance-stabilized anion

Esters resemble carbonyl compounds more than the carboxylic acids—or the other derivatives—do, and, as a result, esters are more prone to undergo substitution reactions in this category.

Physical properties

The members of the carboxylic acid family with low molecular weight are liquids with boiling points appreciably higher than those of hydrocarbons of comparable molecular weight (see Table 24). This is because of extensive hydrogen-bond formation, a type of secondary association between molecules, which makes the acids behave as dimers (two molecules held together as one):

As would be expected from compounds whose molecules contain hydroxyl groups, the lower members of the series are extremely water-soluble—the hydroxyl group (—OH) being structurally similar to the water molecule (HOH) and therefore prone to solubility in it. This property diminishes as the non-carboxylic acid portion of the molecules increases in size, and acids containing nine or more carbon atoms are insoluble. Because of their solubility and acidity, members of the series containing few carbon atoms—such as acetic acid, found in vinegar—have a sour taste. The carboxylic acids with one to three carbons have sharp odours, whereas those with four to eight carbons have rank, disagreeable odours. Rancid butter and strong cheese contain the latter carboxylic acids.

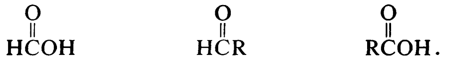
Many carboxylic acid derivatives are less associated (that is, their molecules are held together less strongly) than the free acids. This is especially true of the esters and halides, whose boiling points are much lower than those of the acids from which they are derived (see Table 24). Typical esters of lower molecular weight are volatile liquids.

THE MAJOR CLASSES OF CARBOXYLIC ACIDS

Saturated acids. Formic acid, the simplest member of the carboxylic acid family, was first prepared by distilling ants with water. The stinging nettle owes its irritating quality to the formic acid content of the juice. On a commercial scale, the acid is prepared by adding carbon monoxide under pressure to hot sodium hydroxide. The free acid is liberated by careful reaction with sulfuric acid. The series of reaction is shown below:

$$CO \xrightarrow{NaOH} HCOONa \xrightarrow{H_2SO_4} HCOOH$$

in which the symbols NaOH and H_2SO_4 written above the arrows indicate that the successive reactions occur in the presence of sodium hydroxide and sulfuric acid, respectively. In addition to its acidic properties, formic acid shows pronounced reducing activity (reduction being the chemical opposite of oxidation), a quality not shared by other carboxylic acids. The reducing action stems from the fact that formic acid is in a sense an aldehyde as well as an acid, as shown in the following structural formulas:



$$H\overset{\overset{O}{\|}}{C}OH \qquad H\overset{\overset{O}{\|}}{C}R \qquad R\overset{\overset{O}{\|}}{C}OH.$$

formic acid aldehyde carboxylic acid

Formic and acetic acids

Acetic acid, the next higher homologue—that is, the compound with one more carbon atom in its molecule—can be produced by oxidation of ethyl alcohol and is present as a dilute solution in vinegar, where it is formed by bacterial oxidation of dilute alcoholic liquors. Acetic acid may also be isolated from the liquid called pyroligneous acid, which is formed by the destructive distillation of wood. The most important commercial preparation of acetic acid involves the catalytic atmospheric oxidation of acetaldehyde, itself prepared from acetylene. These reactions are shown below:

$$CH{\equiv}CH \xrightarrow[HgSO_4]{\text{dilute } H_2SO_4} CH_3CHO \xrightarrow[Mn(CH_3COO)_2]{\text{air}} CH_3COOH.$$

Acetic acid is extensively employed in the preparation of metal salts and in the form of acetyl chloride or acetic anhydride in the production of esters and amides. Aspirin, the acetic ester of salicylic acid, is a good example of a commercially important ester prepared from acetic acid. Acetic acid is also recognized as an important substance in the biosynthesis of many biologically important materials. In this case it chiefly appears as an acetyl group bound to coenzyme A—*i.e.,* a molecule necessary for the action of certain enzymes. Acetyl-S-coenzyme A takes part in the biological production of fatty acids, many aromatic compounds, and isoprenoids and steroids. The natural fatty acids have an even number of carbon atoms in their molecules because they are produced from acetyl-S-coenzyme A, which adds carbon atoms to the molecules two at a time.

With increasing numbers of carbon atoms per molecule, the carboxylic acids have increasing possibilities for alternate arrangements of the atoms within the molecules (isomerism), and many branched-chain acids, both natural and synthetic, are known. The straight-chain compounds are, nevertheless, more common, especially those with even numbers of carbon atoms in the chain, and these make up the great percentage of the fatty acid content of common fats.

Carboxylic acids and their derivatives

The lower fatty acids (with four to 10 carbon atoms) occur mainly in milk fats and a few seed fats. Cow's milk contains 10 percent (on a molecular-weight basis) of butyric acid (a four-carbon acid) with smaller amounts of the acids containing six, eight, 10, and 12 carbon atoms; sheep's-milk and goat's-milk fats contain these same acids, with capric (containing 10 carbon atoms) in greatest amount (up to 10 percent). Capric acid also is a major component (60 percent) in the seed fat of the elm, and caprylic and capric acids (each 5–10 percent) accompany the higher proportion of lauric acid (12 carbon atoms) in coconut oil and, to a lesser extent, in palm-kernel oil. Lauric acid and myristic acid (14 carbon atoms) occur extensively in seed fats of the Lauraceae (laurel family) and Myristicaceae (nutmeg family) respectively. Lauric acid, for example, can be obtained from cinnamon oil (80–90 percent), coconut oil (45–50 percent), or palm-kernel oil (45–55 percent) and myristic acid from nutmeg butter (60–75 percent) or from the more readily available coconut and palm-kernel oils (15–18 percent). Palmitic acid (16 carbon atoms), the most widely occurring of the saturated acids, is present in almost every fat examined. Useful sources include cottonseed oil (22–28 percent), palm oil (35–40 percent), and Chinese vegetable tallow (60–70 percent).

Palmitic and stearic acids

Stearic acid (18 carbon atoms) is less common than palmitic acid. It occurs in most vegetable fats but is a major component in only a few, such as cocoa butter (35 percent). It is present in most animal fats but attains major proportions only in the tallows of ruminants (30 percent). Stearic acid is conveniently obtained by hydrogenation of readily accessible unsaturated fats.

Still higher fatty acids are less common but occur in a few seed fats or in some waxes as esters of long-chain alcohols. Acids with odd numbers of carbon atoms in their chains are even rarer, but modern methods of investigation have revealed their presence, often as trace components, in many fats. Acids with hydrocarbon chains containing short branches (side chains of carbon atoms) or rings (circular sequences of carbon atoms) also are uncommon. Those that are found include a series of acids with one or more methyl groups in various positions along the chain, as well as acids with cyclopropane groups. Many branched-chain acids have been synthesized.

Unsaturated acids. Although most of the important unsaturated acids (acids with multiple bonds) are long-chain compounds obtained from fats, some shorter chain acids, such as acrylic, crotonic, methacrylic, and the isomeric angelic and tiglic acids, are also important. The formulas of these acids are shown below:

$CH_2{=}CHCOOH$	acrylic acid
$CH_3CH{=}CHCOOH$	crotonic acid
$CH_2{=}C(CH_3)COOH$	methacrylic acid
	angelic acid
	tiglic acid

Acrylic acid polymers

Acrylic acid, employed as its methyl ester in the production of polymers known as acrylates, is prepared on a large scale from acetylene, carbon monoxide, and water in the presence of a nickel catalyst, as well as by hydrolysis of the substance acrylonitrile ($CH_2{=}CHCN$), an even more important monomer.

Methacrylic acid, in the form of its methyl ester, is also used as a monomer, furnishing Perspex or Plexiglas when polymerized. Crotonic acid exists in *cis* and *trans* forms, which differ in the arrangement of substituents about the double bond. Only the *trans* isomer occurs naturally, in croton oil. Angelic and tiglic acids also are a pair of *cis* and *trans* isomers, both of which occur naturally.

Natural unsaturated acids number more than 200 and are subdivided into three groups: (1) acids with only one unsaturated centre; (2) conjugated (conjugation being an alternation of single and double bonds), polyunsaturated acids; (3) multiply unsaturated, or polyunsaturated, acids that are nonconjugated.

Monounsaturated acids

Apart from two acetylenic (triple-bonded) acids, tariric and stearolic, the natural monounsaturated acids are olefinic (double bonded) and almost entirely *cis* isomers.

Oleic acid, with 18 carbon atoms and a double bond between the ninth and tenth carbon atoms in the chain, is the most common of all fatty acids and the prototype for all monoolefinic acids:

$$CH_3(CH_2)_7CH = CH(CH_2)_7COOH \qquad \text{oleic acid.}$$

More than 90 monoenoic acids, containing 10 to 30 carbon atoms, have been identified in lipid sources. Nature appears to have a preference for certain chain lengths, especially those of 16 and 18 carbons, and for particular positions for the unsaturation, especially between C_9 and C_{10}. These circumstances are a natural consequence of the enzymatic oxygen-dependent desaturation process whereby double bonds are most commonly introduced into fatty acids between carbons 9 and 10, and of the readiness by which natural acids undergo chain elongation by one or more two-carbon units at the carboxyl end of the molecule. In addition to these natural acids, many isomers that do not occur in nature have been synthesized.

The monounsaturated acids show the properties expected of olefins, in addition to those of carboxylic acids. As acids, they form salts, are reduced to primary alcohols, and are converted directly or indirectly to the various types of acyl compounds listed in Table 23. As unsaturated compounds they undergo hydrogenation (that is, the addition of hydrogen to the multiple bond) with hydrogen and a catalyst or with hydrazine; hydroxylation (introduction of hydroxyl groups) with potassium permanganate, osmium tetroxide, performic acid, or peracetic acid; and halogenation (introduction of halogen atoms) with chlorine or bromine or with iodine monochloride. Vigorous oxidation by potassium permanganate or ozone leads to breaks in the carbon chains (chain fission). Atmospheric oxidation first gives unsaturated hydroperoxides (molecules containing two joined oxygen atoms), followed by a variety of secondary reaction products. Among these are volatile short-chain compounds (aldehydes and other substances) responsible for both the acceptable and unacceptable flavours that develop in fat-containing foods.

Polyunsaturated acids

More than 90 nonconjugated, polyunsaturated acids occur naturally. Most are acids with 16, 18, 20, or 22 carbons and two to four double bonds, although more highly unsaturated members are also known. Unsaturation is almost entirely *cis* in the compounds and usually is methylene interrupted; *i.e.,* with successive double bonds separated by single methylene ($-CH_2-$) groups. These structural features are clearly apparent in linoleic acid, linolenic acid, and arachidonic acid, the most important members of this class, the structures of which are shown below:

linoleic acid

$$CH_3(CH_2)_4CH = CHCH_2CH = CH(CH_2)_7CO_2H$$

linolenic acid

$$CH_3CH_2CH = CHCH_2CH = CHCH_2CH = CH(CH_2)_7CO_2H$$

arachidonic acid

$$CH_3(CH_2)_4CH = CHCH_2CH = CHCH_2CH = CHCH_2CH = CH(CH_2)_3CO_2H.$$

Interest in acids of this type has increased since the recognition that some of them, called essential fatty acids, are required for the maintenance of normal animal growth, reproduction, and permeability of the skin. The particular requirement is for methylene-interrupted polyolefinic acids, with unsaturation beginning at the sixth carbon from the methyl end of the chain.

Arachidonic acid is the most effective of the fatty acids for meeting the essential fatty acid requirements. Many authorities consider it likely that essential fatty acids are converted to other compounds before fulfilling their as yet unknown biological function.

Of possible significance in this regard is the discovery of a series of compounds called prostaglandins, which cause certain muscles to contract and lower the blood pressure. These compounds are produced in vivo from essential fatty acids such as arachidonic.

Conjugated polyunsaturated acids are much less common. About 40 are known to occur naturally, almost all of them being 18-carbon acids of plant origin. The best known is eleostearic acid from tung oil.

Substituted acids. Carboxylic acids, particularly those with long hydrocarbon chains, may contain one or more other groups, such as halo, hydroxy, alkoxy, epoxy, or keto groups. The several functional groups usually operate independently, and most substituted acids show only those properties that would be expected from the two functional groups. Sometimes, however, the two functional groups interact to give new properties.

Halogen-substituted acids

Acids substituted with chlorine in the alpha position are prepared by the reaction of chlorine or sulfuryl chloride on an acyl chloride or on the acid itself under reaction conditions that produce an acyl chloride. For example:

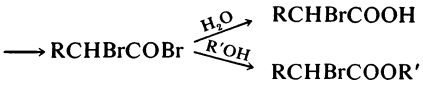
$$RCH_2COCl \xrightarrow{Cl_2,\ I_2} RCHClCOCl \xrightarrow{H_2O} RCHClCOOH$$

$$RCH_2COOH \xrightarrow{Cl_2,P} [RCH_2COCl] \longrightarrow RCHClCOCl \xrightarrow{H_2O} RCHClCOOH$$

$$RCH_2COOH \xrightarrow[SOCl_2]{SO_2Cl_2} [RCH_2COCl] \longrightarrow RCHClCOCl \xrightarrow{H_2O} RCHClCOOH.$$

The corresponding bromo acids are prepared by reactions with bromine and phosphorus, phosphorus trihalide, or thionyl chloride:

$$RCH_2COOH \xrightarrow{Br_2,\ P} [RCH_2COBr]$$



$$\longrightarrow RCHBrCOBr \begin{cases} \xrightarrow{H_2O} RCHBrCOOH \\ \xrightarrow{R'OH} RCHBrCOOR' \end{cases}$$

Iodo acids are best prepared by halogen exchange between potassium iodide and the chloro acid or bromo acid.

Acids substituted with halogen in other positions are produced by standard procedures for preparing alkyl halides, such as the addition of halogen acid to a double bond, or by the conversion of a hydroxyl group to halogen. Examples are:

$$RCH{=}CHCOOH \xrightarrow{HBr} RCHBrCH_2CO_2H$$

$$RCH(OH)(CH_2)_4COOH \xrightarrow{SOCl_2} [RCHCl(CH_2)_4COCl] \xrightarrow{H_2O} RCHCl(CH_2)_4COOH$$

The reactions of halogen-substituted acids and other acyl derivatives include dehydrohalogenation, nucleophilic substitution, and the formation of certain organometallic derivatives:

$$CH_2BrCH_2(CH_2)_nCOOH \xrightarrow{\text{pyridine}} CH_2{=}CH(CH_2)_nCOOH$$

$$RCHBrCOOH \xrightarrow[\text{of } Z^-]{\text{HZ or source}} RCHZCOOH$$

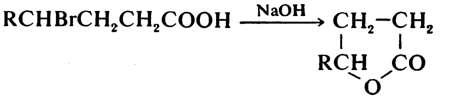
$$(Z{=}-NH_2, -OH, -CN, \text{etc.})$$

$$RCHBrCOOCH_3 \xrightarrow{Zn} RCH(ZnBr)COOCH_3 \xrightarrow{R'CHO} R'CH(OH)CH(R)COOCH_3 \xrightarrow[\text{hydrolysis}]{-H_2O} R'CH{=}C(R)COOH.$$

The presence of the carboxyl group influences the reactions of the 2-, 3-, and 4-halo acids so that each of these furnishes a different save of product when it reacts with alkalies:

$$RCHBrCOOH \xrightarrow{NaOH} RCH(OH)COOH \qquad \textbf{(2-hydroxy acid)}$$

$$RCHBrCH_2COOH \xrightarrow{NaOH} RCH{=}CHCOOH \qquad \textbf{(}\boldsymbol{\alpha, \beta}\textbf{-unsaturated acid)}$$



(γ-lactone)

Among the few naturally occurring halo acids is fluoroacetic acid, a highly toxic compound that occurs as the potassium salt in the African shrub *Dichapetalum cymosum.* Compounds that undergo degradation in vivo to fluoroacetic acid are also highly toxic, and 18-fluorooleic acid, for example, is the poisonous principle in certain unusual seeds.

Hydroxy and amino acids

Hydroxy acids can be prepared from the appropriate carboxylic acid intermediates by standard methods of preparing hydroxy compounds, or from the appropriate hydroxy compounds by methods for producing carboxylic acids. Some of the more important general methods include (1) the hydrolysis of halo acids, (2) the hydrolysis of cyanohydrins, (3) the reaction with α-bromo esters in the presence of zinc, and (4) the reduction of keto esters or half esters of dibasic acids:

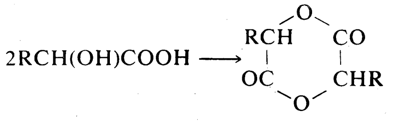
$$(1)\quad RCH_2COOH \xrightarrow{Br_2,\,P} RCHBrCOOH \xrightarrow{NaOH(aq)} RCH(OH)COOH$$

$$(2)\quad \left\{\begin{aligned} &RCHO \xrightarrow{HCN} RCH(OH)CN \xrightarrow{\text{hydrolysis}} RCH(OH)COOH \\ &RCH{=}CH_2 \xrightarrow{HOCl} RCH(OH)CH_2Cl \\ &\xrightarrow{KCN} RCH(OH)CH_2CN \xrightarrow{\text{hydrolysis}} RCH(OH)CH_2COOH \end{aligned}\right.$$

$$(3)\quad RCHO \xrightarrow{BrCH_2COOC_2H_5} RCH(OH)CH_2COOH$$

$$(4)\quad \left\{\begin{aligned} &RCO(CH_2)_nCOOCH_3 \xrightarrow[\text{hydrolysis}]{NaBH_4;} RCH(OH)[CH_2]_nCOOH \\ &HOOC(CH_2)_nCOOCH_3 \xrightarrow{SOCl_2} ClCO(CH_2)_nCOOCH_3 \\ &\xrightarrow[\text{hydrolysis}]{NaBH_4;} HOCH_2(CH_2)_nCOOH \end{aligned}\right.$$

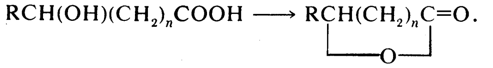
The 2-, 3-, 4-, and 5-hydroxy carboxylic acids differ in their behaviour on heating and give, respectively, a lactide, α, β-unsaturated acid, a γ-lactone, and a δ-lactone:



lactide

$$RCH(OH)CH_2COOH \longrightarrow RCH{=}CHCOOH$$

α, β-unsaturated acid



$$RCH(OH)(CH_2)_nCOOH \longrightarrow RCH(CH_2)_nC{=}O.$$

lactone

There are many naturally occurring hydroxy acids, including glycolic, lactic, and ricinoleic:

$HOCH_2COOH$	$CH_3CH(OH)COOH$
glycolic acid	lactic acid

$$CH_3(CH_2)_5CH(OH)CH_2CH{=}CH(CH_2)_7COOH$$

ricinoleic acid

Ricinoleic is the major acid present in castor oil and provides a source of other useful chemicals prepared on an industrial scale. These include the diene glycerides resulting on dehydration of castor oil, as well as the products of pyrolysis—heptanal and 10-undecenoic acid—and alkali fusion—2-octanone, 2-octanol, 10-hydroxy-decanoic acid, and sebacic acid.

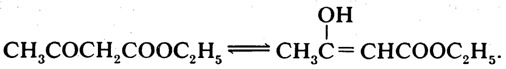
The α-amino acids, $RCH(NH_2)COOH$, are of great importance since they are the monomeric units that make up the peptides and proteins. Twenty different amino acids commonly occur in these materials.

Keto acids

Carboxylic acids that also carry carbonyl groups (aldehydes or ketones) usually can be prepared by oxidation of the corresponding hydroxy acids. The β-keto compounds (in the form of their esters) are of considerable importance and are prepared by special condensation procedures.

Among the more important shorter chain acids bearing extra carbonyl groups are glyoxylic acid (OHCCOOH), pyruvic acid ($CH_3COCOOH$), levulinic acid ($CH_3COCH_2CH_2COOH$), and especially acetoacetic acid (CH_3COCH_2COOH).

Ethyl acetoacetate and most β-keto esters exhibit tautomerism—that is, the esters exist as equilibrium mixtures of two compounds and exhibit the properties of both. The keto form, which preponderates in most cases, contains a normal carbonyl group; the other form, called the enol form, bears an alcoholic group attached directly to one of the carbons of a double bond. The enol form is usually present in small amounts, but it can be detected by its reactions. As the enol form is consumed in a reaction, more is generated from the keto form by re-establishment of the equilibrium:

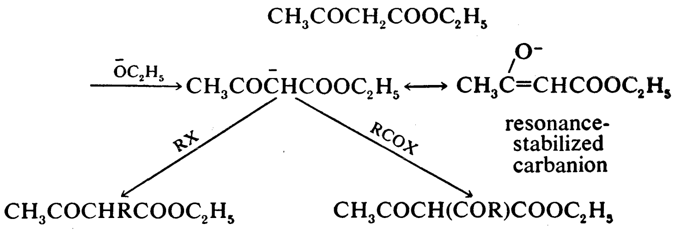


$$CH_3COCH_2COOC_2H_5 \rightleftharpoons CH_3\overset{OH}{C}{=}CHCOOC_2H_5.$$

keto form enol form

Typical reactions of the keto form include reactions with hydrogen cyanide and with hydroxylamine to give cyanohydrins and oximes respectively. On the other hand, reaction with diazomethane to give an *O*-methyl ether and with ferric chloride to yield a coloured complex are considered to be typical of the enolic form.

Of major importance chemically (because it is the basis for many chemical reactions) is the fact that the methylene ($-CH_2-$) group of a β-keto ester, which is flanked by two electron-withdrawing groups ($-CO-$ and $-COOC_2H_5$), can give up one of its protons to a strong base to yield a resonance-stabilized carbanion. Intermediates of this type react readily with alkyl and acyl halides to give alkylated or acylated derivatives of the original β-keto ester, as follows:



The monoalkylated and monoacylated compounds formulated in the above sequence also contain a second hydrogen atom, which can be replaced by a second alkyl or acyl group, not necessarily the same as the first. These alkylated or acylated derivatives yield valuable products after hydrolysis, a reaction that can follow two different courses:

1. Under mild conditions—*i.e.,* with dilute acid or alkali—the ester function is hydrolyzed in the usual way, but the β-keto acid so formed is unstable and decarboxylates readily to give a ketone:

$$CH_3COCH_2COOC_2H_5 \longrightarrow CH_3COCHRCOOC_2H_5$$

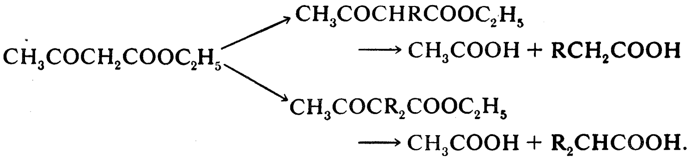
ethyl acetoacetate mono-alkylated derivative

$$\longrightarrow CH_3COCHRCOOH \longrightarrow CH_3COCH_2R.$$

free acid ketone

Reactions of this type are used to prepare monosubstituted and disubstituted derivatives of acetone (CH_3COCH_2R and CH_3COCHR_2) or 1,3-diketones (CH_3COCH_2COR).

2. With stronger alkali, the molecule is attacked at both carbonyl groups to produce acetic acid and alkylated derivatives of that substance, as in the following examples:

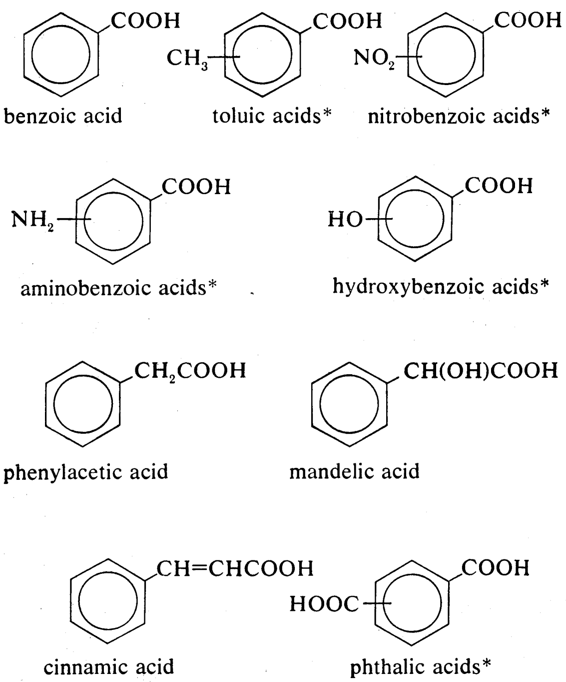


The polyfunctional nature of ethyl acetoacetate and related β-keto esters makes them valuable intermediates in the preparation of many heterocyclic compounds.

Reaction of aromatic carboxylic acids

Aromatic acids. In addition to the typical reactions undergone by the carboxyl group, aromatic acids also enter into the electrophilic substitution reactions commonly displayed by aromatic compounds. A carboxyl group directly attached to an aromatic ring exerts a deactivating influence and directs substituents to one of the two *meta* positions in the ring (*i.e.,* not to the adjacent carbon but the one next to that). Nitration of benzoic acid, for example, requires moderately vigorous conditions and gives first *m*-nitrobenzoic acid and then 3,5-dinitrobenzoic acid.

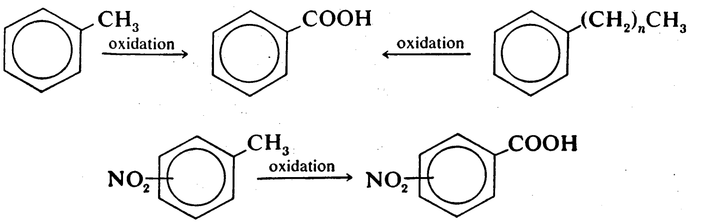
The simplest and best known aromatic acid is benzoic acid; this compound may be considered to be the parent of a wide range of substituted benzoic acids. Those acids in which the carboxyl group is part of an aliphatic side chain and not directly attached to the aromatic ring, such as phenylacetic, mandelic, and cinnamic acids, often are not classed as aromatic acids. Many polybasic acids, such as the isomeric phthalic acids, are commercially important. The most important aromatic acids are:



benzoic acid
toluic acids*
nitrobenzoic acids*
aminobenzoic acids*
hydroxybenzoic acids*
phenylacetic acid
mandelic acid
cinnamic acid
phthalic acids*

*These are convenient representations of the three isomeric acids (*ortho-*, *meta-*, and *para-*), which differ in the relative positions of attachment of the two groups on the ring.

Aromatic carboxylic acids, like their aliphatic counterparts, can be prepared by hydrolysis of nitriles or by the addition of carbon dioxide to organometallic compounds, usually derived from the appropriate halide; also, they often are obtained from aromatic hydrocarbons by oxidation. The aromatic ring is so resistant to oxidation that it remains intact while carbon-linked side chains are degraded to carboxyl groups. Certain noncarbon constituents such as nitro and halo groups survive this treatment, so that nitrotoluenes or halotoluenes may be oxidized to nitrobenzoic or halobenzoic acids:



Benzoic acid

Benzoic acid has been known for centuries, having been first obtained from gum benzoin, a resin extracted from an Indonesian tree. The well-known aromatic hydrocarbon benzene can be prepared by decarboxylation of benzoic acid. By standard procedures benzoic acid can be converted to the usual range of acyl derivatives, including benzoyl chloride, benzoate esters, and benzamides. The acid also enters into several aromatic substitution processes, although certain of the substituted benzoic acids are prepared preferably by alternative routes. Several of these substituted acids, such as salicylic acid (*o*-hydroxybenzoic) and anthranilic acid (*o*-aminobenzoic), are of considerable commercial importance. The latter, which is used as an intermediate in the preparation of many dyes, is generally prepared from phthalimide, itself a derivative of the dibasic acid phthalic acid. Salicylic acid is manufactured chiefly by the reaction of sodium phenolate (C_6H_5ONa) with carbon dioxide under pressure at 120°–140° C. Derivatives of salicylic acid, especially phenyl salicylate, acetylsalicylic acid (aspirin), and 4-aminosalicylic acid are used medicinally.

Phthalic acids

The phthalic acids are prepared by oxidation of appropriate aromatic hydrocarbons. The *ortho* isomer (in which the substituents are on adjacent positions on the ring) readily forms an anhydride. The *para* isomer (in which the substituents are located directly across from one another on the ring), which is also known as terephthalic acid, is used with dihydric alcohols to produce polymers, such as Terylene, which is a linear polymer that is made by the condensation of terephthalic acid and ethylene glycol.

Cinnamic acid, an important acid in which the carboxylic group is not directly attached to the aromatic ring, is prepared from benzaldehyde by several condensation procedures, one of which is carried out as follows:

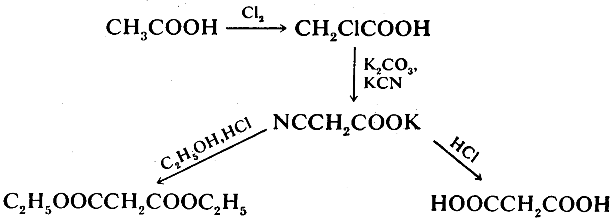
$$C_6H_5CHO \xrightarrow[CH_3COONa]{(CH_3CO)_2O} C_6H_5CH{=}CHCOOH.$$

Polycarboxylic acids. The most common dicarboxylic acids belong to the series of compounds with carboxyl groups at both ends of a hydrocarbon chain; that is, compounds with the general structural formula $HOOC(CH_2)_n$-COOH, in which n can be any of many numbers. Though they can be named systematically, several are generally designated by their common names, including oxalic ($n = 0$), malonic ($n = 1$), succinic ($n = 2$), glutaric ($n = 3$), adipic ($n = 4$), azelaic ($n = 7$), and sebacic ($n = 8$) acids.

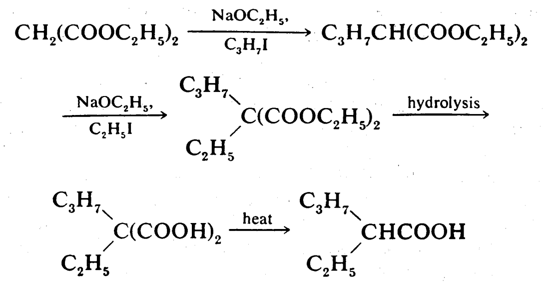
Oxalic acid, a common natural product, is readily obtained by oxidation of table sugar, or other carbohydrates, or by heating sodium formate. Oxalyl chloride (ClCO-COCl) is a useful reagent for preparing acyl halides from other carboxylic acids.

Malonic acid

Malonic acid and its more important ethyl ester are usually prepared from acetic acid by the following synthetic sequences:



The importance of diethyl malonate is that, like ethyl acetoacetate, it readily forms a resonance-stabilized carbanion, which readily can be alkylated and, by way of the corresponding free acid, decarboxylated. Diethyl malonate, therefore, can be used to prepare monosubstituted and disubstituted derivatives of acetic acid, as in the following example:

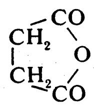


$$CH_2(COOC_2H_5)_2 \xrightarrow[C_3H_7I]{NaOC_2H_5,} C_3H_7CH(COOC_2H_5)_2$$

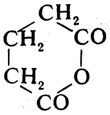
$$\xrightarrow[C_2H_5I]{NaOC_2H_5,} (C_3H_7)(C_2H_5)C(COOC_2H_5)_2 \xrightarrow{\text{hydrolysis}}$$

$$(C_3H_7)(C_2H_5)C(COOH)_2 \xrightarrow{\text{heat}} (C_3H_7)(C_2H_5)CHCOOH$$

Succinic and glutaric acids differ from the other members of this series in that they readily give cyclic anhydrides (see below *Anhydrides*) when heated. Oxalic and malonic acids fail to form cyclic anhydrides, and the members of the series above glutaric usually give linear polymeric anhydrides:

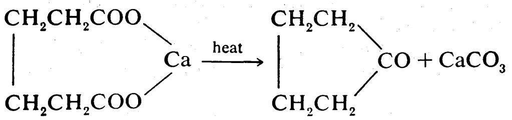


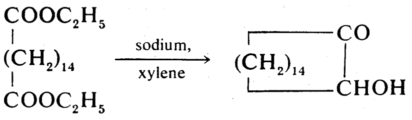
succinic anhydride



glutaric anhydride

Dibasic acids with six or more carbon atoms undergo cyclization reactions of various kinds. The examples given below show the production of a cyclic ketone, cyclopentanone, from the calcium salt of adipic acid and of an α-hydroxyketone (or acyloin) from a 16-carbon dicarboxylic acid ester:





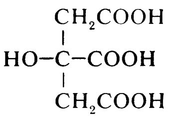
Adipic acid is used in the production of the most common form of nylon—a polyamide made from that dibasic acid and 1,6-hexanediamine. Maleic and fumaric acids are isomeric unsaturated dibasic acids. Malic acid, tartaric acid, and citric acid are important hydroxy-polycarboxylic acids of natural origin:

$HOOCCH(OH)CH_2COOH$

malic acid

$HOOCCH(OH)CH(OH)COOH$

tartaric acid



$$\begin{array}{c} CH_2COOH \\ | \\ HO{-}C{-}COOH \\ | \\ CH_2COOH \end{array}$$

citric acid

THE CARBOXYLIC ACID DERIVATIVES

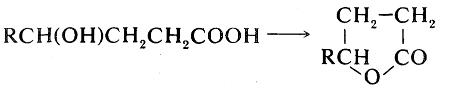
Esters. Formally, an ester with the structure RCOOR′ may be thought to be derived from a carboxylic acid of structure RCOOH, by replacement of hydrogen, —H, by an alkyl group, —R′, but the nature of the esterification process is such that it is more appropriate to describe the change as the replacement of the hydroxyl group, —OH, by an alkoxy group, —OR′. It is established experimentally in most esterification procedures that the alkoxy oxygen atom in an ester does, in fact, come from the alcohol—that is, that it remains attached to the R′ group.

Esterification

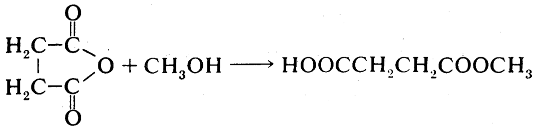
Esters are prepared most often by interaction of an acid and an alcohol in the presence of a catalyst, but other useful procedures also are available. The reversible reaction between alcohols and carboxylic acids is shown by the following equation:

$$RCOOH + R'OH \rightleftharpoons RCOOR' + H_2O.$$

Because the equilibrium is attained only slowly, it is usual to add a catalyst, such as hydrogen chloride or sulfuric acid, and to arrange the experimental conditions so that the equilibrium is shifted to the right. This shift is generally achieved by removal of water by distillation or by adding a large excess of one of the reactants. Hydroxy acids in which the hydroxyl group is three or four carbons from the carboxyl group undergo intramolecular reaction to give cyclic esters known as lactones:



Since acyl halides and acid anhydrides are more reactive than carboxylic acids, they can be esterified without the use of acidic catalysts. This method is especially useful for preparing the half esters of dibasic acids from their cyclic anhydrides and for producing the esters of phenols, which cannot be obtained directly from the acids:



succinic anhydride — methyl hydrogen succinate

$$CH_3COCl + C_6H_5OH \longrightarrow CH_3COOC_6H_5 + HCl.$$

acetyl chloride — phenol — phenyl acetate

The salts of carboxylic acids react with alkyl halides to form esters. The silver salts are most commonly employed for this purpose, but sodium salts may be used when the alkyl halide is a reactive one, *p*-nitrobenzyl bromide, for example:

$$p\text{-}NO_2C_6H_4CH_2Br + NaOOCCH_3 \longrightarrow p\text{-}NO_2C_6H_4CH_2OCOCH_3.$$

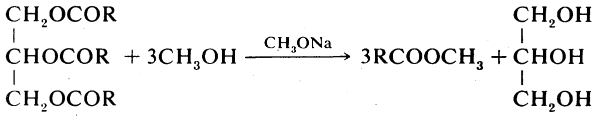
p-nitrobenzyl acetate

Methyl esters are conveniently obtained by reaction of carboxylic acids with diazomethane in ether solution:

$$RCOOH + CH_2N_2 \longrightarrow RCOOCH_3 + N_2.$$

Since esterification is a catalytic, reversible process, one ester can be prepared from another by reaction with an alcohol (alcoholysis), with an acid (acidolysis), or with a second ester (transesterification) in the presence of a suitable acidic or basic catalyst:

alcoholysis



$$\begin{array}{l} CH_2OCOR \\ | \\ CHOCOR \\ | \\ CH_2OCOR \end{array} + 3CH_3OH \xrightarrow{CH_3ONa} 3RCOOCH_3 + \begin{array}{l} CH_2OH \\ | \\ CHOH \\ | \\ CH_2OH \end{array}$$

acidolysis

$$RCOOR' + (NO_2)_2C_6H_3COOH$$

3,5-dinitrobenzoic acid

$$\xrightarrow{H_2SO_4} RCOOH + (NO_2)_2C_6H_3COOR'$$

transesterification

$$RCOOCH_3 + CH_3COOCH{=}CH_2$$

vinyl acetate

$$\xrightarrow{H_2SO_4} RCOOCH{=}CH_2 + CH_3COOCH_3$$

Esters are neutral compounds. The esters of long-chain acids occur naturally as waxes (esters of long-chain alcohols), as glycerides or fats (esters of glycerol), and as phosphoglycerides (esters of glycerophosphoric acid).

Reactions of esters

Esters can be converted to amides by reaction with ammonia, to hydrazides by reaction with hydrazine, and to acids by hydrolysis. They are not converted easily to acid chlorides or anhydrides:

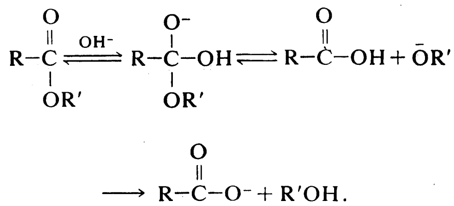
$$RCOOCH_3 + NH_3 \longrightarrow RCONH_2 + CH_3OH$$

$$RCOOCH_3 + N_2H_4 \longrightarrow RCONHNH_2 + CH_3OH$$

$$RCOOCH_3 + NaOH \longrightarrow RCOONa + CH_3OH.$$

Hydrolysis, the most important reaction, is brought about slowly by water and more quickly in the presence of acid or alkali. The alkaline hydrolysis, or saponification, of fats produces salts of long-chain acids, which are known as soaps. In common with many other long-chain compounds, these substances show surface-active properties and have long been used as cleansing agents. The enzyme-catalyzed hydrolysis of esters is important in the metabolism of lipids.

The mechanism of alkaline hydrolysis of esters is as follows:

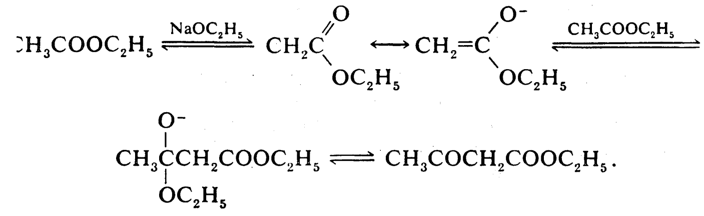


$$R-\underset{OR'}{\overset{O}{\overset{\|}{C}}} \xrightleftharpoons{OH^-} R-\underset{OR'}{\overset{O^-}{C}}-OH \rightleftharpoons R-\overset{O}{\overset{\|}{C}}-OH+\bar{O}R'$$

$$\longrightarrow R-\overset{O}{\overset{\|}{C}}-O^- + R'OH.$$

With sodium in an inert solvent, esters give acyloins (*α*-hydroxy ketones). Esters can be reduced to primary alcohols (RCH_2OH) by several methods, either catalytically with hydrogen and copper oxide–chromium oxide (300° C [572° F] and 250 atmospheres pressure), or chemically by reaction with sodium and alcohol or lithium aluminum hydride or diborane.

As is true of other carbonyl compounds, most esters undergo self-condensation in the presence of a base. The reaction involves the formation of a resonance-stabilized carbanion and reaction of this material with a second molecule of ester to give, finally, a *β*-keto ester. The best known example of this reaction is the preparation of ethyl acetoacetate from ethyl acetate:



$$CH_3COOC_2H_5 \xrightleftharpoons{NaOC_2H_5} CH_2C\begin{smallmatrix}\diagup O\\ \diagdown OC_2H_5\end{smallmatrix} \longleftrightarrow CH_2=C\begin{smallmatrix}\diagup O^-\\ \diagdown OC_2H_5\end{smallmatrix} \xrightleftharpoons{CH_3COOC_2H_5}$$

$$CH_3\underset{OC_2H_5}{\overset{O^-}{C}}CH_2COOC_2H_5 \rightleftharpoons CH_3COCH_2COOC_2H_5.$$

ethyl acetoacetate

Most *β*-keto esters contain a reactive methylene group that readily can be alkylated or acylated.

Anhydrides. Although thermal dehydration of acids is not usually a satisfactory process, anhydrides can be made from carboxylic acids by reaction with acetic anhydride, ketene, methoxyacetylene or ethoxyacetylene, or isopropenyl acetate:

$$2RCOOH+2CH_2=C=O$$

ketene

$$\longrightarrow 2RCOOCOCH_3 \longrightarrow (RCO)_2O+(CH_3CO)_2O$$

mixed anhydride

$$2RCOOH+HC\equiv COR' \longrightarrow (RCO)_2O+CH_3COOR'.$$

From acyl halides, anhydrides can be produced by reaction with the appropriate acid salt ($RCOCl + RCOONa \rightarrow (RCO)_2O + NaCl$). Acyl halides also react with carboxylic acid and pyridine or with acetic anhydride to produce anhydrides.

cetic
nhydride

Acetic anhydride, $(CH_3CO)_2O$, is of sufficient commercial importance to be prepared industrially by atmospheric oxidation of acetaldehyde in the presence of a metal acetate, as well as from acetic acid by reaction with acetylene or ketene:

$$CH_3CHO \xrightarrow{O_2} CH_3COOOH$$
$$\xrightarrow{CH_3CHO} (CH_3CO)_2O + H_2O$$

$$2CH_3COOH + HC\equiv CH \longrightarrow CH_3CH(OCOCH_3)_2$$
$$\longrightarrow (CH_3CO)_2O + CH_3CHO$$

$$CH_3COOH \xrightarrow{700°-800°} CH_2=C=O$$
$$\xrightarrow{CH_3COOH} (CH_3CO)_2O.$$

The anhydrides generally are useful acylating agents, being more reactive for this purpose than acids or esters, but less so than acyl halides. They react with water to give carboxylic acids, with alcohols or phenols to give esters, and with ammonia and amines to give amides. Acetic anhydride, a widely used acetylating agent, for example, reacts with water, an alcohol, and ammonia, according to the following equations:

$$(CH_3CO)_2O+H_2O \longrightarrow 2CH_3COOH$$
$$(CH_3CO)_2O+ROH \longrightarrow CH_3COOH+CH_3COOR$$
$$(CH_3CO)_2O+NH_3 \longrightarrow CH_3COOH+CH_3CONH_2.$$

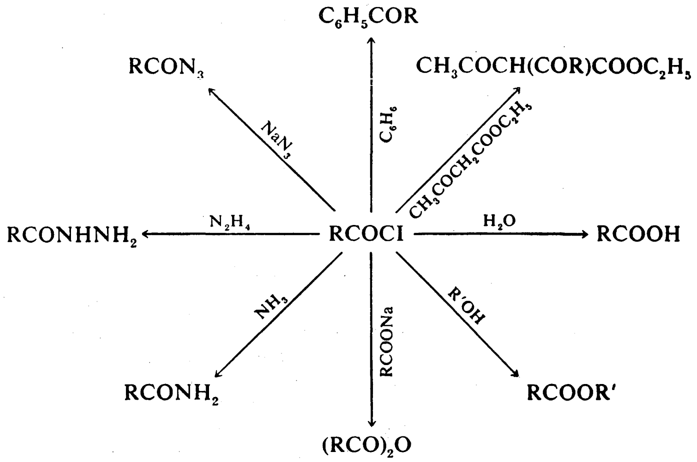
Anhydrides can also be used to acylate aromatic compounds in the presence of aluminum chloride.

Halides. The acyl halides, of which the chlorides are the best known, are among the most reactive of acyl compounds. They are easily made from carboxylic acids or their salts by reaction with phosphorus pentachloride, phosphorus trichloride, thionyl chloride (usually in the presence of pyridine), or oxalyl chloride. The reaction with thionyl chloride may be taken as typical:

$$RCOOH+SOCl_2 \longrightarrow RCOCl+SO_2+HCl.$$

Reactions
of acyl
halides

Acyl halides generally are vigorous acylating agents and react with water to give carboxylic acids; with alcohols and phenols to give esters; with sodium salts of carboxylic acids to give anhydrides; with ammonia and amines to give amides; with hydrazine to give hydrazides; and with sodium azide to give azides. They are also employed, with aluminum chloride as a catalyst, for the acylation of aromatic compounds; they interact with carbanions, such as that derived from ethyl acetoacetate, to give acyl derivatives. A summary of these reactions is shown below:



Acyl chlorides furnish ketones with organometallic compounds, especially those of zinc and of cadmium. They also are reduced to (1) aldehydes, by reaction with hydrogen, using a catalyst; or (2) alcohols, with lithium aluminum hydride or sodium borohydride. Aldehydes also can be prepared from acyl halides by way of *N,N*-dialkylamides, which are reduced with lithium aluminum hydride only to the aldehyde stage:

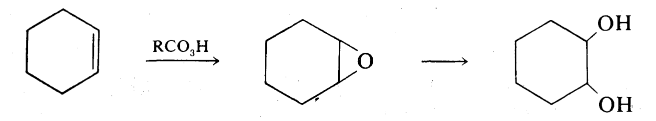
$$\underset{\text{acyl chloride}}{RCOCl} \xrightarrow{R'_2NH} \underset{N,N\text{-dialkylamide}}{RCONR'_2} \xrightarrow{LiAlH_4} \underset{\text{aldehyde}}{RCHO.}$$

Peroxy acids. The peroxy acids, or peracids as they are sometimes called, may be considered as monoacyl derivatives of hydrogen peroxide. They are important oxidizing agents and are prepared from carboxylic acids and hydrogen peroxide in the presence of acidic catalysts (usually sulfuric acid or methanesulfonic acid) or from acid anhydrides and hydrogen peroxide. It is not always necessary to isolate the peracid, and mixtures of carboxylic acid and hydrogen peroxide may be employed as oxidizing agents.

Peracetic acid is manufactured by the atmospheric oxidation of acetaldehyde.

Reactions of peracids

As oxidizing agents, the peracids are used (1) to prepare epoxides and 1,2-diols from alkenes; (2) to convert ketones to esters; and (3) to oxidize amines to amine oxides, nitroso compounds, or nitro compounds. Epoxides result when alkenes are treated with aromatic peracids, such as peroxybenzoic or monoperoxyphthalic acid, or with aliphatic peracids in a buffered solution. Without a buffer the reaction mixture containing the aliphatic acid is so acidic that the epoxide ring is cleaved to give the 1,2-diol:



cyclohexene epoxycyclohexane cyclohexane-1,2-diol

The aliphatic peracids most widely used are peroxyformic, peroxyacetic, and peroxytrifluoroacetic.

Nitrogen-containing derivatives. *Nitriles.* Nitriles, or cyanides, with the general structure RC≡N, are made (1) from alkyl halides (or sulfates) by reaction with sodium or potassium cyanide, (2) from acids by dehydration of the corresponding amides, or (3) from aldehydes by dehydration of the aldoximes. These reactions are shown below:

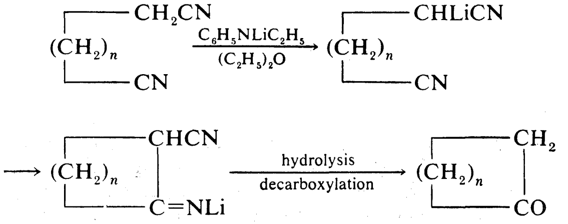
$$RX \longrightarrow RCN$$
$$RCOOH \longrightarrow RCONH_2 \longrightarrow RCN$$
$$RCHO \longrightarrow RCH{=}NOH \longrightarrow RCN.$$

Reactions of nitriles

Nitriles can be hydrolyzed to amides and to acids, or they can be converted directly to esters. They are reduced easily to primary amines; but reaction occurs via imines and, under suitable conditions, reduction can be halted at this stage, with the imine being hydrolyzed subsequently to an aldehyde:

$$RCN \xrightarrow{\text{hydrolysis}} RCONH_2 \xrightarrow{\text{hydrolysis}} RCOOH$$
$$RCN \xrightarrow[(C_2H_5)_2O]{SnCl_2,HCl,} RCH{=}NH \xrightarrow{H_2O} RCHO.$$

Nitriles share with esters the ability to undergo base-catalyzed self-condensation, one molecule acting as a nitrile and the second as a source of carbanion. Dinitriles undergo internal condensation and are used to prepare cyclic compounds in this way:



$$(CH_2)_n\begin{cases} CH_2CN \\ CN \end{cases} \xrightarrow[(C_2H_5)_2O]{C_6H_5NLiC_2H_5} (CH_2)_n\begin{cases} CHLiCN \\ CN \end{cases}$$
$$\longrightarrow (CH_2)_n\begin{cases} CHCN \\ C{=}NLi \end{cases} \xrightarrow[\text{decarboxylation}]{\text{hydrolysis}} (CH_2)_n\begin{cases} CH_2 \\ CO \end{cases}$$

Amides. The preparation of amides from acyl halides or anhydrides (or sometimes esters) is generally accomplished by reaction with ammonia or with a primary or secondary amine. Amides also are the products of the partial hydrolysis of nitriles, and they can be obtained directly from carboxylic acids by reaction with urea, sulfamide (in the presence of pyridine), thiourea, or hexamethylphosphoramide.

Reactions of amides

Amides are hydrolyzed by acid or alkali to carboxylic acids, and they are dehydrated readily to nitriles. Amides are normally reduced to amines, but *N,N*-dialkylated amides give aldehydes. With bromine and alkali, amides are degraded to amines with one less carbon atom, as follows:

$$RCONH_2 \xrightarrow{Br_2,NaOH} [RCONHBr] \longrightarrow [RNCO] \longrightarrow RNH_2 + CO_2.$$

Urea (NH_2CONH_2) is an amide present in mammalian urine and is the form in which many animals excrete waste nitrogen.

Hydrazides and azides. Hydrazides ($RCONHNH_2$) may be considered formally to be derived from carboxylic acids and hydrazine, and acyl azides ($RCON_3$) are analogous to the acyl chlorides, the azide (N_3) group having replaced a chlorine (Cl) atom. In actual practice, the hydrazides and azides are prepared from acyl halides by reaction with hydrazine and sodium azide, respectively. Nitrous acid converts hydrazides to azides:

$$\begin{tikzcd} & RCONHNH_2 \arrow[dd, "HNO_2"] \\ RCOCl \arrow[ur, "N_2H_4"] \arrow[dr, "NaN_3"'] & \\ & RCON_3 \end{tikzcd}$$

THE IDENTIFICATION AND ANALYSIS OF CARBOXYLIC ACIDS AND DERIVATIVES

In the qualitative analysis of organic compounds, carboxylic acids are recognized by their solubility in aqueous alkali and by their ability to liberate carbon dioxide from bicarbonate solutions. When treated with potassium hydroxide and hydroxylamine, esters give hydroxamic acids, which are easily recognized by the deep red or purple colours they give with ferric salts.

Infrared spectra of carboxyl compounds

All acyl compounds have distinctive bands in their infrared spectra (particular patterns of light absorption, instrumentally determined). The absorption is believed to result from energy taken up by certain carbonyl stretching motions in the molecules. The exact frequency of this absorption depends on the molecular environment of the carbonyl group, and it is sometimes possible to distinguish the various types of carbonyls by the frequency of the infrared absorption (see Table 25). A double bond, or an aromatic system in the alpha position with reference to the carbonyl group, causes the absorption in each case to appear at the lower end of the range.

Table 25: Characteristic Infrared Absorption Bands of Selected Classes of Carbonyl Compounds

class	infrared absorption frequency, C=O stretching (cm^{-1})
Anhydrides	1850–1740*
Acyl halides	1815–1750
Esters	1750–1710
Aldehydes	1740–1680
Ketones	1725–1660
Carboxylic acids	1720–1660
Amides	1680–1630

*Two peaks, about 60 cm^{-1} apart.

Carboxylic acids can be characterized by the preparation of a wide range of solid derivatives. Among the most commonly employed are the

amides	($RCONH_2$),
anilides	($RCONHC_6H_5$),
p-toluidides	($RCONHC_6H_4CH_3$),
p-nitrobenzyl esters	($RCOOCH_2C_6H_4NO_2$),
S-benzylthiuronium salts	[$RCO\overset{-}{O}(\overset{+}{N}H_2)_2CSCH_2C_6H_5$],
p-bromophenacyl esters	($RCOOCH_2COC_6H_4Br$),
and hydrazides	($RCONHNH_2$).

Esters and other acyl derivatives usually furnish these compounds after hydrolysis to the acid; or, in some cases, they are converted directly to the compound without production of the free acid.

The reaction of carboxylic acids and esters with alkali is the basis of several procedures for the quantitative estimation of these groups. Acids react quickly at room temperature and can be titrated directly in aqueous or alcoholic solution. Alternatively, they can be treated with excess of alkali, the excess being titrated with standard acid solution. Esters usually react with hot alkali, and the normal procedure for their quantitative determination is heating with excess alkali and titration of the surplus.

This procedure is the basis of the standard method for determining the saponification (hydrolysis) equivalent, or saponification value, of fats. Carboxylic acids can also be quantitatively estimated by determination of (1) the methane liberated during reaction with methylmagnesium iodide or (2) the water formed during esterification.

hroma-
ography of
arboxyl
om-
ounds

Chromatography is a method of separation based on differential adsorption of substances from solution by a solid material (such as alumina). Most of the known chromatographic procedures have been used to separate mixtures of carboxylic acids, as well as mixtures of the various derivatives, and many of the methods have been adapted for qualitative or quantitative identification or both. Indeed many useful developments in chromatography have come about from the need to analyze the mixed amino acids resulting from protein hydrolysis and the mixed fatty acids produced by lipid hydrolysis.

The most important analytical procedure for esters is the form of chromatography known as gas–liquid chromatography. By the use of an appropriate stationary phase, and long capillary columns when necessary, even closely related esters can be separated and quantitatively analyzed. In difficult cases this technique may have to be allied with other separation procedures.

Limited information about the carboxyl group (and other acyl groups) is obtainable by nuclear magnetic resonance spectroscopy, an instrumental technique that gives information about the magnetic properties of atomic nuclei. Although this method may not reveal much about the carboxyl group, it may provide considerable useful information about the remainder of the molecule. Mass spectrometry, the separation of substances on the basis of their respective masses, is an increasingly important tool in the recognition of complex compounds containing carboxyl and other acyl groups, especially those derived from lipids and other natural sources. Fragmentation of the molecule during the mass spectrometry procedure frequently gives valuable information about the molecular structure of the compound or compounds under investigation. Esters, particularly methyl esters, have been more extensively used in mass spectrographic studies than the acids themselves or the other derivatives. (F.D.G.)

Organic halogen compounds

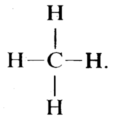
Organic halogen compounds are substances containing atoms of one or more of the so-called halogen elements (fluorine, chlorine, bromine, and iodine) joined to atoms of carbon. In their physical properties and chemical behaviour they are much like other organic compounds (compounds of carbon). Very few organic halogen compounds occur in nature; most are products of the organic chemist's laboratory. Many organic halogen compounds are used as solvents; carbon tetrachloride, for example, is employed as a cleaning fluid. Other members of the family are used as anesthetics and refrigerants. The plastic material polyvinyl chloride is an organic halogen compound; so is the herbicide 2,4-D (2,4-dichlorophenoxyacetic acid). Many organic halogen compounds are used in industry or in the laboratory for conversion to other compounds with useful properties, such as dyes and medicinal agents.

GENERAL CONSIDERATIONS

Hydro-
arbon
leriva-
ives

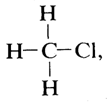
Chemically, organic halogen compounds may be considered to be derivatives of hydrocarbons (compounds composed exclusively of carbon and hydrogen), in which certain of the hydrogen atoms have been replaced by halogen atoms. In the molecules of hydrocarbons, the carbon atoms form a framework, or skeleton, to which the hydrogen atoms are attached. When the halogen atoms replace hydrogen atoms, they too occupy peripheral or terminal positions, leaving the central framework positions in the molecule to the carbon atoms.

In theory, successive replacement of hydrogen atoms with halogen atoms is possible in any hydrocarbon molecule, until all hydrogen atoms have been replaced. The simplest hydrocarbon, for example, is methane, the molecules of which are composed of one carbon atom and four hydrogen atoms. The structural formula of methane is



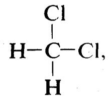
$$\begin{array}{c}\mathrm{H}\\ |\\ \mathrm{H{-}C{-}H.}\\ |\\ \mathrm{H}\end{array}$$

Replacement of one of the hydrogen atoms in methane with a chlorine atom (Cl) gives the substance methyl chloride



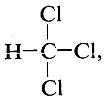
$$\begin{array}{c}\mathrm{H}\\ |\\ \mathrm{H{-}C{-}Cl,}\\ |\\ \mathrm{H}\end{array}$$

or CH_3Cl. Further replacements of hydrogen with chlorine give methylene dichloride



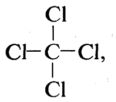
$$\begin{array}{c}\mathrm{Cl}\\ |\\ \mathrm{H{-}C{-}Cl,}\\ |\\ \mathrm{H}\end{array}$$

or CH_2Cl_2; chloroform



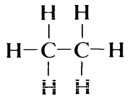
$$\begin{array}{c}\mathrm{Cl}\\ |\\ \mathrm{H{-}C{-}Cl,}\\ |\\ \mathrm{Cl}\end{array}$$

or $CHCl_3$; and carbon tetrachloride



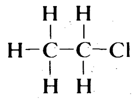
$$\begin{array}{c}\mathrm{Cl}\\ |\\ \mathrm{Cl{-}C{-}Cl,}\\ |\\ \mathrm{Cl}\end{array}$$

or CCl_4. Similar replacements can be carried out in molecules of the hydrocarbon ethane



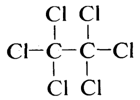
$$\begin{array}{c}\mathrm{H\ \ H}\\ |\ \ \ |\\ \mathrm{H{-}C{-}C{-}H}\\ |\ \ \ |\\ \mathrm{H\ \ H}\end{array}$$

(C_2H_6) to give a series of compounds ranging from ethyl chloride



$$\begin{array}{c}\mathrm{H\ \ H}\\ |\ \ \ |\\ \mathrm{H{-}C{-}C{-}Cl}\\ |\ \ \ |\\ \mathrm{H\ \ H}\end{array}$$

(C_2H_5Cl) to hexachloroethane (C_2Cl_6).



$$\begin{array}{c}\mathrm{Cl\ \ Cl}\\ |\ \ \ \ |\\ \mathrm{Cl{-}C{-}C{-}Cl}\\ |\ \ \ \ |\\ \mathrm{Cl\ \ Cl}\end{array}$$

Atoms of each of the other halogen elements—fluorine (F), bromine (Br), and iodine (I)—can similarly be substituted for hydrogen atoms in hydrocarbons (giving compounds containing atoms of more than one halogen element, as well as compounds with multiple atoms of any one element). When the precise nature of the halogen atom is not important, it is customary to use the symbol X, which can stand for an atom of any halogen element. Thus CH_3X could mean methyl fluoride (CH_3F), methyl chloride (CH_3Cl), methyl bromide (CH_3Br), or methyl iodine (CH_3I).

Although organic halogen compounds can be considered to be derived formally from hydrocarbons by replacement of hydrogen atoms with halogen atoms, this often is not the procedure by which organic halogen compounds are actually prepared in the laboratory. As will be shown, a variety of synthetic procedures is available for preparing organic halogen compounds from other classes of organic compounds.

Nomenclature and classification. Organic halogen compounds, generally, are named according to one of two principles, substitution or the use of organic radicals. In substitution names, the combining form of the name of the halogen element is used as a prefix to the name of the parent hydrocarbon. In this system the compound CH_3Cl is called chloromethane. The analogous combining forms of the other halogen elements are fluoro-, bromo-, and iodo-; halo- is the combining form of the generic term halogen.

In the "radical" system of nomenclature the organic portion of the molecule (everything but the halogen atom) is designated by a combining form, or radical, which is followed by the name of the halogen in its -ide form (*e.g.*, chloride for chlorine). The organic radicals are derived from the names of the hydrocarbons by substituting the ending -yl for a portion of the hydrocarbon name. Thus methane becomes methyl, and the substance designated chloromethane above is also termed methyl chloride. Often, when it is desired not to specify one particular radical, the letter R— is used. In this way $R-Cl$ represents any organic chlorine compound, and the designation $R-X$ stands for the entire class of organic monohalogen compounds.

Almost any class of organic chemical compound—including alcohols, aldehydes, ketones, and carboxylic acids—can carry halogen atoms in its molecules. The phrase "organic halogen compounds," however, is usually taken to refer simply to halogen derivatives of the various hydrocarbons.

General chemical properties. As previously noted, the chemical behaviour of chemical compounds is largely determined by the electronic configuration of their molecules, and this in turn depends upon the electronic configurations of the constituent atoms. The electronic configuration of halogen atoms is quite different from those of carbon and hydrogen atoms, with the result that the incorporation of halogen atoms into hydrocarbon molecules has a marked effect on their chemical behaviour.

Effect of polarizability

Atoms contain varying numbers of negatively charged electrons in what may be defined crudely as concentric shells about the positively charged nucleus. The atoms of the halogen elements, as a group, are characterized by the fact that their outermost electron shells include seven electrons. The halogen elements are differentiated from one another by the number of electron shells, and consequently by the total number of electrons they contain. These numbers increase with the atomic weights of the halogen elements, in the following order: fluorine, chlorine, bromine, and iodine. The seven electrons in the outermost shells, the so-called valence electrons, are farther and farther from the nucleus as the number of shells increases (that is, in the order given above). (The atomic radius of the iodine atom, for example, is rather more than twice that of the fluorine atom.) Consequently the valence electrons are most firmly held by the fluorine nucleus and least firmly held by the iodine nucleus. Because of its small size, fluorine is the most electronegative (electron-attracting) of the halogens, and iodine is the least. In general, less strongly held electrons, such as those of iodine, are more polarizable; *i.e.*, more easily distorted by attractive or repulsive forces near them. Polarizability is an important property that greatly influences the behaviour of halogen atoms with regard to organic molecules, as for example, when free halide ions (halide atoms containing an extra electron, and hence a net negative charge) attack positive centres in organic compounds (as occurs in the synthesis of many organic halogen compounds). In such "nucleophilic" (or positive-charge-seeking) attack, the halide ions attack preferentially in the decreasing order: iodide, bromide, chloride, and fluoride. This explains why hydriodic acid reacts more readily with alcohols to give alkyl halides than do the other halogen acids.

Because carbon is less electronegative than any of the halogen elements, the halogen atom attracts the two electrons that comprise a carbon–halogen bond more strongly than does the carbon atom. As a result, the electrons of the bond are displaced toward the halogen atom, and the bond is polarized. The carbon atom concerned will thus bear a partial positive charge, and will be susceptible to attack by nucleophiles—reagents that seek positive centres. Typical nucleophiles are negatively charged groups, such as the hydroxide ion, a negatively charged group comprised of a linked hydrogen and oxygen atom, OH^-, and molecules having atoms with lone pairs of electrons, such as ammonia, $:NH_3$ (in which the two dots before the N represent a lone pair of electrons). The result of nucleophilic attack on an organic halide is substitution (or replacement) of the halide by the nucleophile. The equation below represents a nucleophilic substitution reaction in which the iodine atom in methyl iodide is replaced by the hydroxide ion acting as a nucleophile:

$$HO^- + \overset{\delta+}{C}H_3 - \overset{\delta-}{I} \longrightarrow HO - CH_3 + I^-$$

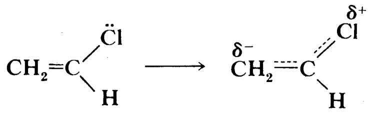
As is usually the case in chemical equations the starting materials are written at the left of the arrow and the products of the reaction are written at the right. In this equation, the polarization of the methyl iodide molecule is indicated by the symbols δ^+ and δ^-, in which δ (delta) means that partial charges (with signs as shown) appear on the atoms in question.

The readiness with which such nucleophilic substitutions occur depends on two factors: (1) the ease of dissociation of the carbon–halogen bond and (2) the nature of the leaving group (the halide ion). The ease of dissociation of a bond is inversely proportional to the bond energy, which for a carbon–halogen bond increases in the order: iodine, bromine, chlorine, and fluorine. A good leaving group, in general, is the anion of a strong acid, and the strengths of the halogen acids decrease in the order hydrogen iodide, hydrogen bromide, hydrogen chloride, and hydrogen fluoride. The bond dissociation energies and the nature of the leaving groups thus act in the same direction for the halides, with the result that the susceptibility of the various alkyl halides to nucleophilic attack decreases in the order: iodide, bromide, chloride, and fluoride.

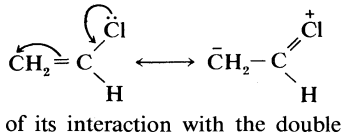
Free-radical reactions

Organic halogen compounds also undergo free-radical reactions, reactions that lead to splitting of a bond, one electron going with each fragment. In such reactions, only the bond dissociation energies are significant, and, in this case, the order of reactivity of the alkyl halides is the same as it is in nucleophilic attack.

When a halogen atom is attached to an unsaturated carbon atom (one in which not all the valence bonds are saturated), as in certain alkenyl halides, such as vinyl chloride, $CH_2{=}CHCl$, the halogen atom still attracts electrons to it, because of its electronegativity, but another factor must also be considered. In vinyl chloride, for example, the orbital (position in space) of one of the lone pairs of electrons of the chlorine atom overlaps with the orbital of certain of the electrons associated with the double bond. These are the so-called pi electrons, two of which (one from each carbon atom) occupy an orbital covering both carbon atoms and form one of the bonds (called a pi bond) uniting the two carbon atoms. These pi bonds occur only in multiple bonds. As a result of the interaction of the chlorine electrons with the pi electrons of the double bond, carbon–chlorine bonds of this particular type themselves have some double-bond character. Since this involves a partial loss of electrons from chlorine and a gain by the double bond, the molecule becomes polarized as shown in the equation below:



in which the dotted lines indicate partial double bond character. This phenomenon also can be described in a different way as a movement of the lone pair of electrons associated with the halogen atom, as shown in the diagram below by a curved arrow. This shift of electrons causes a polarization of the double bond. The actual state of the molecule is between the two extreme forms shown below, connected by a double-headed arrow:

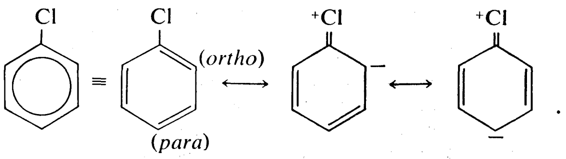


As a result of its interaction with the double bond, the halogen atom of a vinyl halide is much less susceptible to nucleophilic substitution than is an ordinary alkyl halide.

The presence of halogen atoms adjacent to a double bond—the situation in vinyl halides—also has an effect on the chemical reactivity of the double bond. Generally, one of the principal reactions of double bonds is electrophilic addition—a reaction that is initiated by an electron-seeking (electrophilic) reagent and leads to saturation of the double bonds, that is, to production of a molecule with nothing but single bonds. Electrophilic addition is strongly influenced by the polarization of the double bond caused by the halogen atom. As indicated above, a halogen atom on one carbon atom of a double bond leads to a partial negative charge on the other atom of the double bond. This negative charge is the target of an electrophilic reagent, so that the direction of electrophilic addition is dictated by the halogen atom.

When there are several halogen atoms attached to the double bond, their electron-attracting powers become more evident; in fact, they may reduce the negative character of the double bond to such an extent that it adds electrophilic reagents very much less readily than does a double bond without halogen substituents. At the same time, however, it may become more reactive toward nucleophilic reagents (which attack positive centres).

The same situation arises in the aryl halides. In this case, however, there is a more extensive unsaturated system, which can polarize in several different ways, as shown below:



lectro-
hilic
ubsti-
ution

In these diagrams, the hexagon represents a ring of six carbons (carrying single hydrogen atoms except where the chlorine atom is shown); the aromatic nature of the ring system is indicated either by a circle within the hexagon or by three double bonds (the two forms being connected by an identity sign). Forms in which separation of charges occurs (as shown by the plus and minus signs) are connected by double-headed arrows, indicating that they contribute to the overall structure of the molecule. Because this polarization produces partial negative charges at the positions in the ring designated *ortho* and *para* (from Greek roots chosen somewhat arbitrarily before the correct positions were known), electrophilic substitution (*i.e.*, attack by positively charged groups) occurs preferentially at these positions. In aromatic compounds of most varieties, substitution reactions occur more readily than addition reactions because addition destroys the aromaticity of the ring, whereas substitution does not. In polyhalogenated aromatic derivatives, the electronegative halogen atoms reduce the susceptibility of the ring to electrophilic substitution by withdrawing electrons generally from the ring, but, at the same time, they activate the molecule toward nucleophilic attack, of such nature that the halogen atoms themselves are replaced by the attacking nucleophiles.

General physical properties. Generally in organic halogen compounds, the boiling points increase as the atomic weights of the halogen elements increase and as the molecular weights of the compounds themselves increase (see Table 26). On the other hand, the more highly branched the chain of a given number of carbon atoms is, the lower the boiling point of the compound is.

Table 26: Boiling Points of Alkyl Halides (°C)

radical	formula	fluoride	chloride	bromide	iodide
Methyl	CH_3—	−78.4	−23.76	3.45	42.5
Ethyl	CH_3CH_2—	−38.0	+12.5	38.4	72.4
n-Propyl	$CH_3CH_2CH_2$—	− 2.5	46.6	71.0	102.5
Isopropyl	$(CH_3)_2CH$—	− 9.4	34.8	59.4	89.5
n-Butyl	$CH_3(CH_2)_3$—	32.5	78.5	101.5	130.4
Isobutyl	$(CH_3)_2CHCH_2$—	. . .	68.8	91.4	121.0
sec-Butyl	$C_2H_5CH(CH_3)$—	25.1	68.2	91.2	120.0
tert-Butyl	$(CH_3)_3C$—	12.1	50.7	73.2	103.3

Boiling points usually increase with the number of halogen atoms; *e.g.*, methyl chloride (CH_3Cl), −24° C (−11.2° F); methylene chloride (CH_2Cl_2), 40° C (104° F); chloroform ($CHCl_3$), 62° C (143.6° F); carbon tetrachloride (CCl_4), 77° C (170.6° F).

Densities increase with increase in the atomic weight of the halogen and also with the number of halogen atoms in the molecule; *e.g.*, ethyl fluoride (C_2H_5F), 0.818; ethyl chloride (C_2H_5Cl), 0.923; ethyl bromide (C_2H_5Br), 1.47; ethyl iodide (C_2H_5I), 1.98; ethylidene chloride (CH_3CHCl_2), 1.18; ethylene dichloride (CH_2ClCH_2Cl), 1.25; 1,1,1-trichloroethane CH_3CCl_3, 1.35; 1,1,2-trichloroethane $CH_2ClCHCl_2$, 1.44 (the numbers in the names designating the carbon atoms to which the halogens are attached).

Melting
and boiling
points

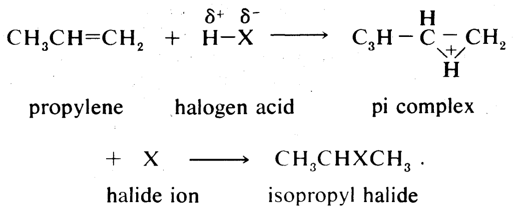
Melting points and boiling points of organic halogen compounds, however, do not depend exclusively on the molecular weights of the molecules concerned; they also are influenced by the intermolecular forces involved and hence on the polar (unsymmetrically charged) nature of the molecule (polar molecules being more attracted to one another than nonpolar molecules and hence more resistant to both melting and boiling). For instance, geometrical isomers—that is, compounds with the same structural framework but different spatial arrangements of the substituent groups of atoms—have different melting and boiling points (which also differ from those of any other isomers of the same compounds) because the halogen atoms are differently oriented with respect to one another. An example of such a circumstance is found in the difluoroethylenes: 1,1-difluoroethylene, $CH_2{=}CF_2$, boils at −84° C (−119.2° F); whereas the two geometrical isomers of 1,2-difluoroethylene, $CHF{=}CHF$, which are known as *cis*- and *trans*-1,2-difluoroethylene, boil at −26° C (−15° F) and −53° C (−43° F) respectively. There is a considerable variation in physical properties among polyhalogenated compounds also because of differences in polarity. For example, a nonpolar fully fluorinated compound often has a lower boiling point than less highly fluorinated compounds with the same carbon skeleton, chiefly because the latter are more polar (see Table 27). Boiling points of representative alkyl halides are given in Table 26, and melting and boiling points of aryl halides are presented in Table 27.

The weak intermolecular forces in fully fluorinated compounds (resulting from their low polarity) also are responsible for the low viscosities these substances exhibit—they are used as oils and greases under carefully controlled conditions. (Their viscosities decreased rapidly with increase in temperature, however, and this fact prevents their more general use.)

The bond dissociation energies of carbon-to-halogen bonds, given in the standard units of kilocalories per mole (a mole being equal to the molecular weight expressed in grams), are carbon–fluorine, 108; carbon–chlorine, 81; carbon–bromine, 67; and carbon–iodine, 53. For purposes of comparison, it may be noted that the carbon–carbon and carbon–hydrogen bond dissociation energies are 84 and 102 kilocalories per mole, respectively. The high dissociation energy of the carbon–fluorine bond and the low dissociation energy of the carbon–iodine bond help to explain why the fluorocarbons are thermally stable whereas organic iodine compounds dissociate readily on heating (with liberation of iodine).

ALKYL HALIDES

Monohalides. *Preparation.* Hydrocarbons bearing one halogen substituent are most commonly prepared by two methods: (1) addition of halogen acids to olefins (alkenes) and (2) replacement of hydroxyl (−OH) groups in alcohols. In its simplest form addition of halogen acids to olefins is an electrophilic addition reaction in which the positively charged end of the polarized halogen acid is attracted to the olefinic double bond. The acid then dissociates producing a halide ion and a proton (hydrogen ion) which, with the pi electrons of the double bond, forms a positively charged intermediate known as a pi complex. Finally, the halide ion reacts with the pi complex to give the ultimate product. A typical reaction of this type is shown in chemical formulas below:



$$\mathrm{CH_3CH{=}CH_2} + \overset{\delta^+\ \delta^-}{\mathrm{H{-}X}} \longrightarrow \mathrm{C_3H{-}\overset{H}{C}\underset{H}{\overset{+}{-}}CH_2}$$

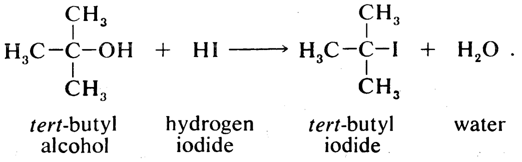
$$+\ \mathrm{X} \longrightarrow \mathrm{CH_3CHXCH_3}\,.$$

The direction of addition to the double bond can be predicted by a consideration of the effects of the alkyl groups (in this case, only methyl, CH_3-) attached to the double bond carbons. The various halogen acids undergo addition to double bonds, in decreasing order of reactivity, as follows: hydrogen iodide, hydrogen bromide, hydrogen chloride, and hydrogen fluoride.

In the presence of traces of peroxides (which can be produced from olefins and traces of oxygen by sunlight), hydrogen bromide reacts with olefins in a different fashion, often to give products in which the addition occurs in the opposite direction to that in the above reaction (that is, with bromine atom appearing on the other double bond carbon atom).

Conversion of alcohols to halides

Alkyl halides are produced from alcohols by means of nucleophilic substitution reactions with hydrogen halides (halogen acids), phosphorus halides, or thionyl halides. The reactivities of the halogen acids in this reaction are, in decreasing order: hydrogen iodide, hydrogen bromide, and hydrogen chloride. (Hydrogen fluoride cannot be used.) Tertiary alcohols (alcohols with three carbon atoms attached to the hydroxyl carbon) undergo this reaction readily. Secondary and primary alcohols (alcohols with two and one carbon atom joined to the hydroxyl carbon, respectively) react with less facility. For example, tertiary butyl alcohol reacts with aqueous hydrogen iodide at room temperature, according to the following equation:



$$\mathrm{H_3C{-}\underset{CH_3}{\overset{CH_3}{C}}{-}OH} + \mathrm{HI} \longrightarrow \mathrm{H_3C{-}\underset{CH_3}{\overset{CH_3}{C}}{-}I} + \mathrm{H_2O}\,.$$

Secondary bromides and iodides (corresponding in structure to secondary alcohols) usually can be prepared in the same way. For primary alkyl chlorides, however, it is necessary to use a catalyst and warm the solution. (Long heating may cause isomerization—rearrangement to another product.)

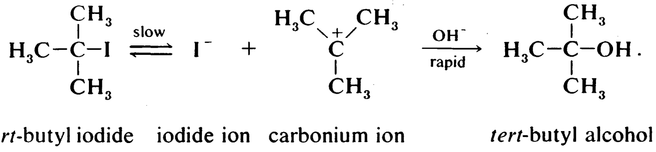
Phosphorus pentachloride, phosphorus tribromide, red phosphorus and bromine, phosphorus triiodide, and red phosphorus and iodine all react with the appropriate alcohols to give primary, secondary, and tertiary halides. Thionyl chloride and thionyl bromide react with primary or secondary alcohols in the presence of an organic base, such as pyridine. Tertiary alcohols need no base.

The various alkyl halides can be interconverted, and they also can be prepared from other alkyl compounds. Either process is one of nucleophilic substitution by halide ions, and the choice of solvent for the reaction is important.

Reactions. In most of their reactions, the alkyl iodides are more reactive than bromides, which are more reactive than the chlorides, and these, in turn, are more reactive than the fluorides. This order of reactivity reflects the relative ease with which the respective carbon–halogen bonds are broken. Also, generally speaking, the tertiary halides react most readily, the secondary less so, and the primary least of all, reflecting the fact that alkyl substituents tend to donate electrons to the carbon atom that carries the halogen, causing it to release the halide ion, and the more alkyl substituents there are (three in tertiary compounds), the more easily is the halide ion lost. The chemical reactions undergone by alkyl halides can be classified under three headings: (1) nucleophilic substitutions, (2) elimination reactions, and (3) free-radical processes.

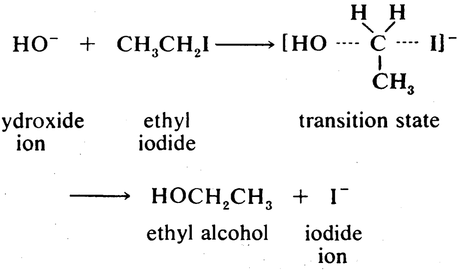
Nucleophilic substitutions

Nucleophilic substitution reactions are classified as unimolecular or bimolecular according to whether the reaction involves one or two molecules. Unimolecular nucleophilic substitutions proceed by way of ionization of the alkyl halide—that is, by cleavage of the molecule to give a positively charged alkyl, or carbonium, ion and a negatively charged halide ion. This type of reaction is undergone most readily by a tertiary alkyl halide in ionizing solvents (aqueous alcohol, for example). Reactions of this type are known to chemists as S_N1 reactions (meaning substitution, nucleophilic, unimolecular). A good example of an S_N1 reaction is the hydrolysis of *tert*-butyl iodide:



$$\mathrm{H_3C{-}\underset{CH_3}{\overset{CH_3}{C}}{-}I} \underset{}{\overset{\text{slow}}{\rightleftharpoons}} \mathrm{I^-} + \underset{\mathrm{CH_3}}{\overset{\mathrm{H_3C\ \ CH_3}}{\overset{+}{\mathrm{C}}}} \xrightarrow[\text{rapid}]{\mathrm{OH^-}} \mathrm{H_3C{-}\underset{CH_3}{\overset{CH_3}{C}}{-}OH}\,.$$

Bimolecular nucleophilic substitutions—S_N2 reactions—proceed through a transition state that includes a nucleophile—for example a hydroxide ion—as well as a molecule of the alkyl halide. They are most common for primary alkyl halides in nonionizing solvents. An example is the reaction of ethyl iodide with a hydroxide ion to give ethyl alcohol and the iodide ion:



$$\mathrm{HO^-} + \mathrm{CH_3CH_2I} \longrightarrow [\mathrm{HO} \cdots \underset{\mathrm{CH_3}}{\overset{\mathrm{H\ \ H}}{\mathrm{C}}} \cdots \mathrm{I}]^-$$

$$\longrightarrow \mathrm{HOCH_2CH_3} + \mathrm{I^-}$$

Nucleophiles other than the hydroxide ion that react in this fashion are ammonia and trimethylamine, and the ethoxide, acetate, cyanide, azide, acid sulfide, and hydride ions.

Elimination reactions

Whenever alkyl halides are hydrolyzed, a certain amount of olefin is formed by an elimination process. Elimination sometimes becomes the main reaction, as in the hydrolysis of tertiary halides, in which the carbonium ion formed can

Table 27: Melting Points and Boiling Points of Aryl Halides (°C)

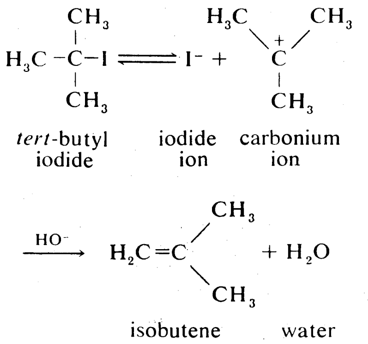
Hexahalobenzene	5	80	229	326	326		340–350	

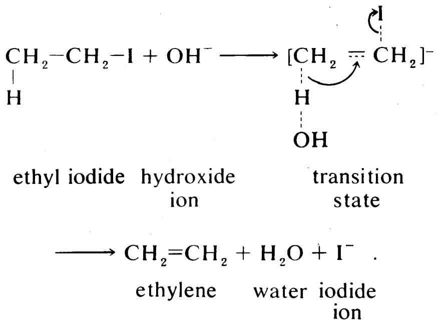
easily eliminate a proton. An example is the hydrolysis of *tert*-butyl iodide to give isobutene:



$$(CH_3)_3C{-}I \rightleftharpoons I^- + (CH_3)_3C^+ \xrightarrow{HO^-} H_2C{=}C(CH_3)_2 + H_2O$$

This is a unimolecular elimination—E_1 reaction—so classified because the rate at which it occurs is governed by the rate of formation of the carbonium ion from the alkyl halide.

Bimolecular eliminations—E_2 reactions—occur mainly with primary halides. They occur by removal of a hydrogen ion from the carbon atom adjacent to that carrying the halogen atom. For example, the elimination reaction involving ethyl iodide proceeds as shown (with the movements of the electrons comprising the various bonds indicated by curved arrows):



$$H{-}CH_2{-}CH_2{-}I + OH^- \longrightarrow [HO\cdots H\cdots CH_2 \cdots CH_2 \cdots I]^- \longrightarrow CH_2{=}CH_2 + H_2O + I^-\ .$$

By suitable choice of the reaction conditions (that is, by selecting the right solvent, temperature, and concentration of nucleophile) it is often possible to influence whether a particular reaction proceeds by bimolecular or unimolecular substitution or by an elimination reaction. Because the products of these reactions often are different, the distinction may be vitally important in a synthetic process.

Alkyl halides usually react with metals by a process that generates free radicals—that is, substances with single (unpaired) electrons. The free radical may then react with a second metal atom, resulting, as shown in the example below, in formation of an organometallic compound (that is, an organic compound with a metal substituent):

$$CH_3(CH_2)_3Br + Li\cdot \longrightarrow LiBr + CH_3(CH_2)_2\dot{C}H_2$$

n-butyl bromide   lithium metal   lithium bromide   *n*-butyl radical

$$\xrightarrow{Li\cdot} CH_3(CH_2)_3Li\ .$$

n-butyllithium

(In the names of these compounds *n*, for normal, indicates that the hydrocarbon chain is straight, or unbranched.) With magnesium, the reaction is carried out in an ether as solvent to give an organomagnesium halide:

$$R{-}I + Mg \longrightarrow R\cdot + \cdot MgI$$

alkyl iodide   magnesium   alkyl radical   iodo-magnesium radical

$$\longrightarrow R{-}Mg{-}I.$$

alkyl-magnesium iodide

In these reactions iodides and bromides are generally used because chlorides and fluorides react much less readily. The reduction of alkyl halides by sodium and alcohol, zinc and dilute acid, or similar reducing agents may also be a free-radical process:

$$RI + H\cdot \longrightarrow R\cdot + HI;$$

alkyl iodide   hydrogen atom   alkyl radical   hydrogen iodide

$$R\cdot + H\cdot \longrightarrow RH.$$

alkyl radical   hydrogen atom   alkane

Polyhalides. *Preparation.* Alkylidene halides, in which two halogen atoms are attached to the same carbon atom, can be made from aldehydes and ketones. For example, isopropylidene chloride is produced from acetone and phosphorus pentachloride; the reaction proceeds according to the following equation:

$$PCl_5 + CH_3COCH_3$$

phosphorus pentachloride   acetone

$$\longrightarrow POCl_3 + CH_3CCl_2CH_3.$$

phosphorus oxychloride   isopropylidene chloride

To prepare the fluorides, sulfur tetrafluoride or phenyl sulfur trifluoride is used with an aldehyde or ketone. Another general method for preparing alkylidene halides is to add a halogen acid to a vinyl halide or an alkyne. An example is the addition of hydrogen chloride to acetylene, vinyl chloride being produced first:

$$HC{\equiv}CH \xrightarrow{HCl} CH_2{=}CHCl \xrightarrow{HCl} CH_3CHCl_2\ .$$

acetylene   vinyl chloride   ethylidene chloride

Alkylene dihalides, in which two halogen atoms are attached to different carbon atoms, are formed from halogens and alkenes by electrophilic addition, or from glycols (compounds with two alcohol groups) by nucleophilic substitution exactly as the alkyl halides are prepared from ordinary alcohols.

Trihaloalkanes

The best known trihaloalkanes are those in which all three halogen atoms are on the same carbon atom; these are the haloforms, of which chloroform, $CHCl_3$, is the most familiar. Haloforms generally are made by the halogenation and subsequent alkaline hydrolysis of compounds containing the acetyl group (CH_3CO-) or structures capable of producing it on oxidation. Fluorination of acetophenone, for instance, followed by hydrolysis of the product, gives fluoroform, as shown:

$$C_6H_5COCH_3 \longrightarrow C_6H_5COCF_3$$

acetophenone   α,α,α-trifluoro-acetophenone

$$\xrightarrow{H_2O} C_6H_5COOH + HCF_3\ .$$

benzoic acid   fluoroform

Larger molecules can be made by the free-radical addition of chloroform to olefins, as follows:

$$CH_2{=}CH_2 + \cdot CCl_3 \longrightarrow \cdot CH_2CH_2CCl_3$$

ethylene   trichloromethyl radical (from $CHCl_3$)   intermediate radical

$$\cdot CH_2CH_2CCl_3 + HCCl_3$$

intermediate radical   chloroform

$$\longrightarrow CH_3CH_2CCl_3 + \cdot CCl_3.$$

1,1,1-trichloro-propane   trichloromethyl radical, regenerated

If the proportion of chloroform present in the reaction mixture is reduced, polymerization (formation of long, chainlike molecules with repeating units) occurs because the intermediate radical reacts with more olefin, giving a series of products of varying chain length, all of which have trichloromethyl end groups. Such products are formed as in the following equations:

$$\underset{\substack{\text{intermediate}\\ \text{radical}}}{\cdot CH_2CH_2CCl_3} + \underset{\text{ethylene}}{nCH_2{=}CH_2} \longrightarrow \underset{\text{polymer radical}}{\cdot CH_2CH_2(CH_2CH_2)_nCCl_3}$$

$$\underset{\text{polymer radical}}{\cdot CH_2CH_2(CH_2CH_2)_nCCl_3} + \underset{\text{chloroform}}{HCCl_3}$$

$$\longrightarrow \underset{\text{polymer product}}{CH_3CH_2(CH_2CH_2)_nCCl_3} + \underset{\substack{\text{trichloromethyl}\\ \text{radical}}}{\cdot CCl_3},$$

in which n is a variable number that depends on the number of times the first step is repeated.

Compounds more highly halogenated than the above classes of polyhalides result from the direct halogenation of alkanes by elemental fluorine, chlorine, or bromine. This process, too, is considered to involve free radicals. Because the energy liberated in replacing hydrogen atoms by fluorine atoms is more than enough to break a carbon-to-carbon bond, the vapour-phase fluorination of alkanes occurs violently unless the reaction is moderated by dilution of the reactants with gaseous nitrogen and unless the heat produced by the reaction is conducted away by a metal surface. As an alternative, metal fluorides can be used instead of elemental fluorine, or an electrochemical process can be employed. In most instances, but not in the electrochemical method, the amount of partly fluorinated material can be adjusted by varying the reaction conditions, but mixtures are always obtained. Chlorination of alkanes with elemental chlorine in the liquid phase gives mainly polychloro compounds but, in the gas phase, it is possible to arrange conditions so as to give more lightly chlorinated material. Bromination is carried out like chlorination; direct iodination, however, is not feasible. Fluorination is such a vigorous process that there is no discrimination in the attack on the different types of hydrogen atoms; in chlorination and, to a greater extent in bromination, tertiary hydrogen atoms are substituted more readily, followed by secondary and primary hydrogens, in order.

Direct halogenation

Reactions. The reactions of alkylene dihalides are very similar to the reactions of alkyl halides, but, when there are two or more halogen atoms on the same carbon atom, there is a sharp decrease in the reactivity of the halogen atoms. In general, as the atomic weight of the halogen atoms increases the stability of the polyhaloalkanes decreases, not only because the carbon–halogen bonds are weaker, but also because of the crowding caused by the packing together of the larger atoms. Stabilities decrease enormously, therefore, in the series from carbon tetrafluoride, through the chloride and bromide to carbon tetraiodide. Furthermore, 1,1,1-trifluoroethane is resistant to hydrolysis by acids, whereas the trichloro compound is easily hydrolyzed to acetic acid. Because the fluorine atom is not much bigger than the hydrogen atom, it is possible to prepare series of fluorocarbon derivatives entirely analogous to the related hydrocarbons. The sizes of the other halogen atoms, however, prevent the formation of many fully halogenated compounds. Fully fluorinated alkanes (called perfluoroalkanes) are particularly stable—both to heat and to chemical reagents—because of the very strong carbon–fluorine bonds and because the fluorine atoms are of just such size that they give good protection to the carbon chains.

Influences on reactivity

Polyhalogenated compounds mainly undergo elimination reactions. Halogen atoms are eliminated either as molecules of the halogen acid (HX) or as molecules of the free halogen itself (X_2). In both cases iodides are most reactive, and fluorides least. Elimination reactions are widely used in the preparation of halogenated alkenes and alkynes (see below *Alkenyl halides* and *Alkynyl halides*). Exchange of one kind of halogen atom for another occurs when polyhalo-compounds are heated with aluminum halides.

ALKENYL HALIDES

Preparation. Alkenyl halides, halogen derivatives of olefins, differ from one another in their chemical behaviour chiefly because of differences in the relationship of the halogen atom to the carbon–carbon double bond. Vinyl halides are those alkenyl halides in which a halogen atom is attached directly to one of the double-bond carbons; allyl halides are those in which the halogen is attached to one of the carbons adjacent to the double-bond carbons. Only in these classes of alkenyl halides is there interaction between the electrons of the halogen atoms and those of the double bond. Therefore, only these alkenyl halides show unique chemical properties; others of the general class resemble ordinary alkyl halides in their properties and methods of preparation.

Varieties of alkenyl halides

One method that is used to prepare vinyl halides of many different types is the addition of an appropriate simple molecule to an alkyne (triply bonded hydrocarbon). These reactions may occur spontaneously, when a simple molecule like a halogen acid is added, or they may need heating, when more complex molecules are to be added. Examples of both are shown below:

$$\underset{\text{acetylene}}{CH{\equiv}CH} + \underset{\substack{\text{hydrogen}\\ \text{chloride}}}{HCl} \longrightarrow \underset{\substack{\text{vinyl}\\ \text{chloride}}}{CH_2{=}CHCl};$$

$$\underset{\substack{\text{trifluoromethyl-}\\ \text{acetylene}}}{CF_3C{\equiv}CH} + \underset{\substack{\text{trichloro-}\\ \text{iodomethane}}}{CCl_3I}$$

$$\xrightarrow{\text{heat}} \underset{\substack{\text{1,1,1-trifluoro-2-iodo-}\\ \text{4,4,4-trichloro-2-butylene}}}{CF_3CI{=}CHCCl_3}$$

The other common methods of preparing vinyl halides are dehydrohalogenation (removal of hydrogen halides) and dehalogenation (removal of halogens) of polyhaloalkanes. Dehydrohalogenation can, in simple cases, be performed by heating with bases, for example:

$$\underset{\substack{\text{ethylene}\\ \text{dichloride}}}{CH_2ClCH_2Cl} + \underset{\substack{\text{sodium}\\ \text{hydroxide}}}{NaOH}$$

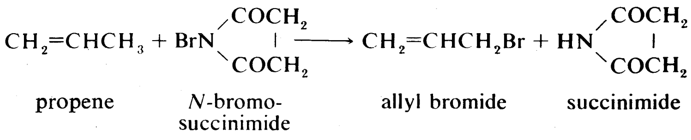
$$\longrightarrow \underset{\substack{\text{vinyl}\\ \text{chloride}}}{CH_2{=}CHCl} + \underset{\substack{\text{sodium}\\ \text{chloride}}}{NaCl} + \underset{\text{water}}{H_2O}.$$

The most common method of dehalogenation is to heat the haloalkane in ethanol solution with zinc dust, as in the following example:

$$\underset{\substack{\text{1-fluoro-1,2-}\\ \text{dibromoethane}}}{CH_2BrCHBrF} \xrightarrow[C_2H_5OH]{Zn} \underset{\text{vinyl fluoride}}{CH_2{=}CHF}.$$

Allyl halides are prepared by the action of the appropriate halogen acid on allyl alcohols. Allyl bromide also is made by treating propene with *N*-bromosuccinimide. The bromide can be converted into other halides by halogen exchange.

Allyl halides



$$\underset{\text{propene}}{CH_2{=}CHCH_3} + \underset{\substack{N\text{-bromo-}\\ \text{succinimide}}}{BrN\begin{matrix}\diagup COCH_2\\ \vert\\ \diagdown COCH_2\end{matrix}} \longrightarrow \underset{\text{allyl bromide}}{CH_2{=}CHCH_2Br} + \underset{\text{succinimide}}{HN\begin{matrix}\diagup COCH_2\\ \vert\\ \diagdown COCH_2\end{matrix}}$$

Reactions. In the vinyl halides, because of the interaction of the electrons of the halogen atom with those of the double bond, the carbon to halogen bond is stronger than it is in ordinary alkyl halides. Moreover, the carbon atom to which the halogen is attached does not carry a positive charge, as does the corresponding carbon atom in typical alkyl halides, and as a result nucleophilic replacement of the halogen atom in vinyl halides does not occur. This lack of positive charge, however, does not prevent the formation of organomagnesium halides, nor does it interfere with normal electrophilic and free radical additions to the double bond.

Polyhalo vinyl compounds

As the number of halogen atoms in a vinyl halide molecule increases, the tendency to undergo electrophilic additions decreases and that to undergo nucleophilic additions increases. Both effects are due to the decrease in electron density of the double bond caused by the electronegative substituents. For polyhalo vinyl compounds, then, the most commonly observed reaction is the addition of nucleophiles, such as alcohols, amines, and thiols. For example, the addition of ethanol to 1,1,2-trichloroethylene gives an ether as an initial reaction product; this is subsequently dehydrohalogenated to dichlorovinyl ethyl ether.

$$\underset{\text{1,1,2-trichloroethylene}}{CCl_2{=}CHCl} + \underset{\text{ethanol}}{C_2H_5OH} \longrightarrow \underset{\text{initial product}}{C_2H_5OCCl_2CH_2Cl}$$

$$\xrightarrow{NaOC_2H_5} \underset{\text{dichlorovinyl ethyl ether}}{C_2H_5OCCl{=}CHCl}$$

Allyl halides, which conform to the structural pattern $CH_2{=}CHCH_2X$, are very much more susceptible to nucleophilic substitution of the halogen atom than are alkyl halides. When a carbonium ion intermediate is formed, (S_N1 reaction) it may be represented by the two formulas:

$$\underset{\gamma}{CH_2}{=}CH{-}\underset{\alpha}{\overset{+}{CH_2}} \longleftrightarrow \underset{\gamma}{\overset{+}{CH_2}}{-}CH{=}\underset{\alpha}{CH_2}.$$

Attack by the nucleophile occurs at either the alpha (α) or gamma (γ) carbon atoms (as shown). This choice becomes significant for unsymmetrical allyl carbonium ions as the product is different in each case. Bimolecular (S_N2) substitution usually involves direct replacement of the allyl halogen atom, but this reaction also can occur with attack at the gamma position to give an alternate product.

Halogenated alkenes of only two carbon atoms usually polymerize readily, but halogenated alkenes bearing large, halogenated alkyl groups attached to the unsaturated carbon atoms may not do so. Fluorinated olefins easily form cyclic dimers when heated above 200° C (392° F). Halogenated alkenes often can be dehydrohalogenated or dehalogenated to alkynes.

ALKYNYL HALIDES

Preparation. In many cases, compounds containing halogen atoms directly joined to triply bonded carbon atoms are formed by reaction between molecular halogen and a metallic derivative of the alkyne. Various sodium acetylides, for example, react with free iodine to give the corresponding iodo compounds.

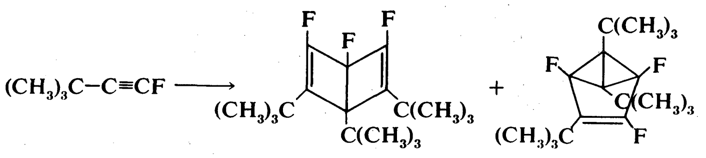
$$RC{\equiv}CNa + I_2 \longrightarrow RC{\equiv}CI + NaI$$

In other instances, alkynyl halides are more easily prepared by dehalogenation or dehydrohalogenation reactions of halogenated alkanes of alkenes. Examples of both reactions, using1,1,2-trichloroethylene as starting material, are shown below:

$$\underset{\text{chloroacetylene}}{CCl{\equiv}CH} \xleftarrow[\text{alcohol}]{\text{Zn}} \underset{\text{1,1,2-trichloroethylene}}{CCl_2{=}CHCl} \xrightarrow[\text{NaOH}]{\text{aq alc}} \underset{\text{dichloroacetylene}}{CCl{\equiv}CCl.}$$

Instability of halo-alkynes

Reactions. Halogenated acetylenes (alkynes), in which the halogen atom is directly bonded to one of the unsaturated carbon atoms, generally are unstable; the lower the molecular weight, the more likely they are to explode. This instability may be due to spontaneous exothermic (heat-producing) polymerization, which, in some cases, can be regulated so that trimerization to halogenated benzenes occurs. Sometimes isomers of benzene derivatives are formed, as for example, in trimerization of *tert*-butylfluoroacetylene:



tert-butylfluoroacetylene — isomeric benzene derivatives

In these structures the polygons represent rings of carbon atoms (the carbon atoms at the angles not being shown), with the lines indicating the bonds between atoms.

A halogen atom attached to an unsaturated carbon atom in a halogenated acetylene is resistant to nucleophilic substitution. Most nucleophiles, therefore, react with haloalkynes first by addition and then by elimination of hydrogen halide. Ammonia, for instance, adds to dichloroacetylene; the initial product then loses hydrogen chloride to give an alkyne, and this in turn isomerizes to a nitrile.

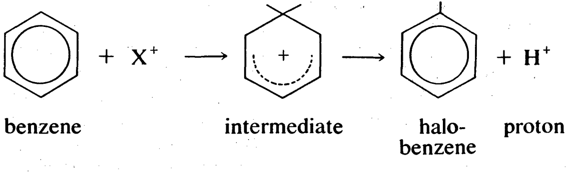
$$\underset{\text{dichloroacetylene}}{ClC{\equiv}CCl} + \underset{\text{ammonia}}{NH_3} \longrightarrow \underset{\text{1,2-dichloroaminoethylene}}{ClCH{=}C(NH_2)Cl}$$

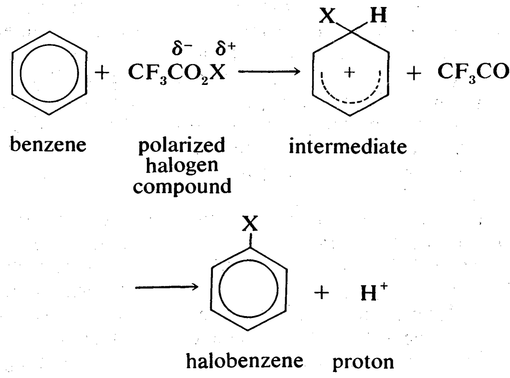
$$\longrightarrow \underset{\text{hydrogen chloride}}{HCl} + \underset{\text{1-amino 2-chloroacetylene}}{ClC{\equiv}CNH_2} \xrightarrow{\text{isomerization}} \underset{\text{chloroacetonitrile}}{CH_2ClC{\equiv}N}$$

In most solvents, such as carbon tetrachloride, electrophilic additions of halogens and halogen acids to alkynyl halides take place, but the reaction is vigorous and must be controlled carefully. The hydrogen in monohaloacetylenes is acidic, as in acetylene itself, and can be replaced by metals. Haloacetylenes in which the halogen is remote from the triple bond are generally stable and show the separate reactivities of alkynes and alkyl halides. The perfluoroalkylalkynes are less unstable than most other alkynes, and they retain the reactivity of the triple bond, readily undergoing free-radical, electrophilic, and nucleophilic addition reactions.

ARYL HALIDES

Nuclear-halogenated aromatic compounds. *Preparation.* There are three main methods for producing aromatic compounds that carry halogen atoms on the aromatic ring (or aromatic nucleus, as it is often called). These are (1) replacement of hydrogen by halogen, (2) replacement of an amino group by halogen, and (3) dehydrohalogenation or dehalogenation of polyhalocyclohexanes or polyhalocyclohexenes.





Replacement of hydrogen

The mechanism of hydrogen replacement is one of electrophilic substitution. It involves, first, the production of either a positively charged halogen ion or a polarized molecule in which the halogen has a partial positive charge (the electrophile). This positive centre then reacts with benzene to form an intermediate from which a proton is subsequently eliminated. Ferric chloride, aluminum chloride, and boron trifluoride are commonly used as catalysts with chlorine or bromine to produce the positively charged halogen ion.

$$\mathrm{Cl_2 + AlCl_3 \rightleftharpoons Cl^+ + AlCl_4^-}$$

Iodination requires the presence of an oxidizing agent, such as nitric acid, to remove hydrogen iodide from the reaction as soon as it is produced, as well as to encourage the formation of positively charged iodine. Hypohalous acids, *N*-chloro- or *N*-bromoamides, and acyl hypohalites are useful halogenating agents because they are polarized in such a way that the halogen atom carries a positive charge.

A chlorine, bromine, or iodine atom in the benzene nucleus deactivates it and causes further substitution to occur in the *ortho* and *para* positions (see above *General chemical properties*). Fluorine also causes *ortho* and *para* orientation, but does not deactivate the nucleus. Excellent yields of nuclear halogenated compounds are formed by chlorinating, brominating, or iodinating substituted benzenes.

Replacement of amino groups

Any of the four halogens can be introduced into the nucleus by diazotizing an aromatic amine and then allowing the resulting diazonium salt to decompose in the presence of a suitable salt of the halogen. Chlorine and bromine, for example, are introduced by heating a diazonium salt in dilute acid solution with cuprous chloride or bromide:

$$Ar\mathrm{NH_2} \longrightarrow Ar\overset{+}{\mathrm{N}}{\equiv}\mathrm{N\ X^-} \xrightarrow[\mathrm{HX}]{\mathrm{Cu_2X_2}} Ar\mathrm{X} + \mathrm{N_2}.$$

aromatic amine	diazonium salt	aryl halide	nitrogen

Ar = any aromatic nucleus

Alternatively, the appropriate diazonium salt can be heated in dilute acid with copper powder:

$$Ar\overset{+}{\mathrm{N}}{\equiv}\mathrm{N\ X^-} \xrightarrow[\mathrm{HX}]{\mathrm{Cu}} Ar\mathrm{X} + \mathrm{N_2}.$$

diazonium salt	aryl halide	nitrogen

Iodine is introduced simply by warming a diazonium salt in the presence of aqueous potassium iodide, for example:

$$\mathrm{C_6H_5\overset{+}{N}{\equiv}N\ Cl^- + KI \longrightarrow C_6H_5I + N_2 + KCl.}$$

benzenediazonium chloride	potassium iodide	iodobenzene	nitrogen	potassium chloride

The most common method used to introduce fluorine is the dry distillation of a diazonium fluoroborate:

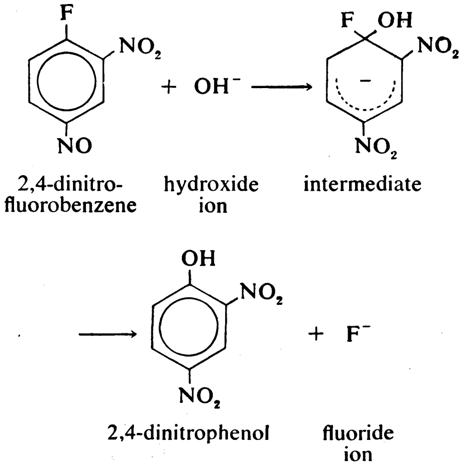
$$Ar\overset{+}{\mathrm{N}}{\equiv}\mathrm{NBF_4^-} \longrightarrow Ar\mathrm{F} + \mathrm{N_2} + \mathrm{BF_3}.$$

diazonium fluoroborate	aryl fluoride	nitrogen	boron trifluoride

The photochemical (*i.e.*, free-radical) chlorination of benzene causes the addition of chlorine to the double bonds and gives a mixture of hexachlorocyclohexanes. Dehydrohalogenation of this mixture by heating with aqueous alcoholic alkali gives a mixture of trichlorobenzenes.

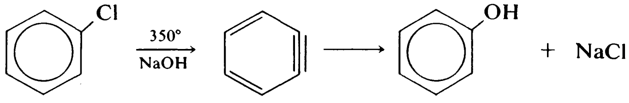
From the mixture obtained by fluorinating benzene with cobalt trifluoride, octa- and nonafluorocyclohexanes can be isolated. Dehydrofluorination of these substances by heating with concentrated aqueous potash gives penta- and hexafluorobenzenes. Deca-, nona-, and octafluorocyclohexanes can be dehydrofluorinated to polyfluorocyclohexenes and -dienes, and these compounds in turn can be defluorinated giving hexa-, penta-, and tetrafluorobenzenes.

Reactions. The main difference between aryl halides and alkyl halides is that the former are much more resistant to nucleophilic attack. If, however, the halogen in an aromatic compound is activated by the presence of other groups in the molecule, or if especially vigorous conditions (such as elevated temperatures and the presence of strong bases) are used, then nucleophilic substitutions or elimination–addition reactions (see below), which give the same end result, can take place. Thus, 2,4-dinitrofluorobenzene on treatment with a nucleophile such as hydroxide ion undergoes a bimolecular substitution to give a phenol. When the nucleus is not activated either stronger bases or much more vigorous conditions are needed for nucleophilic attack; in such cases elimination of hydrogen halide gives a benzyne structure, to which the nucleophile then adds.



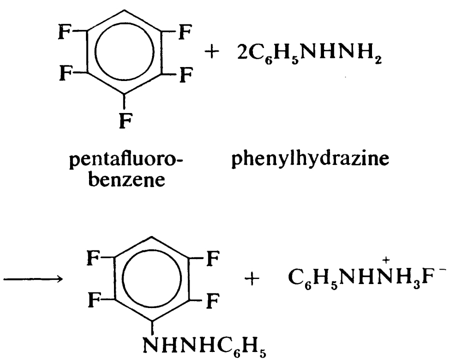
2,4-dinitrofluorobenzene — hydroxide ion — intermediate

2,4-dinitrophenol — fluoride ion



chlorobenzene — benzyne — phenol — sodium chloride

In hexachlorobenzene, the halogen atoms activate the nucleus in the same way as do the nitro groups in dinitrofluorobenzene; and, on heating with potassium fluoride, hexafluoro- and mixed chlorofluorobenzenes are formed by nucleophilic reactions. Pentafluoro- and chlorofluoropyridines are similarly made. Polychloro- and polyfluorobenzenes are highly susceptible to this form of attack. Reagents such as ammonia, sodium methoxide, lithium aluminum hydride, and phenylhydrazine often are used as nucleophiles. An example is given below:



pentafluorobenzene — phenylhydrazine

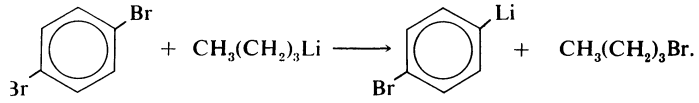
2,3,5,6-tetrafluorohydrazobenzene — phenylhydrazine hydrofluoride

The nuclear hydrogen atoms in aryl halides generally are subject to electrophilic attack and these compounds, therefore, undergo such typical aromatic reactions as halogenation, nitration, and sulfonation. Substitution occurs chiefly in the *para* position, but also in the *ortho* position.

Reactions of aryl halides with metals are similar to those of alkyl halides. Aryl fluorides do not form organomagne-

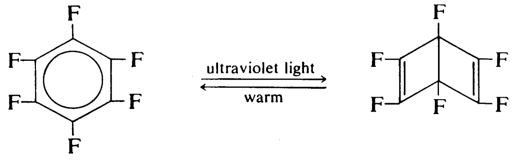
orma-
ion of
rgano-
netallic
om-
ounds

sium halides, and chlorides react sluggishly; bromides and iodides, however, react readily. In polyhalo compounds, any hydrogen atoms left in the molecule are acidic because of the presence of the electronegative halogen atoms, and as a result these compounds regularly form organometallic compounds by hydrogen–metal exchange. Organolithium compounds often are formed by halogen–metal exchange in the less halogenated compounds. For example:



p-dibromobenzene butyllithium *p*-bromophenyllithium butyl bromide

In nuclear halogenated compounds, chlorine, bromine, and iodine atoms are replaced by hydrogen atoms when the compounds are heated with hydrogen gas in the presence of a catalyst such as finely divided nickel, platinum, or palladium. Hexafluorobenzene, on ultraviolet irradiation, is converted into the so-called Dewar isomer (an abnormal form of benzene), which reverts to the normal form on gentle heating, but which may explode.



hexafluorobenzene Dewar isomer

ide-chain
aloge-
ation

Side-chain-halogenated aromatic compounds. *Preparation.* Direct halogenation of an alkyl group (side chain) attached to an aromatic ring is a free-radical process and, as such, it is helped by exposure to visible or ultraviolet light and by boiling the reaction mixture, which aids dissociation of the halogen molecules to free atoms. After substitution is complete, the reagents effecting halogenation also cause saturation of the nuclear double bonds. In side-chain halogenation it is essential to avoid any trace of catalysts that promote nuclear substitution. Fluorine reacts so vigorously that it cannot be introduced preferentially into the side chain in this way, and iodine requires the presence of an oxidizing agent. The method is ideal for chlorine and bromine.

$$Br_2 \xrightarrow[\text{CS}_2 \text{ or CCl}_4 \text{ soln.}]{\text{ultraviolet light}} 2Br\cdot;$$

molecular bromine atomic bromine

$$C_6H_5CH_3 + Br\cdot \xrightarrow[\text{or CCl}_4]{\text{CS}_2} C_6H_5CH_2\cdot + HBr;$$

toluene bromine atom benzyl radical hydrogen bromide

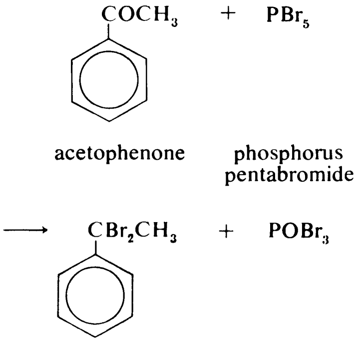
$$C_6H_5CH_2\cdot + Br_2 \longrightarrow C_6H_5CH_2Br + Br\cdot$$

and so on.

Sulfuryl chloride, with a trace of benzoyl peroxide as a free-radical initiator, can be used as a source of chlorine atoms for side-chain chlorination. Such chlorinations proceed rapidly in the dark. Other reagents that produce halogen atoms and therefore start chain reactions are tertiary butyl hypochlorite and hypoiodite and *N*-bromosuccinimide. The degree of halogenation can be controlled by regulating the amount of reagent used, but mixtures are always produced.

Other methods for preparing compounds halogenated in the side chain are similar to those used to prepare alkyl halides, either from the corresponding alcohol, such as benzyl alcohol ($C_6H_5CH_2OH$), or by the electrophilic addition of hydrogen halides or halogens to aryl olefins.

Aromatic aldehydes and ketones react with phosphorus halides or with sulfur tetrafluoride to give dihalo compounds.



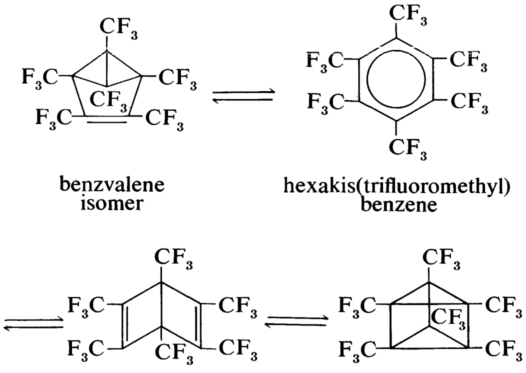
acetophenone phosphorus pentabromide

α,α-dibromoethylbenzene phosphorus oxybromide

Aromatic acids react with sulfur tetrafluoride to give trifluoromethyl derivatives.

Reactions. Typical examples of aromatic compounds with halogen atoms in their side chains are benzyl chloride ($C_6H_5CH_2Cl$), benzylidene chloride ($C_6H_5CHCl_2$), and benzotrichloride ($C_6H_5CCl_3$). The reactivities of these compounds are intermediate between those of the alkyl and allyl halides with similar halogen atoms. Thus, benzyl halides react readily with nucleophiles; hydrolysis of benzylidene halides gives benzaldehyde, and that of benzotrichloride gives benzoic acid. When halogen atoms are not attached to the carbon atom adjacent to the benzene nucleus, the compounds react almost like similar alkyl halides.

Hexakis (trifluoromethyl) benzene undergoes ready photochemical valence bond isomerization to the benzvalene, "Dewar," and prismane isomers, which are surprisingly stable for compounds of this type.

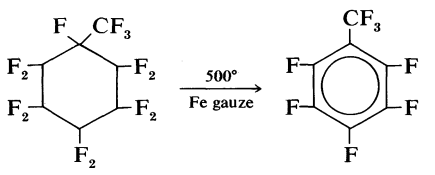


benzvalene isomer hexakis(trifluoromethyl) benzene

Dewar isomer prismane isomer

Nuclear- and side-chain-halogenated aromatic compounds. *Preparations.* Compounds that are lightly halogenated in both nucleus and side chain can obviously be prepared by methods already described. Of those that are highly or completely halogenated, only the polychloro and polyfluoro compounds are known, presumably because bromine and iodine atoms are too large. The photochemical chlorination of the side chains of benzene homologues fully chlorinated in the nucleus proceeds, for example, to the dichloromethyl or the trichloroethyl stage, where it stops. It also is difficult to complete the nuclear chlorination of benzene homologues with fully chlorinated side chains. There is one catalyst, aluminum trichloride and sulfur monochloride with sulfuryl chloride, sufficiently active to give perchloroalkaryl compounds (the prefix per- indicating complete substitution) from starting materials with fully halogenated side chains and nonhalogenated nuclei. Of the simple benzene homologues, only *m*-xylene and mesitylene resist complete chlorination by this method. Perfluoro homologues of benzene are prepared by first converting the hydrocarbons (using cobalt trifluoride) to perfluorocyclohexanes. The latter, then, are defluorinated to the fully fluorinated homologue of benzene.

Fully halogenated compounds



perfluoromethyl cyclohexane
octafluorotoluene

Nuclear fluorinated aromatic compounds can be fluoroalkylated by nucleophilic attack with anions generated from fluoride ion and perfluoroalkenes, as shown below:

$$CF_3CF{=}CF_2 + F^- \longrightarrow CF_3\bar{C}FCF_3;$$

perfluoropropene · fluoride ion · intermediate anion

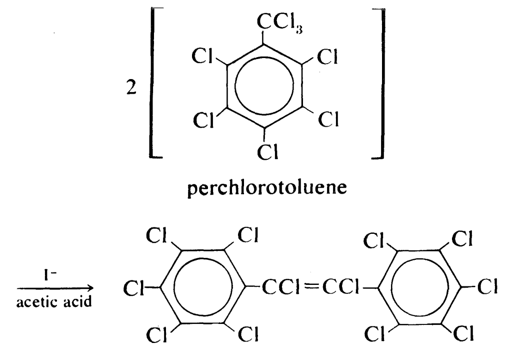
$$C_6F_6 + CF_3\bar{C}FCF_3$$

hexafluorobenzene · anion

$$\longrightarrow C_6F_5CF(CF_3)_2 + F^-.$$

perfluorocumene · fluoride ion

The behaviour of alkylbenzenes lightly halogenated in the nucleus and side chain is predictable on the basis of the separate effects of the two classes of halogen atoms. With perhalogenated compounds, new properties appear. For example, prolonged treatment of perchloro compounds with chlorine, in the presence of a catalyst or ultraviolet light, causes chlorinolysis of the side chain to give hexachlorobenzene and the fully chlorinated alkane. Treatment of perchloro compounds with iodide ion in acetic acid causes dechlorination and sometimes coupling (union of two molecules); for example,

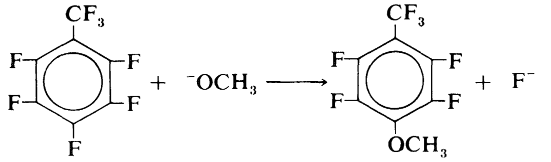


perchlorotoluene

perchlorostilbene

Hydrolysis of side-chain halogens

Chlorinated groups adjacent to the chlorinated benzene nucleus are easily hydrolyzed by heating with concentrated sulfuric acid: $C_6Cl_5CCl_2CCl_3 \rightarrow C_6Cl_5COCCl_3$. Trifluoromethyl groups in perfluoro- or chlorofluorobenzene homologues are similarly hydrolyzed to carboxyl groups. In all of these polyhalo compounds, but particularly in the fluorinated ones, the halogen atoms in the nucleus are susceptible to substitution by nucleophiles, such as lithium aluminum hydride, hydrazine, ammonia, methyllithium, and sodium alkoxides. In the perfluoro compounds, substitution occurs *para* to the perfluoroalkyl group (that is, in the position directly across the benzene ring).



perfluorotoluene · methoxide ion · *p*-methoxyperfluorotoluene · fluoride ion

Polyvalent iodine compounds (preparation and reactions). *Dichloroiodoarenes.* The iodine atom in an aryl iodide can exist in higher states of oxidation; *i.e.,* it can show valencies greater than one. Thus, when chlorine is bubbled into a solution of aryl iodide in cold dry chloroform, a dichloroiodoarene usually crystallizes out as a yellow solid. The formation of dichloroiodobenzene from iodobenzene occurs as follows:

$$C_6H_5I + Cl_2 \longrightarrow C_6H_5ICl_2.$$

These compounds, in which the iodine has a valence of three, are relatively unstable and decompose on heating to about 110° C (230° F). In the case of dichloroiodobenzene the product is *p*-chloroiodobenzene. Dichloro- and difluoroiodoarenes have been used as chlorinating and fluorinating agents.

Iodosyl compounds. When the dichloroiodoarenes are treated with aqueous alkali or aqueous pyridine, compounds containing the iodosyl group (—IO) are formed.

$$C_6H_5ICl_2 + 2NaOH \longrightarrow 2NaCl + H_2O + C_6H_5IO$$

dichloroiodobenzene · sodium hydroxide · sodium chloride · water · iodosylbenzene

Alternatively, these iodosyl compounds can be prepared directly from aryl iodides by oxidation. They behave as though they were anhydrides of the unknown bases, $ArI(OH)_2$, the salts of which can be made by dissolving the neutral iodosyl compounds in the appropriate acids (nitric, hydrochloric, hydrofluoric, and acetic).

Iodosyl compounds are oxidizing agents and liberate iodine quantitatively from acidified potassium iodide solution as follows:

$$C_6H_5IO + 2HI \longrightarrow C_6H_5I + I_2 + H_2O.$$

Iodyl compounds. Disproportionation (spontaneous oxidation and reduction) of iodosyl compounds on boiling with water or, more slowly, on standing, gives iodyl compounds and simple aryl iodides:

$$2C_6H_5IO \longrightarrow C_6H_5I + C_6H_5IO_2.$$

Iodyl compounds also can be made by oxidizing aryl iodides or iodosyl compounds.

Like iodosyl compounds, iodyl compounds are oxidizing agents that are quantitatively reduced by aqueous hydrogen iodide. They must be handled carefully because they explode on impact or on heating.

Iodonium compounds. A mixture of iodyl- and iodosylbenzene, on heating with silver oxide in aqueous suspension, gives a strongly alkaline solution of diphenyliodonium hydroxide:

$$2C_6H_5IO + 2C_6H_5IO_2 + Ag_2O + H_2O$$
$$\longrightarrow 2(C_6H_5)_2I^+\,OH^- + 2AgIO_3\ .$$

The addition of a soluble iodide to a solution of a diphenyliodonium hydroxide yields a precipitate of a diphenyliodonium iodide. Stable salts of iodonium hydroxides can be formed by neutralization with acids. Such salts react with a great variety of nucleophiles, to give nuclear substituted products and aryl iodides:

$$(Ar-\overset{+}{I}-Ar)X^- + OH^-$$
$$\longrightarrow ArOH + ArI + X^-\ .$$

They also decompose to substituted arenes on heating. For example:

$$(p\text{-}CH_3OC_6H_4-\overset{+}{I}-C_6H_5)\overset{-}{Br} \xrightarrow{180^\circ} p\text{-}CH_3OC_6H_4I + C_6H_5Br.$$

p-methoxyphenylphenyliodonium bromide · *p*-iodomethoxybenzene · bromobenzene

TECHNICAL AND ANALYTICAL ASPECTS OF ORGANIC HALOGEN COMPOUNDS

Use as solvents

Commercial uses. The polychloroalkanes and -alkenes are commonly used as solvents for drycleaning, chiefly because of their nonflammability. The most common are carbon tetrachloride and the trichloro- and tetrachloroethylenes. Chloroform is used as a solvent under controlled conditions, but its anesthetic properties make it dangerous. Because of their heavy vapours and their nonflammability some organic halogen compounds (carbon tetrachloride and dibromodifluoromethane, especially) have been used as fire extinguishers. Chloro compounds can be dangerous because under these conditions they give phosgene ($COCl_2$), a poisonous gas. The simple chlorofluoromethanes and -ethanes are used as refrigerants (Freons).

Chloroform was used for many years (mixed with acetone and ether) as an anesthetic. It is dangerous, however, because of the low margin between the lethal dose and the anesthetic dose and because the substance can damage the liver. It has now been completely superseded by fluothane ($CF_3CHBrCl$). Ethyl chloride is used as a local anesthetic.

Use as polymers

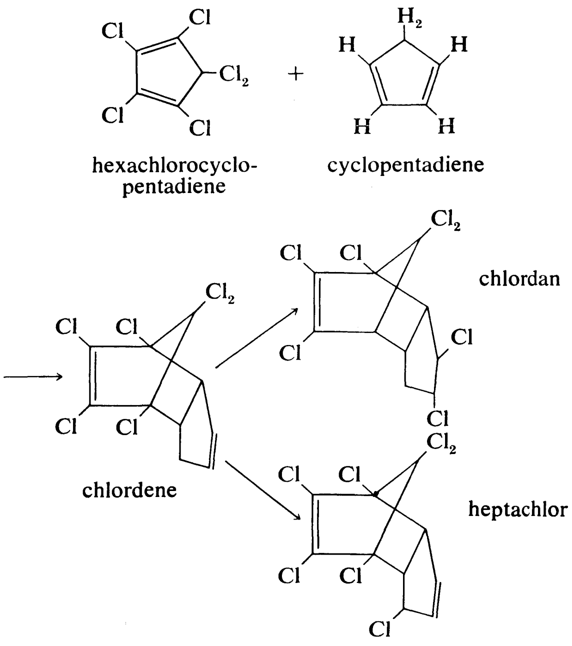
One of the most common polymers is polyvinyl chloride. It is used mainly for electrical insulation and artificial fabrics for rainwear and upholstery. Tetrafluoroethylene and chlorotrifluoroethylene give Teflon (Fluon) and Kel-F polymers, respectively; these have very high thermal stability and electrical resistance. Because of the low intermolecular forces between highly fluorinated compounds, the lower molecular weight Kel-F polymers are used as lubricants, and Teflon is used to pack bearings in motors. Copolymers of hexafluoropropene and vinylidene fluoride (Vitons) are among the most thermally stable elastomers. Electronic apparatus and switchgear are sometimes immersed in fully fluorinated liquid alkanes (Flutec PP5) and cycloalkanes (Flutec PP3), which conduct away the heat developed during operation and act as insulators.

Use as insecticides

Polychloro compounds are most important as insecticides. One of the earliest was DDT (dichlorodiphenyltrichloroethane), which can be made by condensing together chlorobenzene and chloral:

$$2C_6H_5Cl + CCl_3CHO$$
$$\xrightarrow{H_2SO_4} (p\text{-}ClC_6H_4)_2CHCCl_3 + H_2O.$$

Gammexane, the gamma isomer of hexachlorocyclohexane, has properties and uses similar to those of DDT. It is made by the free radical addition of three molecules of chlorine to benzene. Of the nine possible isomers, eight are formed, and—of these—only the gamma form is active. Another important group of insecticides is derived from hexachlorocyclopentadiene. Addition of cyclopentadiene to the hexachloro compound gives chlordene. This substance can be converted either to chlordane by addition of chlorine or to heptachlor by substitution of chlorine for a hydrogen atom:



Use of norbornadiene rather than cyclopentadiene in the above reaction gives aldrin, which can be converted to its epoxide dieldrin. Two similar insecticides, prepared by a slightly different route, are isodrin and endrin. The use of these highly chlorinated compounds has been criticized and curtailed because their stability causes them to accumulate in fish, birds, and animals. Monofluoroacetamide has been used as a systemic insecticide to kill black flies on plants such as roses; sodium monofluoroacetate is used as a rodenticide. Both are dangerous to human beings. Their volatile derivatives (*e.g.,* fluoroacetic acid and ethyl fluoroacetate) were among the first nerve gases.

Use as herbicides

Chlorinated and fluorinated benzenoid and heterocyclic compounds, and also urea derivatives, are used as herbicides. The reaction of chloral and urea gives dichloralurea, which is used as a soil sterilant to prevent the growth of weeds. The substance 3,5-dichloro-4-hydroxydifluoropyridine (Teklon) is used for the control of wild oats and couch grass.

The well-known herbicides 2,4-D and 2,4,5-T (respectively, 2,4-dichloro- and 2,4,5-trichlorophenoxyacetic acids) are used to kill broad-leaved plants and smaller shrubs, respectively.

The compound 5-fluorouracil is thought to replace uracil in nucleic acids and hence interfere with the biochemical operation of living cells. It is used in the treatment of some forms of cancer. The introduction of one or two fluorine atoms into steroid molecules either by replacing hydrogen or by addition across a double bond often enhances the hormonal activity of the steroid. Certain halogenated steroids also are used to reduce skin inflammation.

Separation, identification, and analysis. The introduction of a bromine or iodine atom into a hydrocarbon molecule increases the boiling point of the substance by about 100° to 150° C (180° to 270° F) and creates bonds that are less stable than carbon–hydrogen bonds. In the main, however, alkyl halides, aryl halides, and most polyhalo compounds are stable. The most common are gases or liquids, and the most usual way to purify them is by fractional distillation. Unfortunately, however, polyfluoro compounds have a pronounced tendency to form constant-boiling mixtures, and—as a result—they are often not separable in this way. The technique known as vapour phase chromatography has proved useful in this case, and in fact this method is now used extensively for the separation of mixtures of reasonably volatile halo compounds (with boiling points up to 200° C) of all kinds. Fundamentally, vapour phase chromatography is very similar to fractional distillation, the vapour of the mixture in a stream of nitrogen being adsorbed on and desorbed from a column of nonvolatile solvent supported on a substance like kieselguhr. By varying this stationary phase (dinonyl phthalate, silicone oil, and fluorolube are common materials used) it is usually possible to separate any mixture.

Spectroscopic identification

Apart from the use of melting and boiling points, pure organic halogen compounds are identified most often spectroscopically. There are strong characteristic absorptions in the infrared arising from stretching vibrations of the carbon-to-halogen bonds. Because the frequencies at which these absorptions occur are influenced by neighbouring groups, they give valuable information about the molecular structure, revealing, for example, whether the halide is an alkyl or aryl derivative. In the mass spectrometer, which separates materials on the basis of their relative masses, organic halides are usually sufficiently stable to show an ion derived from the intact molecule. As a result, an accurate molecular weight can easily be found. The breakdown pattern of the ions often gives strong clues to the structure of the parent compound.

Nuclear magnetic resonance spectroscopy, which measures the energy required to change the alignment of magnetic nuclei in a magnetic field, is used to determine the structures of compounds containing hydrogen and fluorine atoms. The resonance peaks associated with these atoms appear at different locations in the spectra of various compounds depending on the atoms adjacent to them. By finding the number of atoms in each different environment, the structure of a compound often can be determined.

By measuring another atomic property, the nuclear quadrupole moment, the structures of compounds containing chlorine and bromine can often be deduced. It is probable, however, that in the future the structures of chlorine-, bromine-, and iodine-containing compounds will best be determined by X-ray induced electron emission spectroscopy. This technique is based on the magnetic or electrostatic analysis of the electrons that are emitted from a substance on irradiation with X-rays. The energies of these electrons are characteristic of the atom from which they are emitted and of the environment of that atom. Hence, the results can be used both for elemental analysis and for structure determination.

Elemental analysis

Conventional elemental analysis of halogens in organic compounds involves, first, fusion of the compound with sodium or potassium, and then estimation of the alkali metal halides. Fluoride can be determined by weight as lead chlorofluoride, and chloride by titrating the alkali liberated by its action on mercuric oxycyanide. Bromide is quantitatively oxidized to bromate by sodium hypochlorite, and this, in turn, is used to liberate iodine from hydrogen iodide. In a similar fashion, iodide is converted to iodate by hypobromite, and this, again, is used to liberate iodine from hydrogen iodide. In both cases the free iodine is titrated with standard sodium thiosulfate.

(W.K.R.M.)

Organic nitrogen compounds

Since, by definition, organic compounds are compounds containing carbon, organic nitrogen compounds are substances the molecules of which contain at least one carbon and one nitrogen atom. Several hundred thousand such compounds are known, and new ones are being prepared or discovered continually. Organic nitrogen compounds are present in all known living organisms, as essential and often major components. Flesh, hair, horn, milk solids, and blood, for example, are composed largely of organic nitrogen compounds. Many drugs and medicinal agents, both natural and synthetic, including most narcotics, local anesthetics, the sulfa drugs, penicillin; most explosives, such as nitroglycerine and TNT (2,4,6-trinitrotoluene); some rocket fuels; many dyes; and some synthetic polymers (substances of high molecular weight made up of a number of identical or similar groups of atoms bonded together), such as nylons and the melamine resins, belong to this class.

No single characterization can be made to apply to the properties of organic nitrogen compounds. Some are gases—*e.g.,* hydrogen cyanide (formula HCN) and methylamine (CH_3NH_2); some liquids—*e.g.,* nitroglycerin

$$[O_2NOCH_2CH(ONO_2)CH_2ONO_2]$$

and aniline ($C_6H_5NH_2$); but most are solids. Some mix completely with water; others are quite insoluble. They may be acidic, basic, or neutral, coloured or colourless, volatile or nonvolatile, intensely poisonous or essential to life.

BONDING IN NITROGEN AND ITS COMPOUNDS

Bonding characteristics of nitrogen. The wide variation in properties of members of the group is directly related to the ability of nitrogen to take part with other elements in a large number and variety of molecular structures. This ability results from the capacity of the nitrogen atom to have a large number of so-called oxidation states.

Oxidation state

The electron pairs of covalent bonds are not shared equally when the bonded atoms are different, a fact that gives rise to the concept of oxidation state (or oxidation number), which is defined as the number of bonds shared with electronegative elements (*i.e.,* those to the right in the periodic table) minus the number of bonds shared with electropositive elements (*i.e.,* those to the left in the periodic table). The oxidation number of nitrogen ranges from −3, as in ammonia (NH_3), through zero, as in elemental nitrogen (N_2), to +5, as in nitric acid (HNO_3), and nitrogen occurs in known organic compounds in these and all intermediate oxidation states (−2, −1, +1, +2, +3, +4).

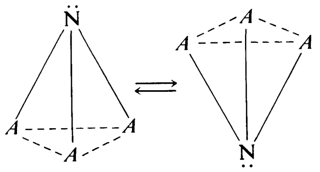
Organic nitrogen compounds are classified on the basis of the inorganic (*i.e.,* not containing carbon) constituent that can be considered the parent compound; *i.e.,* the compound from which the organic compound is produced by removing a hydrogen atom and replacing it with a group of atoms containing carbon. Nitrogen occurs in nature bound to hydrogen, oxygen, carbon, and other nitrogen atoms; it can also form bonds with other elements, including sulfur, phosphorus, fluorine, chlorine, bromine, and iodine.

Nitrogen-compound structures. In almost all organic nitrogen compounds, the three additional electrons required to fill the octet are obtained by sharing an electron pair with another atom, which contributes one electron to the shared pair, thus forming a covalent bond. Three such bonds, adding three electrons to the normal five, result in a filled octet; the fourth pair of electrons of the nitrogen atom is not shared. An example is the reaction shown below (in which *A* represents any atom with one electron available to share, and each electron is represented by a dot); one nitrogen atom combines with three *A* atoms to form a compound in which three pairs of electrons are shared in covalent bonds, and the outer electron shell of the nitrogen atom is filled.

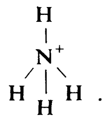
$$\cdot\overset{\cdot\cdot}{\underset{\cdot}{N}}\cdot + 3A\cdot \longrightarrow A{:}\overset{\cdot\cdot}{\underset{\underset{A}{\cdot\cdot}}{N}}{:}A$$

Shapes of nitrogen compounds

It has been shown by experiment and is found consistent with theoretical views that the orbitals (*i.e.,* the regions around the nucleus occupied by the four electron pairs) point to the four corners of a tetrahedron (triangular pyramid). Simple compounds in which three atoms share covalent bonds with nitrogen thus have the shape of a flattened pyramid, with the nitrogen atom at the apex and the unshared electron pair above it. In fact, however, this shape is very mobile and inverts (turns inside out like an umbrella) very rapidly. The interaction between the two forms is represented by an equation in which each bonded pair of electrons is a single line, and each single electron is a dot.

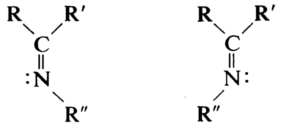


The unshared electron pair is available to form a fourth bond by sharing with another atom having an incomplete outer shell. The fourth bonding results in the formation of a tetrahedral molecule (or ion) with all four corners occupied by other atoms; an example is ammonium ion, NH_4^+, which can be represented:



Such species of bonded atoms maintain their form more or less rigidly when none of the four surrounding atoms is a hydrogen, and, if all four bonded atoms are different, the same kind of dissymmetry (left- and right-handedness, in reference to the position of the four relative to each other) as is encountered in carbon compounds may arise.

When a nitrogen atom shares two electron pairs with the same atom, a double bond results. The atoms joined by the double bond and the atoms attached directly to them then lie all in the same plane, together with the unshared electron pair on the nitrogen. Such compounds may have two geometrically isomeric forms (*i.e.,* forms differing only in the arrangement in space of the groups about a double bond); for example, many imines (compounds in which nitrogen is doubly bound to carbon) have isomers that may be represented as



The formation of a triple bond by sharing three electron pairs is most commonly encountered between a nitrogen and a carbon atom. Such compounds, called nitriles, have a linear structure (*i.e.,* the atoms lie in a straight line), as in the case of a single radical (*R*) bonded to a carbon atom that also shares a triple bond with a nitrogen atom, expressed as $R{-}C{\equiv}N$. (Molecular nitrogen and certain less common classes of compounds, the azides and diazonium salts, are considered to have triple bonds between two nitrogen atoms.)

CLASSIFICATION OF ORGANIC NITROGEN COMPOUNDS

Parent compounds

The parent inorganic compounds from which organic nitrogen compounds are obtained include ammonia (NH_3), hydrazine ($H_2N{-}NH_2$), hydroxylamine ($H_2N{-}OH$), hydrogen azide (HN_3), nitrous acid (HNO_2), nitric acid (HNO_3), and a few very unstable substances: diazene, or diimide, ($HN{=}NH$), nitroxyl (HNO), amino radical ($H_2N\cdot$), aminoxyl ($H_2N{-}O\cdot$), triazene ($H_2N{-}N{=}NH$).

Amines. Compounds derived from ammonia by replacement of one or more hydrogen atoms by hydrocarbon groups, which have varying numbers (indicated by *m* and *n*) of carbon and hydrogen atoms, C_mH_n, are known as amines; alkyl (*R*), or aryl (*Ar*). When only one hydrogen atom is replaced, the resulting compounds are called primary amines and are represented as RNH_2; when two hydrogens are replaced, they are secondary (R_2NH), and, when all three hydrogens are replaced, they are tertiary (R_3N). All such compounds resemble ammonia in that they are basic (*i.e.,* they form salts with acids by virtue of the unshared electron pair). As the hydrocarbon portion (the part consisting of groups containing only carbon and hydrogen atoms) of the molecule becomes larger, the amines become less volatile (*i.e.,* have less tendency to vaporize at ordinary temperature), less soluble in water, and generally more like hydrocarbons. Amines have lower melting points than most other classes of nitrogen compounds, and are more strongly basic. Most naturally occurring compounds of nitrogen are amines or derivatives of them.

Amines are named by prefixing the name of the attached groups to the stem amine, as in dimethylamine $(CH_3)_2NH$. If an aryl group such as the phenyl radical, $=C_6H_5$ (from benzene, C_6H_6), is attached, the compound is usually considered to be a derivative of aniline and is named as substituted aniline, as in 4-chloro-*N*-methylaniline ($ClC_6H_4NHCH_3$).

Derivatives of the ammonium (the "-ium" ending indicates, as in carbonium carbon, the presence of a localized positive charge) ion bearing four hydrocarbon groups (R_4N^+) are quaternary ammonium salts. The quaternary ammonium ions themselves are not basic (there being no longer an unshared electron pair), but their hydroxides (compounds in which the positive charge on the nitrogen atom is neutralized by the negative charge of a hydroxide ion, OH^-), $R_4N^+OH^-$, are strong bases that resemble sodium and potassium hydroxides. They are named by prefixing the names of the substituents to the stem ammonium, as in the tetramethylammonium ion ($[CH_3]_4N^+$).

Double bonds

Imines. Compounds in which nitrogen is bound to carbon by a double bond are known as imines (sometimes called Schiff bases). Imines are distinctly weaker bases than the amines. They are most commonly named by following the name of the related carbonyl compound by the word imine, as in diethyl ketone *N*-methylimine, $(C_2H_5)_2C{=}N{-}CH_3$, related to diethyl ketone, $(C_2H_5)_2C{=}O$.

Carbinolamines. Closely related to the imines, although containing no double bond, are the carbinolamines. They are produced by addition of the elements of water to the double bond and may usually be dehydrated to form imines (providing there is a hydrogen on the carbinolamine nitrogen atom). They are given names on the basis of being amines bearing a 1-hydroxy substituent (OH), as in 1-hydroxyethyldimethylamine,

$$CH_3CH(OH)N(CH_3)_2.$$

Triple bonds

Nitriles. The nitriles have a triple nitrogen-to-carbon bond (which is written $-C{\equiv}N$), generally have low melting points, and are for ordinary considerations totally nonbasic (do not neutralize acids to form salts). They have a close affinity with carboxylic acids—*i.e.,* organic acids containing the carboxylic group, $-COOH$, such as acetic acid, CH_3COOH, and benzoic acid, C_6H_5COOH; the carbons are in the same oxidation state, having in each case three bonds to an atom having higher affinity for electrons (oxygen or nitrogen). They are named by using the root name of the corresponding acid, with the suffix nitrile, as in acetonitrile, $CH_3C{\equiv}N$ (from acetic acid, CH_3COOH).

Amides. The replacement of an acidic hydroxyl group by an amino group produces the class of nitrogen compounds known as amides. The carboxamides, $RCONH_2$, are the most important group; other substituent groups may be attached to the nitrogen. Amides known as sulfonamides, RSO_2NH_2, are also produced from the sulfonic acids, RSO_3H. Most amides are solids, apt to have high melting points, and are essentially nonbasic and of low volatility. Most are named from the corresponding acid, using the suffix "-amide," as in acetamide, CH_3CONH_2, and *N*-ethylbenzenesulfonamide,

$$C_6H_5SO_2NHC_2H_5.$$

Imides. Compounds of the imide class have two carbonyl (*i.e.,* containing the organic radical $\diagdown\!\!\!\diagup C=O-$ *e.g.,* acetyl, CH_3CO-) groups attached to the same nitrogen, as in acetimide, $(CH_3CO)_2NH$. They are weakly acidic (*i.e.,* neutralize alkalies to form salts) if the nitrogen is not otherwise substituted. If both oxygens of a carboxyl group ($-COOH$, the radical characteristic of most organic acids) have been replaced by nitrogen, the amidine structure results. Amidines are moderately strong bases. The general formula is $RC(NH_2)=NH$.

Cyanic acid

Carbonic acid derivatives. The compounds derived from carbonic acid are usually considered as a class by themselves. The nitrile of carbonic acid is cyanic acid, $HO{-}C{\equiv}N$, which in turn can provide two groups of derivatives: the cyanates, $R{-}O{-}C{\equiv}N$, and the isocyanates, $R{-}N{=}C{=}O$. They are named by combining the class name with the name of the substituent, as in ethyl isocyanate, $C_2H_5{-}N{=}C{=}O$.

The amide of cyanic acid, cyanamide, $H_2N{-}C{\equiv}N$, and its tautomer (tautomers are compounds of the same chemical formula but different molecular structure that interconvert reversibly) carbodiimide, $HN{=}C{=}NH$, also yield a group of derivatives.

Carbonic acid, HOCOOH, which has two hydroxyl groups, reacts with ammonia to produce amides in two stages, carbamic acid, NH_2COOH, and urea,

$$NH_2CONH_2.$$

Carbamic acids are unstable in the free state but their salts and esters are well known. A salt is the compound other than water formed by reaction of an acid with a base, and an ester is a derivative of an acid in which a hydrocarbon group is attached to an oxygen atom in place of the acidic hydrogen atom. The esters are often called urethans, after the primitive name of the ethyl ester, $C_2H_5O{-}CO{-}NH_2$. Urea and its derivatives are almost invariably solids of high melting point and low volatility and are commonly named as substituted ureas, as *N,N′*-dimethylurea, $CH_3{-}NH{-}CO{-}NH{-}CH_3$. Thiourea is the compound in which a sulfur atom replaces the oxygen atom of urea.

The amidine of carbamic acid goes by the special name guanidine. The guanidines, $H_2NCNHNH_2$, are in general very strong bases, approaching hydroxide ion (OH^-) in strength.

Hydroxylamine compounds. Nearly all the various derivatives of ammonia (NH_3) have their parallel with hydroxylamine ($H_2N{-}OH$). Hydroxylamine may carry one, two, or three substituents, which may be bonded to either the nitrogen or the oxygen atom; *e.g.*, *N,N*-dimethylhydroxylamine, $(CH_3)_2N-OH$, and ethoxylamine, $C_2H_5-O-NH_2$. Such compounds are similar to amines but are weaker bases. Quaternary compounds corresponding to those of ammonia are of two types: tetrasubstituted salts and amine oxides.

The hydroxylamine compounds analogous to imines are the oximes, $RR'C{=}NOH$, and nitrones,

$$RR'C=\overset{+}{N}RO^-.$$

Nearly all are solids, but the oximes and derivatives have considerably lower melting points than the nitrones.

The most important hydroxylamine derivatives of the carboxyl group are the *N*-acyl compounds, called hydroxamic acids, $RC({=}O)NHOH$.

Hydrazine compounds. Hydrazine is also the parent of a family of structures analogous to the organic derivatives of ammonia. There are compounds of from one to four substituents (mono-, di-, tri-, and tetrasubstituted hydrazines); all are weakly basic. Quaternary hydrazinium compounds

$$R_2N-\overset{+}{N}R_3\,X^-$$

(in which X^- represents any negatively charged atom or group of atoms) are also well known. The analogues of imines, $R_2C{=}N-NR_2$, are called hydrazones and may have any of a range of organic groups bonded to the nitrogen atom. Azines, $R_2C{=}N-N{=}CR_2$, have two imine groups joined by an N—N bond. The only important hydrazine derivatives of the carboxyl group are the hydrazides, which are weakly basic.

Diazene compounds. The derivatives of diazene that have two substituted groups (*i.e.*, are disubstituted), $R-N{=}N-R$, are called azo compounds, such as azobenzene, $C_6H_5-N{=}N-C_6H_5$. They are neutral substances, generally coloured and solid. Monosubstituted diazenes are known but are very unstable.

The diazonium compounds,

$$Ar-\overset{+}{N}\equiv N\,X^- \rightleftharpoons Ar-N=N-X,$$

are closely related. The salts of strong acids are truly ionic (*i.e.*, electrically charged) and show the properties to be expected of a triple bond. They are generally rather unstable substances but of great importance as intermediates (chemicals produced as necessary steps between starting material and finished product) in synthesis. The diazo compounds, such as diazomethane,

$$CH_2=\overset{+}{N}=\overset{-}{N} \rightleftharpoons \overset{-}{C}H_2-\overset{+}{N}\equiv N,$$

also show evidence of a triple bond.

Compounds with three or more nitrogens. Triazenes and azides are among the types of compounds having chains of three or more nitrogens. The word triazene denotes three nitrogen atoms and a double bond, $H_2N-N{=}NH$, and, in analogous fashion, names for longer chains and different degrees of unsaturation (that is, capable of combining directly with additional groups of atoms) may be developed.

Azides of various types, such as methyl azide, CH_3-N_3, phenyl azide, $C_6H_5-N_3$, and acetyl azide, CH_3CO-N_3, all contain the linear (*i.e.*, all the atoms lie in a straight line) azido group

$$-N=\overset{+}{N}=\overset{-}{N} \rightleftharpoons -\overset{-}{N}-\overset{+}{N}\equiv N.$$

The nitroso and nitro compounds, $R-N{=}O$ and $R-NO_2$, represent higher oxidation states. Both are neutral, and the former are all a beautiful blue or green, whereas the latter are colourless to yellow. Most nitroso compounds, such as nitrosobenzene, $C_6H_5-N{=}O$, are in equilibrium with colourless dimers (a dimer is a molecule formed by the union of two simpler molecules), with the nitrogen molecules bonded together. Both classes of compound are invariably named by means of the "nitroso-" or "nitro-" prefix.

Nitrous and nitric acid compounds. The highest oxidation states of nitrogen are represented by the derivatives of nitrous acid (HNO_2) and nitric acid (HNO_3). Among them are the esters, $R-O-N{=}O$ and $R-O-NO_2$, which contain no carbon-to-nitrogen bond. The nitrites that are exceptionally volatile, and the nitrates, such as nitroglycerin (or glyceryl trinitrate), are potentially explosive in proportion as the ratio of oxygen to carbon and hydrogen in the compound approaches the optimum for complete internal combustion to water, oxides of carbon, and molecular nitrogen. Nitrous and nitric acids can give rise to amides, hydroxamic acids, and hydrazides, just as do other acids. All of them are known in the form of organic derivatives.

The volatility of nitrites and nitrates

THE AMINES AND THEIR DERIVATIVES

Physical and chemical properties. The smallest amines are gases, but most amines are liquids, and all of them except the very large have fishy or musty odours. The volatility (*i.e.*, the tendency to vaporize at ordinary temperatures) decreases with increasing molecular weight and increasing number of hydrogens attached to the nitrogen. Primary amines thus have the highest boiling points and tertiary the lowest for comparable molecular weights. The smaller amines are soluble or even completely miscible in water (that is, can be mixed completely without separating into two layers) but, when the size of the molecule exceeds five carbon atoms, the solubility drops rapidly. Nearly all amines are soluble in the common organic solvents. Aliphatic amines (*i.e.*, those in which the nitrogen atom is not attached to a benzene ring) are slightly stronger bases than ammonia and will turn litmus indicator paper blue, but aromatic amines (those in which the nitrogen atom is attached to a carbon atom present in a benzene ring) are considerably weaker, and most of them will not affect litmus.

Aliphatic amines

Salts. Nearly all salts of amines are nonvolatile solids, very soluble in water, to which they give a weak acidic reaction if they are salts of strong acids, such as hydrochloric, nitric, or sulfuric; generally they do not dissolve in nonpolar solvents such as ether and the hydrocarbons. Quaternary ammonium compounds are completely ionic in nature—the hydroxides are alkalies as strong as sodium hydroxide (lye).

Sources and preparation. Some simple aliphatic amines occur naturally, mostly as the products of decay, but there are no practical natural sources. Industrially, aliphatic amines are mostly made from fatty acids (organic acids derived from natural fats and oils), olefins (unsaturated aliphatic compounds whose molecules contain only carbon and hydrogen atoms; *i.e.*, they are hydrocarbons), or alcohols (alcohols are hydroxyl compounds, containing the oxygen–hydrogen radical, OH, bonded to a saturated carbon). The fatty acids (or the fats and oils in which they occur bound) may be reduced to alcohols (one important step in production of detergents), which can then be converted to amines catalytically by reaction with ammonia or by indirect, laboratory methods involving initial conversion to a suitably reactive derivative. Alternatively, the fatty acids may be converted to nitriles (by way of their amides) by reaction with ammonia, followed by hydrogenation (combination of hydrogen with another substance, usually an unsaturated organic compound). These reactions also give rise to secondary and tertiary amines.

A few amines, notably aniline and some of its derivatives, are made by reduction (reduction is an increase in the number of electrons) of nitro compounds, although in recent years it has become more common to produce aniline from chlorobenzene in a continuous process under high pressure.

Reductive alkylation (a process of adding alkyl radicals and hydrogen), whereby an aldehyde or ketone is treated with ammonia and hydrogen in the presence of a catalyst, has both industrial and laboratory utility.

There are three types of reaction by which amines may be prepared on a laboratory scale: displacements on halides or derivatives; reduction of nitriles, amides, oximes, nitro compounds, etc.; and rearrangements (Hofmann, Curtius, Lossen, Beckmann, Schmidt). Many variations of them are described in specialized works.

Chemical behaviour of amines

The chemical behaviour of amines is dominated by their basicity. Nearly all of them form salts even with moderately weak acids, and the aliphatic amines even extract carbon dioxide from moist air to form salts. Since salts in general are soluble in water, most amines will thus dissolve in dilute solutions of acids. Salts also generally crystallize well, and, by reaction with acids, liquid or gaseous amines can be converted to solid derivatives useful for identification.

Oxidation characteristics. Aliphatic amines are not easily oxidized (oxidation is loss of electrons), but aniline and its derivatives commonly become coloured slowly on prolonged contact with air, owing to oxidation of the activated benzene ring to form complex dyes. Since amines are the lowest oxidation state of nitrogen, they are not ordinarily reducible (except for hydrogenolysis of benzylamines and some quaternary ammonium salts, in which a C—N bond is broken with addition of hydrogen to each fragment).

Chlorine and bromine replace the *N*-hydrogens of amines to form *N*-haloamines. Tertiary amines undergo more deep-seated changes.

Nitrogen gas formation

The reaction of amines with nitrous acid is an old and important reaction. It appears that all primary amines give a diazonium salt, $R—N_2^+X^-$, but only with aniline and its derivatives can such products be isolated (or even detected). The observed result with aliphatic primary amines is the formation of mixtures, consisting of olefins, cyclopropanes, and isomeric alcohols, with evolution of nitrogen. The formation of nitrogen gas (effervescence) has been used as a qualitative test for primary amines. From secondary amines, nitrosamines precipitate as nonbasic, yellowish oils, and tertiary amines are degraded to mixtures of nitrosamines with aldehydes or ketones derived from one of the alkyl groups.

Aromatic primary amines are a special case. Cold (about 0° C), they react with dilute nitrous acid to form solutions of diazonium salts, which easily lose nitrogen on warming and form phenols (*Ar*OH).

Alkyl halides, sulfates, and related alkylating agents react more or less readily with free amines so as to add an alkyl group to the nitrogen atom. The process may be repetitive, especially if an inorganic base is present, so that most amines are eventually converted to quaternary salts, if bulk does not interfere.

Reactions with other organic compounds. The reactions of amines with other classes of organic compounds form a vast subject. In the most general terms, they do not react with alcohols or olefins except at high temperatures in the presence of surface catalysts, when they may become alkylated on the nitrogen. Aldehydes and ketones will usually react with primary amines to form imines by addition at the carbonyl group followed by elimination of water, as shown in the equation

$$R-NH_2 + R'_2C=O \longrightarrow R'_2C=NR + H_2O.$$

Carboxylic acids form salts, which may lose water when heated very strongly, forming amides. Primary and secondary amines react to form amides, vigorously with acid chlorides, slightly less vigorously with acid anhydrides, and extremely sluggishly with esters.

$$RCOX + 2R'NH_2 \rightarrow RCONHR' + R'NH_3^+X^-$$

Amines do not react with other bases, weak or strong, except insofar as amines are liberated from their salts. Quaternary ammonium salts, however, undergo the Hofmann reaction when they are converted to the hydroxides (usually by treating them with moist silver oxide) and then heated strongly. One group is cleaved from the nitrogen as an olefin leaving a tertiary amine.

$$R_3\overset{+}{N}-CH_2CH_2R\,OH^- \xrightarrow{\Delta} R_3N + CH_2=CHR + H_2O$$

Compounds with amide linkages. *Physical properties.* The carboxamides and imides are mostly solids of low volatility and thus little odour, although they are likely to have flavour. Unsubstituted amides, RCONH$_2$, have the highest melting and boiling points; substitution of hydrogen by alkyl groups (paraffin hydrocarbon radicals) reduces the intermolecular attraction by removing the capability for hydrogen bonding between N—H of one molecule and C═O of another. The small amides and imides (less than six carbon atoms) are soluble in water, and formamide is completely miscible.

Common characteristics of amides

Similar remarks can be made about most of the other types of amides: thionamides, sulfonamides, ureas, urethans (carbamates), amidines, and imidates (imino esters). The last two types, however, which have no carbonyl group, have lower melting points, and the simple imidates are liquid at room temperature.

Amides in general are neutral in water solution, but they show a feeble basicity toward very strong acids, especially in the absence of water. Imidate esters, however, are almost as basic as alkylamines, and amidines are the strongest organic bases short of the quaternary ammonium hydroxides. Sulfonamides show no basic properties, but those having at least one hydrogen on the nitrogen have acidities similar to those of phenols.

Sources and preparation. There are no practical natural sources of simple amides, although polyamides occur in great abundance as the protein of living systems. Simple amides are made industrially from ammonium salts of carboxylic acids by strong heating; some *N*-substituted amides are made analogously. Esters react with ammonia to form amides, but the general laboratory method is to treat an amine with an acid chloride or anhydride. It is usually desirable to add an equivalent of alkali (base, usually having a hydroxyl group that ionizes to hydroxide ion, OH$^-$, which then combines with the hydrogen ion, H$^+$, of an acid to form water, a process called neutralization) to neutralize the acid that would otherwise bind a second equivalent of amine (Schotten–Baumann procedure).

Imides do not occur naturally except for some complex heterocyclic compounds. For preparative purposes, imides can generally be prepared from amides by treating them with acid chlorides or anhydrides or with metallic sodium or potassium, but cyclic imides, derived from dicarboxylic acids, can in many instances be prepared by strongly heating the ammonium salt of the acid or the half-amide. Imides can also be prepared by heating nitriles with carboxylic acids.

The derivatives of carbonic acid are a special case. Urea is prepared commercially by heating ammonia with carbon dioxide, but substituted ureas are best prepared by the reaction of an isocyanate with an amine. Urethans are also made from isocyanates, by reaction with alcohols.

The most characteristic reaction of amides is hydrolysis (a chemical reaction with water), by which they are converted to an acid and an amine. Amides are generally inert to pure water and require a mineral acid, alkali, or enzyme to catalyze hydrolysis. Wool and nylon, both of which are polyamides, can thus be dissolved by heating them with strong acid or base such as potassium hydroxide (KOH). The equation is

$$RCONR_2 + KOH \longrightarrow RCO_2K + R_2NH.$$

Amides can also be dehydrated, most commonly by heating with phosphorus pentoxide or phosphoryl chloride. Unsubstituted amides give nitriles, and monosubstituted amides give ketenimines, but disubstituted amides are inert. Monosubstituted formamides can be dehydrated to isocyanides.

Amides are not readily oxidized and are inert to most reducing agents. Catalytic hydrogenation will convert amides of aliphatic acids to amines at somewhat high pressures and temperatures, and electrolytic reduction is generally successful with aromatic amides, but the most generally effective reagent is lithium aluminum hydride. Conditions may generally be chosen so as to favour either amines, alcohols, or aldehydes as the products.

Aldehydes but not ketones generally react with amides that have at least one hydrogen on the nitrogen. The first step is addition to the aldehyde carbonyl group, but this may be followed by reaction with a second molecule of amide and elimination of water. The technique of preserving flesh by immersion in formaldehyde solution makes use of these reactions, and the condensation of formaldehyde with urea (carbamide) produces the industrially important urea–formaldehyde resins.

$$H_2NCONH_2 + H_2C=O$$
$$\longrightarrow H_2NCONHCH_2OH + (-NHCONHCH_2-)_n$$

Amides may react with acid chlorides or anhydrides, especially if a base is present, to form imides.

The halogen elements and the hypohalous acids, HO*X*, replace a hydrogen on the nitrogen in the presence of base. The resulting *N*-haloamides are not very stable and easily undergo the Hofmann rearrangement when warmed with excess base. The overall effect is to convert the amide to a primary amine having one fewer carbon atom.

Amides suffer replacement of the amino group by an aryl or alkyl group, to form ketones (formamides yield aldehydes) in two ways: reaction with Grignard reagents or treatment with an aromatic hydrocarbon, such as benzene, in the presence of phosphoryl chloride (Vilsmeier–Haack reaction).

Compounds with double and triple C-N bonds. *Imines, nitriles, isocyanates, etc.* The simplest members of each class in this section are liquids, although little more can be said about the small imines, for they polymerize so readily. Hydrogen cyanide is actually the smallest nitrile. Acetonitrile has an unusually high dielectric constant and is a polar solvent capable of dissolving many salts as well as most other organic compounds. The isomer methyl isocyanide is a liquid of exceptionally revolting stench; methyl isocyanate has a pungent, biting odour; and methyl isothiocyanate smells somewhat savory as well as pungent. Cyanamide forms transparent crystals. The isomeric (forming isomers) carbodiimides polymerize too rapidly for the simpler ones to have been obtained pure, but in general they are liquids similar to the cyanamides.

The small imines, nitriles, cyanamides, and carbodiimides are miscible or soluble in water, but isocyanides, isocyanates, isothiocyanates, cyanates, and thiocyanates are nearly insoluble.

Imines are most generally prepared either by reaction of a ketone or aldehyde with a primary amine or by the addition of Grignard reagents to nitriles. Oxidation (or catalytic dehydrogenation) of amines can also be made to give imines.

Preparation of isocyanates

Isocyanates are nearly always prepared by the reaction of primary amines with phosgene or by a process called, after its discoverer, the Curtius rearrangement of acyl azides, although other methods exist, such as the addition of cyanic acid to olefins, the reaction of potassium cyanate with alkylating agents, such as methyl sulfate, and the cleavage of certain urethans by heat or salts of silver or mercury. Isothiocyanates, *R*—N═C═S, can be obtained naturally in some cases; allyl isothiocyanate, for example, comes from mustard seeds, and an old term for isothiocyanates as a class is mustard oils. Laboratory preparation starts with primary amines, which react with carbon disulfide to form dithiocarbamate salts. These can be decomposed to isothiocyanates, sometimes by heating but more generally by treating with salts of silver or of lead. An important source of thiocyanates is the reaction of alkyl thiosulfates with alkali metal cyanides.

Sources of nitriles

The commonest source of nitriles is the reaction of alkyl halides with sodium (or potassium) cyanide, which goes well with primary alkyl halides but fails when they are tertiary. When silver cyanide is used, a complex is formed, which liberates an isocyanide when broken up with excess potassium cyanide. Aryl halides, which are generally inert toward alkali metal cyanides, can be converted to cyanobenzenes by heating with cuprous cyanide. Both nitriles and isocyanides can be made by dehydrating amides.

An industrially important source of nitriles is the catalytic reaction of hydrocarbons bearing methyl groups with ammonia and oxygen at high temperatures (ammoxidation).

Carbodiimides are prepared from thioureas by treating with reagents that extract hydrogen sulfide (*e.g.,* mercuric oxide), as well as by other methods.

Principal reactions. The double and the triple C—N bonds are susceptible to hydrolysis (reaction with water), generally with catalysis by either acid or base (a catalyst alters the speed of reaction enormously, without being itself used up, generally at a much lower temperature than needed to initiate the reaction without a catalyst), with varying degrees of ease. The ultimate result is replacement of all C—N bonds by C—O bonds, such that imines yield aldehydes or ketones, nitriles yield carboxylic acids, isocyanides yield primary amines and formic acid, and cyanates, isocyanates, and their sulfur analogues yield carbon dioxide (or carbon oxysulfide). When conditions are mild enough or the amount of water is limited, hydrolysis may be stopped at the intermediate stage of amides (from nitriles), formamides (from isocyanides), or ureas (from isocyanates and carbodiimides).

Reactions with alcohols

Hydrolysis is paralleled by reactions with alcohols, of which the two most important examples are the conversion of nitriles to imidate esters and to ortho esters and of isocyanates to urethans. Ammonia and amines react analogously, particularly with isocyanates or isothiocyanates, and are thereby converted to ureas or thioureas, respectively.

Reduction (a category of reactions, the reverse of oxidation and here usually meaning reaction with hydrogen in the presence of a catalyst) in general saturates the double and triple C—N bonds with hydrogen, converting the compounds to amines of one kind or another.

A class of compounds called Grignard reagents reacts readily with nitriles and isocyanates, converting them to imines and amides, respectively. The same conversion can be accomplished by reaction with aromatic hydrocarbons and a class of catalysts called Friedel–Crafts catalysts; *e.g.,* aluminum chloride.

COMPOUNDS WITH N—N BONDS

Physical properties. The smaller hydrazines are hygroscopic liquids with unpleasant odours and are nearly as strongly basic as amines when they bear only one or two alkyl substituents. Successive substitution lowers the basicity, and the tetraalkylhydrazines, R_2N-NR_2, are only feebly basic. Substitution of methyl groups for hydrogen in hydrazine lowers the boiling point, by reducing hydrogen bonding, but larger substituents add so much weight that their net effect is to raise the boiling point.

Substitution of an acyl group for hydrogen, giving a hydrazide, raises both the melting and boiling point, and such compounds are nearly all solids, basic enough to dissolve in dilute mineral acid but weaker than hydrazine. Hydrazones are intermediate in properties and generally are liquids or low-melting solids (unless there are large substituents on the nitrogen atom) and of feeble basicity. Azines, $R_2C=N-N=CR_2$, may be liquids or solids and are generally yellowish and nonbasic.

The derivatives of azobenzene, a typical azo compound, in general are solids, always coloured, insoluble in water, and nonbasic; the larger aliphatic azo compounds are liquids. Monosubstituted analogues, usually named as diazenes, are of low stability, and much less is known about them.

Azoxy compounds resemble the azo compounds but are of paler colour; they are distinct from the oxadiaziridines, with which they were at one time confused.

Diazonium salts are generally colourless, crystalline, water-soluble substances that decompose slowly at room temperature and are capable of exploding. The salts are neutral in reaction, which implies that the diazonium hydroxides are strong bases. In basic solution, however, diazonium salts become converted to diazotate ions, $Ar-N=N-O^-$, which can exist in stereoisomeric forms related to those of the imines illustrated previously. Closely related are the diazo compounds, of which diazomethane, $CH_2=N_2$, is the best known; they are coloured yellow to purple, generally low-melting, and seldom very stable; they are inert to bases but are destroyed by acids.

The azides are colourless compounds, commonly liquid and insoluble in water. They are neutral but may be destroyed by concentrated acids, and though they are more stable than diazo compounds they may be dangerously explosive, especially if they are small.

The most important of the remaining compounds with N—N bonds are the triazenes, $R_2N-N=N-R$, but all are rarely encountered.

Preparative methods

Sources and preparation. Alkyl hydrazines are produced when hydrazine is treated with alkylating agents, and, although mixtures with dialkyl and even trialkyl hydrazines may result, this is usually a satisfactory preparative method. Some alkyl hydrazines are more easily prepared from hydrazides by reduction with lithium aluminum hydride. Reduction of nitrosamines is a good route to *N,N*-disubstituted hydrazines, and reduction of hydrazones has been used to prepare trisubstituted hydrazines. Aryl hydrazines can be obtained in wide variety by reducing diazonium salts; although this is the preferred method, a good alternative is the reaction of azodicarboxylic ester with aromatic hydrocarbons. This reaction produces hydrazine analogues of urethans, which can be hydrolyzed cleanly to aryl hydrazines.

Hydrazones are usually made by the reaction of ketones or aldehydes with hydrazines, although they can also be made by tautomerization of azo compounds. Hydrazides are made by reaction of esters with hydrazine; if acid chlorides are used, diacyl hydrazines are produced.

Aromatic azo compounds can be prepared in great variety by the reaction of diazonium salts with compounds containing reactive benzene rings; this is the method used to prepare azo dyes. Alternatively, an aromatic primary amine and a nitroso compound can be converted to an azo compound by the elimination of water. When the desired azo compound is symmetrical, such as azobenzene, the same effect can be obtained by reducing the corresponding nitrobenzene under suitable conditions. Aliphatic azo compounds are nearly always prepared by oxidizing a hydrazine.

Azoxy compounds are formed by the oxidation of azo compounds with peroxides or by reaction of nitroso compounds with hydroxylamines, with elimination of water. Reduction of a nitrobenzene may be controlled so as to produce the latter two reagents, thereby producing an azoxybenzene.

Diazonium compounds are always prepared by diazotization, the reaction of a primary aromatic amine with cold nitrous acid (although there are some unimportant reactions that also give rise to them).

The most general method among many for preparing diazoalkanes is the treatment of an *N*-nitroso-*N*-alkylamide with a strong base. Oxidation of simple hydrazones is a useful preparative method for larger diazoalkanes.

Aliphatic azides are usually prepared by a simple displacement reaction between an alkyl halide and sodium azide, but aryl azides, which cannot in general be prepared in this way, are easily prepared from diazonium salts and sodium azide. Both aryl and acyl azides can be prepared by the reaction of nitrous acid with the corresponding hydrazine derivative.

Reactions. The most characteristic reactions of alkyl and aryl hydrazines are salt formation and alkylation. Alkyl halides, sulfates, etc., will replace the hydrogens stepwise, usually continuing at the same nitrogen until a quaternary compound is formed. Hydrazones and hydrazides undergo the same type of reaction, although not as readily.

Most organic hydrazine derivatives are reducing agents in some degree, and those that bear no more than one substituent on each nitrogen are especially easily oxidized, forming azo compounds. With two hydrogens on the same nitrogen, oxidation is a little more difficult but can be accomplished with strong oxidizing agents so as to convert disubstituted hydrazines to diazenium salts and hydrazones to diazoalkanes. The N—N bond in hydrazines can be cleaved by reduction to give two molecules of amine; the preferred reagent is hydrogen in the presence of a nickel catalyst.

Nitrous acid attacks most hydrazine derivatives; the initial product in all cases is probably a nitroso (*i.e.,* the molecule contains the —NO group) derivative, but only when the hydrazine is trisubstituted can it usually be isolated. Monoarylhydrazines and simple hydrazides are converted all the way to azides, in an important preparative reaction.

Azo compounds are relatively unreactive. They are inert to alkylating agents, to aldehydes and ketones, and to acylating agents, and are not easily attacked by strong acids or bases. Reduction, their most characteristic reaction, takes place in two stages, first to a hydrazine and then to a pair of amines. Azo compounds having a hydrogen on an adjacent carbon isomerize (*i.e.,* rearrange their molecular structure) rather easily to hydrazones, especially in the presence of a base.

Reaction with acids

The most important general reaction of diazoalkanes is that with acids, which are converted to their esters, usually quantitatively and rapidly. Another important general reaction is the loss of nitrogen to form transient carbenes (electron-deficient species with divalent carbon) when heated or exposed to light. Diazomethane and to a lesser extent other diazoalkanes react with acid chlorides to form diazoalkyl ketones. These undergo the Wolff rearrangement when heated (usually in the presence of a silver catalyst) and form ketenes (or, in the presence of alcohols, water, or ammonia, the corresponding esters, acids, or amides). The overall process thus converts a carboxylic acid through its acid chloride to an acid with one more carbon atom (Arndt–Eistert synthesis).

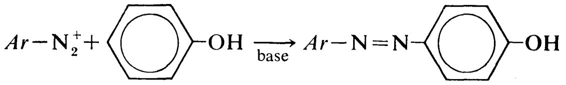
The most important reactions of azides are decomposition by heat, light, or concentrated acids, reduction, and addition of certain very strong bases. Heat or light causes loss of two-thirds of the nitrogen as N_2. In some cases this is accompanied by rearrangement, as in the Curtius rearrangement of acyl azides to isocyanates. In others, a reactive, electron-deficient intermediate, called a nitrene, is produced, which cannot be isolated but reacts very rapidly with itself or the solvent or both.

Many reducing agents, such as hydrogen (with a platinum catalyst) or sodium arsenite, convert azides cleanly to primary amines, for which this process is sometimes a useful preparative method.

The reactions of diazonium salts have been studied intensively since the mid-19th century, and the possibilities are so many and complex that only a small selection can be mentioned here. One important family of reactions involves loss of nitrogen and replacement of the diazonium grouping by another atom or group of atoms. Warming in water solution brings about replacement by OH, giving a phenol. In the presence of inorganic iodides or azides, aryl iodides or azides form rapidly. Replacement by chloride, bromide, or cyanide is brought about with the help of a copper(I) salt as catalyst (Sandmeyer reaction). Replacement by hydrogen may be brought about by alcohol or hypophosphorous acid.

Formation of azo compounds

Another important family of reactions consists of the attachment of another group, usually through a carbon atom, at the end of the diazonium system, to give various types of azo compounds. The most important examples involve reaction with phenols or anilines, forming substituted azobenzenes. When these substances also bear functions that help in binding them to textile fibres, they are azo dyes.



COMPOUNDS WITH N—O BONDS

Classes, sources, and preparation. Hydroxylamines are liquids or low-melting solids, volatile if small, and weakly basic. Oximes are still weaker bases and feeble acids and hydroxamic acids are weak acids similar to phenols. Nearly all hydroxylamine derivatives are soluble in water if they do not contain more than six carbon atoms.

Compounds with a nitroso group attached to carbon are bright blue or green, low-melting, neutral substances, but few of them are well known, owing to their capacity for rapid dimerization (usually reversible). The dimers are colourless solids having structures analogous to azoxy compounds. With many nitrosobenzenes, the colourless dimer dissociates to the green monomer simply on melting or dissolving in an inert solvent.

Most simple nitro compounds are liquids and are only slightly soluble in water, if at all. Many nitrobenzene derivatives are yellow. Nitro compounds are in general neutral, but those that bear a hydrogen on the same carbon as the nitro group are pseudoacids; that is, although only feebly acidic themselves, they react slowly with bases to form salts derived from tautomeric forms (nitronic acids, or *aci*-nitro compounds), which have acid strengths similar to those of carboxylic acids. Trinitromethane, however, exists entirely in the nitronic acid form and is a strong acid. Nitro compounds are polar, and the smaller nitroalkanes dissolve many salts.

The esters of nitrous and nitric acids are liquids, volatile if small, and insoluble in water. The nitrites are not very stable to storage and are also easily hydrolyzed; the nitrates are considerably more stable, if they are pure, and are difficult to hydrolyze. Nitrate esters are sensitive to heat and shock, especially when impure, and can be violently explosive.

Stable organic derivatives, known as nitrosamines, of the unstable amide of nitrous acid are well known. There is no practical natural source of compounds containing N—O bonds, although some of them occur in nature.

The preparation of organic derivatives of hydroxylamine relies heavily on hydroxylamine itself, which reacts with aldehydes and ketones to form oximes and with esters, anhydrides, or acid chlorides to form hydroxamic acids.

Nitroso compounds are most generally made by oxidation of *N*-substituted hydroxylamines, although many nitrosobenzenes can be made conveniently by oxidizing the corresponding aniline with peroxysulfuric acid, and a few can be made by direct nitrosation (addition of nitroso group, NO) of the benzene ring by nitrous acid (*e.g.*, *p*-nitrosodimethylaniline).

Preparation of nitro compounds

Nitro compounds are prepared in great variety by treating aromatic hydrocarbons with nitric and sulfuric acids; with some severe limitations, nitration of aliphatic hydrocarbons (generally at high temperature in the vapour phase) is also of preparative value, but most aliphatic nitro compounds are made by further reactions of the few commercially available nitroalkanes, such as nitromethane.

Esters of nitrous acid are easily made by reaction between dilute nitrous acid and alcohols, but a mixture of nitric and sulfuric acids is generally required to convert alcohols to alkyl nitrates. Nitrosamines are formed easily when secondary amines are brought into contact with nitrous acid, but nitramines require special methods, such as treating primary amines with *a*-cyanoisopropyl nitrate or converting an amine to a carbamyl chloride and then treating it with silver nitrate.

Reactions. Although most hydroxylamines are indefinitely stable as their salts, the free bases do not generally store well; *N*-substituted hydroxylamines slowly transform into amines and azoxy compounds, but *O*-alkyl hydroxylamines are more stable. *N*-aryl hydroxylamines differ from the alkyl analogues in that acid easily brings about a rearrangement to form *p*-aminophenols and other ring-substituted anilines.

Both alkylation with alkyl halides and acylation with esters, anhydrides, and acid chlorides take place easily. Aldehydes and ketones react with *O*-substituted hydroxylamines to form oxime derivatives, but *N*-substituted hydroxylamines generally react only with aldehydes, with which they form nitrones.

Hydroxylamines and oximes can be reduced by various reagents, most generally by catalytic hydrogenation, and then form amines.

Hydroxamic acids are hydrolyzed to the parent carboxylic acids by hot aqueous mineral acid. In the form of their alkali metal salts, they can be alkylated or acylated.

The chemistry of nitroso compounds is dominated by their oxidation and reduction. They are active oxidizing reagents, and a wide variety of reducing agents will convert them first to hydroxylamines and then to amines. Because nitroso compounds react with both of these functional groups, the actual products obtained from a reduction may be further transformation products—azo or azoxy compounds, hydrazines, benzidines, etc. Oxidation of nitroso to nitro compounds requires a strong oxidizing agent, such as permanganate or a peroxy acid.

Aliphatic nitroso compounds are generally so tightly bound up as the dimers that reactions specifically of the monomer are not easily observed. If there is a hydrogen on the same carbon as the nitroso group, the monomer easily and irreversibly isomerizes to an oxime. The nitroso group is an effective trap for free radicals, which add to the nitrogen to form a nitroxide, $RR'\text{N—O}\cdot$. Nitroso compounds react with many other types of compounds under suitable conditions: olefins, aldehydes, Grignard reagents, compounds having active methylene groups, etc.

Reduction of nitro compounds

By far the most important reaction of nitro compounds is their reduction, which, although not so easily accomplished as with nitroso compounds, can still be brought about by a large variety of reducing agents; hydrogen (with catalysts), dissolving metals (iron, tin, zinc, etc.), sulfides, sodium alkoxides, etc. The products may be any of the oxidation states of nitrogen but generally not nitroso compounds, for these are invariably reduced further. If the reducing medium is acidic, reduction almost always goes all the way to an amine. In neutral medium, it is in many cases possible to stop at the hydroxylamine stage. In basic solution, N—N bonds are usually formed, and the products are hydrazo, azo, or azoxy compounds.

The more important part of the chemistry of aliphatic nitro compounds has to do with the reactivity of the hydrogens on the same carbon as the nitro group. Concentrated sulfuric acid isomerizes primary nitroalkanes to hydroxamic acids, which are usually hydrolyzed to carboxylic acids and hydroxylammonium sulfate. Their salts, the nitronates, are not very stable and undergo some unusual reactions. Strong mineral acid cleaves them to aldehydes or ketones and nitrous oxide (Nef reaction). Strong base causes more complex reactions; primary nitroalkanes condense to heterocyclic compounds (isoxazoles) and nitromethane itself is converted in stages to a salt of nitroacetic acid. Heavy-metal salts have distinctive reactions, such as that of the mercuric salt of nitromethane, which loses water to form mercuric fulminate.

Most nitroalkanes decompose above 300° C (572° F) and form olefins, water, and oxides of nitrogen. With aldehydes (and some ketones), primary nitroalkanes react in a way analogous to the base-catalyzed aldol condensation, adding to the carbonyl group to form a nitro alcohol or its dehydration product, a nitro olefin (Henry reaction).

Alkyl nitrites decompose rather easily under the influence of heat or light to produce mixtures of carbonyl and *C*-nitroso compounds or their further transformation products. The first step is apparently loss of NO to form an alkoxy free radical (*i.e.*, a group of atoms with one unpaired electron), $R\text{—O}\cdot$. Alkyl nitrites also react as nitrosating agents, similar to nitrous acid.

Alkyl nitrates begin to decompose near 150° C (302° F). If the heating is carefully controlled, alkyl nitrites may be formed, along with smaller fragments and oxides of carbon, but otherwise explosion ensues, and the entire molecule may be converted to oxides of carbon, water, and nitrogen. Nitrates are most conveniently converted to the parent alcohol by reduction (zinc and acetic acid, ferrous chloride, etc.), which at the same time converts the nitrogen to nitric oxide or ammonia. Alkyl nitrates can function as alkylating agents or nitrating agents.

(P.A.S.S./Ed.)

Organic phosphorus compounds

Organic phosphorus compounds are carbon-containing compounds that also contain one or more atoms of the element phosphorus. Of the several million known organic compounds, several hundred thousand contain phosphorus.

The organic compounds of phosphorus are typically colourless liquids or solids, not physically distinct from other organic compounds of similar molecular size and character. Several types are very toxic, including the phosphines, but they present little danger in normal use because their exceedingly offensive odours generally prevent overexposure. Many toxic phosphorus compounds of other classes, however, are particularly hazardous because they are colourless, almost odourless liquids. Some of them are used as insecticides. Others were developed during World War II as a particularly unpleasant class of chemical warfare agent, the nerve gases.

Insecticides and nerve gases belong to the general fam-

Organic phosphates

ily of organic phosphates, which are probably the most important of the organic phosphorus compounds. Also included in this category are many biochemical compounds essential to life processes, such as the nucleic acids (control factors in heredity) and nucleotide coenzymes (compounds that permit enzymes to function properly). Other organic phosphates find industrial uses—as solvents and flame-retardation agents, for example. Other classes of organic phosphorus compounds are less useful, but some play important roles in the synthesis of complex chemical compounds of various types, such as pharmaceuticals.

There are many problems connected with the naming of organic phosphorus compounds, largely because the first organic phosphorus compounds were made and named in the early part of the 19th century, before complete knowledge of their structures was obtained. Furthermore, different authors in different countries have frequently used different names for the same compound. This situation was improved, however, after an international agreement on nomenclature was reached in 1952. In this article standard international nomenclature is used.

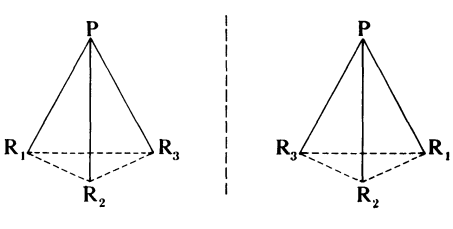
GENERAL PROPERTIES

The chemistry of the organic phosphorus compounds is best understood in terms of the influence of the phosphorus atom on the organic molecule. This influence depends in large measure on the electronic character of that atom.

Electronic configuration. Atoms of phosphorus, like those of other elements, contain a central, positively charged nucleus and, surrounding it, successive concentric rings, or shells, of negatively charged electrons. The electrons of the outermost shell are capable of joining with the electrons of other atoms to form chemical bonds, and they are, therefore, called bonding, or valence, electrons—the term valence referring to the number of other atoms with which a single atom of a given element can combine. In its outermost shell, a phosphorus atom has five electrons in two subshells called—for no important reason—*s* and *p* subshells. Within these subshells the electrons move in particular paths, or orbitals. The five outermost, or valence, electrons of a phosphorus atom occupy one *s* orbital (containing two electrons) and three *p* orbitals. The three *p* electrons are unpaired (each orbital being capable of holding two electrons) and therefore are available to form three single bonds, giving rise to trivalent compounds of phosphorus. Alternatively, however, the two *s* electrons can also become involved in bonding, and this situation leads ultimately to pentavalent phosphorus compounds.

Pyramidal structures

Structure and bonding. Trivalent phosphorus compounds, with the general formula PX_3 (in which P represents a phosphorus atom and X any other atom or group), have pyramidal structures (one atom at each vertex of a three cornered pyramid), that are closely analogous to those of the corresponding and better known nitrogen compounds. One of the main differences between the phosphorus and nitrogen compounds is that the angles between the different $P-X$ bonds are considerably smaller than the corresponding angles between the $N-X$ bonds (in which N is the symbol for nitrogen)—close, in fact, to the 90° expected if bonding involves only the *p* orbitals of phosphorus. Another difference between phosphorus and nitrogen compounds is that the pyramidal configuration in the phosphorus series is much more stable to inversion—that is, to turning inside out, like an umbrella. As a result, trivalent organic phosphorus compounds (phosphines) with three different organic substituents, unlike the corresponding nitrogen compounds (amines), can exist in two separate forms (isomers), which are stable under mild conditions. The two forms are mirror images of one another, as shown by the diagrams below:



In these diagrams, R_1, R_2, and R_3 represent the different organic groups joined to a phosphorus atom. The solid lines represent bonds between the phosphorus atom and the organic groups (and also the edges of the pyramidal structures of the molecules). The dotted lines indicate the bases of the pyramids, and the dashed line is the position of the mirror plane (indicating that each isomer is a mirror image of the other.)

Tetrahedral structures

The great majority of phosphorus compounds, however, are not pyramidal but rather have four substituents arranged tetrahedrally about the phosphorus atom. These tetrahedral compounds include salts of the formally trivalent compounds—formed by utilizing the two *s* electrons and based on the phosphonium ion, PH_4^+ (in which H is hydrogen)—as well as the much larger group of truly pentavalent compounds. Pentavalent compounds can be formed because the phosphorus atom has available unused orbitals—called *d* orbitals—which, in the tetrahedral PX_4^+ state, readily accept electrons from other (donor) atoms to form a fifth bond to phosphorus. The donor atom may be in a separate molecule, in which case a pentacovalent species PX_5 results; several scores of compounds with this structure are known. But the utilization of *d* orbitals is most efficient when the donor atom is already bonded to phosphorus. The phosphorus-oxygen bond, for example, is stabilized in compounds such as the phosphine oxides, $R_3P{=}O$ (in which O is an oxygen atom, R represents an organic group, and the double line indicates a double bond), the *p* electrons of oxygen interacting with the vacant *d* orbitals of phosphorus to form a so-called pi bond. This type of multiple bonding stabilizes an adjacent negatively charged centre very effectively in the phosphinimines, $R_3P{=}NR$, and phosphinemethylenes, $R_3P{=}CR_2$ (C representing a carbon atom), as well as being responsible for the great stability of the phosphorus-oxygen double bond (P=O).

It is also instructive to compare these higher valence compounds of phosphorus to the comparable compounds of nitrogen. Nitrogen atoms, like phosphorus atoms, carry *s* electrons that they are able to use in forming salts—derivatives of the ammonium ion, NH_4^+, just as the related phosphorus compounds are derived from the phosphonium ion, PH_4^+. The nitrogen atom, however, does not have vacant *d* orbitals available for sharing donor electrons, so that pi-bonded compounds comparable to those formed by phosphorus do not occur. Thus, the amine oxides, compounds formulated as $R_3N^+{-}O^-$, cannot form a carbon–nitrogen double bond and are markedly less stable than the comparable phosphorus–oxygen compounds, which do form a phosphorus–oxygen double bond.

This exceptional strength of the phosphorus–oxygen double bond in the phosphoryl compounds has an important influence on much of phosphorus chemistry.

Importance of the phosphorus–oxygen double bond

Chemical reactivity. Trivalent phosphorus compounds are readily converted to their oxides and undergo many other reactions that generate products containing the phosphorus–oxygen double bond. Furthermore, the stabilizing effect of pi bonding can be exerted on more than one phosphorus–oxygen bond simultaneously. As a result, anions (negatively charged ions) such as that formulated  $R_2P(=O)O^-$ are unusually stable (in having two bonds, both of which can show pi bonding). Indeed, compounds formulated as $R_2P(O)OH$ are strong acids; *i.e.,* they readily give up a hydrogen ion to achieve the stable anionic condition. Even such anions as  $RP(=O)(OH){-}O^-$ have acidic properties and in neutral solution are largely dissociated to dianions, RPO_3^{2-}. In these anions, the various oxygen atoms are equivalent and share in the negative charge, while the various phosphorus–oxygen bonds are also equivalent and have equal amounts of partial double bond character.

Chemically, the phosphorus atom of an organophosphorus compound is a centre of high reactivity. Trivalent phosphorus has a lone pair of nonbonded *s* electrons, which gives it basic (the chemical opposite of acidic) character, as well as nucleophilic character (that is, a tendency to be attracted to positively charged groups). Nucleophilic substitution reactions proceed readily at both trivalent and pentavalent phosphorus centres. The only important exceptions to this generalization are the tertiary phosphine oxides, $R_3P{=}O$. These have no readily displaced substituent and, therefore, do not undergo substitution reactions of any kind. Furthermore, the doubly bonded phosphorus–oxygen group, $P{=}O$, does not undergo the ready addition reactions characteristic of the carbon–oxygen doubly bonded group ($C{=}O$, or carbonyl group), the behaviour of which in aldehydes and ketones is an important aspect of general organic chemistry. Thus, the tertiary phosphine oxides, $R_3P{=}O$, show little or none of the chemical reactivity associated with the ketones, $R_2C{=}O$.

Analysis of phosphorus in compounds

The phosphorus content of an organic compound is usually assayed (measured) by first subjecting the compound to reactions (hydrolysis and oxidation) that transform the phosphorus atoms to inorganic phosphate. Some compounds, especially those with phosphorus–carbon bonds, are degraded to inorganic phosphate only by powerful oxidizing agents; *e.g.*, concentrated perchloric acid at the boiling point. The inorganic phosphate formed is converted to a substance called phosphomolybdate, which can be determined either gravimetrically (by weight) or colorimetrically (by measurement of colour intensity).

MAJOR CLASSES

Organic derivatives of phosphorus acids. The organic derivatives of the acids based on phosphorus are derived from the six parent acids shown in Table 28. Conversion to organic derivatives can be considered formally to consist of replacement of any or all of the hydrogen atoms by organic groups (R). In addition, one or more of the oxygen atoms may be replaced by sulfur atoms, giving rise to the large family of thioacids of phosphorus.

Table 28: Trivalent and Pentavalent Forms of the Phosphorus Acids

trivalent form		pentavalent form	
name	formula	name	formula
Phosphinous acid	H_2POH	phosphine oxide	$H_3P{=}O$
Phosphonous acid	$HP(OH)_2$	phosphinic acid	 $H_2P(=O)OH$
Phosphorous acid	$(HO)_3P$	phosphonic acid	 $(HO)_2P(=O)H$
		phosphoric acid	$(HO)_3P{=}O$

The free acids themselves exist overwhelmingly in the pentavalent ($P = O$) forms (shown in the second column of the table), but esters and other derivatives of the trivalent are stable. If this generalization is not appreciated, the nomenclature can be very confusing. Trimethyl phosphite $(CH_3O)_3P$, for example, is a stable liquid that can readily be hydrolyzed (converted by water) to the dimethyl ester. This ester is commonly known, not unreasonably, as dimethyl phosphite, but it exists almost exclusively in the tetrahedral form,  $(CH_3O)_2P(=O)H$, and is, therefore, correctly termed dimethyl phosphonate.

Most organic compounds of phosphorus formally are derivatives of one of the phosphorus acids—the exceptions being those compounds with three or more phosphorus–carbon or phosphorus–hydrogen bonds. The neutral organic compounds of phosphorus are described below, in sections devoted to the trivalent and pentavalent derivatives, respectively. This section deals specifically with the acid forms, including those acid esters in which the parent acid has more than one acidic group. (Most important by far of these are the esters of phosphoric acid.)

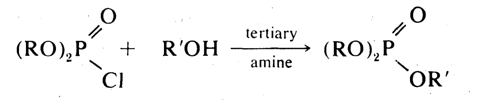
Organic phosphorus acids

Organic acids of phosphorus are moderately strong acids, with dissociation constants (the standard way of comparing acids) in the region of 10^{-1}–10^{-2}. Acids with two hydroxyl ($-OH$) groups have a second dissociation constant, usually between 10^{-7} and 10^{-8}. The lower molecular weight compounds are liquids that are soluble in water. The higher molecular weight acids and those containing aromatic groups (a particularly stable organic grouping) become progressively less soluble in cold water. Even these, however, generally dissolve in neutral or alkaline aqueous solution to form anions. As usual, solubility in organic solvents follows almost the reverse trend: it is higher for nonionized acids and for esters with high molecular weights than for those of low molecular weights. In Table 29 is collected a representative selection of acids and their derivatives based on simple organic groups; it illustrates the system of nomenclature now in use, as well as typical physical properties.

Phosphate esters—the esters of phosphoric acid—like other tetrahedral compounds of pentavalent phosphorus, are usually prepared by nucleophilic substitution of groups located on the phosphorus atom (that is, by attack of a negative group at the positive centre). Syntheses of simple derivatives are based on the readily available substance phosphorus oxychloride, $POCl_3$, which reacts consecutively to lose one, two, or three chloride ions. Triesters are formed when a dialkyl phosphorochloridate (prepared from two molecules of the alcohol to one of phosphorus oxychloride) reacts with an alcohol or phenol in the presence of a tertiary amine, as in the following chemical equation:

Table 29: Organic Phosphorus Acids and Derivatives

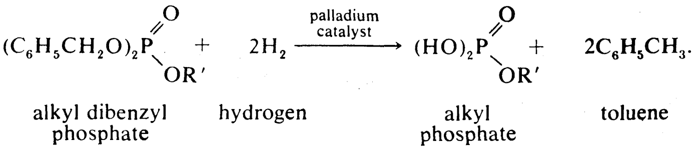
structure	name	melting point (°C)	boiling point (°C)
 $(C_2H_5)_2P(=O)OH$	diethylphosphinic acid	19	310
 $C_6H_5P(=O)(OH)OC_6H_5$	phenyl hydrogen phenylphosphonate	70–72	...
$(C_2H_5O)_3P{=}O$	triethyl phosphate	...	215
$C_2H_5OPOCl_2$	ethyl phosphorodichloridate	...	167
$C_6H_5OPO(OH)_2$	phenyl dihydrogen phosphate	97–98	...
$C_2H_5OPO_3^{2-}\ Mg^{2+}$	magnesium ethyl phosphate	...	...
$H_3\overset{+}{N}PO_3^{2-}\ Na^+$	sodium phosphoramidate	...	...
$(C_2H_5O)_2P(O)OPO(OC_2H_5)_2$	tetraethyl pyrophosphate	...	137/1mm
 $C_2H_5OP(=O)(O^-){-}O{-}P(=O)(O^-){-}O{-}PO_3^{2-}\ 4\ Na^+$	tetrasodium ethyl tripolyphosphate	...	...



$$(RO)_2P(=O)Cl + R'OH \xrightarrow[\text{amine}]{\text{tertiary}} (RO)_2P(=O)OR'$$

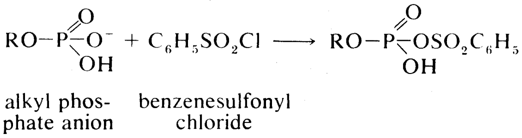
dialkyl phosphorochloridate alcohol trialkyl phosphate

This method provides an unambiguous route to unsymmetrical triesters and is readily adapted to the synthesis of monoesters if the first two alkyl groups (R in the above example) can be removed under conditions that leave the third group unaffected. The benzyl group ($C_6H_5CH_2-$) is a group of this kind frequently used in the preparation of phosphate esters. It can readily be removed by treating the benzyl ester with hydrogen, as in the following example:

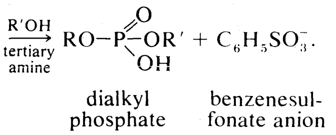


$$(C_6H_5CH_2O)_2\overset{O}{\underset{OR'}{P}} + 2H_2 \xrightarrow{\text{palladium catalyst}} (HO)_2\overset{O}{\underset{OR'}{P}} + 2C_6H_5CH_3.$$

Important variations of this type of reaction can be carried out with condensing agents, such as acid chlorides or anhydrides, on phosphate anions. These condensing agents convert the negatively charged oxygen atom to a group that is easily displaced. An example of such an easily displaceable group is the benzenesulfonate group (introduced by reaction with benzenesulfonyl chloride). The reactions involved are the following:

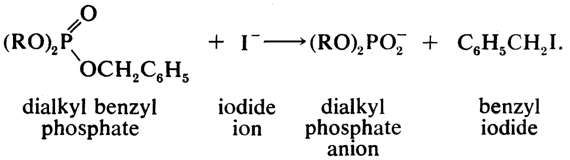


$$RO{-}\overset{O}{\underset{OH}{P}}{-}O^- + C_6H_5SO_2Cl \longrightarrow RO{-}\overset{O}{\underset{OH}{P}}{-}OSO_2C_6H_5$$



$$\xrightarrow[\text{tertiary amine}]{R'OH} RO{-}\overset{O}{\underset{OH}{P}}{-}OR' + C_6H_5SO_3^-.$$

Alternatively, a carbon–oxygen bond may be broken when a powerful but weakly basic nucleophile attacks an ester with a reactive alkyl group, as shown below:



$$(RO)_2\overset{O}{\underset{OCH_2C_6H_5}{P}} + I^- \longrightarrow (RO)_2PO_2^- + C_6H_5CH_2I.$$

Beginning in the 1950s the requirement for phosphate esters of known structure in the nucleotide field (see below) greatly stimulated work on methods of phosphorylation.

In their reactions, phosphate esters, especially the triesters, resemble the better known carboxylic esters. Strongly basic nucleophiles, such as hydroxide ions, readily effect nucleophilic displacement of groups on phosphorus atoms in diesters and triesters, as in this example:

$$(C_6H_5O)_3P{=}O \xrightarrow[\text{hydroxide ion}]{OH^-} (C_6H_5O)_2PO_2^- \xrightarrow{OH^-} C_6H_5OPO_3^{2-}.$$

triphenyl phosphate — diphenyl phosphate anion — phenyl phosphate dianion

Apart from their biochemical importance, organic phosphates play a definite role in the synthesis of organic chemicals containing phosphorus. Organic phosphates and related compounds also find important uses as corrosion and oxidation inhibitors; as plasticizers that confer fire resistance to textiles; as agents for the selective extraction of metals; and as insecticides. Some phosphorylating agents react rapidly and specifically to inhibit certain enzymes, particularly cholinesterase, which is essential for the transmission of nerve impulses. As a result, such compounds are extremely toxic to warm-blooded animals; known as nerve gases, they are particularly hazardous because they can be absorbed through the skin as well as by swallowing or breathing.

Biologically important phosphate esters

Phosphate esters play a vital part in the chemistry of the life process. The genetic code is carried by the deoxyribonucleic acids (DNA), which are high-molecular-weight phosphate esters, built up from four different subunits, called nucleotides. Nucleotides are the phosphate esters of nucleosides (comprised of sugars and organic bases), and in the nucleic-acid structure each nucleotide subunit is joined to the phosphate group of the next by a second ester linkage. The nucleotides themselves also take part in a large number of essential biochemical processes, not only in their monophosphate form but also as diphosphates and triphosphates. Nucleoside triphosphates, especially adenosine triphosphate (ATP), play an important role in the process of phosphate transfer (phosphorylation). This key reaction provides the chemical means by which an organism harnesses the chemical energy available from the degradation of food to do useful work. Phosphorylation is also an important biosynthetic reaction, because a large proportion of the compounds involved in metabolism are present in the organism as their phosphate esters; *e.g.*, the simple-sugar phosphates and phospholipids.

Several other types of phosphorus compounds are found in nature to a minor extent, including several with phosphorus–nitrogen bonds and a few with phosphorus–carbon bonds (phosphonates).

The acid esters have their own characteristic properties. The monesters, $ROPO(OH)_2$, for example, are stable to alkaline hydrolysis because they are converted to the unreactive dianions, $ROPO_3^{2-}$. At the same time, however, these monoesters are rapidly hydrolyzed under slightly acidic conditions in a unique reaction of the monoanion, which is the predominant ionic form under these conditions. Phosphate diesters are relatively unreactive. They show no special reactivity at any acidity and are hydrolyzed only slowly in alkali—under which conditions, as anions, their reaction with hydroxide ion is inhibited but not completely prevented by electrostatic repulsion; that is, repulsion between electrical charges of the same sign.

Certain structural characteristics confer high reactivity on phosphate esters. Diesters and triesters with their phosphorus atoms contained in a five-membered ring structure, for example, are hydrolyzed some 10^7 times as rapidly as the corresponding open-chain compounds. Also activated toward hydrolysis are many esters with neighbouring ionizable groups close enough to interact with the phosphorus centre. The best known example of this situation occurs in the ribonucleic acids, one of the two principal classes of nucleic acids. Ribonucleic acids are rapidly degraded by alkali under conditions in which the deoxyribonucleic acids, the other principal class, are quite stable. The only structural difference between the two classes of compounds is the presence of an extra hydroxyl group adjacent to the phosphate–ester linkage in the ribonucleic acids.

Trivalent organic phosphorus compounds. Compounds with three substituents bonded to a phosphorus atom have structures resembling those of the corresponding and more familiar nitrogen compounds, but the former group includes a much larger number of stable compounds with bonds to electronegative elements, such as oxygen and the halogens (fluorine, chlorine, bromine, and iodine). Nomenclature of the phosphorus compounds is more complicated than that of the nitrogen derivatives, which are named generally as amines. Naming of phosphorus compounds depends on whether phosphorus is joined solely to carbon or hydrogen atoms or both or whether it is bonded to an electronegative element. Compounds with bonds from phosphorus only to carbon or hydrogen are named as derivatives of phosphine, PH_3, by a system similar to that used for the amines. Thus, methylphosphine, CH_3PH_2, dimethylphosphine, $(CH_3)_2PH$, and trimethylphosphine, $(CH_3)_3P$, are primary, secondary, and tertiary phosphines, respectively. The metal salts are called phosphides, and the protonated forms (compounds to which a hydrogen ion is added) and alkylated forms (compounds to which an organic group is added) are called phosphonium compounds. Compounds with one or more bonds from phosphorus to any element other than carbon or hydrogen are named as derivatives of phosphinous, phosphonous, and phosphorous acids (see Table 28). Compounds with groups formulated as P—OR and P—SR are regarded as esters of the appropriate acid and thio (sulfur-containing) acid, respectively. Amino and halogen compounds are considered to be amides and acyl halides of the respective acids. A representative selection of trivalent phosphorus compounds based on simple organic groups is listed in Table 30. In all, a wide range of compounds is possible, with phosphorus making three bonds to any combination of the following groups: H, R (any organic group), NH_2, NHR, NR_2, OR, SR, SeR (Se being selenium), F, Cl, Br, and I. Compounds belonging to nearly all these

Nomenclature of trivalent phosphorus compounds

Table 30: Trivalent Phosphorus Compounds

structure	name	boiling point (°C)
$(C_2H_5)_4P^+ Br^-$	tetraethylphosphonium bromide	*
$(C_2H_5)_3P^+H Cl^-$	triethylphosphonium chloride	
$(C_2H_5)_3P$	triethylphosphine	127
$(C_2H_5)_2P—P(C_2H_5)_2$	tetraethyldiphosphine	
$(C_2H_5)_2PH$	diethylphosphine	85
$C_2H_5PH_2$	ethylphosphine	25
$(C_2H_5)_2P^- K^+$	potassium diethylphosphide	
$(C_2H_5)_2PCl$	diethylphosphinous chloride	60–70/15mm
$(C_2H_5)_2PN(C_2H_5)_2$	tetraethylphosphinous amide	181
$C_2H_5P(NH_2)_2$	ethylphosphonous diamide	—
$(C_2H_5)_2POC_2H_5$	ethyl diethylphosphinite	80–85/15mm
$C_2H_5P(OC_2H_5)_2$	diethyl ethylphosphonite	137–9
$(C_2H_5O)_3P$	triethyl phosphite	156–7
$(C_2H_5S)_3P$	triethyl phosphorotrithioite	140–3/18mm

*Decomposes at 300° C.

categories can be made by nucleophilic substitution reactions at the phosphorus atom, using the readily available phosphorus trihalides, especially phosphorus trichloride, PCl_3. Amines—and alcohols and phenols in the presence of added base—readily displace one or more chloride ions in a phosphorus chloride. Alkyl groups can be introduced by using organic magnesium compounds. A reaction sequence with examples of both reactions is:

$$C_2H_5MgCl \quad + \quad PCl_3 \longrightarrow C_2H_5PCl_2 \; + \; MgCl_2$$

ethylmagnesium chloride	phosphorus trichloride	ethylphosphonous dichloride	magnesium chloride

$$C_2H_5PCl_2 + 2C_2H_5OH \xrightarrow{\text{base}} C_2H_5P(OC_2H_5)_2 + 2HCl.$$

ethylphosphonous dichloride	ethyl alcohol	diethyl ethylphosphonite	hydrogen chloride

The lower phosphines, with phosphorus–hydrogen bonds, can be converted to metal salts, and these are readily alkylated by alkyl halides, as in the following example:

$$K^+PH_2^- \; + \; C_2H_5Br \; \longrightarrow \; C_2H_5PH_2 \; + \; KBr.$$

potassium phosphide	ethyl bromide	ethylphosphine	potassium bromide

These metal salts are easily accessible and useful as synthetic intermediates.

In many important reactions of trivalent phosphorus compounds, the lone pair of *s* electrons on phosphorus is attacked by electrophilic reagents. The most reactive such compounds are the phosphines themselves; electronegative substituents on phosphorus and increasing molecular weight both reduce reactivity. Many aliphatic and some aromatic phosphines, for example, are so readily oxidized by atmospheric oxygen that they are spontaneously flammable in air; these same compounds react explosively with reactive alkylating agents, such as methyl iodide; but triphenyl phosphite, $(C_6H_5O)_3P$, and triphenylphosphine, $(C_6H_5)_3P$, are oxidized and alkylated slowly and can be handled without special precautions. Similarly, triphenylphosphine is only weakly basic, although aliphatic tertiary phosphines (but not primary or secondary) are bases as strong as the corresponding amines.

Three reactions typical of the phosphines are illustrated by the following equations:

$$(C_2H_5)_3P + C_2H_5I \xrightarrow{\text{cold ether solvent}} (C_2H_5)_4P^+I^-,$$

triethylphosphine	ethyl iodide	tetraethylphosphonium iodide

$$(C_6H_{13})_3P \; + \; \tfrac{1}{2}O_2 \xrightarrow{\text{stand in air}} (C_6H_{13})_3P{=}O,$$

tri-*n*-hexylphosphine	oxygen	tri-*n*-hexylphosphine oxide

$$(C_2H_5)_3P \; + \; Br_2 \xrightarrow[\text{solvent}]{\text{cold benzene}} (C_2H_5)_3P^-Br^+ \; Br^-.$$

triethylphosphine	bromine	bromotriethylphosphonium bromide

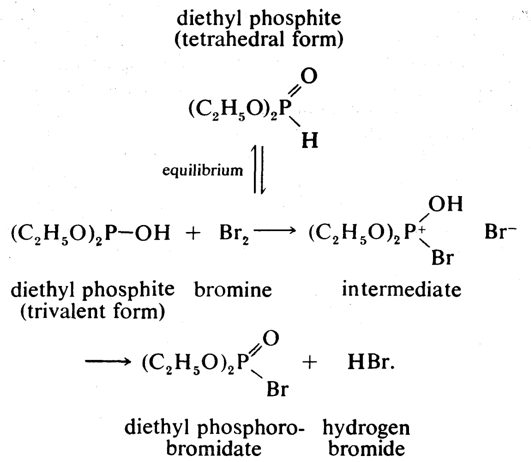
Many trivalent phosphorus compounds remove atoms of oxygen from various molecules, especially when they are attached to nitrogen or sulfur or to another phosphorus centre; for example,

$$(C_2H_5O)_3P \; + \; R_3\overset{+}{N}{-}O^- \longrightarrow (C_2H_5O)_3P{=}O \; + \; R_3N.$$

triethyl phosphite	tertiary amine oxide	triethyl phosphate	tertiary amine

Many classes of trivalent compounds also form series of complex coordination compounds with metal ions.

As stated above, hydroxyl compounds of trivalent phosphorus exist almost exclusively in the tetrahedral P═O form. Extremely small amounts of the trivalent hydroxyl forms are present in equilibrium, however (often much less than one part per million), and these are thought to be responsible for the observed reactions of the compounds with reactive electrophilic reagents. An example is given below:



Phosphonium salts

The availability for bonding of the *d* orbitals of phosphorus has a decisive effect on the chemistry of phosphonium compounds. Generally, the reactions of phosphonium compounds are more important than those of ammonium compounds, and their chemical behaviour is quite different. Some of these compounds form a fifth bond to phosphorus, as in the following example:

$$(C_6H_5)_4P^+ \; Br^- \; + \; C_6H_5Li \; \longrightarrow \; (C_6H_5)_5P \; + \; LiBr.$$

tetraphenylphosphonium bromide	phenyllithium	pentaphenylphosphorane	lithium bromide

Usually, the fifth bond is a pi bond, as in the following:

$$(C_6H_5)_3\overset{+}{P}CH_2C_6H_5Br^- + C_6H_5Li$$

benzyltriphenylphosphonium bromide	phenyllithium

$$\longrightarrow \; (C_6H_5)_3P{=}CHC_6H_5 \; + \; LiBr \; + \; C_6H_6.$$

triphenylbenzylidenephosphorane	lithium bromide	benzene

Most commonly the multiple bond formed is the very stable P═O bond. Alkoxyphosphonium compounds, for example, are rapidly dealkylated by most nucleophiles to give phosphine oxides:

$$(C_2H_5)_3\overset{+}{P}OC_2H_5 \; Br^- \longrightarrow (C_2H_5)_3P{=}O + C_2H_5Br.$$

triethylethoxyphosphonium bromide	triethylphosphine oxide	ethyl bromide

As a result of this reaction, phosphoryl compounds are the final products when any aliphatic esters of trivalent phosphorus acids react with normal alkylating agents, as shown in the following example:

$$(C_2H_5)_2POC_2H_5 + C_2H_5Br \xrightarrow{\text{2 steps}} (C_2H_5)_3P{=}O + C_2H_5Br.$$

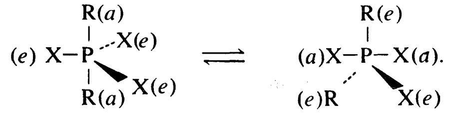
ethyl diethylphosphinite   ethyl bromide   triethylphosphine oxide   ethyl bromide

When the same alkyl group is involved in both ester and alkylating agent, as in the example shown, the alkylating agent is regenerated at the end of the reaction, and only catalytic amounts of it are required. In many instances, the same overall reaction can be brought about simply by strong heating, without the addition of any alkylating agent at all.

Phosphonium compounds are hydrolyzed by strong alkali in an unusual reaction in which an organic group, *R*, is displaced from phosphorus, apparently as the anion R^-. This remarkable result is feasible only because of the great stability of the P═O group of the product and because a mechanism is possible in which two molecules of hydroxide cooperate to break the carbon–phosphorus bond.

Pentavalent organic phosphorus compounds. The organic compounds of pentavalent phosphorus are of two structural types. A small number have five single bonds to phosphorus and trigonal bipyramidal geometry (that is, a structure formed by two pyramids joined base to base). Examples are pentaphenylphosphorane, $(C_6H_5)_5P$, and pentaethoxyphosphorane, $(C_2H_5O)_5P$. In compounds of this structure, two substituents are in axial (*a*) positions, and three are in equatorial positions (*e*), as shown in the structures below. Compounds with substituents in one position can in some cases be distinguished from those with substituents in the other. Complications arise, however, because axial and equatorial substituents can exchange positions by a process of molecular reorganization known as pseudorotation. An example of pseudorotation is shown below:

Two structural types



In this example, the two axial substituents (R) become equatorial substituents by changing of the bond positions. In these diagrams, ordinary lines represent bonds in the plane of the paper, dotted lines are bonds extending to the rear, and the wedges indicate bonds extending forward. Compounds with the PX_5 structure are generally very reactive. They readily revert to tetrahedral compounds, usually by way of an initial reversible ionization of the type $PX_5 \rightleftharpoons PX_4^+ + X^-$. An equilibrium of this sort is possible for any phosphonium system, and whether a particular compound exists predominantly as PX_5 or as $PX_4^+X^-$ depends in borderline cases on the environmental conditions (*e.g.*, solvent, temperature, and so on), as well as on the structure of the molecule. Compounds of the PX_5 structure have electrophilic (Lewis-acid) character also, and they may accept electrons from suitable donors to form the rare six-coordinate compounds PX_6^-. One or two organic examples of this class are known.

Compounds with pi bonds

The great majority of pentavalent organophosphorus compounds and, thus, also of all organic phosphorus compounds have four single bonds to phosphorus, one or more of which is reinforced by an additional bond, a pi bond. For purposes of nomenclature these compounds are classified in the same way as the corresponding trivalent derivatives: those with three bonds to carbon or hydrogen have names based on the parent phosphines, and the remainder are named as derivatives of phosphorus acids—in this case phosphinic or phosphonic acids. The range of structures known is essentially that given above for trivalent compounds, with the addition of the fourth bond, which is commonly a phosphorus to oxygen bond, P═O, or phosphorus–sulfur bond, P═S, but may also be a phosphorus–nitrogen or phosphorus–carbon bond, P═NR or P═CR₂. The selection of compounds listed in Table 31 illustrates the physical properties of these compounds, as well as the ways of naming them.

Table 31: Pentavalent Phosphorus Compounds

structure	name	melting point (°C)	boiling point (°C)

$C_2H_5PO(OC_2H_5)_2$	diethyl ethylphosphonate	—	198
$(C_2H_5O)_3P{=}O$	triethyl phosphate	—	215–16
$(C_2H_5O)_3P{=}S$	*O,O′,O″*-triethyl phosphorothioate	—	105/20mm
$(C_2H_5S)_3P{=}S$	triethyl phosphorotetrathioate	—	110/0.2mm

Tetrahedral compounds of pentavalent phosphorus are generally prepared by reactions involving nucleophilic substitution at phosphorus or oxidation of the appropriate trivalent derivatives. Many reactions of trivalent compounds that give phosphonium compounds as the initial product also lead eventually to phosphoryl derivatives. Several such reactions have been described above. One that is of considerable importance in organic synthesis is the Wittig reaction (named for its discoverer, the German chemist Georg Wittig), in which the oxygen atom of a carbonyl group (carbon and oxygen atoms forming a double bond, C═O) of a ketone or aldehyde is replaced by a doubly bonded carbon atom (methylene group) from a methylenephosphorane, producing an olefin, usually in good yield. The Wittig reagent (the methylenephosphorane) is generated from a phosphonium compound by removing a proton with a strongly basic reagent:

The Wittig reaction

$$(C_6H_5)_3\overset{+}{P}CH_2C_6H_5Cl^- + CH_3(CH_2)_3Li \longrightarrow$$

triphenylbenzylphosphonium chloride   *n*-butyllithium

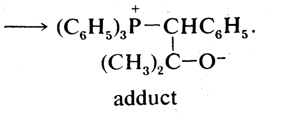
$$(C_6H_5)_3P = CHC_6H_5\ \{\text{or } (C_6H_5)_3\overset{+}{P} - \overset{-}{C}H_6CH_5\}.$$

triphenyl- benzylidenephosphorane

Although the negative charge in the so-called ylide form is largely neutralized by the adjacent positive phosphorus centre (P^+), the unsaturated carbon atom involved remains strongly nucleophilic. In particular, it adds readily to the carbonyl group of aldehydes and ketones, as shown in the example below:

$$(C_6H_5)_3P{=}CHC_6H_5 + (CH_3)_2C{=}O$$

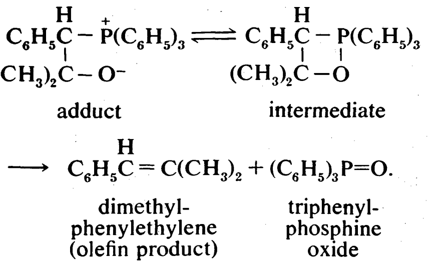
triphenylbenzylidenephosphorane   acetone



$$\longrightarrow (C_6H_5)_3\overset{+}{P}-\underset{(CH_3)_2C-O^-}{\underset{|}{C}}HC_6H_5.$$

adduct

The initial adduct rapidly decomposes to the final products, which are the desired olefin and a phosphine oxide, perhaps by way of a cyclic intermediate, as shown below:



$$\begin{array}{ccc} C_6H_5\overset{H}{C}-\overset{+}{P}(C_6H_5)_3 & \rightleftharpoons & C_6H_5\overset{H}{C}-P(C_6H_5)_3 \\ | & & |\qquad| \\ (CH_3)_2C-O^- & & (CH_3)_2C-O \end{array}$$

adduct intermediate

$$\longrightarrow C_6H_5\overset{H}{C}=C(CH_3)_2+(C_6H_5)_3P{=}O.$$

dimethylphenylethylene (olefin product) triphenylphosphine oxide

As in earlier examples, the formation of the stable P═O group is an important driving force for this reaction.

The important reactions undergone by the tetrahedral pentavalent organophosphorus compounds have already been described for the phosphate esters and their derivatives. The phosphorus–carbon bond is a strong one, and, with the exception of the Wittig reaction, electronegative substituents on phosphorus are the ones normally involved in chemical reactions. (A.J.K.)

Organic sulfur compounds

Organic sulfur compounds constitute a diverse and important subdivision of the class of organic substances. They are widely distributed in nature, often betraying their presence by the strong odours they impart (*e.g.*, to crude petroleum, to certain plants, and to animal secretions). Sulfur-containing amino acids—cysteine, cystine, methionine, and taurine—are important components of biologically important substances, including hormones, enzymes, and coenzymes. Synthetic organic sulfur compounds include numerous insecticides, pharmaceuticals, dyes, solvents, and agents used in flotation processes for refining ores, in improving the performance of lubricating oils, in preparing rubbers, and in making rayon.

After carbon and hydrogen, the elements most commonly occurring in organic compounds are oxygen and nitrogen; sulfur is neither extremely common nor extremely rare, but its effects are sufficiently distinctive that organic sulfur compounds comprise a recognized area of specialized study.

Basic characteristics

The sulfur atom. An uncombined sulfur atom has 16 electrons, 10 of which completely fill the 1*s*, 2*s*, and 2*p* orbitals; of the remaining six (*i.e.*, the valence electrons), two occupy the 3*s* orbital and four are present in 3*p* orbitals: The distribution of electrons in a sulfur atom is abbreviated to $1s^22s^22p^63s^23p^4$. An element closely resembling sulfur in electron configuration is oxygen, which has eight electrons in the configuration $1s^22s^22p^4$. The identical distribution, s^2p^4, of the valence electrons in the two elements leads to many similarities in their chemical behaviour.

Table 32: Organic Sulfur Compounds and Corresponding Organic Oxygen Compounds

sulfur compounds			oxygen compounds		
group of compounds	characteristic structural unit	example	group of compounds	characteristic structural unit	example
Thiols (aliphatic)	—SH	methanethiol	alcohols	—OH	methanol
Thiols (aromatic)	—SH	benzenethiol (thiophenol)	phenols	—OH	phenol
Sulfides	—S—	dimethyl sulfide	ethers	—O—	dimethyl ether
Disulfides	—S—S—	dimethyl disulfide	peroxides	—O—O—	dimethyl peroxide
Thioaldehydes	$-\overset{\overset{S}{\|}}{C}-H$	ethanethial (thioacetaldehyde)	aldehydes	$-\overset{\overset{O}{\|}}{C}-H$	ethanal (acetaldehyde)
Thioketones	$-\overset{\overset{S}{\|}}{C}-$	dimethyl thione (thioacetone)	ketones	$-\overset{\overset{O}{\|}}{C}-$	2-propanone (acetone)
Thiolocarboxylic acids	$-\overset{\overset{O}{\|}}{C}-SH$	thioloacetic acid			
Thionocarboxylic acids	$-\overset{\overset{S}{\|}}{C}-OH$	thionoacetic acid	carboxylic acids	$-\overset{\overset{O}{\|}}{C}-OH$	acetic acid
Dithiocarboxylic acids	$-\overset{\overset{S}{\|}}{C}-SH$	dithioacetic acid			

Important differences, however, arise from the fact that the valence electrons of sulfur interact less strongly with the nucleus than do those of oxygen and that the third electron shell of sulfur includes five *d* orbitals. Although these *d* orbitals are not occupied in the uncombined sulfur atom, their availability makes possible the formation of types of compounds not formed by oxygen. In these compounds, the 3*s* and 3*p* orbitals can, in effect, blend together into a new set of four "hybrid" orbitals that can interact with three or four other atoms, or the 3*s*, the 3*p*, and two of the 3*d* orbitals can hydridize to form a set of orbitals that participate in the formation of hexacovalent compounds.

In Table 32, members of several important groups of organic sulfur compounds are compared with the oxygen compounds possessing similar structures. Table 33 lists some of the most important types of sulfur compounds that have no counterparts among oxygen compounds.

Table 33: Organic Sulfur Compounds with No Oxygen Analogues

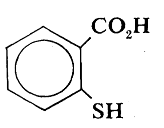
group of compounds	characteristic structural unit	example
Trisulfides	—S—S—S—	dimethyl trisulfide
Polysulfides	(—S—)*n*; *n* = 4,5,6, . . .	dimethyl tetrasulfide, dimethyl pentasulfide, etc.
Sulfoxides	$-\overset{\overset{O}{\|}}{S}-$	dimethyl sulfoxide
Sulfones	$-\underset{\underset{O}{\|}}{\overset{\overset{O}{\|}}{S}}-$	dimethyl sulfone
Sulfenic acids	—S—OH	methanesulfenic acid
Sulfinic acids	$-\overset{\overset{O}{\|}}{S}-OH$	methanesulfinic acid
Sulfonic acids	$-\underset{\underset{O}{\|}}{\overset{\overset{O}{\|}}{S}}-OH$	methanesulfonic acid

ORGANIC COMPOUNDS OF BIVALENT SULFUR

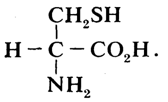
Thiols. The organic sulfur compounds most closely resembling their oxygen analogues are the thiols, also called mercaptans. The functional group of the thiols is the mercapto group (—SH), comparable to the hydroxyl group (—OH) present in alcohols and phenols. In preferred names for thiols, the suffix -thiol is appended to the name of the appropriate hydrocarbon. If another group is designated by a suffix, the prefix mercapto- is used. A few thiols are named by using the prefix thio- to denote the replacement of an oxygen atom of a related compound by a sulfur atom, and a few have names that do not convey structural information. Examples are as follows:

CH_3SH methanethiol

$HSCH_2CO_2H$ mercaptoacetic acid



thiosalicylic acid

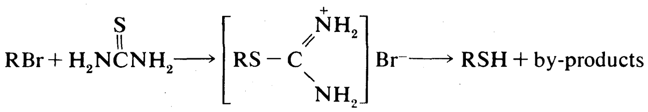


$$H-\underset{NH_2}{\overset{CH_2SH}{C}}-CO_2H.$$

cysteine

Natural thiols

A few thiols are found in nature: crude petroleum contains methanethiol, ethanethiol, and other members of the group. Although they constitute a small fraction of most petroleums, thiols are a serious nuisance. They impart objectionable odours, they are corrosive to the equipment and interfere with the action of catalysts used in refining processes, and their combustion creates the noxious gas sulfur dioxide. Small amounts of thiols are converted into chemical products, but no uses require the amounts that could be recovered from crude oil.

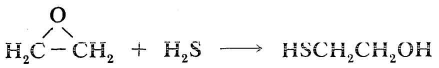


alkyl bromide · thiourea · alkylthiuronium bromide · alkanethiol

olefin or alkene · hydrogen sulfide · thiol

$$ROH + H_2S \xrightarrow{\text{catalyst}} RSH + H_2O$$

alcohol · hydrogen sulfide · thiol · water



ethylene oxide · hydrogen sulfide · 2-mercaptoethanol or 2-hydroxyethanethiol

$$CH_2=CHC\equiv N + H_2S \longrightarrow HSCH_2CH_2C\equiv N.$$

acrylonitrile · hydrogen sulfide · 3-mercapto-propionitrile

Methanethiol arises from the bacterial decomposition of proteins, such as albumin or gelatin, and butanethiol is present in the defensive secretion of the skunk. A thiol group plays an important role in the natural functions of several proteins and of coenzyme A, which participates in many metabolic reactions.

Preparation. Several methods are known for the preparation of thiols. Thiols in which the mercapto group is not attached to an aromatic ring may be made according to the reactions represented by the following equations:

$$RBr + NaSH \longrightarrow RSH + NaBr$$

alkyl bromide · sodium hydrosulfide · alkanethiol · sodium bromide

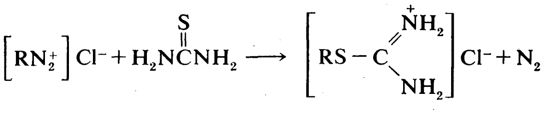
Other methods must be used to make aromatic thiols because of the different nature of reactions typical of aromatic compounds in general. Applicable procedures include those formulated as follows:

$$RSO_2Cl + 3Zn + 5HCl \longrightarrow RSH + 3ZnCl_2 + 2H_2O$$

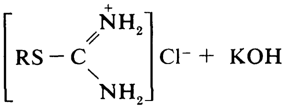
aromatic sulfonyl chloride · zinc · hydrochloric acid · aromatic thiol · zinc chloride · water

$$RSO_2Cl + 3SnCl_2 + 5HCl \longrightarrow RSH + 3SnCl_4 + 2H_2O$$

aromatic sulfonyl chloride · tin(II) chloride · hydrochloric acid · aromatic thiol · tin(IV) chloride · water



aromatic diazonium chloride · thiourea · arylthiuronium chloride · nitrogen



arylthiuronium chloride · potassium hydroxide

$$\longrightarrow RSH + H_2NC\equiv N + KCl + H_2O.$$

aromatic thiol · cyanamide · potassium chloride · water

Reactions. In most of their reactions, thiols resemble alcohols or phenols, the differences being those of degree rather than kind. Thiols react more completely with alkalies, forming salts, than do the corresponding hydroxyl compounds; that is, the thiols are stronger acids, although very weak in comparison to, say, acetic acid. Aromatic thiols are stronger acids than the aliphatic thiols, just as phenols are stronger acids than alcohols. In the presence of salts of heavy metals (as mercury, lead, zinc, or copper), thiols form mercaptides, soluble in organic solvents (as ether, isopropyl alcohol, benzene, chloroform) but insoluble in water. The characteristic formation of these compounds from mercury salts led to the name mercaptan (Latin *mercurium captans,* "seizing mercury"). The mercury mercaptide, sodium ethylmercurithiosalicylate (thimerosal, Merthiolate), is a well-known germicide.

Thiols form sulfides (thioethers) and thioesters in reactions similar to those of hydroxyl compounds. They react with aldehydes and ketones to yield thioacetals and thioketals, respectively; sulfur-containing compounds of this type are more readily formed and more stable than the oxygen compounds and are useful in suppressing the reactivity of carbonyl groups while chemical reactions are performed on another part of a molecule. Dithiols are useful for this purpose. Thiols combine with unsaturated compounds, particularly those that have a carbonyl group adjacent to the double bond, forming sulfides.

Thiols differ from hydroxyl compounds in their reactions with oxidizing agents (as oxygen, iodine, hydrogen peroxide). Alcohols usually are converted to aldehydes or ketones, but thiols are transformed into disulfides; further oxidation results in formation of sulfonic acids:

$$2RSH + H_2O_2 \longrightarrow RSSR + 2H_2O$$

thiol · hydrogen peroxide · disulfide · water

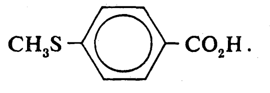
$$RSSR + 5H_2O_2 \longrightarrow 2RSO_3H + 4H_2O.$$

disulfide · hydrogen peroxide · sulfonic acid · water

Sulfides and sulfonium salts. Compounds in which two organic groups are bonded to a sulfur atom are called sulfides; the structurally related oxygen compounds are ethers. The organic groups may be both alkyl, both aryl, or one of each. If no other functional group is present in the molecule, sulfides are named as such: dimethyl sulfide is CH_3-S-CH_3, methyl phenyl sulfide is $CH_3-S-C_6H_5$, and diphenyl sulfide is $C_6H_5-S-C_6H_5$. If another functional group forms part of the molecule, a sulfide group is designated by the particle -thio-:

$HO_2CCH_2SCH_2CO_2H$

thiodiacetic acid



4-(methylthio)benzoic acid

Properties of sulfides

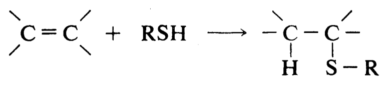
The sulfur atom in sulfides does not cause their physical properties to differ much from those of hydrocarbons of similar molecular size and shape. The sulfides have low solubilities in water, but they are miscible with many organic solvents; they are colourless liquids or solids, many of them possessing odours that are unpleasant, though not as intense as those of the thiols.

Certain sulfides occur in nature: garlic contains diallyl sulfide, and many proteins contain the amino acid methionine, which is a sulfide.

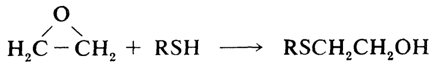
Preparation. Sulfides most often are prepared from thiols; just as preparing a thiol usually involves replacing one of the two hydrogen atoms of hydrogen sulfide, preparation of a sulfide is the replacement of the second, often by similar procedures. Examples are:

$$RSNa + R'Br \longrightarrow RSR' + NaBr$$

thiol sodium salt　alkyl bromide　sulfide　sodium bromide



olefin　thiol　sulfide



ethylene oxide　thiol　alkyl hydroxyethyl sulfide

$$CH_2=CHC\equiv N + RSH \longrightarrow RSCH_2CH_2C\equiv N.$$

acrylonitrile　thiol　3-alkylthiopropionitrile

Production of chlorine-containing sulfides

The reaction of certain olefins with disulfur dichloride produces chlorine-containing sulfides; the best known example of this process is the manufacture of mustard gas, a blister-forming chemical warfare agent, from ethylene. This reaction is not general, however; the products obtained from other olefins are disulfides or mixtures of monosulfides and disulfides.

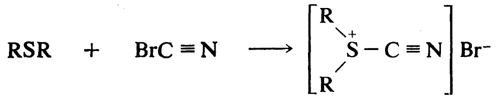
$$2C_2H_4 + S_2Cl_2 \longrightarrow S(CH_2CH_2Cl)_2 + S$$

ethylene　disulfur dichloride　mustard gas (bis[2-chloroethyl] sulfide)　sulfur

$$2CH_2CH=CH_2 + S_2Cl_2 \longrightarrow ClC_3H_6SSC_3H_6Cl$$

propylene　disulfur dichloride　bis(chloropropyl) disulfide

Reactions. Sulfides combine with chlorine, bromine, iodine, or salts of heavy metals to form crystalline compounds. Cyanogen bromide forms an unstable compound that decomposes by breaking a carbon–sulfur bond:

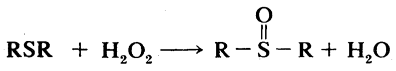


sulfide　cyanogen bromide　unstable sulfonium compound

$$\longrightarrow RBr + RSC\equiv N.$$

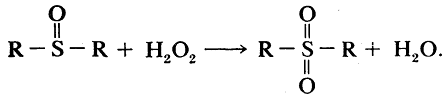
alkyl bromide　alkyl thiocyanate

Oxidizing agents convert sulfides into sulfoxides; if a sufficient amount of the oxidizing agent is present, the sulfoxides undergo oxidation to sulfones:



$$RSR + H_2O_2 \longrightarrow R-\overset{\overset{O}{\|}}{S}-R + H_2O$$

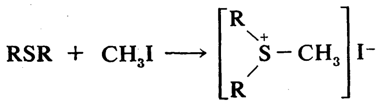
sulfide　hydrogen peroxide　sulfoxide　water



$$R-\overset{\overset{O}{\|}}{S}-R + H_2O_2 \longrightarrow R-\underset{\underset{O}{\|}}{\overset{\overset{O}{\|}}{S}}-R + H_2O.$$

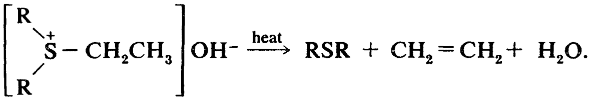
sulfoxide　hydrogen peroxide　sulfone　water

Compounds such as methyl iodide react with sulfides to produce sulfonium salts, in which three organic groups are attached to the positively charged sulfur atom. This process has many parallels in organic chemistry, especially in the reactions of amines and phosphines; it occurs less readily with ethers.



sulfide　methyl iodide　sulfonium iodide

The formation of sulfonium salts from sulfides and alkyl halides can be reversed by heat. The heat-induced decomposition of quaternary ammonium hydroxides (*i.e.*, compounds in which four organic groups are bonded to a positively charged nitrogen atom) is exactly duplicated in the case of sulfonium hydroxides:



sulfonium hydroxide　sulfide　ethylene　water

Disulfides and polysulfides. Disulfides have the structure $R-S-S-R'$, in which R and R′ represent organic groups of any kind. They are named by designating the groups attached to the sulfur atoms or by use of the particle -dithio-:

CH_3SSCH_3

dimethyl disulfide

$CH_3SSCH_2CO_2H$

methyldithioacetic acid

$HO_2CCH_2SSCH_2CO_2H.$

dithiodiacetic acid

Disulfides. The formation of disulfides by oxidation of thiols or by the reaction of disulfur dichloride and olefins has already been mentioned. A few disulfides have been isolated from natural sources, such as onion, garlic, and asafetida. The amino acid cystine, a disulfide, is an important component of many proteins: the sulfur–sulfur bond is partly responsible for maintaining the molecules in shapes essential for their biological activity. The coenzyme lipoic acid, a disulfide necessary for growth of certain microorganisms, may also be involved in photosynthesis and other vital processes of plants and animals.

Most important reactions

In the most important reactions of disulfides, the bond between the two sulfur atoms is broken, as by reducing agents, including hydrogen; by strong alkalies; or by alkyl halides:

$$RSSR + H_2 \longrightarrow 2RSH$$

disulfide　hydrogen　a thiol

$$RSSR + KOH \longrightarrow RSH + (RSO)K$$

disulfide　potassium hydroxide　a thiol　alkanesulfenate (salt)

$$\mathrm{RSSR + 4RI \xrightarrow{HgI_2} 2(R_3S^+)I^- + I_2}\,.$$

disulfide	alkyl iodide	sulfonium iodide	iodine

Chlorine or bromine splits the —S—S— bond of aromatic disulfides but attacks the adjacent carbon atom of an aliphatic disulfide:

$$\mathrm{C_6H_5SSC_6H_5 + Br_2 \longrightarrow 2C_6H_5SBr}$$

diphenyl disulfide	bromine	benzenesulfenyl bromide

$$\mathrm{CH_3SSCH_3 + Cl_2 \longrightarrow CH_3SSCH_2Cl + HCl}\,.$$

dimethyl disulfide	chlorine	chloromethyl methyl disulfide	hydrogen chloride

Polysulfides. The tendency to form chains in which atoms of the same element are joined together by covalent bonds, especially pronounced with carbon, is shown to some extent by sulfur. Organic compounds containing such chains of three, four, or more sulfur atoms are called polysulfides. They are less stable than the corresponding carbon compounds, and their properties are not as fully understood. A group of organic polysulfides has received considerable attention as rubbers and as solid propellants for rockets; these are the Thiokols, which are polymeric compounds, having molecules composed of long chains of repeating units built up from simpler compounds. An example is provided by the product made from ethylene dichloride and sodium tetrasulfide:

Thiokols

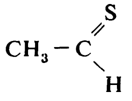
$$n\mathrm{ClCH_2CH_2Cl} + n\mathrm{Na_2S_4}$$

ethylene dichloride	sodium tetrasulfide

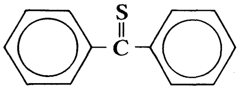
$$\longrightarrow \mathrm{(CH_2CH_2S_4)}_n + 2n\mathrm{NaCl}\,.$$

Thiokol A, a polymer	sodium chloride

Thiocarbonyl compounds. The thiocarbonyl functional group (>C=S), analogous to the carbonyl group, forms part of the structure of thioaldehydes and thioketones. These compounds are named by analogy with the corresponding oxygen compounds:

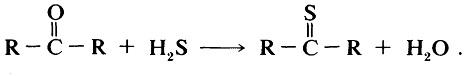


thioacetaldehyde or ethanethial



thiobenzophenone or diphenyl thione

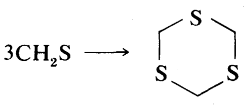
The thiocarbonyl compounds have exceptionally repulsive odours. The general method of preparation, from carbonyl compounds and hydrogen sulfide in the presence of acidic catalysts, is not difficult:



$$\mathrm{R-\overset{\overset{\displaystyle O}{\|}}{C}-R + H_2S \longrightarrow R-\overset{\overset{\displaystyle S}{\|}}{C}-R + H_2O}\,.$$

carbonyl compound	hydrogen sulfide	thiocarbonyl compound	water

The reactions of thiocarbonyl compounds are similar to those of their oxygenated relatives, although they show a greater tendency to undergo cyclotrimerization, in which three molecules unite to form a ring structure:



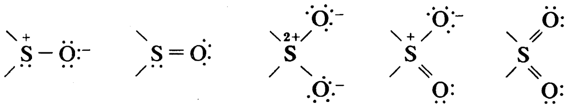
thioformaldehyde trithiane

Although the monomers are blue, the cyclic trimers (trithianes) are colourless; the latter somewhat resemble the dialkyl sulfides in their reactions.

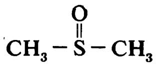
COMPOUNDS CONTAINING POLYVALENT SULFUR

Sulfur–oxygen double bonds

Sulfoxides and sulfones. Two groups of organic sulfur compounds that have no counterparts among organic oxygen compounds are the sulfoxides and the sulfones. In some respects, these compounds resemble carbonyl compounds, containing the group >C=O, in which the carbon and the oxygen atom each interact with eight electrons, four of which are shared in the double bond. Doubly bonded structures for the sulfinyl (>SO) and sulfonyl (>SO$_2$) groups present in sulfoxides and sulfones, respectively, require that the sulfur atom interact with 10 electrons in sulfoxides or with 12 in sulfones. Because these numbers are larger than eight, the number of electrons usually associated with each atom (except hydrogen) in stable covalent compounds, has been the basis of opposition to these formulations. Covalent bond formation by a sulfur atom, however, involves electrons in the third shell, which is larger than the second shell (the one engaged in carbon and oxygen bonding) and has additional orbitals. It is considered that these orbitals (the *d* orbitals) participate in the bonding in sulfoxides and sulfones and that the bonds differ from those of the carbonyl group, showing considerable polarity (separation of electrical charges). Their structures are regarded as intermediate between those with single bonds of high polarity and those with double bonds of low polarity but high electron density on the sulfur atom.

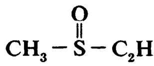


Sulfoxides are named by simply designating the two organic groups attached to the >SO group, with the word sulfoxide, or by forming a prefix from the name of the simpler of the two groups and the particle -sulfinyl-, as shown in the examples:



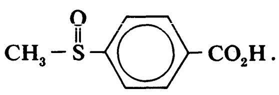
$$\mathrm{CH_3-\overset{\overset{\displaystyle O}{\|}}{S}-CH_3}$$

dimethyl sulfoxide



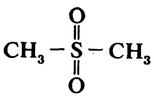
$$\mathrm{CH_3-\overset{\overset{\displaystyle O}{\|}}{S}-C_2H_5}$$

ethyl methyl sulfoxide



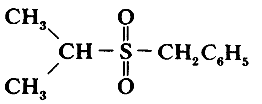
4-(methylsulfinyl) benzoic acid

The nomenclature of sulfones is like that of sulfoxides; the particle -sulfonyl- is used in complicated structures:

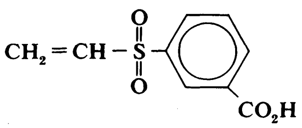


$$\mathrm{CH_3-\underset{\underset{\displaystyle O}{\|}}{\overset{\overset{\displaystyle O}{\|}}{S}}-CH_3}$$

dimethyl sulfone



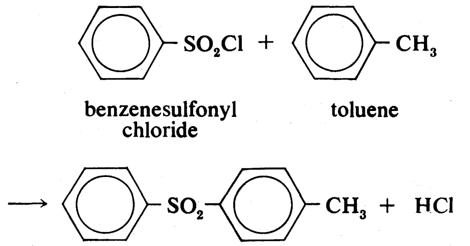
benzyl isopropyl sulfone



3-(vinylsulfonyl) benzoic acid

Most sulfoxides are colourless liquids or solids with low melting points; they are more soluble in water and possess much higher boiling points than hydrocarbons or carbonyl compounds of similar molecular size. Sulfoxides of low molecular weight have faint odours and tastes described as metallic or garlic-like. In general, sulfones are colourless, crystalline solids at room temperature.

Occurrence and preparation. Several sulfoxides are found in the turnip, garlic, and several species of mustard; another has been isolated from the cockroach. Oxidation of sulfides to sulfoxides and sulfones by hydrogen peroxide has been mentioned; certain aromatic sulfones can be made by the reaction of sulfonyl chlorides (see below *Sulfonic acids*) with aromatic hydrocarbons.



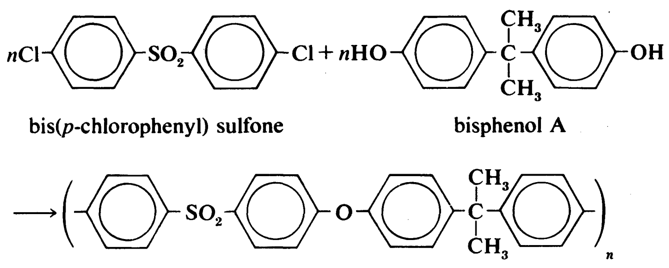
benzenesulfonyl chloride — toluene

phenyl *p*-tolyl sulfone — hydrogen chloride

The reaction of a metal salt of a sulfinic with a halogen compound is sometimes used to make sulfones.

Polymeric sulfones

A class of polymeric sulfones results from the reaction of sulfur dioxide with olefins. These products have not been found useful, although members of a different class of polysulfones have properties that make them valuable as wire coatings. The latter group is made from chlorine-containing aromatic sulfones and a compound (bisphenol A) of two molecules of phenol linked through a hydrocarbon group:

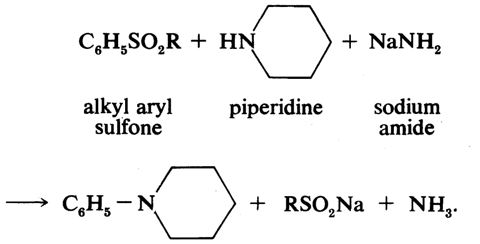


bis(*p*-chlorophenyl) sulfone — bisphenol A

polymer

Reactions. Sulfoxides can be converted to sulfides by powerful reducing agents, such as lithium aluminum hydride, hydriodic acid, or zinc in the presence of sulfuric acid. Sulfoxides are very weak bases, forming salts with strong acids (*e.g.*, hydrochloric acid); they are also very weak acids, giving up a proton only to very strong bases, such as sodium hydride or sodium amide.

Sulfones are generally unreactive compounds and are not attacked by most reducing agents. The bond joining the sulfur atom to an aromatic ring can be cleaved by piperidine in the presence of sodium amide:



alkyl aryl sulfone — piperidine — sodium amide

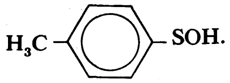
N-phenylpiperidine — sulfinate (salt) — ammonia

If two or three sulfonyl groups are bonded to the same carbon atom, a hydrogen atom bonded to that atom shows somewhat acidic properties; that is, it can be removed by a base.

Dimethyl sulfoxide has been investigated as a topical analgesic and as a carrier for drugs (it rapidly penetrates the skin); the disulfones sulfonal, trional, and tetronal have been used in medicine as hypnotics but have been replaced by less toxic compounds.

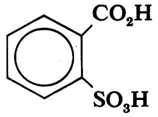
Sulfonic, sulfinic, and sulfenic acids. Three sulfur-containing functional groups confer acidity upon compounds in which they are present; these compounds are the sulfonic acids, in which the group SO_3H is present; the sulfinic acids, with the group SO_2H; and the sulfenic acids, with the group SOH. All three types of compounds are named by attaching the name of the functional group to the name of the compound in which that group replaces a hydrogen atom:

Cl_3CSO_3H $C_2H_5SO_2H$

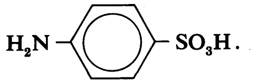


trichloromethanesulfonic acid — ethanesulfinic acid — *p*-toluenesulfenic acid

Occasionally, sulfonic acids are named using the prefix sulfo- or by arbitrary names:



o-sulfobenzoic acid



sulfanilic acid

The sulfonic acids are very strong—comparable to the mineral acids, hydrochloric, nitric, or sulfuric—and are the most common of the sulfur-containing acids. Most of them are colourless, odourless, crystalline compounds; the characteristic water solubility of these acids and most of their salts has made them useful as detergents that perform well in hard water and as dyes that can be applied to textiles from aqueous solutions.

Water solubility

Sulfinic acids are weaker, less soluble in water, and less stable than sulfonic acids; they are most often prepared in the form of their metal salts, which are more stable. Sulfenic acids and their salts are unstable compounds, rarely isolated; many substances named as derivatives of sulfenic acids are not actually obtainable from them.

Preparation

Sulfonic acids. Aromatic sulfonic acids usually are made by the reaction (sulfonation) of an aromatic hydrocarbon with sulfuric acid. Aliphatic hydrocarbons seldom react similarly with sulfuric acid, but aliphatic sulfonic acids may be obtained by oxidation of thiols or other sulfur-containing starting materials or by treatment of certain halogen compounds with sodium sulfite:

$$C_6H_6 + H_2SO_4 \longrightarrow C_6H_5SO_3H + H_2O$$

benzene	sulfuric acid	benzenesulfonic acid	water

$$RSH + 6HNO_3 \longrightarrow RSO_3H + 6NO_2 + 3H_2O$$

thiol	nitric acid	sulfonic acid	nitrogen dioxide	water

$$ClCH_2R + Na_2SO_3 \longrightarrow NaO_3SCH_2R + NaCl.$$

alkyl chloride	sodium sulfite	sodium alkanesulfonate	sodium chloride

The formation of sulfonic acids from sulfuric acid and aromatic compounds can be reversed by reaction with water, although strenuous conditions are sometimes necessary (*e.g.*, use of superheated steam). When aromatic sulfonic acids are heated with caustic alkalies, the sulfo ($-SO_3H$) group is replaced by a hydroxyl ($-OH$) group; this reaction is useful for preparing phenols:

$$C_6H_5SO_3H + NaOH \longrightarrow C_6H_5OH + NaHSO_3.$$

benzenesulfonic acid	sodium hydroxide	phenol	sodium bisulfite

In certain cases, the sulfo group can be replaced by various others, including cyano ($-CN$), nitro ($-NO_2$), formyl ($-CHO$), amino ($-NH_2$), or alkylthio ($-SR$).

Sulfonyl chlorides may be prepared from sulfonic acids by reaction with phosphorus pentachloride, chlorosulfuric acid, or certain other reagents:

$$C_6H_5SO_3H + PCl_5 \longrightarrow C_6H_5SO_2Cl + POCl_3 + HCl.$$

benzenesulfonic acid	phosphorus pentachloride	benzenesulfonyl chloride	phosphoryl chloride	hydrogen chloride

Sulfonyl chlorides are widely employed in preparing sulfonamides, sulfonates (esters of sulfonic acids), and sulfinic acids; their use in making sulfones has already been mentioned. Other sulfonyl halides (fluorides, bromides, or iodides) are less frequently made.

Sulfonamides result from the reaction of sulfonyl chlorides with ammonia or primary or secondary amines, compounds that all have the structure R_2NH, in which R represents a hydrogen atom or an organic group:

$$R'SO_2Cl + 2R_2NH \longrightarrow R'SO_2NR_2 + R_2NH_2^+Cl^-.$$

sulfonyl chloride	**primary or secondary amine or ammonia**	**sulfonamide**	**hydrochloride**

Sulfonates are obtained by treating alcohols or phenols with sulfonyl chlorides in the presence of a tertiary amine:

$$RSO_2Cl + R'{-}OH + R''_3N \longrightarrow RSO_2OR' + R''_3NH^+Cl^-.$$

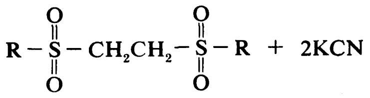
sulfonyl chloride	**alcohol**	**tertiary amine**	**sulfonate ester**	**amine hydrochloride**

Sulfinic acids. Sulfinic acids usually are made by treating a sulfonyl chloride with finely divided zinc or with sodium sulfite:

$$2RSO_2Cl + 2Zn \longrightarrow (RSO_2)_2Zn + ZnCl_2.$$

sulfonyl chloride	zinc	sulfinic acid (zinc salt)	zinc chloride

Aliphatic sulfinic acids can be made by this reaction, but the necessary sulfonyl chlorides are not always available; in such cases, the reaction of ethylene disulfones with potassium cyanide can be employed:



$$R-\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}-CH_2CH_2-\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}-R + 2KCN$$

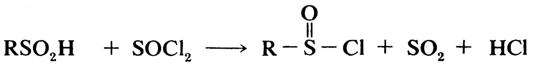
ethylene disulfone	potassium cyanide

$$\longrightarrow 2RSO_2K + N\equiv CCH_2CH_2C\equiv N.$$

potassium sulfinate	succinonitrile

Several other reactions have been utilized for making sulfinic acids, but they do not have general applicability. One of these reactions is the basis of the manufacture of the sodium salt of hydroxymethanesulfinic acid, sometimes called sodium formaldehydesulfoxylate, used in stripping dyes from textiles and in the discharge printing process for producing dyed designs on fabrics.

Sulfinic acids are oxidized to sulfonic acids by hydrogen peroxide or by nitric acid but to sulfonyl halides by chlorine, bromine, or iodine. The reaction of a sulfinic acid with thionyl chloride can be used to prepare sulfinyl chlorides, which are useful in the synthesis of sulfinamides and sulfinic esters (sulfinates):



$$RSO_2H + SOCl_2 \longrightarrow R-\overset{\overset{O}{\|}}{S}-Cl + SO_2 + HCl$$

sulfinic acid	thionyl chloride	sulfinyl chloride	sulfur dioxide	hydrogen chloride

Sulfenic acids. Sulfenic acids or their salts are formed as the initial products in reactions in which the sulfur-sulfur bond of disulfides is broken by the attack of alkalies; the molecules of sulfenic acids react rapidly with one another, producing sulfinic acids and thiols:

$$2RSOK \longrightarrow RSO_2K + RSK.$$

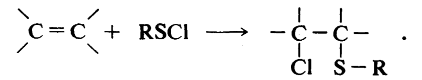
sulfenate (salt)	sulfinate (salt)	thiol (salt)

The sulfenyl chlorides are more stable than the sulfenic acids; they are formed in the reaction of chlorine with disulfides (see above *Disulfides and polysulfides*). The chlorides can be converted into other derivatives of sulfenic acids, such as amides, esters, or anhydrides:

$$2RSCl + H_2O \longrightarrow RSOSR + 2HCl.$$

sulfenyl chloride	water	sulfenic anhydride	hydrogen chloride

They also react with olefins to produce chlorine-containing sulfides:



olefin	sulfenyl chloride	chloroalkyl sulfide

LESS COMMON ORGANIC SULFUR COMPOUNDS

Organic derivatives of inorganic sulfur-containing acids. Several inorganic acids contain one or more atoms of sulfur in their molecules. The most important of these are sulfuric acid, H_2SO_4, and sulfurous acid, H_2SO_3. Most other inorganic acids contain one or more oxygen atoms that can be replaced by sulfur atoms. Nearly all of these acids have organic derivatives, such as esters or amides.

Sulfuric acid. Several esters of sulfuric acid are important industrial chemicals; dimethyl sulfate and diethyl sulfate, made from the alcohols and oleum (a solution of sulfur trioxide in sulfuric acid), are used to introduce methyl and ethyl groups into organic molecules. Certain monoesters of sulfuric acid occur as water-soluble forms in which substances are eliminated from the body.

Thiosulfuric acid. Monoesters of thiosulfuric acid, called Bunte salts, are prepared as intermediates in the synthesis of thiols:

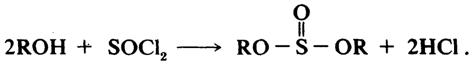
$$RBr + Na_2S_2O_3 \longrightarrow RSSO_3Na + NaBr$$

alkyl bromide	sodium thiosulfate	Bunte salt	sodium bromide

$$RSSO_3Na + NaOH \longrightarrow R-SH + Na_2SO_3.$$

Bunte salt	sodium hydroxide	thiol	sodium sulfite

Sulfurous acid. Esters of sulfurous acid can be made from alcohols and thionyl chloride:

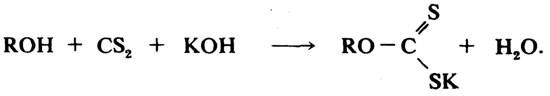


$$2ROH + SOCl_2 \longrightarrow RO-\overset{\overset{O}{\|}}{S}-OR + 2HCl.$$

alcohol	thionyl chloride	dialkyl sulfite	hydrogen chloride

Xanthates, rayon, and cellophane

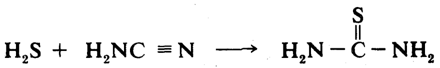
Carbonic acid. The derivatives of carbonic acid, H_2CO_3, have counterparts in which any or all of the oxygen atoms have been replaced by sulfur atoms. One of the important groups of these compounds is that of the xanthates (Greek *xanthos*, "yellow," from the colour of their copper salts), which are made from hydroxyl compounds and carbon disulfide:



alcohol	carbon disulfide	potassium hydroxide	xanthate (salt)	water

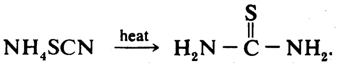
This reaction is used to produce a soluble form of cellulose that can be extruded into an acidic solution, which disrupts the xanthate group, regenerating the cellulose in the form of fibres (rayon) or films (cellophane). Xanthates of simpler alcohols are used as collectors in ore flotation (that is, agents that preferentially attach themselves to the surface of certain minerals, making air bubbles cling to them so that they float to the surface).

Thiourea, the diamide of thiocarbonic acid, is manufactured from hydrogen sulfide and cyanamide or by heating ammonium thiocyanate:



$$H_2S + H_2NC\equiv N \longrightarrow H_2N-\overset{\overset{S}{\|}}{C}-NH_2$$

hydrogen sulfide	cyanamide	thiourea

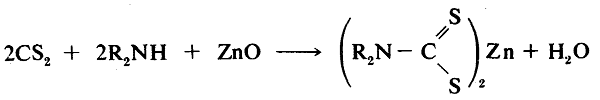


$$NH_4SCN \xrightarrow{heat} H_2N-\overset{\overset{S}{\|}}{C}-NH_2.$$

ammonium thiocyanate

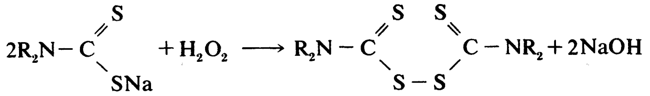
It is used as a component of photocopying papers and silver polishes and in a synthesis of thiols that prevents the formation of sulfides as by-products.

Several derivatives of dithiocarbamic acid are used as accelerators of the vulcanization of rubber. The following equations show typical methods of preparing these compounds:



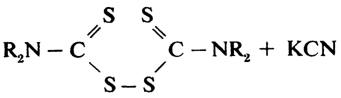
$$2CS_2 + 2R_2NH + ZnO \longrightarrow \left(R_2N-C(=S)S\right)_2Zn + H_2O$$

carbon disulfide · secondary amine · zinc oxide · zinc dialkyldithiocarbamate · water



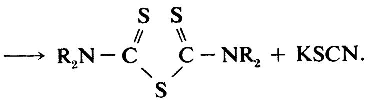
$$2R_2N-C(=S)SNa + H_2O_2 \longrightarrow R_2N-C(=S)-S-S-C(=S)-NR_2 + 2NaOH$$

sodium dialkyldithiocarbamate · hydrogen peroxide · tetraalkylthiuram disulfide · sodium hydroxide



$$R_2N-C(=S)-S-S-C(=S)-NR_2 + KCN$$

potassium cyanide



$$\longrightarrow R_2N-C(=S)-S-C(=S)-NR_2 + KSCN.$$

tetraalkylthiuram sulfide · potassium thiocyanate

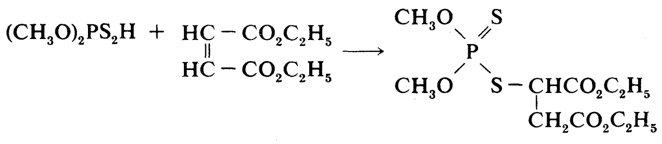
Phosphoric acid. Sulfur-containing derivatives of phosphoric acid, H_3PO_4, are useful insecticides, lubricant additives, and ore flotation agents. Some are made from tetraphosphorus dectasulfide or thiophosphoryl chloride:

$$P_4S_{10} + 8ROH \longrightarrow 4(RO)_2PS_2H + 2H_2S$$

tetraphosphorus decasulfide · alcohol · *O,O′*-dialkylphosphorodithioic acid · hydrogen sulfide

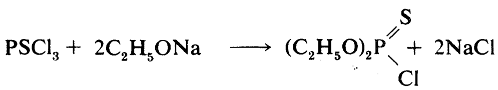
$$2(RO)_2PS_2H + ZnO \longrightarrow [(RO)_2PS_2]_2Zn + H_2O$$

zinc oxide · zinc *O,O′*-dialkylphosphorodithioate



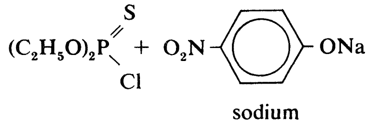
$$(CH_3O)_2PS_2H + \begin{matrix}HC-CO_2C_2H_5\\ \|\\ HC-CO_2C_2H_5\end{matrix} \longrightarrow (CH_3O)_2P(=S)-S-\begin{matrix}CHCO_2C_2H_5\\ |\\ CH_2CO_2C_2H_5\end{matrix}$$

O,O′-dimethylphosphorodithioic acid · diethyl maleate · Malathion

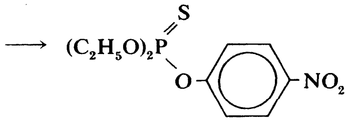


$$PSCl_3 + 2C_2H_5ONa \longrightarrow (C_2H_5O)_2P(=S)Cl + 2NaCl$$

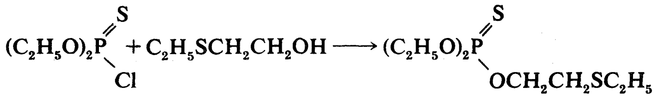
thiophosphoryl chloride · sodium ethoxide · *O,O′*-diethyl phosphorochloridothioate



sodium *p*-nitrophenoxide



parathion

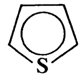


$$(C_2H_5O)_2P(=S)Cl + C_2H_5SCH_2CH_2OH \longrightarrow (C_2H_5O)_2P(=S)OCH_2CH_2SC_2H_5$$

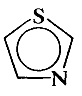
2-ethylthioethanol · Systox

Heterocyclic sulfur compounds. In several groups of organic compounds, sulfur atoms are present in a ring structure (see below *Heterocyclic compounds*). The most important of these cyclic compounds have the following molecular formulas:

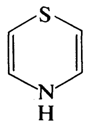
Ring structure



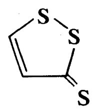
thiophene



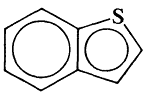
thiazole



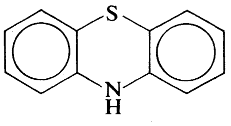
1,4-thiazine



1,2-dithiole-3-thione



thianaphthene or benzothiophene



phenothiazine

(J.V.K.)

Heterocyclic compounds

Heterocyclic compounds are a major class of organic chemical compounds, characterized by the fact that the atoms in their molecules are joined into rings, or circles, containing at least one atom of an element other than carbon. These compounds are of great importance because many of the biochemical materials essential to life belong to the class. Nucleic acids, for example, the chemical substances that carry the genetic information controlling inheritance, consist of long chains of heterocyclic units held together by other types of materials. Many naturally occurring pigments, vitamins, and antibiotics are heterocyclic compounds, as are most hallucinogens, substances that produce hallucinations. Modern society is dependent on synthetic heterocycles for use as pharmaceuticals, pesticides, and herbicides, as well as dyes and plastics.

The most common heterocycles are those with five- or six-membered rings, containing atoms of nitrogen, oxygen, or sulfur. The best known of the simple heterocyclic compounds are pyridine, pyrrole, furan, and thiophene. Pyridine and pyrrole are both nitrogen heterocycles; that is, their molecules contain nitrogen atoms in the rings with carbon. Because the molecules of many biological materials consist in part of pyridine and pyrrole rings, strong heating of such materials produces small amounts of pyridine and pyrrole. In fact, both of these substances were discovered in the 1850s in an oily mixture of substances formed by strong heating of bones. Today, however, pyridine and pyrrole are generally obtained from coal tar or are prepared by synthetic reactions. The chief commercial interest in both compounds lies in their conversion to other substances, chiefly dyestuffs and drugs. Pyridine is used also as a solvent, a waterproofing agent, a rubber additive, an alcohol denaturant, and a dyeing adjunct. Furan is an oxygen-containing heterocycle, used primarily for conversion to other substances (including pyrrole). Furfural, a close chemical relative of furan, is obtained from oat hulls and corncobs and is used in the production of ingredients of nylon. Thiophene, a sulfur heterocycle, resembles benzene in its chemical and physical properties. It is a frequent contaminant of benzene from natural sources and was first discovered during purification of benzene. Like the other compounds, it is used primarily for conversion to other substances. Furan and thiophene both were discovered in the latter part of the 19th century.

The common simple heterocyclic compounds

Each of the molecules of pyridine contains a ring of six atoms, five of which are carbon atoms and one of which is a nitrogen atom. Pyrrole, furan, and thiophene molecules contain five-membered rings, composed of four atoms of carbon and one atom of nitrogen, oxygen, or sulfur, respectively.

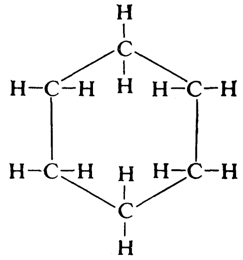
In general, the physical and chemical properties of heterocyclic compounds are best understood by comparing them with ordinary organic compounds that do not contain hetero-atoms (noncarbon atoms). In this section, the comparative aspects of heterocyclic compounds will be considered first, followed by a brief survey of the different classes of heterocyclic compounds, arranged according to the size and nature of the ring.

GENERAL ASPECTS OF HETEROCYCLIC SYSTEMS

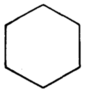
Comparison with carbocyclic compounds. The molecules of organic chemical compounds are built up from a framework or backbone of carbon (C) atoms to which are attached hydrogen (H), oxygen (O), or other heteroatoms. Carbon atoms have the unique property of being able to join with one another to form chains of atoms. When the ends of the chains are joined together, ring—that is, cyclic—compounds result; such substances often are referred to as alicyclic or carbocyclic compounds. Substitution of one or more of the ring carbon atoms in the molecules of a carbocyclic compound with a heteroatom gives a heterocyclic compound.

Carbocyclic compounds

A typical carbocyclic compound is cyclohexane (C_6H_{12}), the molecular structure of which is indicated by the following formula

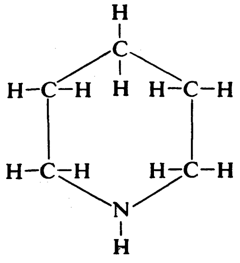


in which the letters represent atoms of the elements of which they are symbols and the lines represent bonds (linkages) between the atoms. For convenience such formulas are often written in the simplified polygonal form, such as

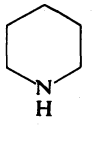


for cyclohexane, in which each angle of the polygon represents a carbon atom (it being understood that hydrogen atoms are joined to the carbon atoms as required).

When one of the carbon atoms of cyclohexane is replaced with an atom of nitrogen, the compound piperidine (a chemical relative of pyridine, above) is produced. The structural formula of piperidine is written as follows:



; or for convenience:



.

Other heterocyclic compounds can be envisioned as having been produced (similarly) from cyclohexane by substitution with other hetero-atoms or from other carbocyclic compounds by substitution with nitrogen or other hetero-atoms.

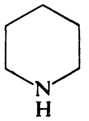
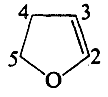
om-
ounds

The simplest organic compounds are the hydrocarbons, compounds of carbon and hydrogen only. Hydrocarbons are classed as paraffinic if all the potential bonds of the carbon atoms are saturated—that is, if the four possible bonds of each carbon atom are joined singly to another carbon atom or to a hydrogen atom. They are classified as olefinic if they contain a double bond (also called an unsaturated linkage) between any two of the carbon atoms; and they are classed as aromatic if they contain a ring of alternating single and double bonds. Compounds with unsaturation are highly reactive—that is, they readily undergo additions of atoms or groups of atoms to the carbon atoms of their double bonds, giving each carbon four groups joined to it. Aromatic compounds, though unsaturated, are extremely stable and do not undergo the addition reactions characteristic of other unsaturated compounds. The stability and unreactivity of the aromatic system are associated with presence of three pairs of electrons, the so-called pi electrons, associated with the three double bonds of the ring. Together these electrons, comprising the so-called aromatic sextet, form an unusually stable structure, associated with the aromatic ring as a whole rather than with the individual atoms.

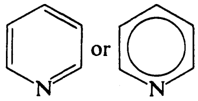
Heterocycles, too, may be classified as paraffinic, olefinic, and aromatic. Thus, piperidine is a heteroparaffinic compound containing no double bond, whereas 4,5-dihydrofuran is a hetero-olefinic compound, and pyridine is a typical hetero-aromatic substance, as shown in the following structural formulas, in the first of which the double bonds are shown and in the second of which the aromatic sextet is indicated by a circle.



piperidine

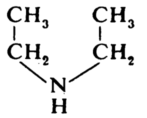


4,5-dihydrofuran

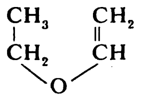


pyridine

This classification relates the chemistry of heterocycles directly with that of nonheterocyclic derivatives, which are usually better known. In general, synthetic methods and physical and chemical properties of the saturated heteroparaffinic and the partly unsaturated hetero-olefinic compounds closely resemble those for their acyclic (noncyclic) analogues. Thus, piperidine may be considered as a cyclic secondary amine (organic nitrogen compound) and has much in common with the acyclic amine, diethylamine, which is represented as follows:



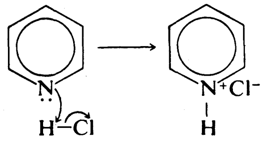
Similarly, 4,5-dihydrofuran mirrors many of the properties of the unsaturated ether, ethyl vinyl ether, written as follows:



It is within the area of hetero-aromatic compounds that most of the novel chemistry of the class is to be found, and for that reason hetero-aromatics will be emphasized in this section.

Chemical reactions. Every chemical reaction involves the forming or breaking of a chemical bond: for heterocycles the bonds in question are generally covalent bonds—linkages consisting of a pair of electrons shared by two atoms. Reactions generally can be placed in one of several categories, depending upon the origin, or disposition, of the electron pair of the bond that is formed or broken. The first of these categories is heterolytic reactions, in which the electron pair is supplied by one of the reactants (known as the nucleophile) to the other reactant (known as the electrophile). In the formation of pyridinium chloride, for example, which occurs as shown in the following equation:

Heterolytic reactions



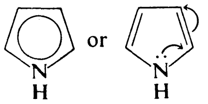
in which, as is customary, the structure of the starting material is written at the left, the product is written at the right, and an arrow in between the two indicates the reaction. In these structural formulas the presence of a free electron pair on the nitrogen atom is indicated by two dots, the movements of electrons are shown by curved arrows, and plus and minus signs indicate positive and negative charges. In this reaction, the pyridine molecule behaves as a nucleophile, the electron pair that initially resided on the nitrogen atom finally being shared between that atom and the hydrogen atom of the hydrogen chloride (which acts, therefore, as an electrophile). In homolytic reactions, an electron-pair bond is formed (or broken) and in this process each of the reagents donates (or receives) a single electron. In some reactions, cyclic transition states are involved, which must be classified separately.

In a heterolytic bond-forming reaction the reagent that accepts the electrons is known as an electrophilic reagent; for instance, in the coordination reaction with hydrogen chloride (above), the nitrogen atom of pyridine acts as a nucleophilic reagent. This behaviour is characteristic of pyridine. The nitrogen atom in pyrrole, by contrast, does not act as a nucleophilic centre, a distinction that can be rationalized by the different type of electronic interaction present in these two hetero-aromatic molecules (as explained below).

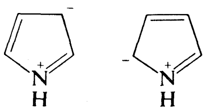
The nature of hetero-aromaticity. Aromaticity denotes the significant stabilization of a ring compound by cyclic conjugation in which six pi electrons generally participate. A nitrogen atom in a ring can carry a positive or negative charge, or it can be in the neutral form. Ring oxygen and sulfur atoms can occur either in the neutral form or with a positive charge. A fundamental distinction is usually made between: (1) those hetero-atoms that enter into aromatic conjugation by means of a lone electron pair in an orbital perpendicular to the plane of the ring, and (2) those hetero-atoms that enter into conjugation because they are connected to another atom by means of a double bond.

Pyrrole- and pyridine-type hetero-atoms

An example of an atom of the first type is the nitrogen atom in pyrrole. In pyrrole, the aromatic electron sextet is made up by the participation of two electrons from each carbon–carbon double bond, as well as the two electrons that comprise the unshared pair of the nitrogen atom. As a consequence, there tends to be a net flow of electron density from the nitrogen to the carbon atoms as the nitrogen electrons are drawn into the aromatic sextet; this movement may be indicated as follows,

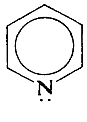


in which the curved arrows depict the movement, or tendency toward movement, of the electron pair. Alternatively, the pyrrole molecule may be described as a resonance hybrid—that is, a molecule whose true structure can only be approximated by two or more different forms, called resonance forms. With pyrrole, resonance forms such as the following make important contributions to the overall structure.

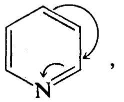


In these forms the nitrogen atom is depleted of electrons, as indicated by the positive charge.

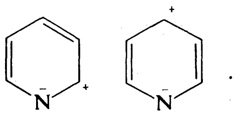
An example of a hetero-atom of the second type is the nitrogen atom in pyridine. Pyridine also has a pi electron sextet; but the nitrogen atom contributes only one electron to it, one further electron being contributed by each of the five carbon atoms. In particular, the lone electron pair on the nitrogen atom is not involved, as indicated in the following formulation:



Moreover, because of the greater attraction for electrons (electronegativity) of the nitrogen atom as compared to carbon atoms, there is a tendency for an electron flow toward the nitrogen atom, rather than away from it, as in pyrrole. This movement of electrons is shown as below

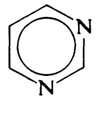


or it can be expressed in terms of contributions of the resonance forms as follows:

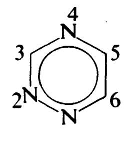


Quite generally, hetero-atoms may be referred to as pyrrole-like or pyridine-like, depending upon whether they fall into the first or second class, respectively, above. The pyrrole-like hetero-atoms —NR— (R being a hydrocarbon group), $-N^{-}-$, —O—, and —S— tend to donate electrons into the pi electron system, whereas the pyridine-like hetero-atoms —N=, $-N^{+}R=$, $-O^{+}=$, and $-S^{+}=$ tend to attract the pi electrons of a double bond.

A six-membered hetero-aromatic ring contains one or more pyridine-like hetero-atoms (usually nitrogen), as is the case with the compounds pyrimidine and 1,2,4-triazine.

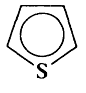


pyrimidine

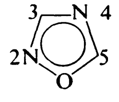


1,2,4-triazine

A six-membered hetero-aromatic compound cannot normally contain any pyrrole-like hetero-atoms. A five-membered hetero-aromatic ring, however, always contains one pyrrole-like nitrogen, oxygen, or sulfur atom, and it may also contain up to four pyridine-like hetero-atoms, as shown by the compounds below.



thiophene



1,2,4-oxadiazole

Measurements of aromaticity

The quantitative measurement, or even the precise definition, of aromaticity is difficult; two methods have been widely used to measure the aromaticity of carbocyclic compounds. The first method depends on the determination of the heat given off on complete combustion of the aromatic compound—say, benzene—compared with that expected for the corresponding carbocyclic compound containing three conventional double bonds—say, a cyclohexatriene. Because the heat of combustion is related to the energy content of the molecule, comparisons of the above kind reveal the reduction of energy associated with the aromatic system. The second method depends on measurement of magnetic ring currents set up in aromatic systems by external magnetic fields. The measurement is made with a nuclear magnetic resonance spectrometer, and the degree of observed magnetic effect is related to the degree of aromaticity. Both methods are difficult to apply to hetero-aromatic systems because of complications

Table 34: Aromatic Stabilization Energies for Benzene and Some Hetero-aromatic Rings
(kcal/mol)

benzene	pyridine	pyrazine
36	32	24
pyrrole	thiophene	furan
14–31	24–31	17–23
pyrazole	imidazole	1,2,4-triazole
27–41	12–32	20–49

arising from the presence of the heteroatoms. Table 34 gives some values for aromatic stabilization determined by combustion or related methods. Unfortunately, high errors are involved, as indicated by the wide variations in some of the values.

With regard to its chemical reactivity, an aromatic compound is characterized by extra stability of the conjugated system it contains; this characteristic, in turn, is denoted by the tendency of the compound to react by substitution (replacement of a hydrogen atom) rather than by addition to the double bonds. From a reactivity standpoint, therefore, the degree of aromaticity is measured by the relative tendency toward substitution rather than addition. Judging by this criterion, pyridine is more aromatic than furan, but it is difficult to say how much more aromatic it is.

Physical properties. Physical properties are important as criteria for judging the purity of heterocycles, just as for other organic compounds. The melting point was once the criterion most widely used, but now the optical spectra (based on light absorption), mass spectra (based on relative masses), and magnetic-resonance spectra (based on nuclear properties) have been increasingly used. Nevertheless, knowledge of the boiling point or melting point is still helpful in following purification of a compound. Organic compounds generally show great regularity regarding their physical properties, and heterocycles are no exception.

Criteria for purity

Table 35: Boiling Points of Saturated Heterocycles and Carbocycles of the Same Ring Size
(°C at 1 atm)

7	one	138	120	174	119

*Corrected to atmospheric pressure by the method of Hass and Newton, *Handbook of Chemistry and Physics*, 51st ed., edited by R.C. Weast, 1970.

Melting and boiling points. The boiling points of certain saturated heterocycles compared with the corresponding cycloalkanes are listed in Table 35. The melting or boiling points of common hetero-aromatic ring compounds and their substituted derivatives are compared with those for benzene and its derivatives in Table 36. It can be seen from the table that replacement of a two-carbon unit (with molecule weight equal to 26) by a sulfur atom (atomic weight 32) has little effect on the melting or boiling point (compare corresponding benzene and thiophene compounds). On the other hand, replacement of a two-carbon unit by an oxygen atom (atomic weight 16) lowers the boiling point by about 40° C, or 104° F (compare corresponding benzene and furan compounds), which is to be expected because of the decreased molecular weight (lighter compounds being more volatile). The introduction of nitrogen atoms into the benzene ring is accompanied by less regular changes. Replacement of a two-carbon unit by an imino (NH) group, or of a single carbon by a nitrogen atom, increases the boiling point. Furthermore, if these two changes are made simultaneously, the boiling point is increased by an especially large amount, probably the result of association by hydrogen bonding (a weak form of attachment through certain types of hydrogen atoms) between the nitrogen atom and the imino group.

Effects of substituents

The effects of substituent groups in hetero-aromatic rings show considerable regularity. Thus, methyl and ethyl groups attached to ring carbon atoms usually increase the boiling point by about 20°–30° C (68°–86° F) and 50°–60° C (122°–140° F), respectively, whereas conversion of an imino (NH) group into an amino (NR, in which R is a hydrocarbon chain) group (*e.g.,* pyrazole → 1-methylpyrazole) significantly decreases the boiling point because of decreased ease of association by hydrogen bonding (the active hydrogen having been replaced by a hydrocarbon group). Carboxylic acids and amides are all solids; carboxy derivatives of compounds containing a ring nitrogen atom usually melt at higher temperatures than those containing ring oxygen or sulfur atoms because of hydrogen bonding. Compounds containing both a ring nitrogen atom and a hydroxyl or amino group are usually relatively high melting solids. Chloro compounds usually have boiling points similar to those of the corresponding ethyl compounds.

Ultraviolet, infrared, nuclear magnetic resonance and mass spectra. Spectroscopic studies of heterocyclic compounds, as have those of other organic compounds, have become of great importance as means of identification of unknown materials, as criteria of purity, and as probes for investigating the electronic structures of molecules, thereby explaining and helping to predict their reactions. The pattern of light absorption in the ultraviolet region of the spectrum (the so-called ultraviolet spectrum) of a compound is characteristic of the pi electron system of the molecule; *i.e.,* of the arrangement of double bonds within the structure. The ultraviolet spectra of hetero-aromatic

Measurements of pi electrons

compounds (given in Table 37) show general similarity to those of benzenoid compounds, and the effects of substituents can usually be rationalized in a similar way. The infrared spectrum of an organic compound, with its complexity of bands, provides an excellent "fingerprint" of the compound (far more characteristic than the melting point), and it can also be used to identify certain common groups, such as carbonyl (C=O) and imino (N—H) groups, as well as various of the heterocyclic ring systems (Table 38). Although magnetic resonance spectra were not widely used until about 1955, they have since become indispensable to any serious study of heterocyclic chemistry. Proton resonance spectra (the most common type), for example, yield information regarding the number of hydrogen atoms present in the molecule, as well as their chemical environment and their relative orientations in space (Table 39). Still later, mass spectra have been used to determine not only the complete molecular formula of the compound but also, from the way the molecule is fragmented, the arrangement of many of the atoms.

Table 38: Ranges for Some Characteristic Infrared Absorption Maxima for Ring-Stretching Modes of Common Hetero-aromatic Compounds

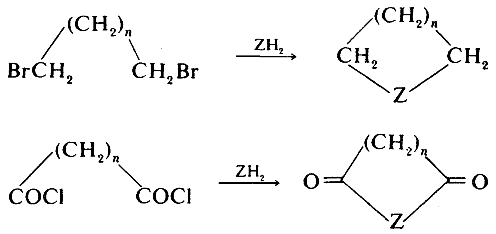
Synthesis and modification of heterocyclic rings. The important methods for synthesizing heterocyclic compounds may be classified under five headings, of which the first three are ways of forming new heterocyclic rings from precursors containing one less ring, the fourth covers the formation of a heterocyclic ring either from another heterocycle or from a carbocyclic ring, and the fifth includes the modification of substituents on a pre-existing heterocyclic ring. The key step in the formation of rings from noncyclic precursors (the first instance above) often is the formation of the carbon hetero-atom linkage (C—Z, in which Z represents an atom of nitrogen, oxygen, or sulfur). The actual ring closure, or cyclization, however, may involve the formation of a carbon–carbon bond. In any case, ring formation reactions are subdivided into three categories according to whether the cyclization reaction occurs primarily as a result of (1) nucleophilic or (2) electrophilic attack, or (3) by way of a cyclic transition state.

Classification by methods of ring closure

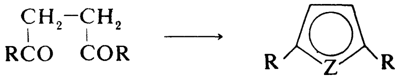
Nucleophilic ring closure. To prepare compounds containing one hetero-atom, a compound containing two halides (chloride [Cl], bromide [Br], or iodide [I]) or acyl halides (that is, halide derivatives of carboxylic acids) will react with the dihydro form of the hetero-atom, ZH_2 (or an equivalent reagent such as ammonia or sodium sulfide), to give nonaromatic heterocycles:



in which n equals only an integer

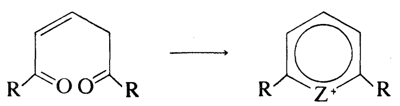
Diketones

Diketones (ketones being compounds with oxygen atoms joined to carbon by double bonds) also can react with dihydro-Z compounds to give heterocycles. Diketones with the keto groups separated by two carbon atoms, for example, can be cyclized to form aromatic pyrroles, furans, and thiophenes as shown:



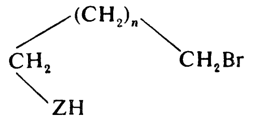
in which R is a hydrocarbon chain

With diketones separated by three carbons, such as the unsaturated compound below, six-membered rings may be formed:

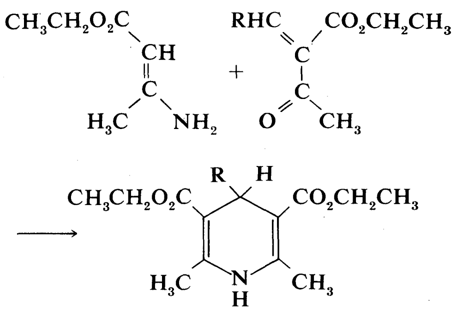


In each of these reactions the hetero-atom Z acts as a nucleophile in attacking the positively charged carbon atom produced by electron withdrawal due to the halogen atom (in the first instance above) or to the oxygen atom (in the second).

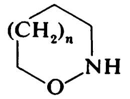
Usually, reactions like these proceed by means of intermediates in which only one of the C—Z bonds has been formed. In reactions of the first type in this section, for instance, compounds like the one shown below may be formed first.



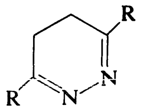
It is frequently possible to synthesize such intermediate compounds by other routes, and they then cyclize readily. One form of pyridine synthesis, for example, involves the condensation of an intermediate with the carbon–nitrogen bond already formed as shown:



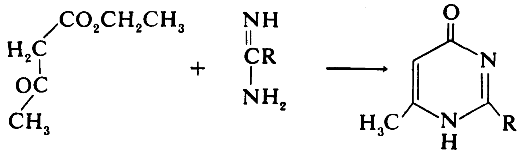
Heterocycles containing two adjacent nitrogen atoms and oxygen atoms, or both, also may be prepared from precursors of the type shown in the first example of this section by using hydrazine (N_2H_4), hydroxylamine (NH_2OH), or hydrogen peroxide (H_2O_2) in place of the dihydro-Z compound (ZH_2). With hydroxylamine, for example, the compound shown below is formed.



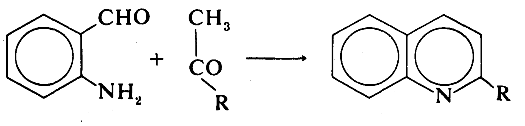
Similarly, two adjacent hetero-atoms can be introduced by reactions with diketones (the second reaction here), producing such compounds as the following:

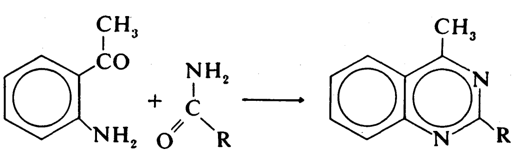


When it is desired to prepare a compound containing two nonadjacent hetero-atoms, appropriate components can be put together as illustrated in the following synthesis of pyrimidines:

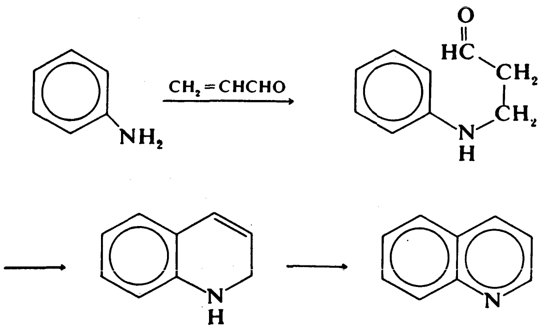


Ring synthesis reactions, in which the hetero-atom acts as a nucleophile, also involve orthodisubstituted benzenes (ortho substituents being on adjacent carbon atoms in the benzene ring), as in the preparation of many heterocycles fused to benzene rings. The formation of quinoline and quinazoline rings are examples of this type:



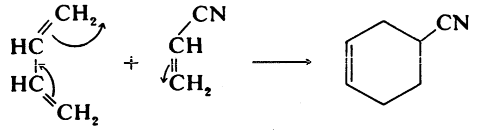


Electrophilic ring closure. Formation of heterocyclic rings by reactions in which the hetero-atom acts as an electrophilic (electron-seeking) reagent are rare, because the nitrogen, oxygen, and sulfur atoms are themselves electron-rich centres that react generally as nucleophiles. Electrophilic ring-closure reactions are known, however, in which a heterocyclic ring is formed by a reaction in which a carbon atom of the ring acts as an electrophile. Usually such reactions involve ring closure onto a benzene ring (or other aromatic system), an electron-rich system that is generally subject to attack by electrophilic reagents. An example of ring closures of this type is the formation of quinoline from aniline and acrolein, a dehydration product of glycerol. As shown below, the initial product of the reaction is a dihydroquinoline, which must be dehydrogenated to the fully aromatic product, quinoline itself:

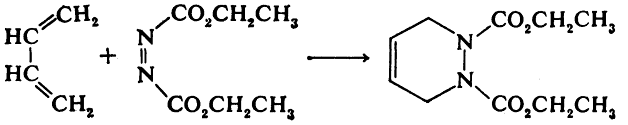


Ring closure by way of cyclic transition states. A most important method for the synthesis of carbocyclic six-membered rings is the so-called Diels–Alder diene reaction (named for its discoverers, two German Nobel Prize-winning chemists, Otto Diels and Kurt Alder). In this reaction, as illustrated below, a diene (a compound with two double bonds) reacts with a dienophile (a diene-seeking reagent) to yield a cyclohexene:

The Diels–Alder reaction



In this reaction, it is not possible to determine whether the electrons move clockwise (as shown by the curved arrows) or whether they move in the reverse, counterclockwise fashion. For this reason, in reactions of this type the movements of electrons are thought to be synchronous rather than sequential, and the reactions are said to possess cyclic transition states. Heterocycles can also be prepared by the diene synthesis, as illustrated by this preparation of a tetrahydropyridazine:



Of far greater use, however, is the related method referred to as the Huisgen cyclic dipolar addition reaction; it is an important method for the preparation of many types of five-membered rings, especially those containing several hetero-atoms. Pyrazoles and isoxazoles, and many less common heterocycles, also are prepared by this method.

Conversion of one heterocyclic ring into another. There are many reactions of theoretical, and a few of practical, importance in which one heterocyclic ring is converted into another. The ring-atom exchange reactions of pyridine derivatives (see below, *Six-membered rings with one hetero-atom*) are good examples. In addition, ring-atom rearrangement or "shuffling" can be brought about with light (photochemically) in five- and six-membered hetero-aromatic compounds, and ring contraction by extrusion of an atom or group can occur under certain conditions.

Modification of an existing ring. Dehydrogenation of saturated or partially saturated rings to hetero-aromatic compounds by heating with sulfur or treatment with a palladium catalyst is analogous to similar reactions with carbocyclic compounds. The hydrogenation of heteroaromatic rings is, by contrast, usually more difficult, for the hetero-atoms tend to poison the catalyst. Finally, the modification of substituents on heterocyclic rings is of highest importance in synthesis; reactions by which substituents may be altered are among the most useful in heterocyclic chemistry.

Common and systematic nomenclature

Nomenclature. Naming heterocyclic compounds is complicated because of the existence of many common names, in addition to the internationally agreed systematic nomenclature. A brief account of systematic nomenclature is given here, but for common names the reader is referred to the systematic survey in the next section.

The types of hetero-atoms present in a ring are indicated by prefixes; in particular "oxa," "thia," and "aza" denote oxygen, sulfur, and nitrogen atoms, respectively. The number of hetero-atoms of each kind are indicated by number prefixes joined to the hetero-atom prefixes as "dioxa" and "triaza." The presence of different heteroatoms is indicated by combining the above prefixes, using the following order of preference: oxa first, followed by thia, then aza. Ring size and the number of double bonds are indicated by suffixes as shown in Table 40.

Table 40: Suffixes Used in Naming Monocyclic Heterocycles

ring size	rings with nitrogen			rings without nitrogen		
	maximum unsaturated	one double bond	saturated	maximum unsaturated	one double bond	saturated
3	-irine	—	-iridine	-irene	—	-irane
4	-ete	-etine	-etidine	-ete	-etene	-etane
5	-ole	-oline	-olidine	-ole	-olene	-olane
6	-ine	—	—	-ine	—	-ane
7	-epine	—	—	-epine	—	-epane

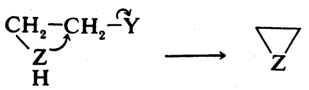
In this table, "maximum unsaturation" refers to rings possessing the largest possible number of noncumulative (that is, with no atom in common) double bonds but with oxygen and sulfur atoms in their normal, divalent forms. In addition, partially saturated rings are indicated by the prefixes "dihydro," "tetrahydro," and so on, according to the number of excess hydrogen atoms. The positions of hetero-atoms, extra hydrogen atoms, and substituents are indicated by arabic numerals, for which the numbering starts at an oxygen atom, if one is present, or at a sulfur or nitrogen atom, and continues in such a way that the hetero-atoms are assigned the lowest possible numbers. Other things being equal, numbering starts at a nitrogen atom that carries a substituent rather than at a multiply-bonded nitrogen. In compounds with maximum unsaturation, if the double bonds can be arranged in more than one way, their positions are defined by indicating the nitrogen or carbon atoms that are not multiply-bonded, and consequently carry an "extra" hydrogen atom (or substituent), as follows: 1H–, 2H–, and so on.

Numbering systems

MAJOR CLASSES OF HETEROCYCLIC COMPOUNDS

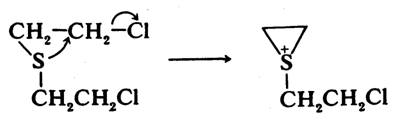
The major classes of heterocycles containing the common hetero-atoms (nitrogen, oxygen, sulfur) are reviewed first, in order of ring size (from smallest to largest), leaving compounds with other hetero-atoms to a final section. The classification by ring size is convenient because heterocyclic rings of a given size have many common features. For heterocyclic (as for carbocyclic) rings, the following broad generalizations can be made: 3- and 4-membered rings are strained and thus readily opened; they are also readily formed: such heterocycles are well-known reactive intermediates. Five- and six-membered rings are readily formed and are very stable: these sizes of ring also allow the development of aromatic character. Seven- and larger-membered rings are stable but not readily formed and are therefore relatively little investigated.

Three-membered rings. The three-membered-ring heterocycles containing single atoms of nitrogen, oxygen, and sulfur—aziridine, oxirane (or ethylene oxide), and thiirane, respectively—and their derivatives can all be prepared by nucleophilic reactions, of the type shown below.



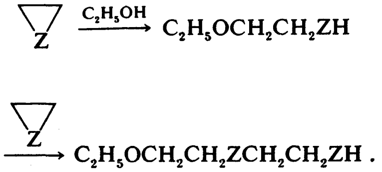
aziridine: Z=NH
oxirane: Z=O
thiirane: Z=S
(Y equals a group displaced by the heteroatom Z)

Thus, aziridine itself is formed by heating β-aminoethyl hydrogen sulfate with base (in which case Y is $-OSO_3H$). A reaction of this type is involved in the action of mustard gas, or dichlorodiethyl sulfide, a poison gas used in World War I. The mustard gas itself ringcloses to give a thiirane derivative, the biologically active agent, according to the reaction below:



Commercially, oxirane and aziridine (to a lesser extent) are important bulk industrial chemicals; oxirane is prepared on a large scale by the direct reaction of ethylene with oxygen.

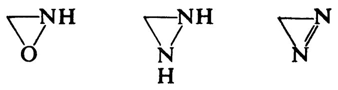
The chemical reaction characteristic of these three-membered rings is susceptibility to attack by nucleophilic reagents to open the ring as shown below:



The first step shown is the reverse of the formation reaction above. As indicated, a second molecule of the three-membered ring may react with the first product. Further reaction leads to long, chainlike molecules (polymers) of the type $C_2H_5O(CH_2CH_2Z)_nCH_2CH_2ZH$. Polymers and copolymers of oxirane and aziridine are useful plastics. Although aziridine, oxirane, and thiirane are heteroparaffinic, they are much more reactive than the corresponding normal amines, ethers, or sulfides because of the strain inherent in the three-membered ring. This behaviour reflects the comparable enhanced reactivity of the related carbocyclic compound cyclopropane.

Three-membered rings with two hetero-atoms

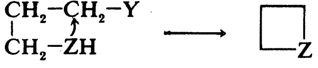
Since 1950, three different classes of three-membered-ring compounds with two hetero-atoms have been discovered. They are derivatives of the parent ring systems oxaziridine, diaziridine, and diazirine, the chemical structures of which are shown below:



oxaziridine diaziridine diazirine

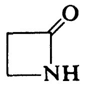
These compounds have no practical importance, but they are stable enough for easy handling and offer interesting possibilities for future use.

Four-membered rings. Azetidine, oxetane, and thietane—the four-membered rings containing, respectively, nitrogen, oxygen, and sulfur atoms—are prepared by nucleophilic displacement reactions such as those used to prepare the corresponding three-membered rings, as shown:

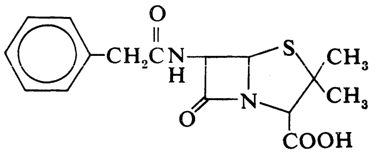


azetidine: Z=NH
oxetane: Z=O
thietane: Z=S

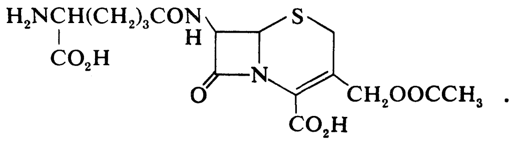
With the four-membered rings, however, the reactions proceed less readily than do the analogous reactions for the formation of the three-membered rings. Similarly, the ring-opening reactions of the four-membered heterocycles qualitatively resemble those of the corresponding three-membered rings, but they occur rather less readily. The most important heterocycles with four-membered rings are two related series of antibiotics, the penicillins and cephalosporins, both of which contain the azetidinone ring:



The chemistry of azetidinones, or β-lactams, as they are also called, was explored thoroughly during the intensive research into penicillin structure and synthesis that took place during World War II, a practical synthesis of penicillin not being achieved, however, until 1959. The complete chemical structures of a representative penicillin and a cephalosporin are shown below:

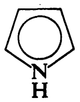


benzylpenicillin

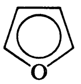


cephalosporin C

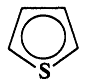
Five-membered rings with one hetero-atom. The parent aromatic compounds of the family—pyrrole, furan, and thiophene—have the structures shown:



pyrrole

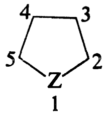


furan

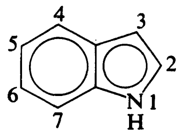


thiophene

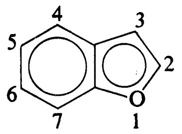
Five-membered heterocycles with one hetero-atom conform to the general structure:



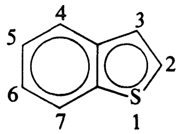
with numbering to indicate substituents as shown. The saturated analogues are called pyrrolidine, tetrahydrofuran, and thiophane, respectively. The bicyclic compounds containing a benzene ring fused to a pyrrole, furan, or thiophene ring are known, respectively, as indole, benzofuran, and thionaphthene; their structures are as shown:



indole



benzofuran



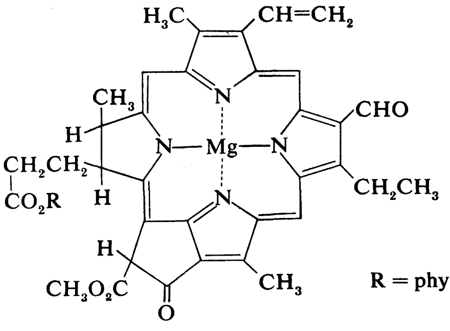
thionaphthene

The common numbering system is shown only for indole.

As mentioned earlier, pyrrole occurs in bone oil, in which it is formed by the pyrolytic decomposition of proteins (induced by strong heating). Reduced pyrrole rings are found in the essential amino acids proline and hydroxyproline, which are components of most proteins.

Occurrence of pyrrole derivatives

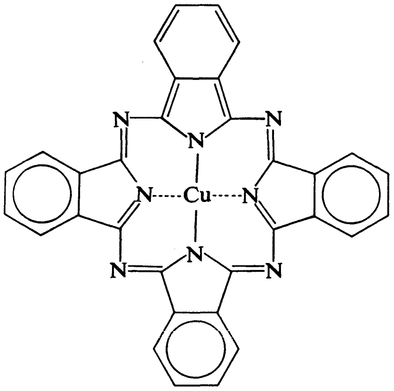
Pyrrole derivatives are of widespread natural occurrence: the blood pigment hemoglobin and related compounds, the chlorophylls, and also vitamin B_{12} all are formed from four pyrrole nuclei arranged in a large ring, such as that of chlorophyll b, shown below:



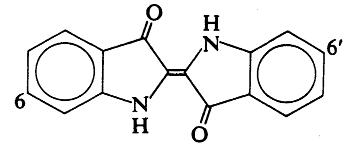
R = phytyl, $C_{20}H_{39}$

chlorophyll b
(plant pigment)

The phthalocyanins are a group of synthetic pigments that contain four benzopyrrole rings linked together in a large ring; a typical member of the family is Monastral blue with the structure shown:



The important vat dye indigo was formerly obtained from natural sources but is now synthesized on a large scale.

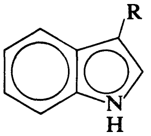


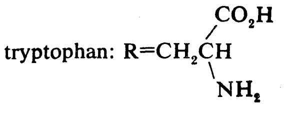
indigo

Tyrian purple, a dye used in classical times, is 6,6′-dibromoindigo (with bromine atoms at the numbered carbons).

Indole compounds

Other indole derivatives occur in nature. Tryptophan is an essential amino acid found in most proteins, and one of its degradation products is skatole, found in feces. Indole-3-acetic acid is a plant growth hormone, and many plant alkaloids contain indole rings. The structures of these compounds are:

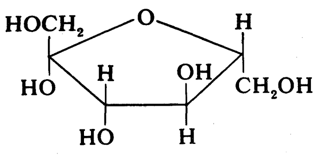




tryptophan: $R{=}CH_2CH(CO_2H)(NH_2)$

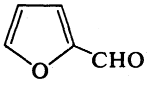
skatole: $R{=}CH_3$
indole-3-acetic acid: $R{=}CH_2CO_2H$

All carbohydrates, the biochemical family that includes the sugars and starches, are composed of one or more sugar (monosaccharide) units. These sugars are polyhydroxyaldehydes or -ketones (carbonyl compounds), which frequently exist as furanoside, that is, as a cyclized form with a five-membered, furanose, ring—*e.g.*, fructose, or fruit sugar—as the fructofuranose shown below:

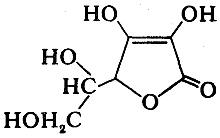


fructofuranose

Dehydration (removal of water) of certain carbohydrates yields furan derivatives; of great commercial importance is the conversion of a carbohydrate in corncobs into furan-2-aldehyde, or furfural, which is extensively used as a solvent, in the manufacture of plastics, and in the preparation of other furan derivatives. Many other reduced furans occur naturally, including vitamin C. The structures of furfural and vitamin C are as follows:

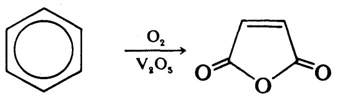


furfural

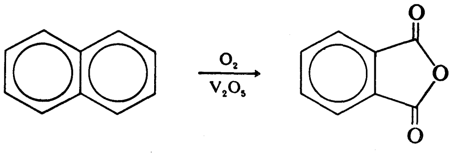


ascorbic acid
(vitamin C)

Other derivatives of furan of industrial importance are the solvent tetrahydrofuran prepared from furfural, and maleic and phthalic anhydrides, important constituents of resins and plastics. These compounds are prepared in quantity by the oxidation of benzene and naphthalene, respectively, as shown:

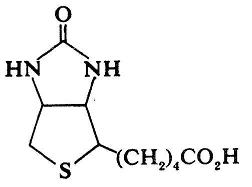


benzene maleic anhydride



naphthalene phthalic anhydride

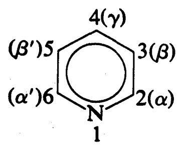
Thiophene and related compounds are found in coal tar and crude petroleum. The most important biologically occurring derivative is the vitamin biotin, with the structure:



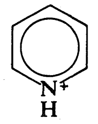
biotin
(vitamin H)

Pyridine
and
derivatives

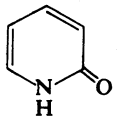
Six-membered rings with one hetero-atom. The nomenclature used for the various monocyclic nitrogencontaining six-membered ring compounds is as shown below, with numbering as shown for pyridine, arabic numerals being preferred to Greek letters (though both systems are used). The pyridones are aromatic compounds because of contributions to the resonance hybrid from charged canonical forms such as that shown for 4-pyridone. Mono-, di-, and trimethylpyridines are called picolines, lutidines, and collidines, respectively, with the position of the methyl groups denoted by the appropriate numbers; *e.g.*, 2, 4, 6-collidine. Pyridine-2-, -3-, and -4- carboxylic acids also have widely used trivial names; picolinic, nicotinic (derived from nicotine, of which it is an oxidation product), and isonicotinic acid, respectively. Pyridine and the picolines, lutidines, and collidines occur in coal tar and bone oil. Pyridine



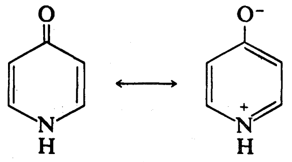
pyridine



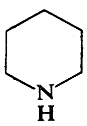
pyridinium ion



2-pyridone,
2(1H)-pyridone,
or 1,2-dihydro-
2-oxopyridine

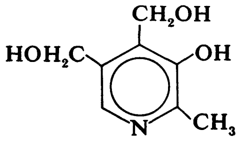


4-pyridone

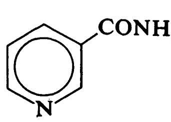


piperidine

derivatives are also of great biological importance: vitamin B$_6$ is pyridoxine, and another B-group vitamin is nicotinamide. Their structures are as follows:

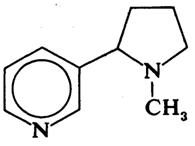


pyridoxine
(vitamin B$_6$)

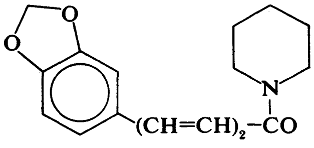


nicotinamide

Coenzymes I and II are derived from nicotinamide, and codecarboxylase from pyridoxine. Many alkaloids are derived from pyridine or piperidine, among them nicotine (in tobacco) and piperine (in pepper), with the structures shown.

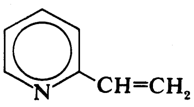


nicotine

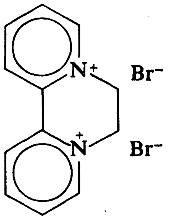


piperine

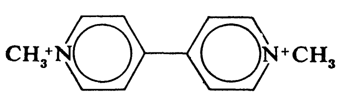
Pyridine, which is now prepared catalytically on a large scale from tetrahydrofurfuryl alcohol and ammonia, is an important solvent and intermediate used to make other compounds. Vinyl-pyridines, such as



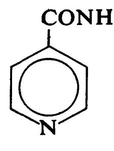
are important monomers used to make plastics. Pharmaceutically important pyridines include the tuberculostat isoniazid, the local anesthetic α-eucaine, the sulfa drug sulfapyridine, and the respiratory stimulant coramine. The chemical structures of these compounds are as follows:



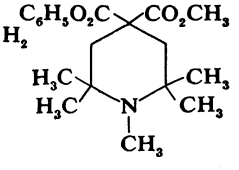
diquat



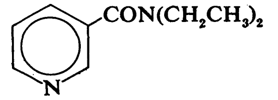
paraquat
(herbicide)



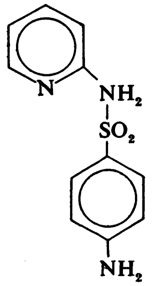
isoniazid



α-eucaine

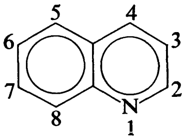


coramine

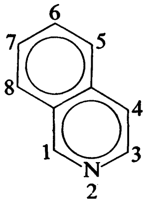


sulfapyridine

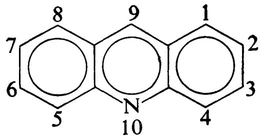
The structures of two isomeric benzopyridines and of two isomeric dibenzopyridines, with their common names and accepted numberings, are shown in the diagrams below:



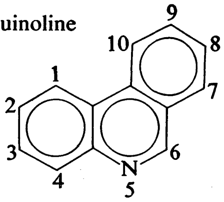
quinoline



isoquinoline



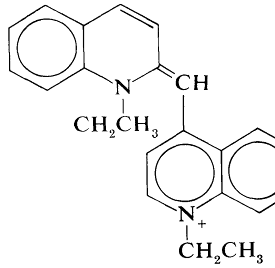
acridine



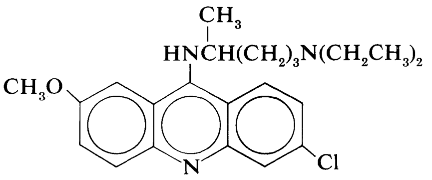
phenanthridine

Coal tar as a source

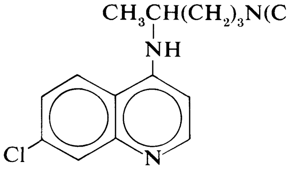
All four of these compounds and some of their alkyl derivatives have been obtained from coal tar. Each of them also is the parent substance of a class of alkaloids; of these, the quinoline (*e.g.,* quinine) and the isoquinoline (*e.g.,* morphine) groups are particularly well known. (For detailed coverage of this family of compounds, see the section *Alkaloids* below.) Important synthetic derivatives of the benzo- and dibenzopyridines include members of the family of cyanine dyes, some of which—*e.g.,* ethyl red—are photographic sensitizing agents and others are useful antiseptics for staphylococcal organisms; antimalarials such as mepacrine (also called quinacrine or Atabrine) and chloroquine; antibacterials such as acriflavine (Trypaflavine); trypanocides such as phenidium chloride; and the reagent oxine (8-hydroxyquinoline or 8-quinolinol), used in analytical chemistry. The structures of these compounds are as follows:



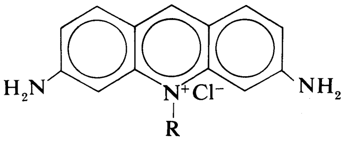
ethyl red



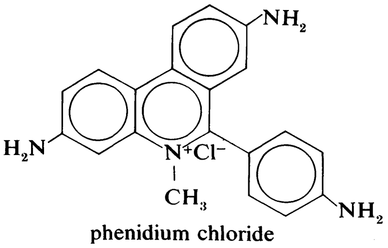
mepacrine



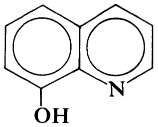
chloroquine



acriflavine (R = H or CH_3)

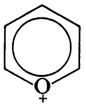


phenidium chloride

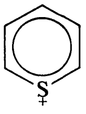


oxine

The parent six-membered, aromatic, monocyclic, oxygen and sulfur compounds are the pyrylium and thiopyrylium compounds bearing positive charges (cations) with the following structures:

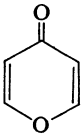


pyrylium cation

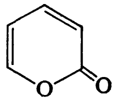


thiopyrylium cation

An uncharged aromatic (completely conjugated) six-membered ring containing an oxygen or sulfur atom is possible only if the ring contains a carbonyl group as in the pyrones:

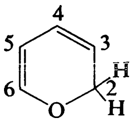


4-pyrone



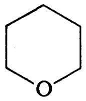
2-pyrone

The pyrans contain extra hydrogen atoms, the position of which is indicated by a number followed by an *H,* as shown:



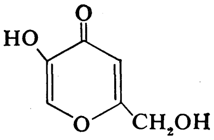
2[*H*]-pyran

Certain sugars are called pyranoses because they contain six-membered tetrahydropyran rings, with the structure:

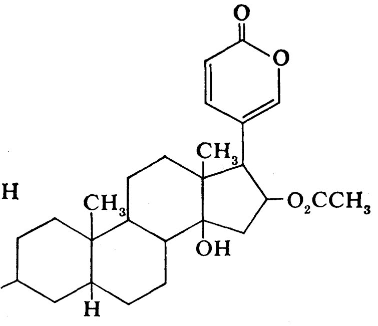


tetrahydropyran

Pyrone derivatives are present in natural products; *e.g.,* kojic acid, an antibiotic derived by the action of certain molds on starches or sugars, and bufotoxin—a poisonous ester of the steroid bufotalin—obtainable from the skin glands of toads. The structures of kojic acid and bufotalin are shown below:

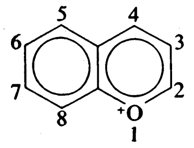


kojic acid

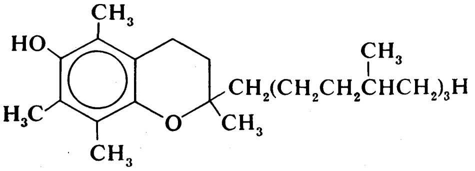


bufotalin

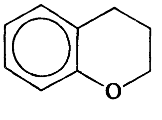
The benzopyrylium cation is the parent of a large number of natural products. Vitamin E is a substituted chroman, whereas dicoumarol, a blood anticoagulant, is a derivative of coumarin. The structures of these compounds are given below.



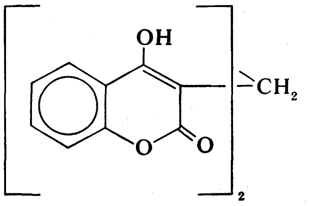
benzopyrylium ion



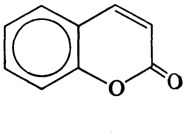
vitamin E



chroman

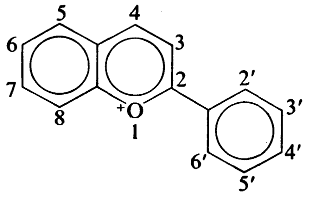


dicoumarol



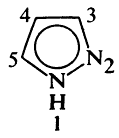
coumarin

The flavylium cation is the parent of the anthocyanidines, substances that are combined with sugars to form the anthocyanin pigments, the common red and blue colouring matters of flowers and fruits. The flavylium ion has the following structure:

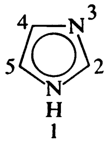


flavylium ion

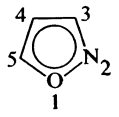
Five- and six-membered rings with two or more hetero-atoms. The names and numbering systems for the five-membered hetero-aromatic rings with two hetero-atoms are shown below:



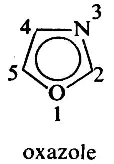
pyrazole



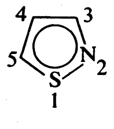
imidazole



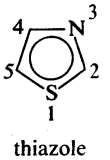
isoxazole



oxazole

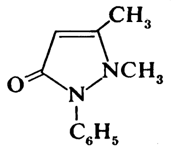


isothiazole

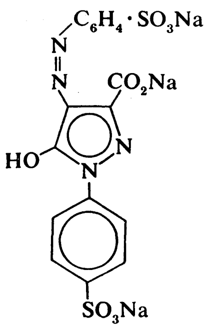


thiazole

Few pyrazoles occur naturally; the antipyretic (fever-reducing) and analgesic (pain-killing) antipyrine and the food and photographic dye tartrazine are important synthetic pyrazoles, with the following structures:



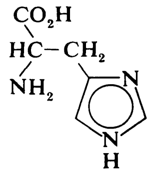
antipyrine



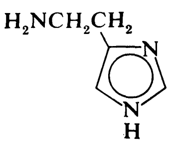
tartrazine

Imidazoles

Imidazoles are most important biologically; histidine, for example, is an essential amino acid, known to be of particular importance in enzyme reactions. A breakdown product of histidine, called histamine, is thought to be responsible for the development of allergies, hence the importance of antihistamine drugs. Histidine and histamine have the structures:

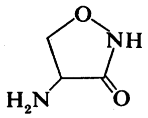


histidine



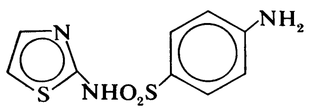
histamine

The antibiotic cycloserine, with structure shown, is one of the few naturally occurring isoxazoles:



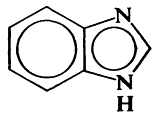
cycloserine

Thiazoles are of great biological importance. This ring system occurs in thiamine (vitamin B_1) and penicillin (see above). Sulfathiazole, an important sulfa drug, has the structure:



sulfathiazole

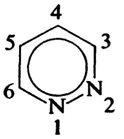
Most bicyclic systems derived from these five-membered rings are named systematically; *i.e.*, by use of the prefix "benz-" to indicate the presence of the benzene ring. Benzimidazole, for example, is the name for the compound:



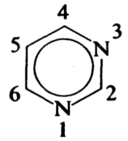
benzimidazole

A benzimidazole unit occurs in vitamin B_{12}.

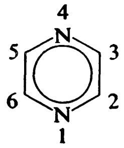
The three monocyclic diazines (six-membered-ring compounds with two nitrogen atoms) are named and numbered as follows:



pyridazine

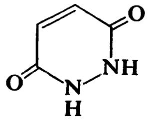


pyrimidine

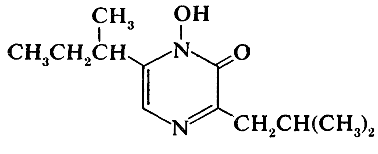


pyrazine

The pyridazine derivative maleic hydrazide is a herbicide, and some pyrazines occur naturally; *e.g.*, the antibiotic aspergillic acid. The structures of these compounds are:

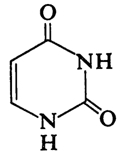


maleic hydrazide

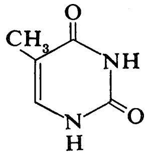


aspergillic acid

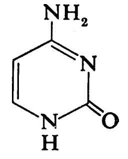
The pyrimidines, however, are the compounds of this group that are most important. Uracil, thymine, and cytosine, for example, with the structures shown, are constituents of nucleic acids.



uracil

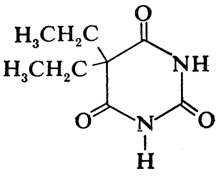


thymine

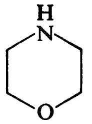


cytosine

Vitamin B_1 contains a pyrimidine ring, and synthetic barbiturates, such as Veronal, with the structure given here, are widely used drugs. Various oxazines and thiazines are known but are of little importance, except for the solvent morpholine:

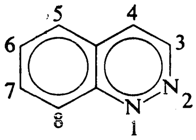


veronal

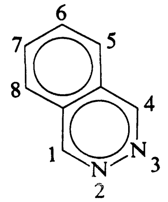


morpholine

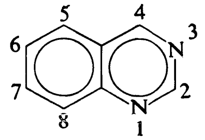
Many of the benzodiazines have common names; the structures and numbering of these compounds are as follows:



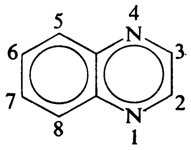
cinnoline



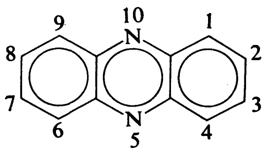
phthalazine



quinazoline

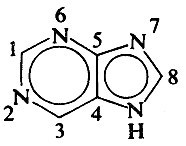


quinoxaline

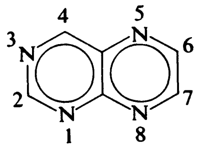


phenazine

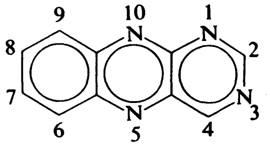
Five other polycyclic systems in this general family are of some significance; their structures and numbering system also are given:



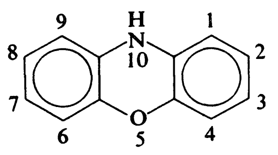
purine



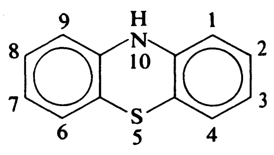
pteridine



alloxazine

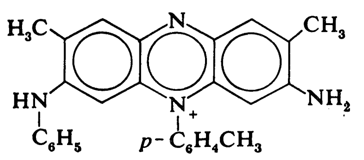


phenoxazine



phenothiazine

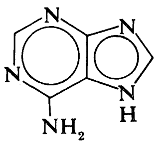
A few quinoxaline alkaloids exist; there are some phenazine natural products, and phenazine dyes are used for fabrics, the first synthetic dyestuff, Mauve, being historically important—its structure is as follows:



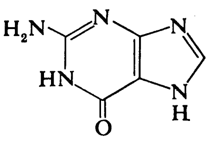
mauve

Purines and pteridines

Biologically, however, the purines and pteridines are of more importance. Two purines, adenine and guanine, occur, together with the pyrimidine bases mentioned previously, in all nucleic acids.

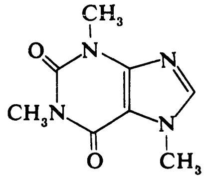


adenine

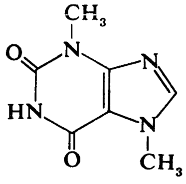


guanine

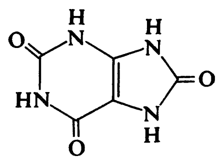
Other natural purines include caffeine (found in tea and coffee), theobromine (found in cocoa), and uric acid (a metabolic product). The structures of these compounds are as follows:



caffeine

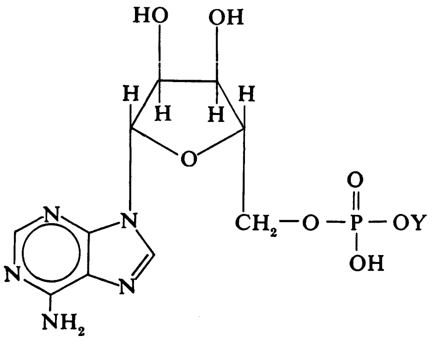


theobromine



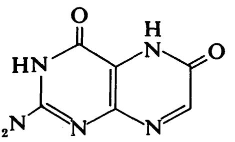
uric acid

Adenosine mono-, di-, and tri-phosphate (AMP, ADP, ATP, respectively) with the structures shown, are important in biological energy processes.



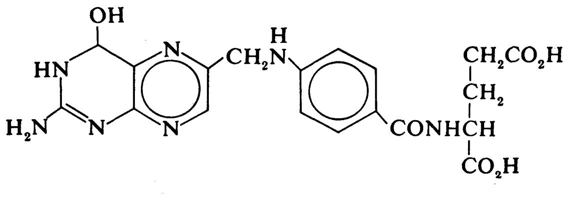
adenosine monophosphate: $Y = H$
adenosine diphosphate: $Y = PO_3H_2$
adenosine triphosphate: $Y = P_2O_6H_3$

The biological significance of pteridine compounds has become apparent. The first pteridines were discovered as pigments of butterfly wings; *e.g.*, one with the structure:



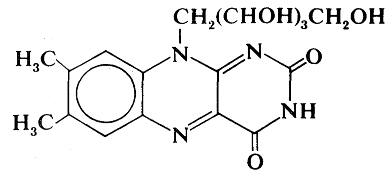
2-amino-4,6-pteridinedione

Folic acid, also a pteridine, is an important growth factor.



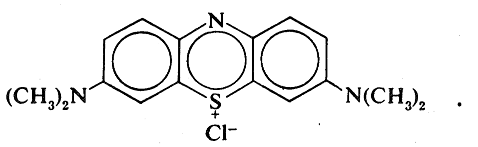
folic acid

Riboflavin, a derivative of alloxazine, is a B-vitamin:



riboflavin

Phenothiazine is an anthelmintic (worm-killing agent) as well as the parent of a family of dyes, such as methylene blue, a substance widely used as a biological stain and as an oxidation-reduction indicator. The structure of methylene blue is:



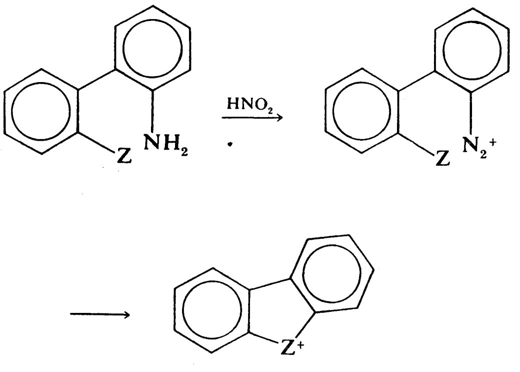
methylene blue

High stability

Rings with seven or more members. As the size of the ring increases, the range of compounds obtainable by variation of the number, type, and location of the heteroatoms increases enormously. Nevertheless, the chemistry of heterocyclic compounds with seven-membered rings, or larger, is still relatively undeveloped, chiefly because the formation of such rings is generally difficult, just as is the formation of large carbocyclic rings. These larger rings, however, can be very stable, once they are formed, and knowledge of their chemistry is likely to increase rapidly in the near future. Some larger ring heterocycles exist in natural products; the porphyrins are widely distributed as pigments; *e.g.*, the chlorophylls and hemoglobins mentioned above.

Rings with uncommon hetero-atoms. Although nitrogen, oxygen, and sulfur are the common atoms found together with carbon in heterocyclic rings, a large number of other elements also form such rings—of greater or lesser stability. Such compounds are as yet of little practical importance. The principal ones known to date contain elements of the classes described below.

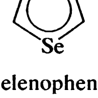
Halogens. Certain cyclic chloronium, bromonium, and iodonium ions have been prepared by the following reaction:



Z = Cl, Br, or I

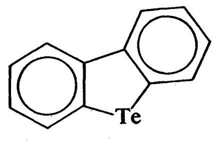
Of these, only the iodine derivative has much stability.

Selenium and tellurium. Many selenium heterocycles are known. Selenium shows much similarity in its behaviour to sulfur; hence selenophene, with the structure shown,



selenophene

resembles thiophene quite closely. Tellurium heterocycles are more rare, and less stable; an example is dibenzotellurophene:

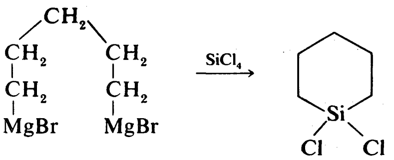


dibenzotellurophene

Phosphorus, arsenic, and antimony. Phosphorus, arsenic, and antimony, all members of Group V of the periodic table of elements, form a closely related group of heterocycles. There is, however, little similarity between their properties and those of the corresponding derivatives of nitrogen, a member of the same group. With few exceptions, no hetero-aromatic compounds are formed by these elements, and the cyclic derivatives resemble their open-chain analogues.

Silicon, germanium, and tin. Although silicon, germanium, and tin fall in the same periodic group as carbon, their atoms form neither stable chains nor double bonds; hence no hetero-aromatic derivatives of these compounds are known. Many saturated heterocyclic derivatives are known, however, including cyclic silanes, which may be prepared as shown by the following example:

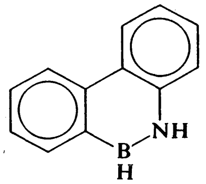
Silanes



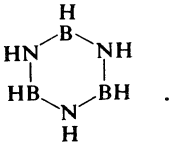
1,1-dichlorosilacyclohexane

All these elements, particularly silicon, readily form rings in which the atoms of these elements alternate with oxygen atoms. Considering this fact, many silicates are, strictly speaking, heterocyclic compounds, but their chemistry is always considered with that of other inorganic compounds, which they closely resemble.

Boron. Although boron heterocyclic chemistry is not yet extensively developed, it has a large potential. A boron and a nitrogen atom together contain the same number of electrons as two carbon atoms. Not surprisingly, it has been found that a boron-nitrogen unit can replace a carbon-carbon unit in benzenoid compounds to give stable hetero-aromatics; a good example is 9-aza-10-boraphenanthrene; its structure is as follows:



Borazine, or borazole, which has been referred to as inorganic benzene, has the following structure:



(A.R.K.)

Dyestuffs and pigments

Dyestuffs and pigments are intensely coloured substances used for imparting colour to other materials. Technically, dyestuffs are soluble in the medium in which they are applied, whereas pigments are insoluble.

Colour in materials originates either from organic or inorganic substances present in the material, or from a purely physical effect, such as that observed in oil films on water. Organic colouring matters are compounds of the element carbon, including animal or vegetable colouring matters, as well as synthetic materials, like the coal-tar dyes. Colour in inorganic substances is commonly observed in rocks, Organic and inorganic colouring matters

minerals, ceramics, fired enamels, coloured glass, precious stones, and certain pigments. Colours produced by physical effects result from dispersion, refraction, or scattering of light. Examples of such physically produced colours are the rainbow; the blue of the sky; the iridescence of opal; and the blue, green, and violet colorations of birds, butterflies, fish, and insects. In some living organisms organic and physical coloration occur together.

There is scarcely any manufactured product that does not at some stage incorporate or require the use of products of the dyestuff and pigment industry. About 7,000 different dyestuffs are currently made and sold under some 35,000 different trade names, and about 200 new ones are introduced every year.

Reasons for the existence of the great number of commercial dyestuffs include the variety of fibres and other materials requiring coloration and the fact that colour in textiles must withstand a variety of stresses, depending upon the methods of manufacture and use.

Use of pigments

All dyestuffs and many pigments are complex organic compounds, mainly prepared synthetically from chemical products of the coal-tar and petrochemical industries. The syntheses consist typically of sequences of carefully regulated procedures carried out under strict scientific control, and they are the result of extensive research. Dyes are ordinarily dissolved in water for application to textiles, paper, leather, and many other substances. Pigments are used as finely ground solid particles rather than as solutions. They are employed, for example, in paints, printing inks, and plastics. Some pigments are entirely inorganic in origin; *e.g.,* iron oxide. These are cheap, but rather dull in hue. The brighter pigments are organic compounds, and in fact may simply be dyestuffs insoluble in the medium. Many products are thus used in both capacities; *i.e.,* in soluble form for dyeing textiles, paper, and other materials and in insoluble form for colouring such substances as paints and inks.

All organic coloured substances, whether natural animal and vegetable materials or synthetic dyestuffs, rely for their colour on certain aspects of their chemical structures. Organic dyestuffs and pigments, with which this section largely deals, are classified as colorants.

HISTORY

Development of natural dyestuffs. The Bible tells us that Moses was instructed to accept gifts of "blue, and purple, and scarlet and fine linen and goats' hair." These names of colours most probably referred to materials dyed with dyes known as indigo, Tyrian purple, and kermes. Indigo was extracted from plants of the *Indigofera* genus, Tyrian purple from mollusks of the genera *Murex* and *Purpura,* and kermes from a dried insect, *Kermes ilicis.* The Bible, therefore, illustrates the antiquity of the craft of dyeing and the variety of natural products used in ancient times as sources of dyestuffs. Dyed fabrics discovered in Egyptian tombs show that dyeing was practiced at least as early as the 25th century BC. It is believed that the craft originated in India (the name indigo is derived from *indikos,* the Greek word for Indian) and spread westward to Persia, Phoenicia, and Egypt.

The method of producing a variety of hues by mixing red, blue, and yellow dyestuffs was known in ancient times. Fabrics found in caves in the Dead Sea area and dating from AD 135 were found to have been dyed with various mixtures of safflower yellow on alum mordant (fixative), kermes on alum, and indigo blue.

Until the 19th century all dyestuffs were natural products, obtained mainly from vegetable sources. Many different plants were used. The craft of dyeing demanded a high degree of skill, and details of its recipes were largely secret. Some of the most important natural dyestuffs that were in use until the advent of synthetic products are shown in Table 41.

Table 41: Sources of Some Important Natural Dyestuffs

Yellow	
Persian berries*	the fruit of a *Rhamnus* species
Weld*	the leaves, seeds, and stem of the plant *Reseda luteola*
Fustic*	the wood of *Morus* or *Maclura tinctoria* (Central or South America)
Quercitron bark*	from *Quercus nigra* or *tinctoria* (U.S.)
Brown	
Catechu or cutch*	acacia, etc., wood (Far East)
Reds	
Kermes	a dried insect, *Kermes ilicis* (Mediterranean region)
Lac dye	the shellac-producing insect *Coccus lacca* (Far East)
Cochineal*	the dried female of the insect *Coccus cacti* (Mexico, etc.)
Archil and cudbear	prepared by fermentation of various lichens, *e.g., Roccella tinctoria*
Madder (Turkey red)*	the root of *Rubia tinctorum* (Asia Minor)
Safflower	the dried flower head of the Dyer's Thistle (*Carthamus tinctorius*)
Blue	
Indigo	prepared from the leaves of various *Indigofera* plants, also the *Isatis tinctoria* or woad plant
Violet	
Tyrian purple	prepared from various mollusks; *e.g., Murex brandaris*
Black	
Logwood*	the wood of the West Indian tree *Haematoxylon campechianum*†

*Used with mordants. †Before the discovery of America, blacks were prepared from tannins (*e.g.,* from oak galls or sumac) and salts of iron.

With few exceptions these natural dyestuffs have no affinity for cellulose, and thus they could be applied to cotton only with the aid of an auxiliary inorganic compound or mordant (Lat. *mordere,* "to bite"), which precipitated the colouring matter in a less soluble form in the fibre. Mordants were also used on wool and silk, both to improve fastness and to obtain a wide variety of hues, different mordants yielding different hues with the same dye. The mordants in common use in ancient times were alum (potassium aluminum sulfate) and salts of iron, copper, or tin. Salts of chromium came into use about 1850. Eventually, on account of the superiority in fastness of the dyeings they produce, chromium mordants almost entirely displaced all other metal salts. Chromium mordants are still widely used for dyeing wool and to a lesser extent for silk and nylon, but are no longer of importance for cellulose fibres.

Ancient use of mordants

Following the introduction of synthetic dyes in the 19th century, natural dyestuffs have steadily declined in importance. Now only one, logwood, employed to dye nylon black, is used in any significant quantity.

Development of the chemistry of dyestuffs and dyeing. "The Liquors that Dyers imploy to tinge," wrote Robert Boyle, an English physicist, in 1664 in the first book dealing with the science of coloration, "are qualified to do so by multitudes of little Corpuscles of Colour . . . insinuating themselves into, and filling all the Pores of the Body to be Dyed, ..." Even today this remains a good description of the chemistry of dyeing.

As early as the mid-17th century, therefore, leading scientists were concerned with the processes of dyeing, and one of the first actions of the Royal Society after its foundation was to assist dyers by publication of a paper, "An Apparatus to the History of the Common Practices of Dyeing," read to them by Sir William Petty in 1662, describing the methods of dyeing then in use.

Petty, in his paper, classified dyestuffs into the fundamental colours, red, yellow, and "blew," and discussed the use of alum as a mordant, suggesting that it first is taken up by the fibre, where it then becomes combined with the dye. Thus, the dye is fixed in the fibre. This is also the modern view.

Early chemical interest in dyeing

From that period onward the craft of dyeing was aided by the discoveries of chemists and, especially in the period 1670–1830, by a series of French chemists, whose interest appears to have stemmed from the action of Louis XIV's comptroller general of France, who, in order to establish high standards in the wool textile industry, laid down regulations controlling dyeing methods. Distinction was made at that time between *bon teint* and *petit teint,* or fast and nonfast colours; *i.e.,* dyeings that were fast or fugitive, respectively, to light and washing. When in 1729 the regulations were redrafted, the first system of controlled testing of fastness of dyed textiles was introduced.

During the early part of the 19th century, dyeing continued to attract some scientific notice. Even greater interest was created by the advent of synthetic dyestuffs. William Henry Perkin's discovery (1856) of mauve, the first commercial synthetic dyestuff (see below), and the subsequent development of a great variety of dyestuffs of known chemical constitution initiated the modern expansion of the subject into a distinct branch of chemistry. This growth has been particularly noteworthy since World War I. In addition to the availability of a continually growing number of dyestuffs, the reasons for this development include improved instrumentation, increased knowledge of the structure of fibres, and the application of classical chemical principles to the dyeing process.

The introduction of synthetic dyestuffs challenged organic chemists with the problem of determining the molecular structure of these complex materials and opened the way to the development of theories of the causes of colour in organic compounds in general. The idea of valence (fixed numbers of bonds for atoms of different kinds), and in particular the quadrivalence of carbon, had already been formulated when the new dyestuffs began to appear. Shortly afterward the ring structure of the benzene molecule and the three-dimensional nature of organic molecules in general were suggested. These advances greatly assisted in the understanding of the molecular structures of organic dyestuffs.

Chromophores and auxochromes

One of the most important contributions to the understanding of the relationship between colour and structure was the so-called "chromophore" theory proposed in 1876 by a German chemist, Otto N. Witt. In every dye molecule, Witt identified a chromophoric ("colour-bearing") group of atoms together with one or more "auxochromes"; *i.e.,* associated groups whose function was to intensify the colour. In 1888 an English chemist, Henry Edward Armstrong, showed that many chromophores could be depicted as quinones (oxidized structures derived from the benzene ring). These theories are substantially those held today, although they have been broadened by recognition that the function of the chromophore is to produce a strong absorption of radiation, either in the ultraviolet or in the visible region of the spectrum, and that of the auxochrome is to shift the absorption to give more intense coloration (see below *Dependence of properties upon molecular structure*).

The development of the quantum theory in the 20th century also brought greater insight into the mode of interaction between light and organic molecules. In current terminology, the absorption of visible radiation by a dye raises the electronic energy of the molecule to a so-called "excited state." The energy must then be dissipated either as heat, as phosphorescence or fluorescence, or in a chemical reaction with the surroundings, in which case the dye decomposes and loses its original colour.

Development of synthetic dyestuffs. In 1856 William Henry Perkin, a chemistry student in London, discovered a purple colouring matter that had dyeing properties in a product he obtained by chemical treatment of aniline, a material from coal tar. This chance discovery, made in a simple laboratory Perkin had fitted out at his home, laid the foundation of the manufacture of synthetic dyestuffs and pigments, and indeed of the entire world-wide synthetic organic chemical industry.

The discovery of mauve

Perkin patented his dye and, with foresight and courage, in 1857, established a factory to manufacture what he at at first called Aniline Purple, or Tyrian Purple, and later Mauve, a French word for the mallow, a plant with a purplish flower. Perkin, moreover, developed new methods of applying the dyestuff and visited dyers to show them how they should be used.

Mauve was an immediate success, and the general method of its preparation, the oxidation of aniline, was varied and elaborated by other investigators to produce many new dyestuffs, first the crimson Fuchsine or magenta, and later, blues, violets, and green. These were the first basic or cationic (positively charged) dyestuffs, a class that later became overshadowed in importance by others, though in recent years interest in it has revived. Because of their origin, these earliest synthetic dyestuffs were called aniline dyes, a term still used. Unfortunately, their somewhat fugitive nature caused all synthetic dyestuffs to be considered inferior to the natural products, though this is certainly not the case.

In 1868 a team of German chemists proved that alizarin, the colouring principle of madder root, is a derivative of the chemical compound anthraquinone. (Figure 10 shows the colours yellow to purple obtained with pigments manufactured by modifying the molecular structures of anthraquinone compounds.) Their synthesis of alizarin from anthraquinone was the first preparation of a natural vegetable dyestuff by purely chemical means. Upon the introduction of synthetic alizarin, the use of the natural madder root died out. But, at the same time, new and related products were introduced. The technique of sulfonation (that is, the introduction of sulfonic acid groups), developed earlier, was applied from 1893 onward to the development of a new class of valuable bright, fast dyestuffs for wool, the sulfonated anthraquinone derivatives. This class is one of the most important for wool, and the unsulfonated counterparts are used to dye modern man-made fibres.

From *Journal of the Oil and Colour Chemists Association* (January 1963)

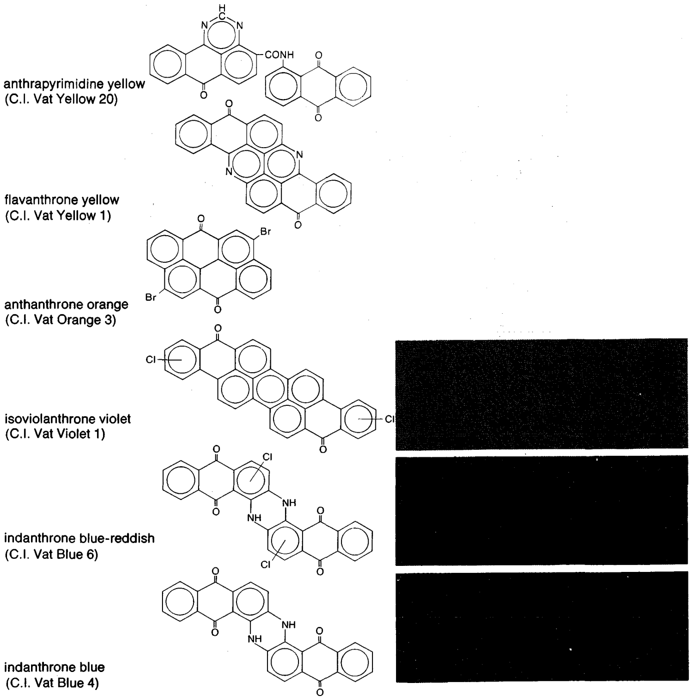


Figure 10: *Colours obtained from various anthraquinone pigments.*
By modifying the benzene rings of the anthraquinone group, a range from yellow to purple can be produced. A great many other derivatives of anthraquinone are used for industrial purposes.

The azo dyestuffs

Meanwhile, an entirely new type of colouring matter, the azo dyes, which now comprise the largest group of dyestuffs, was being developed. Johann Peter Griess, a young German, then working in the laboratory of an English brewery, discovered the diazonium compounds in 1858. These are very reactive substances, formed from the reaction of aromatic amines (nitrogen-containing organic compounds) with nitrous acid. Diazonium salts readily combine with aromatic amines or phenols to give deeply coloured substances containing the azo group (two nitrogen atoms joined by a double bond). The discovery was not, however, fully exploited until the 1870s, when the full tide of development of the azo dyestuffs set in, stimulated by the discovery that the addition of sulfonic acid groups gives highly water-soluble materials with excellent affinity for wool. By treating naphthalene derivatives with sulfuric acid, various sulfonated aminonaphthalenes and hydroxynaphthalenes were made, from which azo dyestuffs could be prepared in a range of shades—from orange to black. And by use of derivatives of pyrazolone instead of naphthalene, yellow azo dyestuffs also were prepared. In 1884 Congo red was produced; this is a bisazo dyestuff; *i.e.,* one containing two azo groups in its molecules. Congo red was the forerunner of a long series of successful dyestuffs, still of importance, named "direct cotton" or "direct" dyestuffs, which can dye cotton without a mordant.

Vat dyestuffs

Indigo for a time was the sole example of a "vat" dyestuff; *i.e.,* one applied from a "vat" containing alkali and a reducing agent in which the insoluble dyestuff was temporarily solubilized during dyeing. In 1901 Indanthrone blue, the first of the modern type of vat dyestuff, based on anthraquinone, was introduced; and this class, including dyestuffs of the very greatest fastness, has become of great importance.

Four other important new classes of dyestuffs were introduced in the 20th century:

1. The azoic dyestuffs. As early as 1880, a substance called β-naphthol had been applied in alkaline solution to cotton and then coupled with a diazonium compound to produce an insoluble dyestuff in the cotton fibre. Little progress was made with this type of dyeing, however, until Naphthol AS (a more complex chemical compound derived from β-naphthol) was discovered in 1912 and used to replace β-naphthol. Later a whole series of such compounds—and new bases to be diazotized and coupled with them—appeared, giving bright, fast dyes, ranging in colour from yellow to black, but especially useful for oranges and reds.

2. The disperse or nonionic dyestuffs. These substances were discovered in 1923 and at first were used with the then new cellulose acetate fibre, but later were also used for nylon and polyester fibres.

3. The phthalocyanine dyestuffs and pigments. Discovered in 1907 and 1927 by European chemists who failed to realize their importance, phthalocyanine derivatives (a class of metal-containing organic compounds) were rediscovered by accident in Scotland in 1928. The first member of this class, a brilliant blue, was found to have a remarkable molecular structure, resembling those of chlorophyll and hemoglobin, natural colouring matters. It proved to be a pigment of outstanding properties. Chlorinated and brominated derivatives give bright green dyes that together with the parent compound are used in very large quantities mainly as pigments; modified products are used for dyeing. Although no other useful shades have been obtained from phthalocyanine derivatives, quinacridone (a red compound discovered in 1955) is capable of preparation in red or violet forms as a pigment of fastness comparable to phthalocyanine.

The first reactive dyestuffs

4. The reactive dyestuffs for cellulose. First introduced in 1956, these dyes represent an entirely new principle, in that the dyestuff becomes a part of the actual fibre molecule and, therefore, is highly resistant to washing. Unlike other fast dyestuffs for cellulose, many reactive dyestuffs have very bright shades. Later, reactive dyestuffs adapted for wool and nylon were introduced.

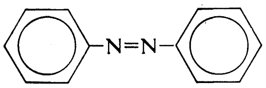
DEPENDENCE OF PROPERTIES UPON MOLECULAR STRUCTURE

To be useful, dyestuffs and pigments must have: (1) intense colour and (2) fastness; *i.e.,* resistance to the various chemical and mechanical stresses they meet in the manufacture or use of the finished coloured product. In addition, dyestuffs, but not pigments, must have: (3) solubility in the medium of application, which in almost all cases is water, and (4) ability to be adsorbed and retained by the fibre (substantivity) or to be chemically combined with it (reactivity). Pigments also have to meet unique requirements somewhat different from those of dyestuffs, including such physical and mechanical properties as the ability to flow in the media of application and insolubility in oils. These properties are favoured by making the molecule large, and insolubility is also promoted by particular dispositions of the substituent groups—that is, the peripheral units attached to the main body of the molecule.

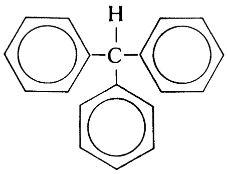
In all cases these properties depend in large part upon the molecular structures of the colorants themselves. The relationship between the properties of the dyestuffs and pigments and their molecular structure is dealt with in the following sections.

Colour. Organic colouring matters are complex unsaturated compounds—that is, compounds with multiple bonds between the atoms—and each such compound has a molecular structure containing one of the fundamental chromophores. Three of the most important chromophores in dyestuffs are called azobenzene, triphenylmethane, and anthraquinone. Their molecular structures are as follows:

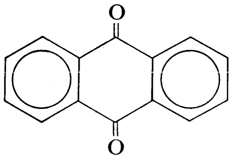
Structures of chromophores



azobenzene



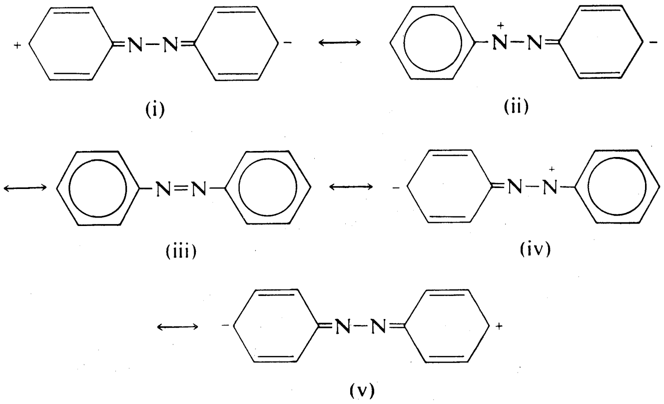
triphenylmethane



anthraquinone

in which the letters N, C, H, and O stand for atoms of nitrogen, carbon, hydrogen, and oxygen, respectively; the short single and double lines represent single and double bonds between them, and the hexagons with circles in them represent benzene rings, each composed of six carbon atoms. The chromophoric compounds themselves usually have very weak colours because the conjugated chain (the system of alternate single and double bonds, including the benzene ring) in the molecules is relatively short. If this chain is greatly extended, as in the natural carotene pigments, for example (see below), deep colour develops. Such extended chains, however, are not conveniently introduced into synthetic dyestuffs, which instead rely upon the above-mentioned substituent groups called auxochromes for colour intensification. Auxochromes generally are polar substituents—that is, atoms or groups favouring separation of electrical charges—including such substituents as chloro, nitro, hydroxy, methoxy, amino, methylamino, dimethylamino, and trifluoromethyl groups.

In the conjugated systems of alternate double and single bonds of the chromophores, some of the electrons, called pi electrons, are able to move through the molecule. It is possible to write various electronic structures of the molecule; *i.e.,* the so-called resonance forms. None of these structures describes the molecule as it really exists, but the molecule may be considered as a hybrid to which the imaginary structures contribute. Thus forms i–v below represent some of the forms contributing to the hybrid structure of azobenzene. Of these, iii is the most stable, because no energy is required to separate charges (as in the other forms).

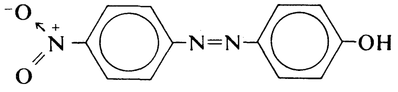


(i) (ii) (iii) (iv) (v)

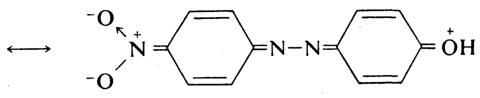
In this representation, double-headed arrows are used between resonance forms of a single hybrid structure.

Influence of auxochromes

The function of the auxochromic groups is to increase the stability of the alternative resonance forms. They do so because they can retain electrical charges more readily than carbon atoms can. For example, when two auxochromic groups are attached to an azobenzene molecule, the resulting structure may consist of new hybrid forms, as in the example below:



(vi)



(vii)

In this instance the alternative electronic configuration vii is more stable than i, ii, iv, or v above, because the charges are now held on oxygen and nitrogen atoms, which can retain them more readily than carbon. The result is that this compound has a more intense colour than azobenzene does.

With the increase in stability of the contributing electronic structures of a molecule, its electrons may be considered to move more readily along the chromophore. Thus its natural frequency of vibration is decreased. A simple analogy can be drawn with a violin string: the longer the string, the lower is the frequency and the longer is the wavelength of the note it emits when plucked. In general, the wavelength increases with the length of the oscillator. This applies to the absorption as well as the emission of energy, whether it be sound energy or light energy, because any oscillator absorbs energy most readily at the wavelength of its natural frequency of vibration.

The chromophores described above absorb most energy at short wavelengths—that is, in the ultraviolet region of the spectrum; and consequently they appear colourless or have only a faint yellow colour. When an auxochrome is present the wavelength of absorption increases and moves into the visible region, thus causing colour to appear. For example, anthraquinone is almost colourless, but 1-methylaminoanthraquinone has an intense red colour. The resulting hue is said to be "deeper."

Table 42: Effect of Wavelength of Absorption on Colour Observed

region of maximum absorption*	colour seen†
Ultraviolet	none
Violet	yellow
Blue	orange
Green	bluish-red
Yellow	violet
Orange	blue
Red	blue-green

*Listed in order of increasing wavelength. †Listed in order of increasing depth of hue.

Light absorption and colour

Table 42 shows the changes that occur in the colour of a given chromophoric system with the progress of its main absorption band across the spectrum from short to long wavelengths. Such a succession of changes can often be produced by substitution of the chromophore with a succession of selected auxochromes, one or more at a time, if these auxochromes have increasing effectiveness in enhancing the mobility of the electrons of the chromophoric system. In the case of azo dyestuffs, for example, the hue can be deepened by substitution in either of the aromatic nuclei attached to the azo group, and if both are substituted, the effect is further enhanced.

The intensity of the colour of dyestuffs is among the highest found in any type of substance. The degree of this intensity, known as the molar extinction coefficient, is measured at the wavelength of maximum absorption of light. The molar extinction coefficient for dyestuffs is about 10^4. In practice, this means that a 1 gram percent solution of a dyestuff only 1/100th of a millimetre deep reduces the intensity of the most strongly absorbed light to about one-half of the original value. There is another way to visualize the colour intensity of dyestuffs; it requires from about 10 to 100 single layers of dyestuff molecules, placed one on top of another, to produce a visible colour; and, allowing for the minimum area the substance must have in order to be seen by the naked eye under the best conditions, a total of about 10,000 molecules, or about 10^{-18} gram, must be concentrated together before the colour becomes visible.

Fastness to light and to washing

Fastness. Ability to withstand washing without changing colour, "wash fastness," and ability to withstand exposure to light, "light fastness," are two of the properties of most importance to the user of coloured fabrics. Dyestuffs that are chemically bonded to the fibre—*i.e.,* reactive dyestuffs—or those that are present as water insoluble particles of low solubility in soap solutions, such as vat dyestuffs, have the highest wash fastness. Water-soluble dyestuffs often have lower wash fastness, but the resistance to removal by soap varies greatly from one dyestuff to another, fastness generally being aided by high molecular weight of the dyestuff molecule and a minimum number of solubilizing groups.

All organic colouring matters fade when exposed to light; hardly any inorganic colours, and no physically produced colours, do. Light fading is the most complex of the reactions that dyestuffs undergo during use, and a great deal of research has been devoted to discovering its causes, which are not yet fully understood.

The light fastness of any dyed material depends not only on the nature of the dyestuff itself, but also on many other factors, including the method of application, the depth of shade, the type of fibre and its moisture content, the relative humidity and oxygen content of the air, and the nature of the illumination.

Solubility. Because normal dyeing takes place from aqueous solutions, the dyestuff must contain substituent groups conferring solubility in water. Table 43 includes the most important solubilizing groups used in dyestuff molecules.

Solubility in water may be needed only temporarily during the actual dyeing operation, the dye later being treated so that it becomes water-insoluble on the fibre. Such temporary solubility may be obtained with an insoluble, nonionic dyestuff molecule containing quinone groups, for example, by chemical reduction (addition of electrons) in the presence of alkali to produce a salt of the corresponding hydroquinone; the original quinone is then regenerated on the fibre after dyeing by oxidation. This

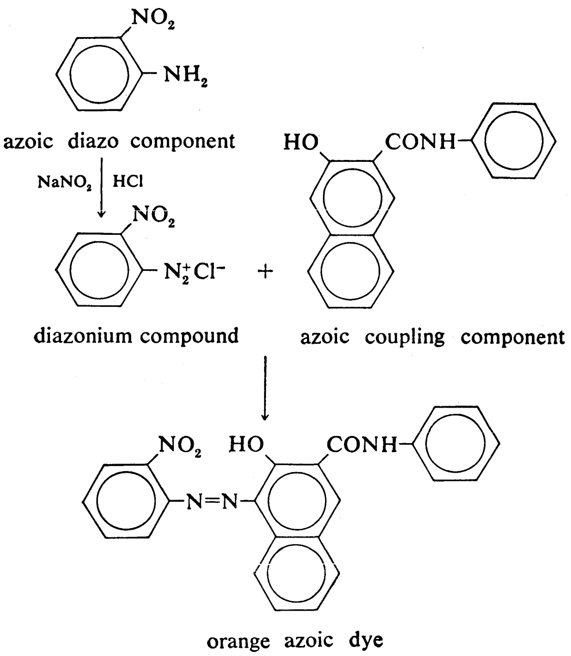
Table 43: Solubilizing Groups Used with Various Classes of Dyestuffs

name	structure*	type of dyestuff
Permanent		
Sodium sulfonate	$-SO_3Na$	direct cotton, acid wool, chrome mordant; 1:1 dye–metal complex for wool
Amine hydrochloride	$-\overset{+}{N}H_3Cl^-, -\overset{+}{N}R_3Cl^-$	basic, for cellulose, wool, silk, and acrylic fibres
Hydroxy, amino, and sulfamido groups	$-OH, -NH_2, -SO_2NH_2$	disperse, for cellulose acetate, nylon, polyester fibres; 2:1 dye–metal complexes for wool and nylon
Temporary		
Sodium phenolate	$-O^-Na^+$	certain classes of dyestuffs for cellulose; *i.e.,* naphthols for subsequent azo coupling on the fibre; and vat dyestuffs
Isothiouronium groups	$\left.-CH_2SC\begin{matrix}\diagup NR_2\\ \overset{+}{\diagdown} NR_2\end{matrix}\right\}Cl^-$	phthalocyanine dyestuffs for cellulose

*R = an alkyl or aryl group.

reduction-oxidation procedure is the basis of the vat dyeing process. Usually sodium dithionite (also called sodium hydrosulfite, formula $Na_2S_2O_4$) is the reducing agent used, and sodium hydroxide is the alkali, with the result that the sodium salt of the reduced form of the dye, known as the leuco compound, is formed. The entire process of alkaline reduction is known as vatting. The leuco compound is generally unstable in air, being rapidly oxidized back to the original dye.

In the method of dyeing cellulose fibres known as azoic coupling, a single soluble component, usually a naphthol, is applied to the fibre from solution in sodium hydroxide; this component is then converted into a water-insoluble azo dyestuff on the fibre by coupling with a soluble diazotized base. The procedure is illustrated in the following reaction sequence:



The so-called disperse dyestuffs used to colour cellulose acetates, nylon, and polyester fibres are employed as dispersions—that is, as fine suspensions of the solid in liquid—rather than as true solutions. These substances, however, are slightly soluble in water due to the presence of several nonionic water-attracting substituent groups on their molecules, and dyeing probably takes place from the very dilute solutions they produce.

There is considerable interest in processes for dyeing certain man-made fibres with disperse dyestuffs from solutions in organic solvents instead of water. Another process also being considered is the use of vaporized dyestuffs, at high temperature (above 200° C [392° F]).

Porosity and surface area

Attachment. Many solid materials adsorb dyestuffs from their solutions, but fibres do so particularly well because of their porosity and their ability to exert chemical forces upon the dyestuff molecules. There is an immense number of submicroscopic pores in a fibre, mainly directed parallel to the length of the fibre; there are, in fact, about 10 million in the cross section of a normal textile fibre. The total surface of the walls of these pores is extremely high, and in natural fibres, such as cotton or wool, the pore surface amounts to no less than about five acres per pound. This value is about one thousand times as great as the external surface of the fibres.

Since 1,000 to 10,000 dyestuff molecules placed one above another are needed to produce a deep coloration, a single layer of dyestuff molecules adsorbed on the walls of all the pores of a fibre would be more than enough to produce a satisfactory depth of shade. Actually, a large proportion of the pores are too small to allow a dyestuff molecule to enter, but, even so, enough dye is adsorbed to produce satisfactory depth of shade. For this action to occur, however, forces on the molecular scale must operate between the fibre molecules exposed in the pore surfaces, and the dyestuff molecules in the contiguous solution. The strongest of these forces are the forces of true chemical bonding by which the so-called reactive dyestuffs are fixed. Other types of dyestuff are attracted by a variety of weaker forces that operate between molecules. As already mentioned, some types of dyestuff are solubilized only during the dyeing operation; in such cases, after the subsequent insolubilization, the dyestuff particles remain held in the fibre by purely mechanical action.

With regard to the dyestuff molecule, attachments to the fibre resulting simply from intermolecular attraction are considered substantive, whereas those involving chemical bonding are considered reactive.

Substantivity. The presence of one or more of certain specific groups in a dyestuff molecule determines its substantivity, or affinity, for any given type of fibre, and hence its dyeing method. These groups include the following:

1. Anionic or cationic groups. These (respectively) negatively- or positively-charged groups confer solubility on dyestuffs and also affinity for the appropriate fibres with ionic properties.
2. Polar groups. Although these substituents are electrically neutral they do contribute to charge separation within a molecule. This effect increases the affinity of nonionic (disperse) dyestuffs for man-made fibres and considerably influences the colour.
3. Groups that induce flatness (planarity) in the molecule as a whole. Substituents promoting planarity are essential in producing useful affinity in dyestuffs for cellulose, cellulose acetates, or polyesters.
4. Lengthy conjugated chains. If a dyestuff molecule is planar, its affinity for cellulose fibres increases regularly with the length of its chain of alternate single and double bonds. To have useful affinity it should have at least eight conjugative double bonds.
5. Phenolic groups. When situated in dyestuff molecules adjacent to certain other groups, phenolic groups confer the ability of combination with a metal mordant.
6. Quinone groups. In the absence of permanent ionic groups, quinones enable a dyestuff to be used for dyeing cellulose fibres by temporary solubilization.
7. Primary amino groups. Primary amino groups on the bases used for azoic dyestuffs can be diazotized and coupled with naphthols (or other materials) already adsorbed on the fibre.
8. Paraffinic chains. Saturated hydrocarbon (paraffinic) chains are used in a few members of several classes of

Table 44: Types of Reactive Groups in Dyestuffs

dyestuff. For example, when attached to an acidic molecule for dyeing wool, a paraffin chain of moderate length (containing four to 12 carbons) improves fastness to washing and other wet treatments. Also, when inserted between the polar group and aromatic nucleus of a disperse dyestuff molecule, a short (two- or three-carbon) chain improves the fastness to dry heat. And when inserted between a quaternary ammonium group and an aromatic nucleus, such a chain appears to improve the light fastness of cationic dyes applied to polyacrylonitrile fibres.

In an overall sense, a dye molecule that is either small in total volume, or slim in its cross section, makes rapid dyeing possible because of its ready accessibility to the pores of the fibres.

Formation of chemical bonds

Reactivity. The reactive dyestuffs rely for their retention on the fibre on a principle different from that which controls the dyeing of most other types of dyestuff; that is, they form a covalent (nonionic) chemical bond with the fibre molecules. Such bonds are formed by a reaction between a specific chemical substituent group in the dyestuff molecule with part of the molecule of the fibre.

The reactive groups associated with several classes of dyestuffs are shown in Table 44. Other groups also are employed, and new types of groups are introduced from time to time.

In summary, the molecule of any colouring matter can be viewed as a structure built up step by step, each step designed to give the molecule certain properties and enable it to fulfill certain functions. In Table 45 details of chemical structure that confer the above listed properties on the molecule are presented, and the molecular constitutions of some typical important colouring matters, chosen from nature and from industry, illustrate these principles.

TECHNOLOGY

In this section will be found limited aspects of the classification, manufacture, use, and testing of dyes (for a detailed account of the technology of dyeing, see the article INDUSTRIES, TEXTILE: *Dyeing*).

Classification. Dyestuffs and pigments are classified by chemical constitution, by method of application, by hue, or even by the name of the manufacturer. Generally, the commercial name of a particular colorant consists of: (1) a brand name denoting application class (each one specific to each manufacturer); (2) the name of the hue; (3) suffix letters (often German in origin)—*e.g.,* B, G, or R (blau, gelb, rot); (4) a strength indication—*e.g.,* 150 percent, 250, denoting brands with less diluent (usually salt) than the normal.

Colour Index references

In addition, there is a *Colour Index* which lists (and describes) all commercial dyestuffs by application class and by chemical constitution. For example, the dye Orange II has a *Colour Index* Part I reference as "C.I. Acid Orange 7" and a Part II reference as "C.I. 15510." In the first it is described as a dye for wool, silk, or nylon, used for garment dyeing and for colouring coir and sisal fibres. Also included are details of the grading for fastness to thirteen different agents such as washing, milling, chlorination, light, and so on. Further, the dye is shown as being marketed by about 60 different manufacturers under about 45 commercial names. The Part II reference gives the chemical constitution, method of manufacture, and colour reactions of the dye with common reagents, together with a number of literature references and the information that the dyestuff was discovered by one Z. Roussin in 1876. The manufacturing process for this dyestuff is outlined below.

Manufacture. The dyestuff industry uses hundreds of different chemical compounds to produce the thousands of different colorants it markets. These are manufactured by complex and often lengthy series of chemical reactions, utilizing a variety of techniques. The starting materials are relatively few, mainly the aromatic hydrocarbons, of which benzene, toluene, naphthalene, and anthracene are the most important.

Manufacture of intermediates

From these compounds many hundreds of other substances, known as intermediates, are manufactured. The intermediates usually are not dyestuffs, but from them, ultimately, the dyes are derived. In general, intermediates are formed by one or more of a variety of chemical operations, such as nitration, sulfonation, chlorination, acylation, and so on. Among the most important of the products thus formed are aniline, alkylaniline, acylaniline, chloroaniline, nitroaniline, alkoxyaniline; a large variety of sulfonated aminonaphthalenes and hydroxy-naphthalenes; and aminoanthraquinone and hydroxy-anthraquinone. Further details of the production of dyes are covered in the article INDUSTRIES, CHEMICAL PROCESS: *Dyes.*

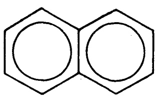
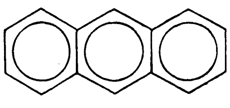
toluene



naphthalene



anthracene

Uses. Although the principal use of dyestuffs is in the dyeing of fibres and fabrics, dyestuffs and pigments are used in large quantities for many other purposes, including the printing of textiles and the colouring of many materials other than textiles, such as leather, paper, and plastics. Pigments are widely employed in paints, varnishes, printing inks, artists' colours, and writing and copying inks. Several colorants are used in foodstuffs, oils, and cosmetics. Dyestuffs also are important as histological stains and for measuring the surface area and porosity of industrial powders.

Special types of dyestuff (chiefly cyanine dyes) are used in making photographic emulsions and others in colour photography. Furs and human hair are dyed by processes involving the application of dyestuffs or related chemical compounds. For foodstuff colouring, specially purified dyestuffs, free from poisonous metals, are used. Only a few dyestuffs are permitted in foods in most countries; these have been rigorously screened, particularly for freedom from carcinogenic properties.

Plastics may be mass-coloured; *i.e.,* the plastic may be ground with a pigment before the final shaping operation, a process that gives an opaque product, or they may be surface-dyed after shaping, by immersion in a dye solution. The latter method does not produce opacity and is suitable for colouring rolls of transparent plastic film or small, transparent articles, such as toothbrush handles.

Standardization, testing, analysis, and identification. After manufacture, water-soluble dyestuffs can be separated from the solution in which they have been prepared by salting out—that is, made insoluble by the addition of salts—after which the dyestuffs are filtered off and dried. Insoluble dyestuffs, which must be easily suspended in water, are finely ground in water with a dispersing agent before drying.

Methods of standardization

Commercial dyestuff products must meet standards of shade, strength, wettability, and so on, so that successive deliveries of any particular material are the same. Even with the best control of manufacturing processes, however, the shade varies slightly from one manufactured batch to another, and the products in their final processing may have to be adjusted to the shade and strength of a standard by addition of little colouring matter of a different hue (but with similar properties) or of a diluent such as salt.

For normal dyeing operations on a technical or a laboratory scale, commercial dyestuffs are used without pretreatment, but for laboratory research purposes it is often necessary to use specially purified dyestuffs, and to check their purity by chemical analysis. Most water-soluble dyestuffs are not as readily purified as are most organic compounds because dyestuffs often are strongly ionic and therefore insoluble in organic solvents. They cannot, therefore, be recrystallized from such solvents. Recrystallization from water often is not satisfactory either because the dyestuff is not sufficiently soluble, or because it does not separate readily on cooling (or if it does, it may do so in a form difficult to remove by filtration). Moreover, most commercial dyes contain large quantities of diluent material, usually common salt, which is difficult to remove completely. For chemical research, therefore, the so-called batch dyestuffs, *i.e.,* dyes obtained directly from the manufacturing plant and unmixed with diluent, are preferable. To purify a water-soluble dyestuff for which a process has not been previously worked out, recrystallization usually is attempted, first from water alone and then, if this is not suitable, from a simple water-miscible solvent, such as acetone, ethanol, propanol, or butanol, or from mixtures of these with water. If all such methods fail, repeated salting out of the dyestuff from water, by additions of sodium acetate, is used, followed by filtration and washing of the precipitate with ethanol, which removes any residual sodium acetate. This procedure gives a product of high purity but in a rather low yield, because much of the dyestuff is lost in the filtrates and in the washings.

Dyestuffs and pigments can be analyzed by the normal methods of analysis used in organic chemistry; *i.e.,* by determination of the total content of the various elements present—carbon, hydrogen, oxygen, sulfur, and so on. With improvement in speed and accuracy, these methods, which now require very small amounts of the test sample, have tended to displace older procedures. They do not, however, detect traces of the coloured impurities, which are often present even after careful purification and which may or may not interfere with the use of the product. Detection of these is best made by the separation method known as chromatography, which is based upon adsorption of the material to be separated on a solid support.

Methods of analysis

Often it is necessary to identify dyes on samples of textile or other coloured material. This usually involves a systematic analysis in which the material is treated in succession with a variety of chemical reagents and solvents, the changes in colour produced or the amount of colour dissolved by the solvent being observed. Such schemes of analysis often are designed merely to identify the dyeing class to which the colouring matter belongs, and this may be all the information needed. Other schemes, however, enable a precise identification of many individual dyes.

(C.H.Gi.)

Alkaloids

Alkaloids, a specific class of chemical compounds found in plants and, occasionally, animals, are notable chiefly for their physiological activity; many have long histories as poisons, narcotics, hallucinogens, and medicinal agents. Generally, alkaloids are basic, or alkaline, substances—*i.e.,* they neutralize acids; their molecules contain chiefly atoms of carbon, hydrogen, and nitrogen, which is the source of their basicity.

Historical background. During the long period when the early art of healing involved magical or religious beliefs, the use of minerals, plants, and animal organs as medicine was not necessarily related to any active constituents they might contain. Not until alchemy evolved into chemistry and medicine became more scientific was it apparent that the medicinal virtues of plant and animal tissues had to depend upon specific compounds in the mixture of components contained therein. Chemists were challenged to separate the constituents and determine by experiment which activities could be attributed to them.

First isolation of an alkaloid

In this regard no drug known to the ancients offered modern research more of a challenge than opium. The first recorded isolation of a crystalline constituent from opium, now thought to have been the alkaloid called narcotine, took place in 1803. In the following year another chemist described what was probably morphine, and a few years later a German chemist purified morphine and recognized its nature as a base. Soon a number of similar substances were recognized and grouped into a new class of compounds known as vegetable alkalies; these later became known as alkaloids.

Progress in the study of the pharmacological properties of alkaloids was stimulated by their potent physiological effects that suggested worthwhile medicinal uses. The chemical study of them, however, was slower and depended upon the growth of organic chemistry, for not until simple organic bases (and acid–base reactions generally) were well understood could the intricate structures of the alkaloids be unravelled.

The first major step came with the study of coniine, an alkaloid from hemlock (a poison known to the ancient Greeks). It had been isolated as early as 1827 and recognized as a derivative of pyridine, an organic base obtained from coal tar. The synthesis of coniine was achieved in 1886—the first synthesis of an alkaloid.

General classification and nomenclature. It is difficult to categorize alkaloids in precise terms. In general it is agreed that an alkaloid must be a product of plant or animal metabolism and must contain at least one nitrogen atom that can be active as a base in acid–base reactions. There are exceptions to this, however—the substance called rutaecarpine, which contains three nitrogen atoms, none of which is basic, is nevertheless classified as an alkaloid because its reactions and the method by which it is synthesized in the plant (biosynthesis) are typical of alkaloids. At the same time, the nitrogenous bases known as purines, of which caffeine is a good example, though they used to be, are no longer treated in works on alkaloids. On the other hand, the substance triacanthine, which belongs to the purine family, is frequently classified as an alkaloid. In principle, alkaloids could be classified either by the biological systems in which they occur or by their chemical structures. In practice both methods are used. For example, it is common to speak of the opium alkaloids because they occur in the opium poppy (*Papaver somniferum*); but it is also common practice to speak of those alkaloids that contain a ring system called indole as the indole alkaloids. This dual classification system actually produces little confusion because there is a rough correlation between the chemical types of the alkaloids and their biological distribution (see below *Biological distribution*).

Basis of alkaloid names

Because most alkaloids were isolated from natural sources before their chemical structures had been determined, they generally bear coined names, which do not denote their chemical structures. Such names may reflect the names of the discoverer (*e.g.,* pelletierine, after the 19th-century French chemist Pierre-Joseph Pelletier), the botanical source (strychnine, isolated from *Strychnos* species), or the biological effect (emetine, an emetic). As a rule, alkaloid names end in -ine, a reference to their chemical classification as amines (see above). In certain cases, alkaloid names are derived in whole or in part from systematic nomenclature systems used in organic chemistry (see above *Organic chemical compounds*). These same systems are encountered in the names of compounds derived from the chemical breakdown, or degradation, products of the alkaloids and synthetic substances related to them. Most alkaloids have one or more of their nitrogen atoms as part of a ring of atoms, frequently called a cyclic system.

In this section alkaloids are grouped into several categories for discussion and, necessarily, many of them appear in each category. These categories are: physiological activity, general chemistry, distribution, classification by structure, and general biology.

GENERAL PHYSIOLOGICAL ACTIVITY

The physiological activity of alkaloids is of importance not only in medicine but also in agriculture and in forensic chemistry. Narcotics addiction and the use of alkaloids as hallucinogens are major social problems. In medicine, alkaloids are employed as narcotics, analgesics, antimalarials, and local anesthetics; as cardiac, uterine, and respiratory stimulants; and as materials that raise the blood pressure, cause the pupils to dilate, or bring about relaxation of the skeletal muscles.

Grouping by physiological effects. A comprehensive survey cannot be made here and, in the following discussion, only the most important of the alkaloids are mentioned.

Poisons. Many alkaloids are of medical importance because they are the cause of occasional poisoning of livestock or man. For example, the senecio alkaloids, and their close relatives isolated from *Crotalaria* and *Heliotropium* species, are only mildly toxic but, in repeated small doses, cause cirrhosis of the liver. The disease is common in livestock in areas where these plants grow, and it has been variously named in the different areas. Another example is the group of ergot alkaloids, produced by a fungus (ergot) that grows on cereal grains; it finds legitimate use in medicine, but the ingestion of cereals

Ergot alkaloids

containing ergot was the source of much serious illness (ergotism) until the cause was well understood. Not everything is known about the chelerythrine-type alkaloids and there has been a suggestion that the ingestion of even very small amounts can induce glaucoma. The alkaloids of the horsetails (*Equisetum*) have come under suspicion in instances of livestock poisoning.

Analgesics. The narcotic of major importance, both in legitimate medicine and in illicit drug traffic, is morphine. Although there are now certain synthetics that substitute for morphine in the relief of pain, this alkaloid is still the most suitable drug for that purpose. Were it not for its addictive properties and the fact that it is sometimes not tolerated well, morphine would be the analgesic and narcotic of choice. Codeine, the methyl ether derivative of morphine, is an excellent analgesic essentially devoid of addictive effects. Diacetylmorphine, best known as heroin, is more powerful as an analgesic but is a strongly addictive drug, which induces in the addict an intense euphoria not obtained with morphine.

Cardiac stimulants. The use of heart stimulants to restore the actions of a malfunctioning heart to normal does not necessarily remedy the causes that underlie the malfunction. The cinchona alkaloid quinidine is the cardiac stimulant used to correct arrhythmias of the auricle (one of the chambers of the heart), and cinchona and rauwolfia alkaloids are used for arrhythmias of the ventricle (the other chamber of the heart). There are no generally acceptable alkaloids for congestive heart failure, in which the pumping action of the heart is inadequate though its rhythm is normal. Generally, another type of material, the digitalis glycosides, is the drug of choice for this kind of heart disease.

Nicotine

Respiratory stimulants. Respiratory stimulants and depressants act on the body by several different mechanisms; owing to the complex nature of these effects, stimulation is often followed by depression, with the result that large doses of stimulants can lead to death by respiratory arrest. As typical respiratory stimulants, nicotine and cytisine show this effect, but they have been used clinically, nonetheless. The alkaloid lobeline is safer in this respect, because eventual arrest of respiration is not as likely, but some alkaloids closely related to lobeline are even more toxic than nicotine. Coniine, too, stimulates respiration, but depression and asphyxia soon follow. Coniine is the main alkaloid from poison hemlock (*Conium maculatum*) and was surely the major ingredient in the hemlock used to kill Socrates. It has been surmised that that poison also contained opium.

Many alkaloids influence respiration; virtually all of them, however, produce other, and often unwanted, effects. Atropine, for example, stimulates respiration in moderate doses, even when respiration has been depressed by morphine, but it also has a number of effects on the brain and dilates the pupils of the eyes.

Certain alkaloids find some use in medicine because they are capable of raising blood pressure. This action can take place in a variety of ways, such as by constriction of the blood vessels or stimulation of the heart or by both at once. Other effects, such as dilation of the pupils, inhibition of gastrointestinal peristalsis, and excitation of the intestines and the uterus, are common.

Ephedrine

Blood vessel constrictors. Ergonovine, one of the ergot alkaloids, finds extensive use in obstetrics to reduce uterine hemorrhage following childbirth, its action being primarily constriction of the blood vessels. Ephedrine also causes constriction of blood vessels and, because of this action, it is widely used to alleviate the discomfort of common colds, sinusitis, hay fever, and bronchial asthma. Certain synthetic agents have now partially replaced the drug for this use. The pupil-dilating action of ephedrine, unlike that of atropine, does not abolish the light reflexes and the accommodation reflexes of the eye. There are a number of other useful dilators and, of these, scopolamine is one of the more powerful. Cocaine, a potent local anesthetic, is also a dilator.

Local anesthetics. Many alkaloids possess local anesthetic characteristics, and some of them do not produce the undesirable effects of cocaine. Extensive experimental modifications of the molecular structure of cocaine have yielded a few compounds that are more effective and less toxic than the parent alkaloid as well as many that are less effective. Modern synthetic local anesthetics, cheaper and often superior to cocaine, have largely, but not entirely, displaced the alkaloid. Although they are not used extensively, the following alkaloids possess acceptable local anesthetic characteristics: derivatives of certain cinchona alkaloids, the erythrophleum alkaloids, an alkaloid from *Fritillaria sewerzowii,* and several derivatives of cotarnine.

Cinchona alkaloids

It is remarkable that only the cinchona alkaloids, especially quinine, have gained and retained prime importance in the treatment of malaria. Extensive modifications of the molecular structures of these alkaloids also have yielded no superior products. An apparent exception to the first generalization is febrifugine, an alkaloid first isolated from *Dichroa febrifuga,* which is a potent antimalarial, especially against bird and monkey infections. Its curative dose, however, is near its toxic dose, and it is not suitable for use in humans. A number of entirely synthetic compounds, however, allow a degree of malaria control that could not be attained with any of the alkaloids.

Muscle relaxants. Relaxation of muscles similar to that produced by the South American arrow poison, curare, is important in medicine, particularly surgery. Useful synthetics are available for this purpose, but the alkaloids of South American species of *Strychnos* and *Menispermum* are much used. These alkaloids, which are the active ingredients of the native curare, are quaternary salts of bisbenzylisoquinolines, the most active being the substances called toxiferine and tubocurarine. They are effective as muscle relaxants only when given subcutaneously or intravenously. On the other hand, dihydro-β-erythroidine, one of the most active tertiary bases from *Erythrina* species, acts as a muscle relaxant only when taken orally.

An important consideration in the therapeutic use of alkaloids is that the physiological actions are generally rather complicated; it is rare that an alkaloid exerts only one type of physiological response. As a result of the study of the relationships between the structural and physiological aspects of alkaloids, it has been possible to direct research into the syntheses of model compounds, which show amplification of one type of activity at the expense of another. It is thus possible in some cases to accentuate desirable effects and minimize unwanted or toxic ones.

Mescaline and LSD

Psychedelics. Many of the so-called psychedelic drugs are alkaloids or their derivatives. Those derived from cacti of the various *Anhalonium* species have long been known and are used in the rituals of some American Indian tribes. Mescaline, the chief of these, causes mainly visual hallucinations. More potent is psilocybin, an alkaloid found in *Psilocybe* species of fungi. Still more potent is LSD, the diethylamide of natural lysergic acid—an alkaloid from ergot—which produces a variety of effects. The dimethylamide of lysergic acid, which is found in some morning-glory (*Convolvulus*) species, is less active.

Morphine and derivatives

Fate of alkaloids in the body. When a toxic substance is presented to a body it may be dealt with in one of three ways: (1) it may be eliminated unchanged in the exhaled breath, the urine, or the feces; (2) it may be chemically altered to a less toxic substance; or (3) it may be conjugated—that is, combined with another substance—to give a product more readily eliminated or tolerated. As an example, morphine is excreted in all three ways: unchanged, chemically altered, and in conjugated form. The conjugate—of unknown nature, though possibly a combination with a sugar molecule—can be hydrolyzed (broken down) to morphine by heating with acid, and it can thus be assayed as morphine following such treatment. For reasons not yet understood, addicts excrete a larger proportion of the conjugate than do nonaddicts. When morphine labelled with carbon-14 in the methyl group attached to the nitrogen atom is given, a portion of the radioactivity appears in the carbon dioxide exhaled from the lungs.

The fate of heroin has not been studied as extensively as morphine, but it is known that there are enzymes in the body capable of removing either or both of the acetyl groups. Since heroin is a more potent narcotic than morphine, it has been assumed that its enzymatic conversion to morphine does not account for its activity. It is possible, nevertheless, that the acetylated substance (heroin) can achieve easier access to the site of its action, where it is then hydrolyzed to the active material.

Small amounts of ingested or injected cocaine are recoverable from urine, but the fate of most of it is not known. When *N,N*-dimethyltryptamine, a naturally occurring psychotomimetic (psychosis-mimicking) drug, is ingested, it is metabolized rapidly and excreted chiefly as indoleacetic acid. At the same time the urine is enriched with 5-hydroxyindoleacetic acid, which may be derived from oxidation of indoleacetic acid or from increased metabolism of serotonin, a substance in the brain that plays a role in the transmission of nerve impulses and may be involved in the action of psychotomimetic drugs.

BIOLOGICAL DISTRIBUTION

The distribution of alkaloids in the plant kingdom is largely confined to the flowering plants, though certain nonflowering forms also produce alkaloids; *Lycopodium,* or club moss, is particularly rich in alkaloids, and a fungus, *Rhizoctonia leguminicola,* produces the alkaloid slaframine. The scent glands of the North American beaver (*Castor canadensis*) contain the alkaloid castoramine, which is structurally related to the nuphar alkaloids found in the yellow pond lilies (*Nuphar* species). The skin glands of a salamander, *Salamandra maculosa,* contain a group of alkaloids that are related to steroids. It is likely that these alkaloids are generated by the animal from steroids in its diet.

Plant families rich in alkaloids

Plants of a number of families are particularly rich in alkaloids. All plants of the poppy family (Papaveraceae) are thought to contain them. In the buttercup family (Ranunculaceae) alkaloids occur in a few genera. Other families containing alkaloids are barberry (Berberidaceae), amaryllis (Amaryllidaceae), pea (Fabaceae), dogbane (Apocynaceae), moonseed (Menispermaceae), custard-apple (Annonaceae), and nightshade (Solanaceae).

The types of alkaloids produced are often characteristic of a particular family or genus. All alkaloids so far obtained from the poppy and custard-apple families are isoquinoline alkaloids (see *Classes of Alkaloids* below for structures and descriptions of this and other alkaloid classes). Although the alkaloids found in plants of the buttercup family are of several types, those from the monkshoods (*Aconitum*) and larkspurs (*Delphinium*) are all of only one type, the aconite alkaloids, and those from the meadow rues (*Thalictrum*) are mostly of another type, the bisbenzylisoquinolines. The cinchonas (*Cinchona*) in the madder family (Rubiaceae) yield mainly the quinine type of alkaloid, whereas the poison nuts (*Strychnos*) in the related Logania family (Loganiaceae) give rise to the highly complex strychnine type. Almost without exception, the alkaloids from the dogbane family are indole derivatives.

Role of alkaloids in plants

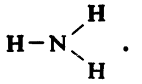
The role that alkaloids play in the life of plants is still largely a matter for speculation. Belladona (*Atropa*) and tobacco (*Nicotiana*) plants produce large quantities of alkaloids, whereas related tomato (*Lycopersicon*) plants do not. When grafts of tomato are grown on stocks of belladona or tobacco, they are almost devoid of alkaloids, whereas the reverse grafts generate fair quantities of them. In the light of these results, the alkaloids would seem to play no essential role in the metabolism of the plants that produce them. That they play some role is suggested by the fact that in many plants prior to seed formation there is a high concentration of alkaloids, which is almost entirely depleted when the seed is ripe. An example of this behaviour is found in the opium poppy (*Papaver somniferum*). In some plants, such as the larkspurs (*Delphinium*), both the seeds and the growing plant are rich in alkaloids. In others (for example, the sweet shrubs [*Calycanthus*]) the seeds are particularly rich, whereas the growing plants contain only traces of alkaloids.

It is thought that the alkaloid content of some plants may protect them from depredation by insects, but there are few, if any plants—even those rich in alkaloids—that are avoided by all insects. *Solanum demissum* seems to be avoided by the larvae of the potato beetle, and several relatively unsuccessful attempts have been made to introduce the genes that control this immunity into other *Solanum* species, especially the potato. Several species of alkaloid-containing groundsel (*Senecio vulgaris* and *S. jacobaea*) are the preferred and possibly the only food for the larvae of the cinnabar moth (*Callimorpha jacobaea*). These larvae have an even higher concentration of alkaloids than the plants on which they have fed; they are not eaten by predators that prey on larvae of related species, presumably because of the alkaloid content.

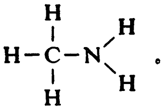
GENERAL CHEMISTRY

Structures of nitrogen compounds

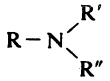
Molecular structure. The structures of the various alkaloid molecules can be understood best by comparison with simpler compounds of nitrogen. In its compounds the nitrogen atom generally forms chemical bonds with three other atoms. In chemical terms, this is to say that nitrogen has a valence of three. For example, the valence bonds of nitrogen in the simple substance ammonia are completed by hydrogen atoms (symbol H, valence one). In representations of molecular structure these bonds are symbolized by lines. Thus, ammonia is denoted by



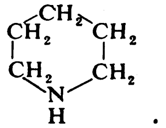
Carbon atoms (symbol C, valence four) also can be joined to the nitrogen atom, giving molecules like that of methylamine, the formula of which is CH_3NH_2:



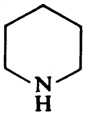
Other combinations of carbon and hydrogen atoms in hydrocarbon chains can be joined to the nitrogen atom, giving the large family of compounds known as amines and represented by the general formula



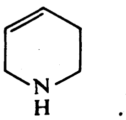
in which R, R′, and R″ are various hydrocarbon groups that may be considered as replacing the hydrogen atoms of ammonia, NH_3; replacement of one, two, or all three of the hydrogen atoms gives primary, secondary, or tertiary amines, respectively. In some amines the hydrocarbon chains are so joined as to form complete rings of atoms. A simple example of this is the substance piperidine, which has the structure



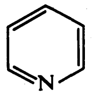
Structures of this type usually are represented diagrammatically by regular polygons in which the corners are understood to signify carbon atoms bearing as many hydrogen atoms as necessary to complete their valences. In this convention, piperidine is represented as



In some hydrocarbons, or hydrocarbon derivatives such as the amines, hydrogen atoms are missing, and the chains or rings are said to be unsaturated or to contain double bonds. Double bonds are indicated in structural diagrams by double lines, as in the formula

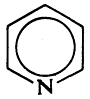


Some unsaturated, cyclic compounds contain series of alternating double and single bonds, which give the molecules special properties. An example is pyridine



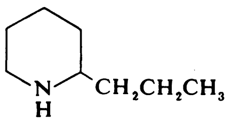
.

Because these compounds, which are called aromatic, do not behave like typical unsaturated compounds, their structures are frequently drawn with circles within the polygons rather than double lines. In this convention pyridine is written



.

The molecules of the various alkaloids are of a great many different types, which are variations and elaborations of the simple structures discussed above. The alkaloid coniine, for example, is closely related to piperidine (and, therefore, also to pyridine). Its structure is



.

Rings in alkaloid molecules

As indicated, most alkaloids contain at least one basic nitrogen atom—that is, a nitrogen atom in an amine-type structure. Generally, also, alkaloids have this or another nitrogen atom in some type of ring system, either aromatic or nonaromatic (aliphatic). But this is not an absolute requirement, for in the molecules of some alkaloids the nitrogen atom is joined to a simple aliphatic hydrocarbon chain. Besides the obligatory carbon, hydrogen, and nitrogen atoms, many alkaloid molecules also contain oxygen atoms, and a small number contain sulfur or chlorine atoms. (See also the section *Organic nitrogen compounds* above.)

Isolation, purification, and analysis. Like other bases, most alkaloids yield salts that are soluble in water when treated with acids, and the separation of these alkaloids from neutral and insoluble plant constituents by salt formation is, therefore, relatively straightforward.

Isolation. Special methods have been developed for isolating commercially useful alkaloids such as morphine. In the main, however, plant and animal tissue is processed in one of three ways to obtain aqueous solutions of the alkaloids. (1) The source material, either fresh or dried, is treated (by a method called extraction that involves the dissolving with reagents of only some components of a mixture) directly with a dilute aqueous solution of an acid that reacts with the alkaloid to produce a soluble alkaloid salt. (2) The material is extracted with an alcoholic solvent, with or without the addition of an acid, after which the solvent is removed by evaporation and the residue—consisting of fats, wax, resins, and other material, as well as the alkaloids—is stirred in contact with a dilute aqueous acid solution that forms soluble alkaloid salts. (3) The material is rendered basic by the addition of aqueous ammonia or sodium carbonate; the mixture is extracted with a water-immiscible solvent, such as ether, and finally, this solution is extracted with dilute aqueous acid. The alkaloids are recovered from the aqueous acid solution prepared by one of the above methods by making the solution alkaline and then extracting it with an immiscible solvent. The last process does not yield alkaloids in which the nitrogen is fixed in a saltlike form; such alkaloids must be precipitated from aqueous solution as complex salts.

Since very few plants elaborate only one alkaloid there still remains the problem of separating and purifying the different alkaloids from the mixture of alkaloids obtained by extraction. The number of constituents, and some indication of their relative abundances, can be learned from analyzing the crude mixture using a system of analysis called chromatography. This is a method of separation that takes advantage of the different degrees of adsorption of the substances to be separated on a solid material, such as alumina or silica. When it comes to actual separation of the alkaloids, chromatography again may be used, or attempts may be made to obtain the alkaloids from solution in crystalline form. The list of solvents from which alkaloids can be crystallized is an extensive one. (The following solvents, in order of increasingly favourable solvent action on alkaloids, are commonly used: hexane, ether, methanol, acetone and ethyl acetate, carbon tetrachloride, dichloromethane, chloroform, dioxane, and pyridine.) There are, of course, exceptions, in which a particular alkaloid is unusually soluble or insoluble in a given solvent, and these can be used to advantage to separate pure alkaloids from the mixtures.

Methods of separation

Separation. Important methods of separation depend upon formation of salts, which often can be crystallized easily. In this case, also, a wide range of solvents is available, including water, methanol, ethanol, acetone, and various mixtures of these solvents with one another and with others, such as chloroform. Picrate salts (salts formed with picric acid) often are used with low-molecular-weight alkaloids, such as nicotine. Picrates crystallize readily and often have sharp melting points, a property that aids in their identification. Hydrochlorides and hydrobromides (salts formed with hydrochloric and hydrobromic acids, respectively) often are easily crystallized, sparingly soluble, and not difficult to purify. Nitrates and oxalates (formed from nitric and oxalic acids), in a few cases, are crystallized easily, often from alcoholic solvents, but they are frequently hydrated (contain water) and seldom have sharp melting points. Those alkaloids that carry a phenolic hydroxyl group (an $-OH$ attached to an aromatic ring) have acidic properties; they form water-soluble salts in the presence of strong bases and therefore are separated easily from their relatives lacking phenolic groups.

Purification. Distillation and sublimation (vaporization of a solid) in a vacuum are practical methods for separating alkaloids of moderate molecular weight. Countercurrent distribution, a separation technique that depends on repeated partition between an immiscible solvent and an aqueous phase at controlled acidity, is a useful procedure for separating certain alkaloids, but it is laborious unless an automatic instrument for carrying out the process is available.

Determining the amount of individual alkaloids present in a sample is important in the drug trade and in forensic practice. Reliable procedures for the analysis of frequently encountered alkaloids have been developed and are much used.

Combustion analysis

Structure determination. The molecular formula of an alkaloid, which gives only the kinds and numbers of atoms present in the molecules, can be determined by combustion analysis—that is, by burning the alkaloid to end products, such as carbon dioxide and water, which can be collected and weighed. The functional groups (active groupings of atoms) present must be detected by specific chemical tests, characteristic of each group.

Mass spectrometry. A modern technique known as high-resolution mass spectrometry breaks down the molecule into fragments and accurately measures the mass of each. This not only provides a precise molecular formula but at the same time reveals details of how the atoms are joined in the molecules. Many types of alkaloids have been examined by this technique, and the fragmentation patterns exhibited by the various types are now well understood.

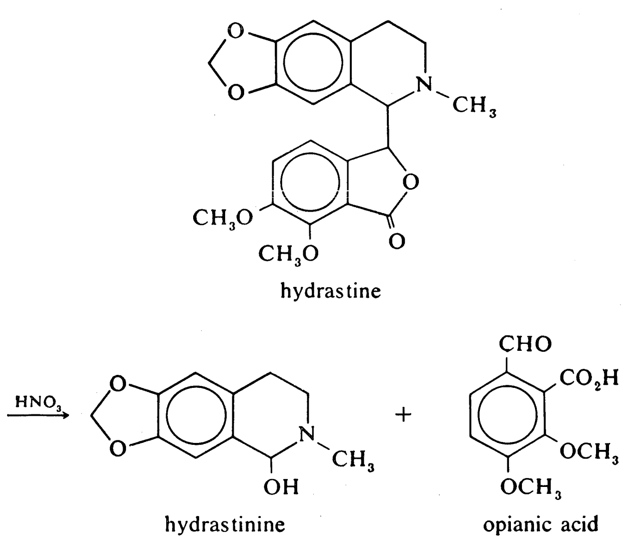
Spectroscopy. Infrared spectra (patterns of absorption of light in the infrared region) give information about the presence or absence of a number of functional groups, chief of which are the carbonyl, hydroxyl, and amino groups. Ultraviolet spectra (light absorption in the ultraviolet region), give valuable information about aromatic systems and unsaturated groups conjugated with aromatic rings or carbonyl groups.

Nuclear magnetic resonance. A measure of the nuclear behaviour of the atoms and detailed information on the nature and environment of the hydrogen atoms may be derived by nuclear magnetic resonance; such information frequently tells much about the structure of the molecule as a whole.

X-ray diffraction. The X-ray is an extremely powerful tool for structure determination. It depends for its success on the interpretation of patterns obtained when X-rays are diffracted by the atoms in crystals. Preferably carried out with a crystalline salt or other derivative containing a heavy atom, such as bromine or iodine, it also has been used with alkaloids containing as elements only carbon, hydrogen, oxygen, and nitrogen. There are several advantages to the method: if suitable crystals can be grown, a complete study can be carried out with very small amounts of material; the method requires no previous knowledge of the functional groups present; and, most important, it can be used in cases in which chemical degradation does not work (see below).

Oxidation

Chemical methods. The structure of an alkaloid can be determined by chemical reactions that break the intact molecule into fragments, the structures of which are already known or can be determined. In ideal cases, all of the carbon and nitrogen atoms can be accounted for in the various fragments, which result either from a single type of chemical assault on the molecule or from the use of a number of breakdown reaction paths. Oxidation of the alkaloid is the most direct attack and, in selected cases, gives enough information to deduce the total structure of the original alkaloid. Upon oxidation with partly diluted nitric acid, the alkaloid hydrastine, for example generates the known compounds hydrastinine and opianic acid, as shown in the equation:

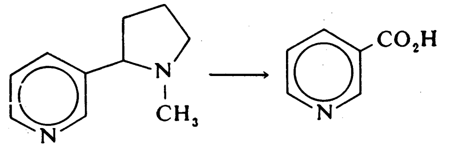


hydrastine

hydrastinine

opianic acid

Together these compounds account for all the carbon, nitrogen, and oxygen atoms of the original alkaloid and permit its hypothetical reconstruction. On the other hand, oxidation often destroys much of the molecule. Nicotine, for example, upon oxidation with a variety of oxidizing agents gives mainly nicotinic acid, the remainder of the molecule being converted into small fragments of no value in deducing the structure:



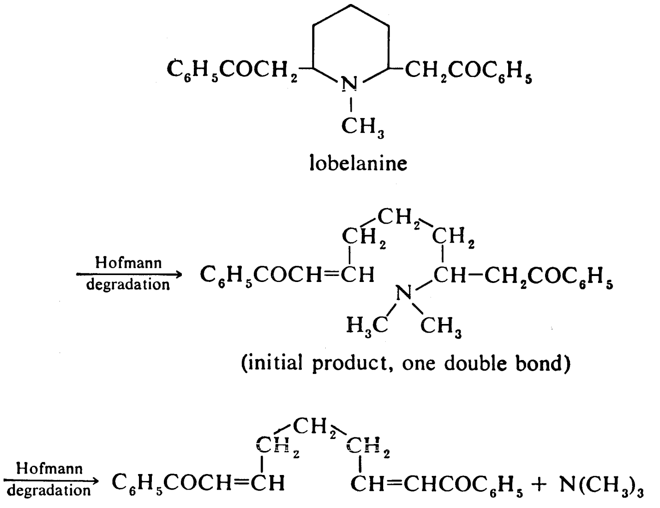
nicotine

nicotinic acid

Strychnine (see below) upon oxidation, again wih a variety of oxidizing agents, gives a number of oxidation products, all of which provide useful structural information, but only upon further degradation.

Hofmann degradation

To obtain structural information in greater detail, it is convenient to use the method known as the Hofmann degradation. This procedure, developed by a German chemist, August Wilhelm von Hofmann, consists of treating the alkaloid with methyl iodide to convert the basic nitrogen atom into its quaternary, or salt, form; the resulting quaternary iodide is then subjected to strong alkali. Under favourable conditions, any ring containing a nitrogen atom will be opened by this procedure, with the introduction of a double bond into the molecule at the point where the nitrogen atom was attached. At the same time, the nitrogen atom remains part of the molecule as a methylamine derivative. A repetition of the process may generate a second double bond and a new tertiary base, but this occurs only when the nitrogen atom in the original alkaloid is part of two rings. Otherwise the second Hofmann degradation gives a methylamine and a nitrogen-free compound containing two double bonds. These reactions are illustrated by the following equations:



lobelanine

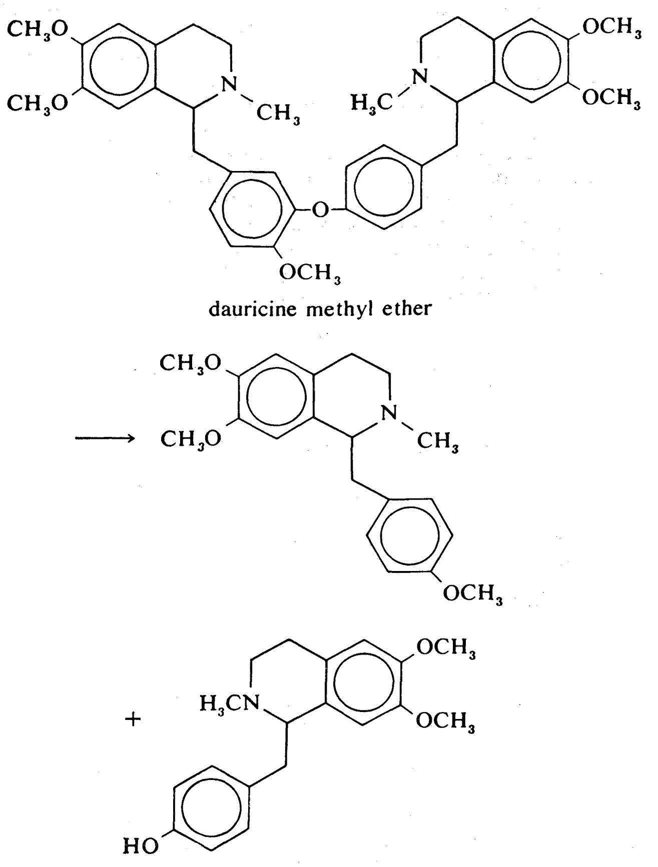
(initial product, one double bond)

(final product, two double bonds) trimethylamine

If the amine formed in the second-stage Hofmann degradation is trimethylamine, then the original alkaloid must have contained an *N*-methyl group. If the second Hofmann degradation has not eliminated nitrogen from the molecule, a third-stage degradation is sometimes possible, leading to a triply unsaturated carbon compound. There are many alkaloids that do not lend themselves to Hofmann degradation, however, and the reaction may fail at any of the stages. Nevertheless, when it can be employed, this method of degradation is especially useful, because it generates unsaturation in the molecule, which may then open the way to oxidative degradation. A related process achieves the same result as the Hofmann degradation, but with concomitant reduction of the double bond. It is carried out by reacting the methiodide with sodium amalgam or occasionally by reduction with sodium borohydride or with hydrogen in the presence of a catalyst.

Frequently, Hofmann degradation and subsequent oxidations proceed satisfactorily, but the final product, an acid, is difficult to identify because of its complexity.

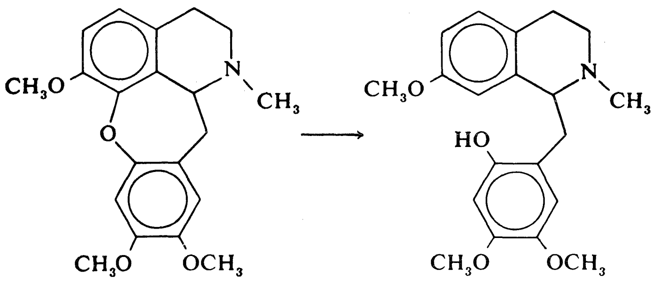
Special cases. *Bisbenzylisoquinolines.* Such is particularly the case with the bisbenzylisoquinoline alkaloids. In addition to relatively simple and identifiable phthalic acids, these alkaloids give rise to extremely complex acids (such as the alkoxyphenylether dibasic acids), which are difficult to identify because their syntheses are so difficult. A reaction is available that eliminates such problems by dividing the molecule into two approximately equal parts at the diphenyl ether junction. For example, when the methyl ether of the bisbenzylisoquinoline alkaloid dauricine is dissolved in ether or tetrahydrofuran and added to a freshly prepared solution of metallic sodium in ammonia, it gives rise to two simple benzylisoquinolines that are easily identifiable. The cleavage reaction is depicted as follows:



dauricine methyl ether

(easily identifiable benzylisoquinoline products)

The somewhat simpler alkaloid cularine was the first to be subjected to this reaction, and the product, also a benzylisoquinoline, was relatively easy to identify:

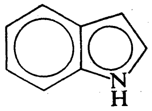


cularine

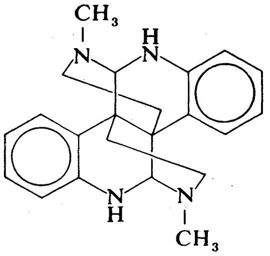
(benzylisoquinoline product)

The results of degradation reactions must always be interpreted with caution.

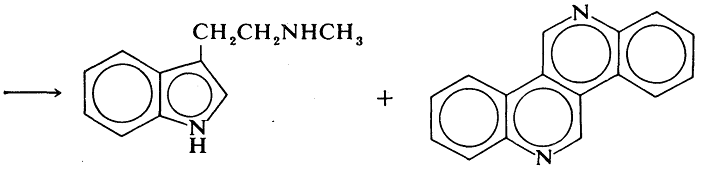
Calycanthine. An example of misleading information obtained by degradation is found with the alkaloid calycanthine. Attempts to degrade the alkaloid by the Hofmann procedure were unsuccessful but, by chance, it was found that benzoylation of the alkaloid yielded a product that was easily identified as a benzoyl derivative of *N*-methyltrypamine. This strengthened the suspicion that calycanthine was an indole derivative, like *N*-methyltryptamine, as already suggested by a colour reaction, which is given usually only by indole compounds. In a further experiment, however, calycanthine was heated to a high temperature wih zinc dust in an inert atmosphere, giving *N*-methyltryptamine, as well as a product that was later named calycanine:



indole



calycanthine



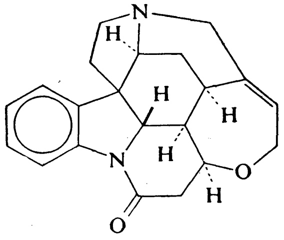
N-methyltryptamine

calycanine

Surprisingly enough, the structure of calycanine was shown by synthesis not to be an indole derivative. An X-ray diffraction study of the calycanthine molecule showed that its structure did not include indole nuclei, and it was concluded that the extreme conditions of the pyrolysis, which could have induced great structural changes, had only eliminated molecular fragments, whereas the mild benzoylation reaction had actually brought about deep-seated molecular rearrangements.

Strychnine. A similar, though still more complicated, example of misleading results of degradative experiments is presented by investigations of the strychnine molecule. Elucidation of this extraordinary complex structure of overlapping rings drawn as

Determining the structure of strychnine

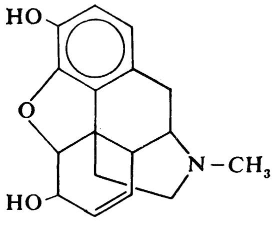


strychnine

(bonds shown - - - extend below the plane of the paper, – above it)

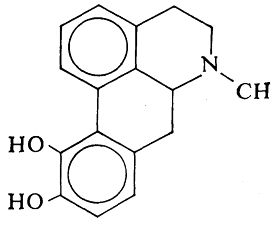
is often cited as a major triumph of the classical techniques of degradative chemistry. For more than a century the structure remained a puzzle. That the structure yielded finally to attack was due chiefly to the skill of a British chemist, Sir Robert Robinson, and an American chemist, Robert Burns Woodward. Strychnine had been subjected at an early date to pyrolysis under a variety of conditions, from which a number of degradation products had been identified. When the structure was finally known, it was recognized that proper juxtaposition of these fragments was sufficient to write the complete structure of the alkaloid.

Morphine. The determination of the structure of morphine, which is



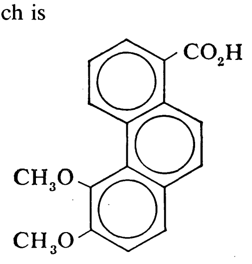
morphine

was thwarted by rearrangements that occurred when the molecule was subjected to chemical attacks. A partly reduced phenanthrene skeleton (composed of three fused six-membered rings) was postulated for the alkaloid because phenanthrene was obtained when the alkaloid was heated with zinc dust. Other degradations led to hydroxyphenanthrenes, and heating the alkaloid to 130° C (266° F) with strong hydrochloric acid generated the substance called apomorphine, the structure of which



apomorphine

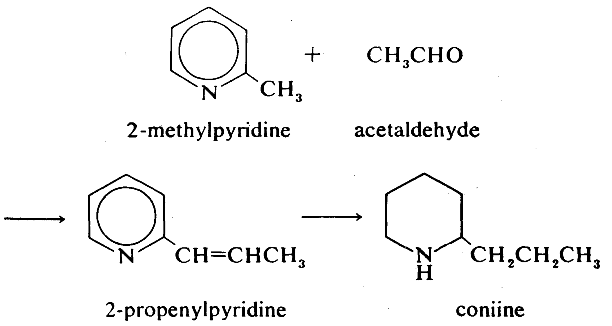
was ascertained by reactions that have since become standard. Furthermore, on Hofmann degradation, the dimethyl ether of the alkaloid gave a vinylphenanthrene, which on oxidation was converted to the corresponding acid, the structure of which is



(acid product)

The structure of this compound was proved by synthesis. Nonetheless, structures of morphine, based upon that of these products—apomorphine, in particular—were untenable because the nature of the rearrangement that gave apomorphine was not understood. A great deal of degradative and synthetic chemistry was necessary before these misleading results could be reinterpreted and the finally accepted structure could be written.

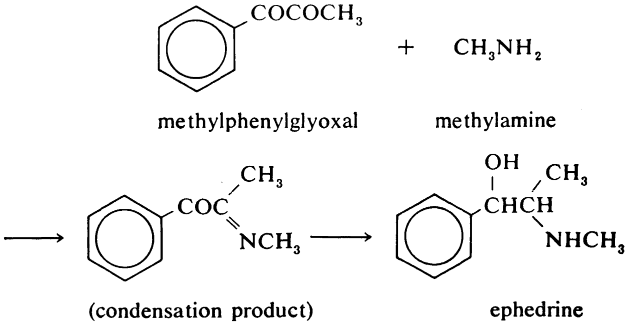
Synthesis. As mentioned above, the first synthesis of an alkaloid was that of coniine. In this synthesis, acetaldehyde was condensed with 2-methylpyridine to give 2-propenylpyridin; on reduction with sodium in ethanol this substance gave synthetic coniine:



The synthetic product is not quite identical with the natural alkaloid because it does not exhibit the optical activity of that substance. Optical activity is a property of materials that is only detected when plane polarized light is passed through a crystal or solution of the substance; the observed effect is the rotation of the plane of polarization of the light (as determined in an instrument called a polarimeter). Optical activity results when molecules are capable of existing in two isomeric forms that are related to one another like mirror images, or right- and left-hand gloves. These forms are designated *dextro (d)* or *levo (l),* according to whether they rotate plane polarized light to the right or left, respectively. The molecules of many alkaloids, like those of other biological materials, exist in nature in only one of the optically active forms. Synthetic processes, however, usually produce mixtures of both isomers, which are called *dl–* forms. Separation of the forms, a process called resolution, often can be achieved by crystallizing the *dl–* mixture with another substance already optically active. In the case of coniine, the natural material is the *d–* form, and resolution of the synthetic mixture is carried out by crystallizing the salt formed with *d*–tartaric acid.

Resolutions of *dl–* mixtures

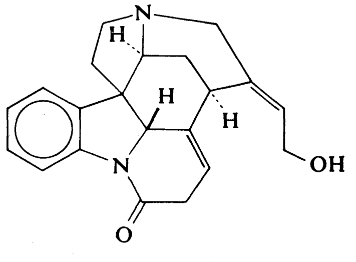
The alkaloid ephedrine, used as a nasal decongestant, has been synthesized by several methods; the most direct of these, a process used commercially, consists in condensation of methylphenylglyoxal with methylamine and reduction without isolation of the initial condensation product. The sequence of reactions is as follows:



In this case, too, it is necessary to resolve the product into *d* and *l* forms, only one of which (in this case, the *l* form) corresponds to the natural substance. The *l–* and *d–* mandelic acids, respectively, proved to be satisfactory for this purpose, each combining with the oppositely rotating form of the mixture to produce a salt that can be purified by crystallization. Conversely, the *d–* and *l*–ephedrines can be used to prepare pure *l–* and *d*–mandelic acids, respectively. The examples of coniine and ephedrine illustrate the general principle that the synthesis of an alkaloid usually necessitates a resolution of the forms, either as a final or intermediate step.

Synthesis of strychnine

The synthesis of the poisonous alkaloid strychnine posed as great a challenge to chemists as did the determination of its structure and, for the same reason, the extreme complexity of the molecule. The final synthesis of the alkaloid was reported in 1954. Complicating the problem are six asymmetric carbon atoms in the strychnine molecule (the spatial arrangement of which is shown above). No less than 15 sequential reactions were necessary to achieve the synthesis of isostrychnine of the correct configuration:

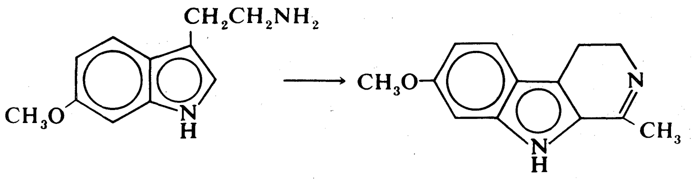


isostrychnine

bonds shown --- extend below the plane of the paper, —above it.

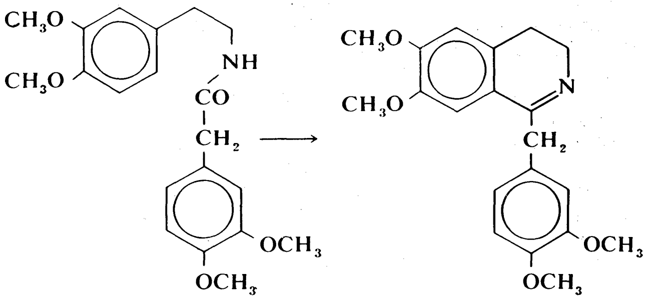
It was necessary to insure that the correct stereochemistry was achieved at each step; in one instance optical resolution of an intermediate was needed. Since isostrychnine can be prepared from strychnine, and since it can be reconverted to the alkaloid, synthesis of it represents a synthesis of strychnine itself.

Of chiefly historical interest is the relatively simple alkaloid harmaline; it was the first alkaloid of the indole type the structure of which was determined, and the first indole alkaloid to be synthesized. Since the initial synthesis, there have been a number of others. Typically these begin with the substance 6-methoxytryptamine:



6-methoxytryptamine harmaline

Quite analogous syntheses of 1-substituted isoquinolines can be carried out beginning with β-arylphenethylamines. A typical example is the preparation of dihydropapaverine from N-(3,4-dimethoxyphenethyl)-3,4-dimethoxyphenylacetamide:



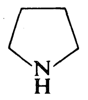
N-(3,4-dimethoxyphenethyl)-3,4-dimethoxyphenylacetamide dihydropapaverine

Conversion of the dihydro- derivative to the alkaloid papaverine by dehydrogenation can be accomplished by a variety of procedures.

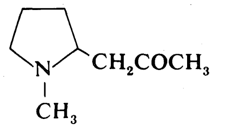
CLASSES OF ALKALOIDS

It is convenient to classify alkaloids according to their structural types, taking into consideration the nature and number of their nulei (rings of atoms) and the substituents attached to these. The simplest, aside from purely aliphatic bases that contain no rings, are the alkaloids the molecules of which include the five-membered pyrrole ring composed of one nitrogen and four carbon atoms. The more complex structures vary considerably in the types of ring systems present and in the number of nitrogen atoms they contain.

Pyrrolidines. The unsubstituted compound, pyrrolidine itself, has been found in the carrot, *Daucus carota,* and in tobacco; its N-methyl derivative has also been isolated from tobacco and from belladonna. Hygrine, found in the leaves of the cocoa plant, is among the few other pyrrolidine alkaloids.



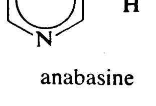
pyrrolidine



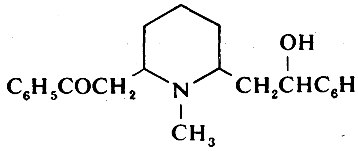
hygrine

Pyridines. The pyridine alkaloids constitute a large group in which the pyridine nucleus is present in fully aromatic, partly reduced, or fully reduced form. Those alkaloids in which the pyridine ring is fused to a second ring are discussed under other classes. The best known of the pyridine alkaloids is nicotine, which has both a pyridine and a pyrrolidine nucleus. Anabasine is formed by the union of two pyridine nuclei. The important lobelia and sedum alkaloids, of which there are well over 20, are mostly 2-monosubstituted and 2,6-disubstituted piperidines, with or without a methyl group on the nitrogen atom. The substitutes are of the type $-CH_2COR$ or $-CH_2CH(OH)R$, in which R may be methyl ($-CH_3$), ethyl ($-C_2H_3$), or phenyl ($-C_6H_5$). Lobeline is the chief alkaloid of the family used in medicine. The alkaloid carpaine from papaya (*Carica papaya*) had long been given the formula $C_{14}H_{25}O_2N$ and assigned a structure that included a 13-membered lactone ring. Mass spectral data, however, showed that the correct formula is $C_{28}H_{50}O_4N_2$ and that the alkaloid contains a double lactone ring of 26 atoms, as shown in the structural formula:

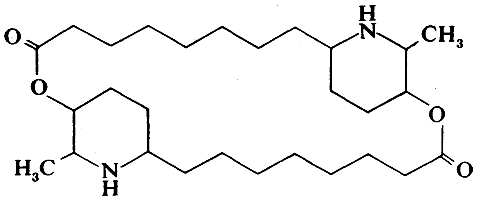
Lobeline



anabasine

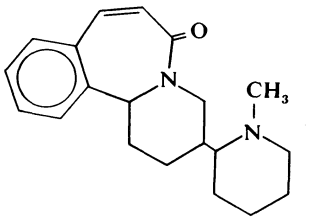


lobeline



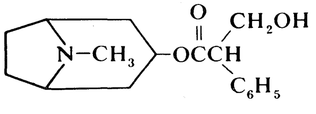
carpaine

There are many possible ways of combining several pyridine nuclei, as well as forming extra rings and adding substituents (see below). Astrocasine from *Astrocasia phyllanthoides* is one example.



astrocasine

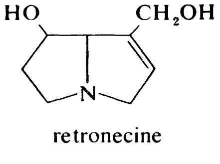
Tropanes. Bridging of the 2,6- position of piperidine (fully reduced pyridine) by a two-carbon unit gives the nucleus of the tropanes. Tropinone (see below *Emulation of biosynthesis*) is the keto derivative of this nucleus, and tropine is the corresponding alcohol. Esterification of tropine with tropic acid gives the alkaloid atropine, one optically active form of which is hyoscyamine:



atropine (hyoscyamine)

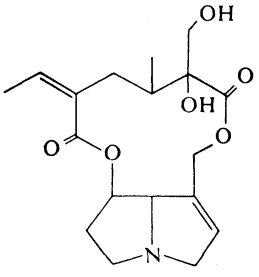
Pyrrolizidines. The ring system formed by the fusion of two five-membered rings with a common nitrogen atom is known as pyrrolizidine. The base itself has not been found to occur naturally but some important derivatives are widespread. The most common and most important of these is retronecine, which occurs in an esterified form

Retronecine



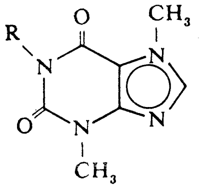
retronecine

in a number of genera in the families Compositae, Leguminosae, and Boraginaceae. These esters are commonly referred to as senecio alkaloids because of their abundance in *Senecio* and closely related genera. More often than not esterification is by a dibasic acid, often containing isoprene units, so that large ring systems may be present. Those alkaloids, such as retrorsine, that are cyclic diesters of acids with branched chains are more toxic than straight-chain diesters. These alkaloids are mutagenic in fruit flies (*Drosophila*) and can cause liver tumours in rats. A number of senecio alkaloids occur in plants as amine oxides, and these are equally toxic. Retrorsine has the structure:



retrorsine

Purines. Although the purine bases (with two rings in the molecules, five- and six-membered, respectively, each including two nitrogen atoms) are nitrogenous compounds elaborated by many different plant species and genera, many of them are not considered alkaloids because of their major biochemical roles. Caffeine, having the following structure,



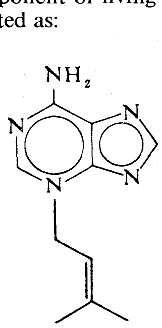
caffeine ($R=CH_3$)
theobromine ($R=H$)

however, is generally classified as an alkaloid and is the most widespread of the purine alkaloids. Aside from its presence in tea and coffee, it occurs in a number of species of holly (*Ilex*) and in many other plants.

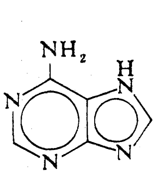
Caffeine

The stimulating effects of caffeine are well known and doses larger than one gram in man may cause alarming symptoms though there seem to be no recorded fatalities from overdoses. Dogs are more sensitive to this alkaloid, and poisoning by theobromine, a closely related alkaloid, has been noted often when cacao meal has been used as food for pigs and chickens. Such meal may contain up to 5 percent of theobromine, which can be recovered and converted commercially into caffeine by methylation with methyl chloride in the presence of caustic soda.

The purine nucleus also is present in the alkaloid triacanthine, which occurs in *Gleditsia triacanthos,* and which is remarkable because of its high nitrogen content. It is cleaved by strong acids to adenine, an extremely important component of living cells. Triacanthine and adenine are depicted as:



triacanthine



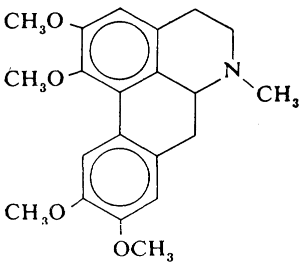
adenine

Isoquinolines. The isoquinoline nucleus consists of two fused six-membered rings, one of which contains a nitrogen atom. In most isoquinoline alkaloids there are substituents on the 1- position of the isoquinoine nucleus and the pyridine ring is in its tetrahydro- form. Most frequently the 1- substituent is a benzyl group, although it may be other alkyl, aryl, or arylethyl groups. Furthermore, the 1-benzylisoquinolines undergo a series of transformations, with or without the addition of carbon fragments, to generate various polycyclic types.

Morphine and codeine

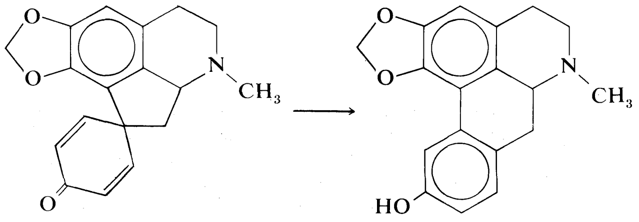
The isoquinoline alkaloid classes represented by papaverine, protoberberine, and protopine have already been mentioned. Morphine (see above) and codeine do not, on superficial examination, belong here, but alkaloids found with them in the plants are benzylisoquinolines; they themselves may be transformed into benzylisoquinolines; and they arise biogenetically from benzylisoquinolines. The structures of morphine and codeine were long obscured by the observation that morphine is converted into apomorphine when heated with strong acid. The alkaloid sinomenine has a similar nuclear structure but lacks the oxygen bridge.

Apomorphine is only one representative of a large variety of alkaloids known as aporphines. These differ from apomorphine only in the position, number, and type of substituents on the nucleus. Glaucine, first isolated from the horn poppy (*Glaucium flavum*) and subsequently found in many other plants, was the first aporphine to be synthesized. Pharmacologically the aporphines are not important. Glaucine has the structure:



glaucine

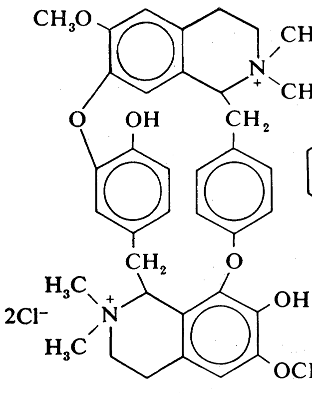
The proaporphine group of alkaloids was more recently discovered. They occur in *Croton* (Euphorbiaceae), *Nelumbo* (Nymphaeaceae), *Stephania* (Menispermaceae), *Ocotea* and *Neolitsea* (Lauraceae), and *Papaver* and *Meconopsis* (Papaveraceae). They are prepared synthetically by phenolic oxidation of benzylisoquinolines, and their biogenetic origin seems to be similar. There is evidence that they are precursors of some aporphines. Mecambrine has the typical nuclear structure of these alkaloids, which differ from one another in the number and position of substituents and the degree of unsaturation of the quinone nucleus. When mecambrine is heated in dilute hydrochloric acid it undergoes rearrangement to mecambroline.



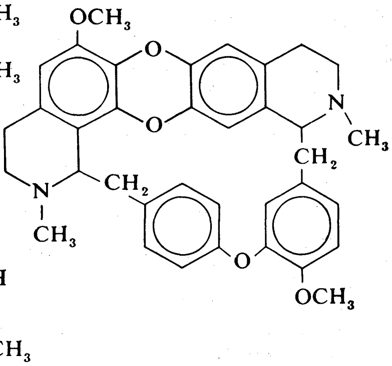
mecambrine mecambroline

Bisbenzylisoquinolines

The bisbenzylisoquinolines also are generated biologically by oxidation of benzylisoquinoline—in this case, two being incorporated per molecule. These alkaloids also occur in a number of genera belonging to several plant families. The simplest representative is dauricine, found in some *Menispermum* species. There is much variation in the structures of this group of alkaloids. Tubocurarine, already mentioned for its use in surgery, is a quaternary base containing two diphenyl ether linkage in a large ring; isotrilobine is an example of the alkaloids of this family that have three diphenyl ether linkages.

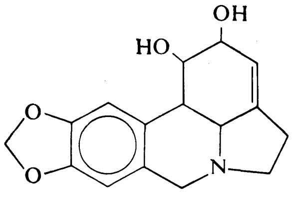


tubocurarine chloride

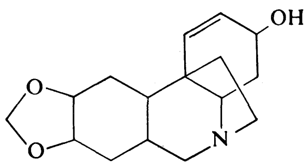


isotrilobine

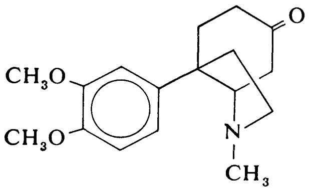
A rather distinct class of isoquinoline alkaloids is represented by the numerous alkaloids of the Amaryllidaceae. Included are a variety of nuclear structures, that of lycorine being representative of one group. Crinine is a variant of this type and an "open" form of this structure is represented by mesembrine, an alkaloid from *Sceletium* species (Ficoidaceae). The last named base still retains the polyhydroindole system present, sometimes in disguised form, in all of these alkaloids, the structural formulas of which are:



lycorine



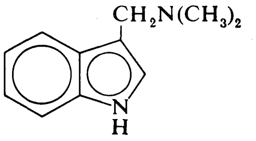
crinine



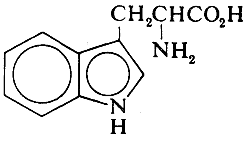
mesembrine

Gramine and strychnine

Indoles. Gramine, a simple indole derivative, and strychnine, a far more complex one, already have been mentioned. The alkaloids of the indole family, without exception, are derived biogenetically from the amino acid tryptophan, and with only one exception, namely that of gramine, they retain the aminoethyl chain of tryptamine.



gramine



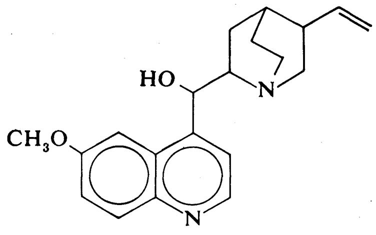
tryptophan

These alkaloids have been isolated from plants representing well over 30 families, the Apocynaceae, Rubiaceae, and Loganiaceae being particularly rich sources. These alkaloids often evince powerful physiological action, and one particularly complex group has shown promise in the control of leukemia. Vincaleucoblastine, one of some 10 alkaloids present in *Catharanthus roseus* (*Vinca rosea*) being used clinically to treat leukemia, is a representive of one of the indoline-indole dimeric alkaloids.

The determination of the structure of such a complex molecule required the combined techniques of organic chemistry and spetroscopy, the study of light absorption and its relation to molecular structure. Even alkaloids containing only one indole nucleus have presented challenges to the structural chemist.

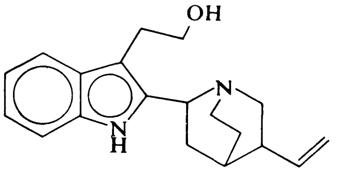
Quinine

Quinolines. The quinolines, too, constitute a large group of alkaloids. Remarkably enough, they are also derived from tryptophan. The biogenesis of quinine, which has the following structures,



quinine

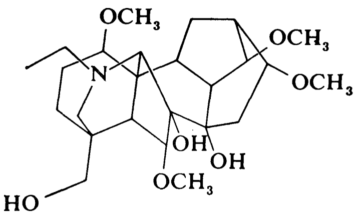
is not understood in detail but it is known that the indole nitrogen of tryptophan remains in the quinoline portion, and that the side chain nitrogen appears in the quinuclidine moiety. There is some evidence that cinchonamine, which is present along with quinine, is an intermediate in the synthesis of quinine.



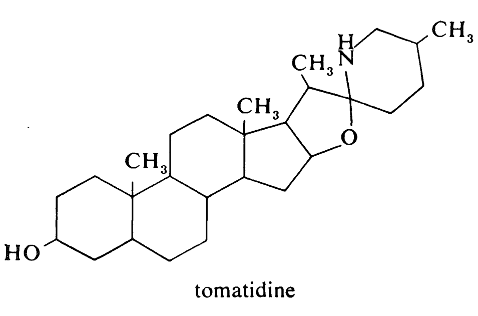
cinchonamine

The alkaloid calycanthine (seen above), which for long had been regarded as an indole alkaloid and can be readily converted into indole derivatives, also has its origin in tryptophan.

Terpenoids and steroids. Most of the terpenoid and steroid alkaloids can be viewed as derivatives of the nonnitrogenous terpenoids and steroids. These are common constituents of many living systems and are derived from mevalonic acid. In these alkaloids a nitrogen atom from ammonia presumably has been incorporated into the terpenoid or steroid molecule. The alkaloids also are distributed widely in plants (and are found occasionally in animals); the family Ranunculaceae yields many terpenoid bases, such as lycoctonine, and the Solanaceae yield largely steroid alkaloids, as represented by tomatidine.



lycoctonine

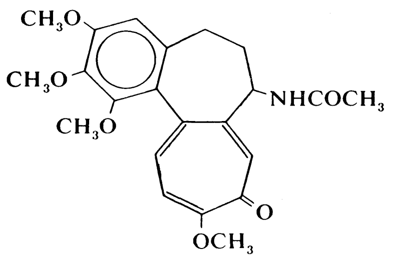


tomatidine

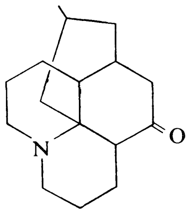
Miscellaneous. Since plants do not elaborate alkaloids for the convenience of classification, many alkaloids do not fit neatly into classes. All of those that have been subjected to scrutiny with labelled precursors, however, fall into one or another of the recognized pathways of biosynthesis.

Colchicine

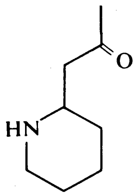
Among the miscellaneous alkaloids, colchicine, from the autumn crocus (*Colchicum autumnale*), is of importance not only because it has been used to cure gout but because it has been the cause of many deaths following accidental ingestion. Colchicine was one of the first compounds known to bring about profound chromosomal changes in plant cells. The lycopodium alkaloids, typified by lycopodine, are represented by over 30 known examples. They appear to be derived from two isopelletierine units. The quinolizidine alkaloids, commonly found in *Lupinus* species and other leguminous genera, are typified by sparteine.



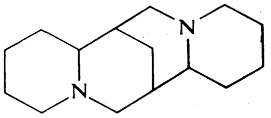
colchicine



lycopodine

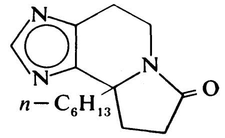


isopelletierine



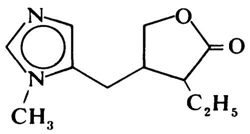
sparteine

Glochidicine is one of three closely related alkaloids found in *Glochidion philippicum* (Euphorbiaceae).

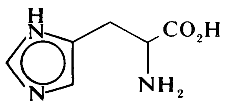


glochidicine

It is of interest because, like pilocarpine, which is used in medicine as an agent to induce perspiration, it is one of the few alkaloids derived from the amino acid histidine:



pilocarpine



histidine

In addition to the alkaloids mentioned here there are many others that are of interest because of their molecular structure and physiological activity.

GENERAL BIOLOGY

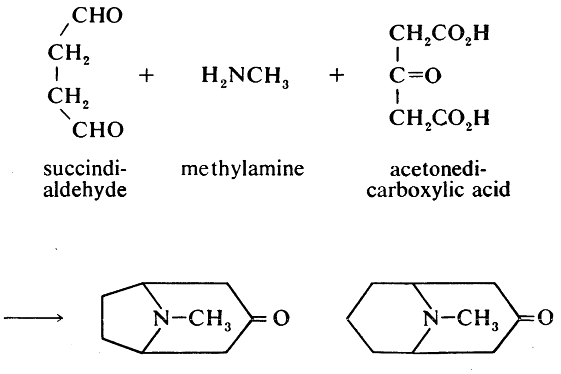
Biosynthesis. It has long been suspected that the nitrogen atoms and some of the carbon atoms of alkaloids have their origin in amino acids, nitrogen-containing organic compounds that are constituents of proteins and other biological materials. A proposal describing in detail how certain alkaloids could have been derived from amino acids was made in 1917. When the radioactive isotope of carbon, carbon-14, was made generally available, it became possible to introduce radioactively labelled amino acids into plants and verify that the label appeared in the alkaloid under investigation, confirming the incorporation of the amino acid into the alkaloid. Even earlier, indirect evidence had been obtained to explain the structures of the various alkaloid types on the basis of their origin from different amino acids. It became feasible to select the more plausible of alternate structures of a new alkaloid on the basis of the possibility of origin of the structure from known amino acids.

Derivation from amino acids

Emulation of biosynthesis. Attempts to emulate the presumed biological synthesis (biogenesis) of an alkaloid by in vitro experiments often met with unqualified success. These experiments were conducted with compounds known or thought to be present in the plant and were carried out under conditions that might prevail in the plant cell, namely, aqueous neutral solutions maintained at room temperature. The first such successful experiment was a spectacular synthesis of the alkaloid tropinone achieved simply by bringing together succindialdehyde, methylamine, and acetone in aqueous solution.

In vitro processes

The yield was improved when acetonedicarboxylic acid was substituted for acetone, decarboxylation of the product taking place either spontaneously or by heating in acid solution. Extension of this synthetic scheme to pseudopelletierine required the replacement of succindialdehyde by its homologue glutardialdehyde.

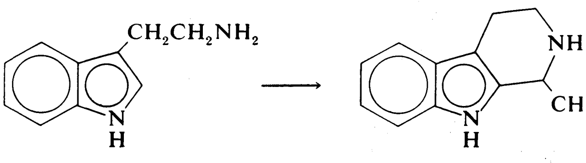


$$\begin{matrix} CHO \\ CH_2 \\ | \\ CH_2 \\ CHO \end{matrix} \quad + \quad H_2NCH_3 \quad + \quad \begin{matrix} CH_2CO_2H \\ | \\ C{=}O \\ | \\ CH_2CO_2H \end{matrix}$$

succindialdehyde methylamine acetonedicarboxylic acid

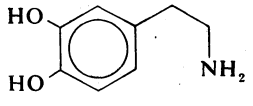
tropinone pseudopelletierine

Subsequently, many successful syntheses of alkaloids of varied structural types were achieved under equally mild conditions. Tryptamine, an indole base derived from the amino acid tryptophan, in the presence of acetaldehyde readily yielded tetrahydroharman:

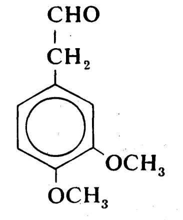


tryptamine tetrahydroharman

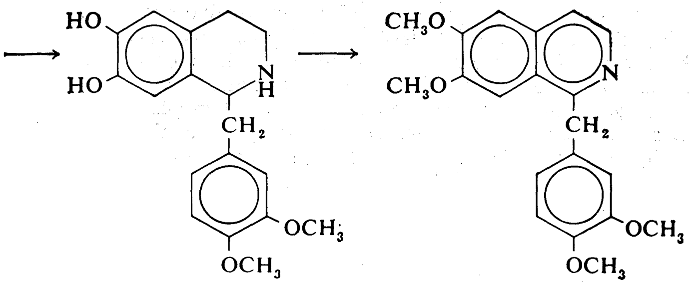
Similarly, 3,4-dihydroxy-β-phenethylamine and 3,4-dimethoxyphenylacetaldehyde yielded a tetrahydroisoquinoline, which on methylation of the oxygen atoms and dehydrogenation was converted to papaverine:



3,4-dihydroxy-β-phenethylamine



3,4-dimethoxyphenylacetaldehyde



(a tetrahydroisoquinoline) papaverine

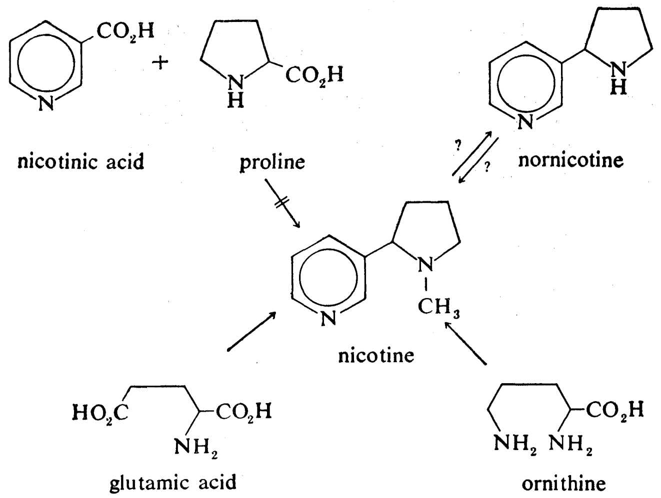
The pyruvic acid, of which the above aldehyde is a decarboxylation product, underwent the same reaction. This acid could be prepared from the amino acid tyrosine. The phenethylamine involved in the reaction is a decarboxylation product of dihydroxyphenylalanine, which also is known to be derived ultimately from tyrosine.

Radioactive labelling and biosynthesis

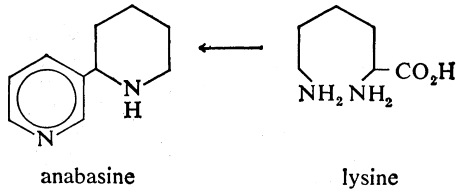
Use of tracers. With the aid of carbon-14-labelled substances, it became possible to test biogenetic hypotheses by direct experiments and, with a few exceptions, results were as expected. In many cases labelling experiments provided additional detail lacking in the original biogenetic hypotheses. In the meantime the processes by which the precursor amino acids are synthesized in the cell from carbon dioxide and ammonia also were being determined.

As early as 1912 it had been surmised that nicotine arose biologically from a combination of nicotinic acid with the amino acid proline. Experiments involving living tissues of *Nicotiana* species, however, have shown that two other amino acids, glutamic acid and ornithine, are incorporated into the five-membered ring of nicotine instead of proline. It proved difficult to trace the exact sequence of reactions leading to nicotine, and it is still unclear whether the nornicotine (nicotine missing its methyl group) is a precursor or a conversion product of nicotine.

The relationships among these compounds are shown in the following scheme:



The biogenesis of a structurally related alkaloid, anabasine, also is subject to some uncertainty, although the amino acid lysine is known to be incorporated into the saturated six-membered ring of the compound:

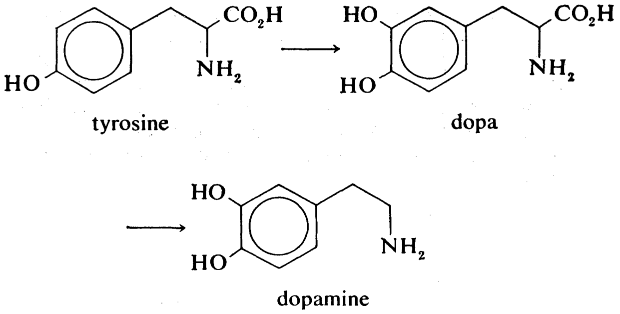


A particular advantage of labelling techniques is that they permit one to determine not only what precursors are involved in the biosynthesis of a given product but also the way in which the precursors are used—that is, the specific atoms of precursor molecules that become atoms in the molecules of the products. This information is secured by synthesizing precursor molecules bearing labelled atoms at known positions in the molecule, introducing them into the organism and, after an appropriate time period, isolating the product from the organism. If, as expected, the product bears the radioactive label, it is carefully degraded chemically, each atom being isolated in turn so that it can be determined whether or not it is radioactive. The correspondence reveals precisely what molecular transformations have taken place. Such experiments are, of course, extremely laborious; however, they yield information that can be obtained in no other manner.

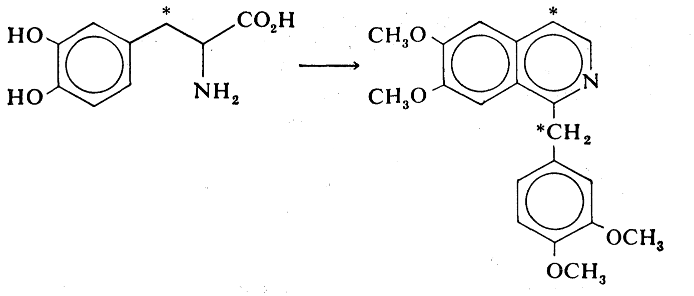
Biosynthesis with duplicate amino acids

Radioactive labelling experiments also have been useful in unravelling the tangled situations that arise when two molecules of a single amino acid are involved in the biosynthesis of a given alkaloid molecule. In such cases the two units may go through separate pathways of transformation, with the ultimate result that they are incorporated in different forms, and possibly to different extents, in the alkaloid molecule. On the other hand, both units may be incorporated into the alkaloid in an identical form or, after incorporation, they may form a symmetrical intermediate; in either of these latter cases the alkaloid will show an identical degree of incorporation of the two units. The relative degree of incorporation of two amino acid units into an alkaloid structure is best shown by radioactive labelling. An example of this situation and the procedure used to clarify it is given by the amino acid tyrosine, two molecules of which are believed to be incorporated into the molecules of a number of alkaloids (papaverine, morphine, narcotine, thebaine, hydrastine, berberine, and chelidonine, to name a few). Furthermore it is known that tyrosine is transformed in plant cells into a substance called dopa (for dihydroxyphenylalanine), which also is believed to be incorporated into these alkaloids to the extent of two units for every alkaloid molecule. A further transformation product of dopa (called dopamine), however, is incorporated only into one part of the molecules of these alkaloids. The progression from tyrosine to dopamine is represented as follows:

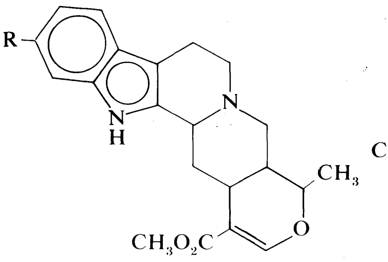
Dopa



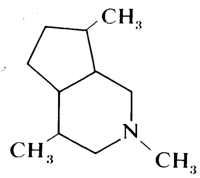
It seems, therefore, that there must be two separate routes by which dopa is incorporated into the alkaloid molecules. This conclusion was verified by the finding that radioactively labelled dopa was incorporated into papaverine in such a way that the two labelled carbons were both radioactive but to different extents.



labeled dopa labeled papaverine

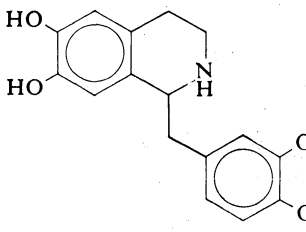


ajmalicine (R = H)
reserpinine (R = OCH_3)

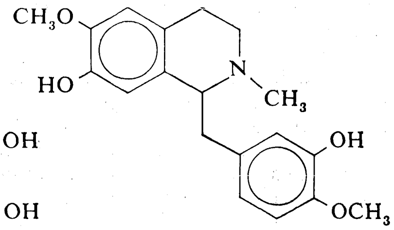


skytanthine

It seems likely that the substance norlaudanosoline, or a close relative of it, is the primary condensation product of two molecules (which may or may not be identical) derived from dopa, and the related base reticuline is actually known to occur in a number of plants that elaborate alkaloids of this type. With the aid of labelling experiments, it has been verified that reticuline is indeed the precursor of the simple benzylisoquinolines and their subsequent biological descendants, which are many of the alkaloids under discussion. Indeed, it has been shown that some of these alkaloids are intermediates in the synthesis of others in living plants.



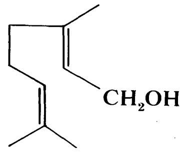
norlaudanosoline



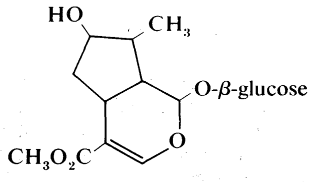
reticuline

It should be emphasized that the incorporation of amino acids into biosynthetic pathways involves more often than not a partly broken down (catabolized) amino acid in which one or more of the functional groups had been either eliminated or altered. Long before biosynthetic studies with labelled compounds became possible the degradation of amino acids into a variety of catabolites by living cells had been recognized.

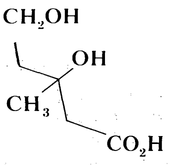
Special cases. There are, however, a large number of alkaloids whose biosynthesis cannot be explained solely by using the degradation products of amino acids. Many of the indole alkaloids, for example, such as ajmalicine and reserpinine, include as part of their molecular structures a 10-carbon fragment derived from naturally occurring hydrocarbons, the monoterpenes, like geraniol or loganin. Loganin itself occurs in the Madagascar periwinkle *Catharanthus roseus* plant (*Vinca rosea*). Mevalonic acid, the source of the five-carbon-atom (isoprene) unit in such other natural products as the terpenes and steroids, is the precursor of geraniol and loganin. Radioactive labelling experiments have shown that two units of mevalonic acid are incorporated into skytanthine, an alkaloid that has been isolated from the South American plant *Skytanthus acutus*. The structures of these related compounds are shown below.



geraniol



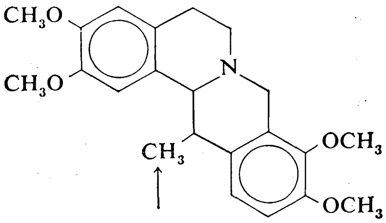
loganin



mevalonic acid

Origin of methyl groups

Many alkaloids contain methyl ($-CH_3$) groups joined to oxygen or nitrogen atoms and, in virtually all instances studied so far, this methyl group has originated (joined to a sulfur atom, as $S-CH_3$) in methionine [$CH_3-S-CH_2-CH_2-CH(NH_2)-CO_2H$], an amino acid that occurs in free form in plant sap and in combined form in many proteins. In addition, methyl groups attached to carbon atoms also come from methionine in certain alkaloids, corydaline, for example. The carbon atoms of the methylenedioxy ($-O-CH_2-O-$) groups of protopine also originate from methionine. It has been shown that the methylenedioxy group is formed by a process in which one of the oxygen atoms is methylated first and then, with removal of two hydrogens, ring closure with the adjacent oxygen atom takes place. The mechanism of this reaction is unknown, and it has not been possible to duplicate it in the test tube. A somewhat similar example of the removal of hydrogen atoms with consequent ring closure, also not duplicated in the laboratory, takes place in the biosynthesis of tetrahydropalmatine from *N*-methyltetrahydropapaverine, represented in the formulas:



corydaline

Isoprenoids

Isoprenoids are members of a class of organic compounds formed in plants and animals by combination into larger molecules of units containing five carbon atoms arranged in the characteristic pattern present in the simple substance isoprene, from which the class takes its name. The name terpene, or terpenoid, derived from turpentine, which is a mixture of isoprenoids, is also applied to this class of compounds. In plants, isoprenoids occur in the essential oils, in the gummy exudates (oleoresins and latices) of many trees and shrubs, as substances affecting growth (such as the hormone gibberellic acid), and as red, yellow, and orange pigments (carotenoids). Chlorophyll, the green pigment essential in photosynthesis, is partly isoprenoid, as are certain alkaloids, nitrogen-containing compounds present in many plants. In animals, isoprenoids comprise various oily or waxy substances as fish-liver oils, wool wax, and the yellow pigments in egg yolk, butterfat, feathers, and fish scales.

Several isoprenoids are vitally important in metabolic processes in animals: vitamins A, E, and K are wholly or partly isoprenoid in molecular structure, as are the ubiquinones (coenzymes Q), which are involved in the derivation of energy by the oxidation of food. In insects, certain isoprenoid substances influence maturation and mating behaviour or are used to communicate alarm or to repel predators. Steroids, a class of compounds of great importance in both plants and animals, are not isoprenoids but are derived directly from them. Among many isoprenoids that are valuable in industry and commerce, turpentine, rosin, camphor, menthol, and natural rubber may be mentioned.

Studies of the isoprenoids

The problems in molecular structure presented by the isoprenoids have challenged the imagination and skill of organic chemists since the latter part of the 19th century. The first studies were mainly concerned with the structures of the monoterpenes, the molecules of which contain 10 carbon atoms, but, as those structural patterns became familiar and techniques for investigation were developed, attention was turned increasingly toward those isoprenoids containing 15 to 40 carbon atoms. Otto Wallach, a German chemist, recognized in 1887 that the numerous ways in which the 10 carbon atoms are arranged in the molecules of the monoterpenes, or the 15 carbon atoms in the sesquiterpenes, all could be regarded as resulting from various combinations of a fundamental unit that contains five carbon atoms that are always connected in one of several possible ways. Wallach's proposal, called the isoprene rule, was of great help in understanding the structures of the more complex members of the class. By the mid-20th century, emphasis had fallen upon the origin of isoprenoids in biological systems, their relationships to other classes of natural products, and their powerful physiological effects in plants and animals.

CHEMISTRY OF ISOPRENOIDS

The six-carbon ring

Structural features. A structural feature especially common among isoprenoid compounds is a ring of six carbon atoms; the simplest compound possessing this structure is cyclohexane (not an isoprenoid), which is represented by the structural formula **1**, by a condensed version **2**, or simply by the hexagon **3**. In compounds of this kind, the six ring atoms are not coplanar, but the ring usually is puckered, as shown in **4** and **5**. Molecules that can be regarded as formed by replacing one or more hydrogen atoms of cyclohexane (although few of them can actually be prepared in this way) by other atoms or by radicals (groups of atoms) can exist in different forms, depending on which hydrogen atoms are replaced. In the isoprenoid alcohol menthol, for example, three of the hydrogen atoms of cyclohexane have been replaced, each by a different radical: structure **6** shows only the bonding pattern without implying the spatial arrangement, but **7** and **8** specify the orientation of the bonds and the conformation of the ring in the natural form of menthol.

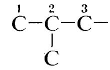
Carbon skelton

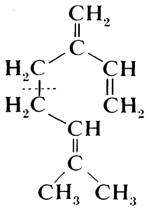
The term carbon skeleton is used to describe the pattern in which the carbon atoms are bonded together in a molecule, disregarding atoms of other elements and differences between single and multiple bonds. Most chemical reactions of organic compounds do not break bonds between carbon atoms and therefore leave the carbon skeleton unchanged. In many isoprenoids, rings of three, four, or five carbon atoms form part of the molecular structure. In these small rings, the bond angles are severely distorted from the values typical of stable molecules, and the carbon–carbon bonds can be broken with unusual ease. Many reactions in which carbon skeletons are rearranged were first observed during investigations of the isoprenoids and caused considerable confusion until the causes of their occurrence were recognized.

Classification. The isoprenoids are broadly classified according to the number of isoprene (C_5H_8) units they contain, and they range in size from volatile oils of molecular formula $C_{10}H_{16}$ to giant molecules such as that of natural rubber, which contains about 4,000 isoprene units. The classes are: monoterpenes, $C_{10}H_{16}$; sesquiterpenes, $C_{15}H_{24}$; diterpenes, $C_{20}H_{32}$; triterpenes, $C_{30}H_{48}$; tetraterpenes, $C_{40}H_{64}$; polyterpenes, $(C_5H_8)_n$. Many of the isoprenoids possess carbon skeletons that may be regarded as built up from isoprene units



$$\overset{1}{C}-\underset{\underset{C}{|}}{\overset{2}{C}}-\overset{3}{C}-\overset{4}{C}$$

linked "head to tail"; that is, carbon atom 1 of one unit is bonded to carbon atom 4 of the next. Formation of additional bonds in a variety of ways leads to monocyclic, bicyclic, and further subclasses in which one, two, or larger numbers of rings are present. *β*-myrcene (**9**), an acyclic monoterpene; limonene (**10**), a monocyclic monoterpene; *α*-pinene (**11**), a bicyclic monoterpene; and vitamin A (**12**), an oxygenated monocyclic diterpene, exemplify this further classification; the dotted lines in the structural formulas indicate the division of the carbon skeletons into isoprene units. The structures of most triterpenes and tetraterpenes show that they were formed by establishment of a tail-to-tail bond between two smaller units: in the structural formula of the important triterpene hydrocarbon squalene (**13**), for example, the arrow indicates the bond uniting two sesquiterpene portions.



9

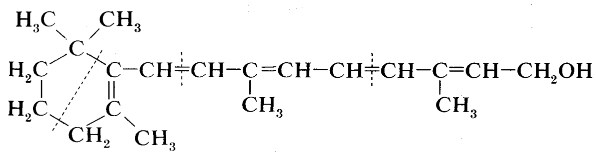
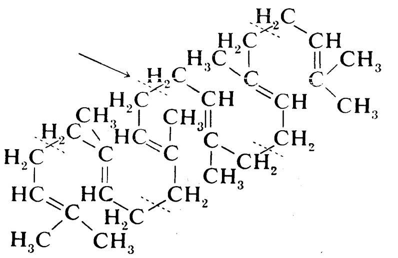
11



12



13

Natural sources. Isoprenoids are not uniformly distributed among plants or animals, but certain classes of these compounds are typical of broad groups of tissues. The essential oils—more or less volatile materials obtainable from odorous plants by physical means, such as extraction with solvents, distillation, or expression—are most often monoterpene or sesquiterpene hydrocarbons or their oxygenated derivatives, such as alcohols, aldehydes, or ketones. Menthol, citral, camphor, limonene, and α-pinene are examples of this group; often a single species or group of related species is characterized by the presence of one of these compounds. The nonvolatile substances present in resins produced by trees of the pine family contain diterpene carboxylic acids belonging to three types, abietic, palustric, and elliotinoic; the latices of a few species of plants contain the polyterpene hydrocarbons rubber or gutta-percha.

Essential oils

The livers of fishes and other animals are particularly rich in oils that are largely acyclic triterpenoid hydrocarbons, especially squalene. Tetraterpene hydrocarbons and a few of their oxygenated derivatives make up most of the carotenoid pigments that are widespread in plants and animals.

Importance. *Biological functions.* The natural biological functions of isoprenoids are, in many cases, unknown. Those that have been deduced, however, are extremely diversified. In both plants and animals, isoprenoids are intermediates in the formation of steroids, which, in animals, have been shown to perform numerous essential tasks. In plants, tetraterpene carotenoid pigments are closely associated with chlorophyll (a partially isoprenoid compound) in photosynthesis; the same group of pigments are, in animals, the source of vitamin A, a substance essential to visual processes. Vitamin A is also involved in growth, reproductive function, and neural development in animals. Other vitamins that are wholly or partly isoprenoid include vitamin E, important in reproduction, and vitamin K, necessary for the blood-clotting process.

The role of the monoterpenes and sesquiterpenes produced by plants has not been established, although it has been suggested that they attract certain insects and repel others. This idea is connected with the presence in insects of some of the very same compounds, which are used to signal alarm, to repulse predators, to mark the way between food sources and the nest, to attract members of the opposite sex and stimulate mating. Certain plants produce isoprenoids that are very similar to hormones involved in the development of insects that prey on those plants; the plant substances prevent the maturation of the insect, thus serving to defend the plant. The rosin acids of pine trees and the rubber and gutta-percha in latices of various plants may serve as wound-sealing agents.

Uses. Of the uses that man has found for isoprenoids, many were established in antiquity, as ingredients of perfumes and incenses, flavourings and spices, and varnishes and medicinals. Amber, a fossilized isoprenoid resin, has been prized as a gemstone since prehistoric times. Rubber was in use by the Central and South American Indians before the Spanish conquest.

Modern applications are extremely diversified. Turpentine, long employed as a solvent, is now mostly used as a source of its individual components, which are raw materials for chemical processing. Products derived from turpentine include ingredients for perfumes, vitamin A, lubricant additives, insecticides, resins used in adhesives, and industrial chemicals. Rosin, usually modified by chemical treatment, is widely used to make inexpensive soaps and coating materials.

Isolation and identification. Numerous procedures have been developed for the isolation of isoprenoids from their natural sources. The selection of a technique is influenced by such factors as the chemical and physical properties of the compound and its abundance and distribution in nature. Volatile and plentiful substances as turpentine are obtainable by distillation of oleoresins; rosin acids and fatty acids occur together in tall oil, a by-product obtained in the manufacture of paper pulp from pine wood, and they are separated by fractional distillation at reduced pressure. Extremely rare compounds, as the insect hormones, have been isolated by chromatography (a method of separating the components of a solution, or mixture, based on selective adsorption onto a layer or column of suitable material). For the isolation of heat-sensitive perfume ingredients from flower petals, the laborious process of enfleurage is employed: the petals are placed in thin layers of carefully purified fat, in which the floral oils dissolve; they are recovered from the fat by washing with alcohol.

Isolation techniques

Chemical identification of isoprenoids, like that of organic compounds in general, falls into a classical pattern of steps that has the goal of furnishing a complete description of the molecule. This description includes specification of the number and kinds of the atoms present, the chemical bonds that hold the atoms together, and the three-dimensional arrangement of these atoms and bonds. The sequence of operations necessary for such an identification comprises purification, determination of atomic composition, and assignment of structure. Verification of the assignment is accomplished by synthesis of the compound from others of previously established structure by chemical reactions that proceed in known ways.

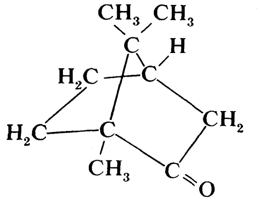
Purification. Isoprenoids can be purified by various techniques that depend primarily upon the physical properties of the compound, as melting or boiling points or solubilities in various other substances. The chemical properties may be an advantage or a disadvantage in the application of these methods: a compound in which heating induces a chemical reaction would be destroyed rather than purified by a procedure requiring the application of heat, as distillation or sublimation. On the other hand, methods depending on physical properties often cannot effect a satisfactory separation of a mixture of compounds possessing very similar physical properties; sometimes such mixtures can be converted by chemical treatment into a mixture of new substances that can be more readily separated; the separated components may then be reconverted into the original compounds.

In general, solid compounds can be purified by recrystallization; and volatile compounds (either solid or liquid), by distillation. Nonvolatile liquids or solids contaminated by very similar substances can be purified by chromatography. Because even small amounts of contaminants can give rise to seriously misleading results in chemical identification, purification of a compound for this purpose must be carried to the highest attainable degree; it is highly desirable to subject a substance to a succession of purification procedures based upon different principles, as distillation and crystallization. The rigour of this requirement is far higher than in purification of a substance for the purpose of suiting it to typical practical applications, for which it is often sufficient only to remove components that would be objectionable in the intended application (*e.g.,* those that impart unwanted odour, colour, or flavour).

Analysis. Determination of the elemental composition of isoprenoids seldom presents difficulty because many of them are hydrocarbons, and a simple, reliable procedure for quantitative analysis of carbon and hydrogen has been available since the early 19th century. The only other element commonly present in isoprenoids is oxygen, which does not interfere with the analysis for carbon and hydrogen, although it is difficult to determine directly: usually it is assumed to comprise the proportion of the compound not accounted for as carbon, hydrogen, and any other elements that have been measured.

Classical structural determination

Determination of structure. Assignment of structures to isoprenoids presented a very difficult problem. In the period when the monoterpenes were first investigated, the method of determining the structure of an organic compound was based entirely on studies of chemical reactions, usually those in which one or a few bonds in the compound were broken, giving successively simpler compounds, each of which was isolated, purified, and analyzed. These sequences of reactions eventually led to compounds possessing known structures, and the path back to the original substance was inferred from knowledge of the structural changes associated with the reactions employed. Frequently it was impossible to distinguish among alternate proposals; that is, more than one structure would be considered consistent with the information available. The situation was aggravated by the facts that many of the isoprenoids possess structures of a kind never previously observed, in which carbon atoms are linked together in small rings, and that, in many isoprenoids, the original carbon skeleton changes to a different one in the course of a reaction. One of the most difficult cases was the compound camphor, for which more than 30 different structures were proposed before the correct one (**14**) was established.



14

Modern techniques for determination of molecular structure lean heavily upon correlations between structural features and physical properties; many relationships of this kind have been established. Measurements of the wavelengths and intensities of absorption of ultraviolet, visible, and infrared light allow the chemist to draw very reliable inferences concerning the presence or absence of certain atomic groups and the distribution of electrons in the chemical bonding system. Determination of the intensity of magnetic fields at the nuclei of the atoms, especially the hydrogen atoms, permits him to deduce the molecular environment of those atoms. For example, the presence of an oxygen atom in the molecule of camphor was evident from the elemental analysis, which was performed in 1833, but the fact that that atom is part of a carbonyl ($>C{=}O$) group was established only in 1883, after many unsuccessful attempts to bring about a chemical reaction that would reveal that group. Nowadays, the presence of a carbonyl group would be instantly recognized by its characteristic absorption of infrared light. In favourable cases, complete structures have been revealed by X-ray crystal analysis. Mass spectra and optical rotatory dispersion measurements often elucidate fine structural details.

Laboratory synthesis. Once a structural formula has been deduced for a compound, the proposed structure becomes the objective of chemical synthesis as a test of the validity of the assignment. In certain cases, synthesis has been undertaken when the available evidence is consistent with more than one structure, but it appears simpler to synthesize all the likely candidates and to compare each of them with the unidentified compound than to seek further information from studies of chemical or physical properties.

In selecting a sequence of reactions by which a compound is to be synthesized for the purpose of confirming the assignment of a proposed structure, great care must be taken that, at every stage along the way, the transformations have occurred as predicted by the scheme. Such assurance is ordinarily provided by limiting the choice of reactions to those that have been thoroughly studied and shown to proceed in predictable ways and by careful examination of each intermediate compound to verify its identity. The first laboratory synthesis of camphor required 11 reactions and was a major achievement at the time (1903), although much more complicated compounds have been synthesized since then.

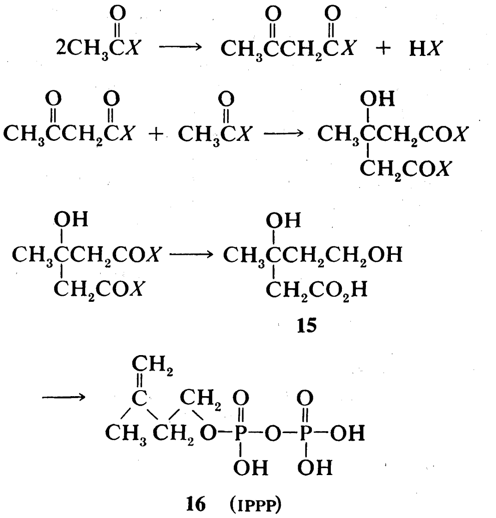
Camphor has been synthesized commercially by a series of reactions utilizing isoprenoids obtained from turpentine as the starting materials. Vitamin A is another isoprenoid manufactured by synthetic processes; several alternative reaction sequences have been developed for this compound.

Isoprenoids from acetate

Biosynthesis. By the late 1940s, the ubiquity of the five-carbon isoprene unit had been recognized for a long time, but the identity of the compounds actually involved in the physiological assembly of the isoprenoids was not known, although it had been suggested that they were somehow built up from acetic acid, the molecule of which contains only two carbon atoms. During the 1950s, it was shown that the synthesis of isoprenoids in nature indeed begins with acetylcoenzyme A, sometimes called activated acetate, a compound derived from acetic acid and coenzyme A, a complex substance that participates in many reactions that are controlled by enzymes. Previously unknown compounds, mevalonic acid and isopentenyl pyrophosphate (IPPP), occur as important intermediates in the process. The 1964 Nobel Prize for Physiology or Medicine was awarded to two German-born biochemists, Konrad Bloch and Feodor Lynen, for their contributions to this research.

The molecule of isopentenyl pyrophosphate is the long-sought physiological isoprene unit, containing five carbon atoms bonded together in the pattern discerned by Wallach in the 19th century. Most of the natural isoprenoids have structures that reveal the joining of two, three, four, six, or eight isoprene units; rubber is an isoprenoid in which several thousands of these units are connected in a long chain.

The process by which acetic acid units combine to form mevalonic acid (**15**) and isopentenyl pyrophosphate (**16**) is indicated by the equations below, in which *X* represents the complicated molecular structure of coenzyme A.



$$2CH_3\overset{O}{\overset{\|}{C}}X \longrightarrow CH_3\overset{O}{\overset{\|}{C}}CH_2\overset{O}{\overset{\|}{C}}X + HX$$

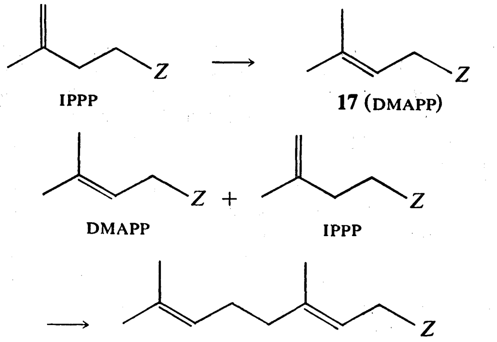
$$CH_3\overset{O}{\overset{\|}{C}}CH_2\overset{O}{\overset{\|}{C}}X + CH_3\overset{O}{\overset{\|}{C}}X \longrightarrow CH_3\overset{OH}{\overset{|}{\underset{\underset{CH_2COX}{|}}{C}}}CH_2COX$$

$$CH_3\overset{OH}{\overset{|}{\underset{\underset{CH_2COX}{|}}{C}}}CH_2COX \longrightarrow CH_3\overset{OH}{\overset{|}{\underset{\underset{CH_2CO_2H}{|}}{C}}}CH_2CH_2OH$$

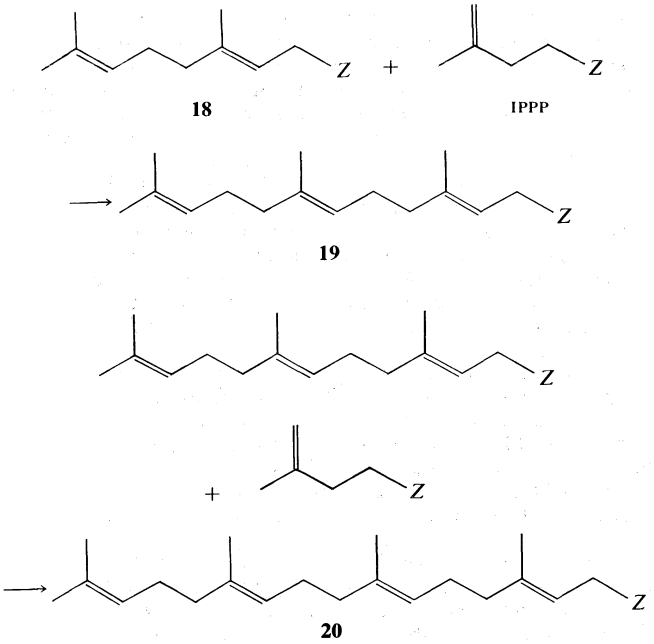
15

16 (IPPP)

The formation of geranyl pyrophosphate (**18**), the precursor of the monoterpenes, from two molecules of IPPP requires that one of them be transformed to dimethylallyl pyrophosphate (DMAPP, **17**). In the equations below, only the covalent bonds of the carbon skeletons are shown, and Z stands for the pyrophosphate group.



A similar reaction of geranyl pyrophosphate with IPPP leads to the 15-carbon compound, farnesyl pyrophosphate (**19**), from which the sesquiterpenes are derived, which, in turn, is converted to the 20-carbon precursor (**20**) of the diterpenes.



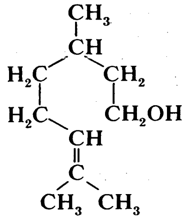
All these reactions produce substances in which the isoprene units are joined head-to-tail; many of the larger isoprenoid molecules (triterpenes and tetraterpenes) are not built up by further incorporation of IPPP units but by tail-to-tail coupling of 15- or 20-carbon compounds. The structure of squalene (**13**), a triterpene, illustrates this point. The tetraterpene carotenoids apparently arise from a similar reaction of two 20-carbon isoprenoids.

COMPARATIVE SURVEY OF ISOPRENOID COMPOUNDS

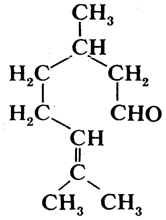
Monoterpenes. The monoterpenes are isolated from their natural sources by distillation of the plant matter with steam. They are volatile oils, less dense than water, and have normal boiling points in the range 150°–185° C (300°–365° F). Purification is usually achieved by fractional distillation at reduced pressures or by regeneration from a crystalline derivative. Acyclic monoterpene hydrocarbons are few in number, but their oxygenated derivatives are more widespread in nature and of greater importance.

Acyclic monoterpenes

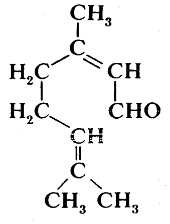
Important oxygenated acyclic monoterpene derivatives include the terpene alcohol citronellol (**21**) and the corresponding aldehyde citronellal (**22**), both of which occur in oil of citronella, as well as citral (**23**), found in lemongrass oil, and geraniol (**24**), which occurs in Turkish geranium oil.



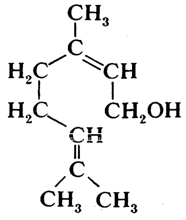
21



22

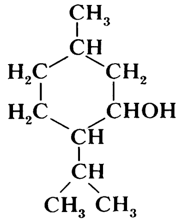


23

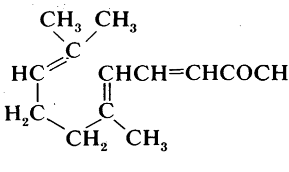


24

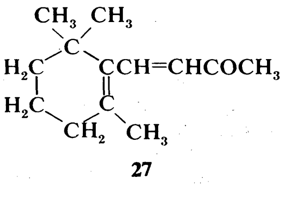
Citronellal is converted by treatment with acid into the monocyclic monoterpene alcohol isopulegol, from which a mixture of stereoisomeric menthols (**25**) is produced on catalytic hydrogenation. The process is used commercially to supplement the natural sources of menthol (oil of peppermint), widely used as a flavouring and in medicinal preparations. Citral (**23**), upon reduction with sodium amalgam, yields geraniol (**24**), an important component of rose perfumes. Citral may be condensed with acetone to yield the important intermediate pseudoionone (**26**),



25



26

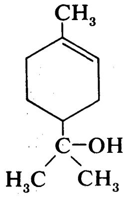


27

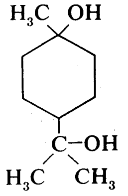
from which *β*-ionone (**27**) results on treatment with acid. Although *β*-ionone cannot be regarded as a terpene, it is of great importance as a starting material for the synthesis of vitamin A (**12**) and as a component of violet-scented perfumes.

Monocyclic monoterpenes

Limonene (**10**), an oil of normal boiling point 178° C (352° F), is a major component of orange and lemon oils and is typical of the monocyclic monoterpene hydrocarbons. Others of this class are terpinolene, *α*- and *β*-phellandrene, and *α*-, *β*-, and *γ*-terpinene, all of which have the same carbon skeleton as limonene and differ only in the location of the two carbon-to-carbon double bonds. Limonene is optically active (it rotates the plane of polarized light), as are most of the terpenes and their derivatives that contain an asymmetric carbon atom—that is, one bonded to four different groups. Limonene is converted to isoprene by contact with a heated metallic filament. Few commercial uses, other than as flavourings, exist for the monocyclic monoterpene hydrocarbons. Menthol (**25**), which has already been mentioned, and the oxygenated derivatives *α*-terpineol (**28**) and terpin (terpin hydrate; **29**) are chemicals of commerce. Mixtures of terpin, *α*-terpineol, terpinolene, and the terpinenes result from the treatment of *α*-pinene (**11**) with acid, and the mixture finds use as pine oil, an inexpensive disinfectant, deodorant, and wetting agent.



28



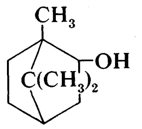
29

Bicyclic monoterpenes

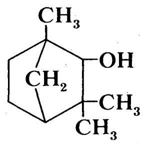
Of normal boiling point 156° C (313° F), *α*-pinene is representative of the bicyclic monoterpenes and is the most abundant and important monoterpene. It is the major component of ordinary turpentine, which is prepared from pine trees or stumps either by extraction followed by rectification or by distillation with steam. It is a major component of sulfate turpentine, a by-product of the manufacture of paper, and is important as a component of paints and varnishes and as a raw material for the production of a wide variety of products employed in chemical industry.

Its use in coating materials depends upon its good properties as a solvent and upon its conversion by air oxidation into a polymeric, resinous film. Its function as a starting material for conversion to more useful products results from its abundance and its structure, which has a high degree of chemical reactivity. The chemical reactions of *α*-pinene have been studied more thoroughly than those of any other terpene, and the study has contributed greatly to the understanding of molecular rearrangements in organic chemistry.

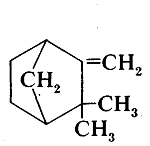
Treatment of *α*-pinene with acids under various conditions leads to a host of products, among which are terpinolene, the terpinenes, *α*-terpineol (**28**), and terpin (**29**), previously mentioned, and, in addition, borneol (**30**), fenchyl alcohol (**31**), and the hydrocarbon camphene (**32**).



30



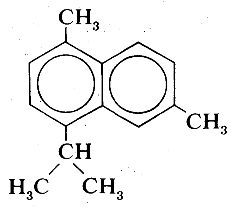
31



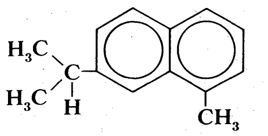
32

The formation of the latter three compounds involves molecular rearrangement, and advantage has been taken of the structural changes to provide a commercial synthesis of the important bicyclic terpene ketone, camphor (**14**).

Sesquiterpenes. Sesquiterpenes, $C_{15}H_{24}$, are isolated from their natural sources by distillation with steam or by extraction because they are of lower volatility than the monoterpenes. They are purified by fractional distillation *in vacuo* or by chromatography. The sesquiterpenes demonstrate an even greater complexity of structure than the monoterpenes, and oxygenated sesquiterpenes are commonly encountered.

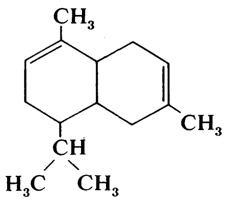


33

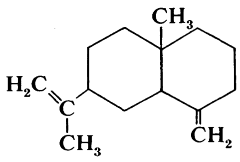


34

Two arrangements of isoprene units are found in bicyclic sesquiterpenes, the cadalene (**33**) and the eudalene (**34**) types, and the carbon skeleton of a sesquiterpene may frequently be determined by heating it with sulfur or selenium to effect dehydrogenation to the corresponding naphthalenic hydrocarbons: cadalene, 4-isopropyl-1,6-dimethylnaphthalene; or eudalene, 7-isopropyl-1-methylnaphthalene. In those cases in which sulfur dehydrogenation fails to yield information about the carbon skeleton of a sesquiterpene, a systematic degradation by oxidation to compounds of known structure is necessary.



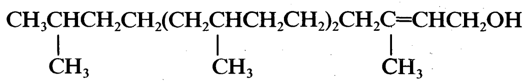
35



36

Cadinene (**35**), the principal component of oils of cubeb and cade, is a typical sesquiterpene of the cadalene type. It is an optically active oil of normal boiling point 274° C (525° F). *β*-Selinene (**36**), present in celery oil, is typical of the eudalene type.

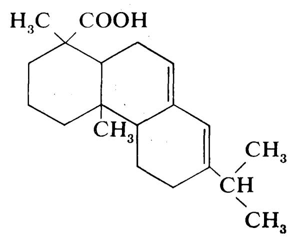
Diterpenes. Phytol (**37**), an oxygenated acyclic diterpene, is an important building block of the chlorophyll molecule, from which it is obtained on treatment with alkali solution. The arrangement of isoprene units in phytol is identical with that in vitamin A (**12**), a monocyclic diterpene derivative, and is typical of the head-to-tail arrangement of isoprene units found in most terpenes.



$$\mathrm{\underset{CH_3}{CH_3CH}CH_2CH_2(CH_2\underset{CH_3}{CH}CH_2CH_2)_2CH_2\underset{CH_3}{C}{=}CHCH_2OH}$$

37

The commercial importance of the bicyclic monoterpene *α*-pinene is paralleled in the diterpenes by abietic acid (**38**), a tricyclic carboxylic acid that constitutes the major portion of rosin. Rosin is the nonvolatile portion of the oleoresin of members of the pine family and is the residue left after the isolation of turpentine. Rosin is used as such in the production of varnish and coating materials and, in the form of its sodium salt, for sizing paper, as an emulsifying agent in producing synthetic rubber, and in yellow laundry soap. It is among the cheapest organic acids.



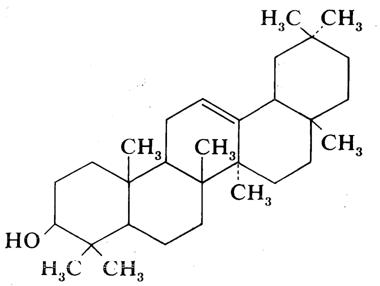
38

Squalene

Triterpenes. The acyclic triterpene hydrocarbon squalene (**13**) constitutes more than half of the liver oil of certain species of sharks and is otherwise rather widely distributed in nature. It has been found in other fish-liver oils, in vegetable oils, in fungi, and in human earwax and sebaceous secretions. The biochemical importance of squalene as a metabolic intermediate in the biosynthesis of cholesterol was demonstrated by the use of radioactive carbon labelling.

Although cholesterol is not a terpene, the demonstration that it has a terpene as precursor in metabolism represented a major advance in understanding the biochemical relationship between the two important classes of compounds.

Although tricyclic and tetracyclic triterpenes are known, by far the most abundant triterpenes found in nature are those having five carbon rings. The pentacyclic triterpenes, either free or combined with sugars in glycosides (saponins), occur in all parts of many plants. The structures of many of the pentacyclic triterpenes are now known in full detail; that of β-amyrin (**39**) exemplifies the important structural features of this class of substances. The best source of β-amyrin is the resin of the tropical tree elemi, although it has been isolated from more than 50 plant sources. The carbon skeleton of β-amyrin bears a striking relationship to those of squalene and cholesterol, and it has been shown that squalene is a common precursor of the pentacyclic triterpenes and the sterols in biosynthesis.

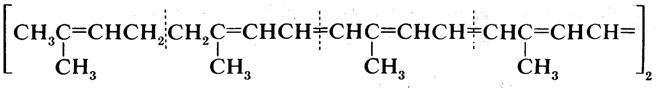


39

Carotenoids

Tetraterpenes. The large class of yellow, orange, or red, fat-soluble plant and animal pigments known as carotenoids are classed as tetraterpenes, although they have in general the molecular formula $C_{40}H_{56}$ rather than $C_{40}H_{64}$ as required by $(C_5H_8)_8$. The fact that their structures can be built up from isoprene units justifies their classification as terpenes. The carotenoids are isolated from their natural sources by solvent extraction and purified by chromatography.

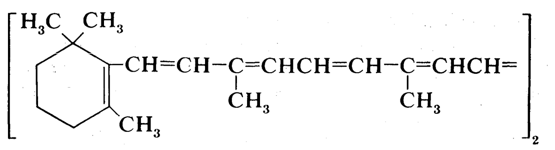
Lycopene (**40**) the red pigment of the ripe tomato, exemplifies the class of acyclic tetraterpenes. The dotted lines in the formula show the division into isoprene units, and it is to be noted that the usual head-to-tail attachment of isoprene units is interrupted in the centre of the molecule with a single tail-to-tail attachment that produces a symmetrical structure. This feature is generally encountered in the tetraterpenes, as is the long series of alternating single and double, carbon-to-carbon bonds (conjugated system) that is responsible for the absorption of light and hence the bright colours of the compounds.



$$\left[\mathrm{CH_3\underset{CH_3}{C}{=}CHCH_2\vdots CH_2\underset{CH_3}{C}{=}CHCH\vdots CH\underset{CH_3}{C}{=}CHCH\vdots CH\underset{CH_3}{C}{=}CHCH{=}}\right]_2$$

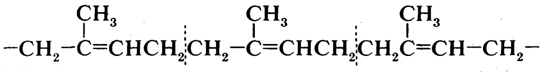
40

The most important and abundant tetraterpene is β-carotene (**41**), the principal yellow pigment of the carrot; β-carotene is of nutritional importance because the animal organism is apparently able to cleave the molecule at the point of symmetry with the production of vitamin A. The role of vitamin A and structurally related terpenoid molecules in the synthesis of the pigments in the eye necessary for vision has been demonstrated.



41

Polyterpenes. Rubber, which occurs in the latex of the rubber tree, is a polyterpene hydrocarbon, $(C_5H_8)_n$, in which n is 4,000–5,000. Chemical degradation by oxidation and X-ray-diffraction studies have revealed a repeating unit (**42**) in rubber. Division into isoprene units



$$\mathrm{-CH_2-\overset{CH_3}{C}{=}CHCH_2\vdots CH_2-\overset{CH_3}{C}{=}CHCH_2\vdots CH_2\overset{CH_3}{C}{=}CH-CH_2-}$$

42

is indicated. The vulcanization of rubber involves the establishment of cross-linking between the chains through sulfur atoms. Gutta-percha differs from rubber in the way in which methylene ($-CH_2-$) groups are arranged; in gutta-percha they are on opposite sides (*trans* arrangement) of the double bond, and in rubber they are on the same side (*cis* arrangement). (R.H.E./Ed.)

Steroids

Steroids are a class of naturally occurring organic substances and their derivatives that are of great importance in biology, medicine, and chemistry. The steroid group includes all sex hormones, adrenal cortical hormones, bile acids, and sterols of vertebrates, the molting hormones of insects, and many other physiologically active substances of animals and plants. Among the synthetic steroids of therapeutic value are a large number of anti-inflammatory agents, anabolic (growth-stimulating) agents, and oral contraceptives. Different categories of steroids are frequently distinguished from each other by names that relate to their biological source—*e.g.,* phytosterols (found in plants), adrenal steroids, bile acids—or to some important physiological function—*e.g.,* gestogens (promoting gestation), androgens (favouring development of masculine characteristics), cardiotonic steroids (facilitating proper heart function). Because steroids of similar function and origin tend to fall into families of closely related structure, biological categorization underlies an internationally accepted systematic chemical nomenclature.

HISTORICAL BACKGROUND

Studies of steroids commenced in the early 19th century with investigations of the unsaponifiable (*i.e.,* remaining undissolved after heating with excess of alkali) material, largely cholesterol, of animal fat and gallstones and of acids obtainable from bile. This early work, with which many of the noted chemists of the time were associated, led to the isolation of cholesterol and some bile acids in reasonable purity and established some significant features of their chemistry. Insight into the complex polycyclic steroid structure, however, came only after the turn of the 20th century, following the consolidation of chemical theory and the development of chemical techniques by which such molecules could be broken down step by step. Arduous studies, notably by the research groups of the German chemists Adolf Windaus and Heinrich Wieland, ultimately established the structures of cholesterol; of the related sterols, stigmasterol and ergosterol; and of the bile acids. Investigation of ergosterol was stimulated by the realization that it can be converted into vitamin D. Only in the final stages of this work (1932) was the arrangement of the component rings of the nucleus clarified by results obtained by pyrolytic (heat-induced bond-breaking) dehydrogenation and X-ray crystallography.

The foundations of steroid chemistry

With the foundations of steroid chemistry firmly laid, the next decade saw the elucidation of the structures of most of the physiologically potent steroid hormones of the gonads and the adrenal cortex. Added impetus was given to steroid research when the Americans Philip S.

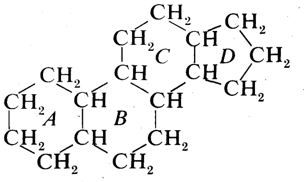
Hench and Edward C. Kendall announced in 1949 that the thitherto intractable symptoms of rheumatoid arthritis were dramatically alleviated by the adrenal hormone cortisone. New routes of synthesis of steroids were developed, and many novel analogues were therapeutically tested in a variety of disease states. From these beginnings there has developed a flourishing steroid pharmaceutical industry and, with it, a vastly expanded fundamental knowledge of steroid reactions that has influenced many other areas of chemistry.

Knowledge of the biochemistry of steroids has grown at a comparable rate, assisted by the use of radioisotopes and new analytical techniques. The metabolic pathways (sequences of chemical transformations in the body), both of synthesis and of decomposition, have become known in considerable detail for most steroids present in mammals, and much current research relates to control of these pathways and to the mechanisms by which steroid hormones exert their effects. The hormonal role of steroids in lower organisms is also of growing interest.

CHEMISTRY OF STEROIDS

Molecular structure

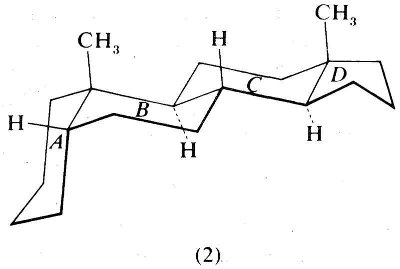
Steroid numbering system and nomenclature. All steroids are related to a characteristic molecular structure composed of 17 carbon atoms—arranged in four rings conventionally denoted by the letters *A, B, C,* and *D*—bonded to 28 hydrogen atoms. This parent structure, indicated in Diagram 1,



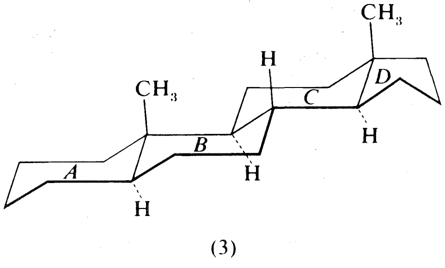
(1)

named gonane and often referred to as the steroid nucleus, may be modified in a practically unlimited number of ways by removal, replacement, or addition of a few atoms at a time; hundreds of steroids have been isolated from plants and animals, and thousands more have been prepared by chemical treatment of natural steroids or by synthesis from simpler compounds.

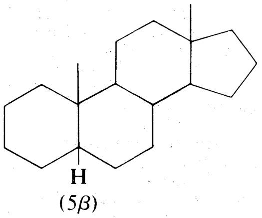
The steroid nucleus is a three-dimensional structure, and atoms or groups are attached to it by spatially directed bonds. Although many stereoisomers (compounds that are alike bond for bond but different in three-dimensional arrangement of atoms) of this nucleus are possible (and may be synthesized), the saturated nuclear structures of most classes of natural steroids are alike, except at the junction of rings *A* and *B*. Simplified three-dimensional diagrams may be used to illustrate stereochemical details. For example, Diagrams 2 and 3 show the alternative forms of the skeletal structure, androstane, common to a number of natural and synthetic steroids, in which the *A/B* ring fusions are called *cis-* and *trans-,* respectively. Note that at the common side of rings *A* and *B* in Diagram 2, bonds to the methyl group, CH_3, and to the hydrogen atom, H, both project upward from the general plane defined by the rest of the molecule, whereas in diagram 3, CH_3 projects up, and H projects down. Usually, however, steroid structures are represented as plane projection diagrams such as 4 and 5, which correspond to 2 and 3, respectively.



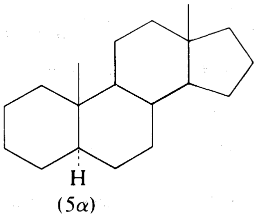
(2)



(3)



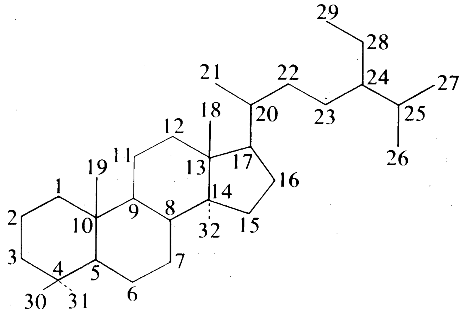
(4)



(5)

The stereochemistry of rings *A* and *B* must be specified by showing the orientation of the hydrogen atom attached at C-5 (that is, carbon atom number five; steroid numbering is explained below) as either above the plane of the diagram (designated *β*) or below it (*α*). The *α*-, *β*-symbolism is used similarly to indicate the orientation of any substituent group that is attached to a saturated (fully substituted) carbon of the steroid ring system. Groups attached to unsaturated carbons lie in the same plane as the adjacent carbons of the ring system (as in ethylene), and no orientation need be specified. When the orientation of a substituent is unknown, it is assigned the symbol *ξ*- (xi). Bonding of *β*-attached substituents is shown diagrammatically as in 4 by a full line; that of *α*-substituents by a broken line, as in 5, and that of *ξ*-substituents by a wavy line.

Each carbon atom of a steroid molecule is numbered, and the number is reserved to a particular position in the hypothetical parent skeletal structure (6) whether this position is occupied by a carbon atom or not.



(6)

Principal structural types

Steroids are named by modification of the names of skeletal root structures according to systematic rules agreed upon by the International Union of Pure and Applied Chemistry (IUPAC). By attaching prefixes and suffixes to the name of the appropriate root structure, the character of substituent groups or other structural modification is indicated. The prefixes and suffixes include numbers, called locants, indicative of the position in the carbon skeleton at which the modification occurs, and, where necessary, the orientation of a substituent is shown as *α*- or *β*-. The carbon atom at position 3, for example, is referred to as C-3; a hydroxyl group attached to C-3 is referred to as a 3-OH group or, more specifically, as a 3*α*-OH or 3*β*-OH group. In addition to differences in details of the steroid nucleus, the various classes of steroids are distinguished by variations in the size and structure of an atomic group (the side chain) attached at position 17. The derivations of the names of the more common root structures from those of naturally occurring compounds or classes of compounds of which they are most typical are indicated in Table 46. For unambiguous use of the names given in Table 46,

Table 46: Names of Fundamental Structures Most Often Used in Steroid Nomenclature

	carbon atoms present (as numbered in Diagram 6)	naturally occurring general classes	examples shown in the text
Gonane	1–17	none	gonane* (1)
Estrane	1–18	estrogens	estradiol (17 f)
Androstane	1–19	androgens	androstane* (2–5); testosterone (17 c); androstanedione (17 c)
Pregnane	1–21	gestogens and adrenal steroids	progesterone (17 a); cortisol (17 b); aldosterone (17 d); batrachotoxin (14)
Cholane	1–24	bile acids	cholic acid (10 a); sodium glycocholate (10 b)
Cholestane	1–27	sterols	cholesterol (16 d); scymnol (11 a)
Ergostane	1–28	sterols	ergosterol (8); cyasterone (22)
Stigmastane	1–29	sterols	stigmasterol (7); antheridiol (12)
Lanostane	1–27, 30–32	trimethyl sterols	lanosterol (16 c); 22,25-oxido-holothurinogenin (13)
Cardanolide	1–23	cardiac glycosides	digitoxigenin (23)
Bufanolide	1–24	toad poisons	bufotoxin (24)
Spirostan	1–27	sapogenins	dioscin (25)

*Gonane and androstane themselves do not occur in nature.

the orientation (*α* or *β*) of hydrogen at C-5 must be specified. If no other modification is indicated, the nucleus is assumed to be as shown in 2 and 3, except in the cardanolides and bufanolides: compounds of these types characteristically possess the 5*β*,14*β* configurations which, however, are specified.

For brevity in discussion and in trivial nomenclature, a number of prefixes are often attached, with locants, to the names of steroids to indicate specific modifications of the structure. In addition to the usual chemical notations for substituent groups replacing hydrogen atoms (*e.g.*, methyl-, chloro-, hydroxy-, oxo-), the following prefixes are commonly used: dehydro- (lacking two hydrogen atoms from adjacent positions); dihydro- (possessing two additional hydrogen atoms in adjacent positions); deoxy- (hydroxyl group replaced by a hydrogen atom); epi- (differing in configuration of a carbon atom bonded to two other carbon atoms); iso- (differing in configuration of a carbon atom bonded to three other carbon atoms); nor- (lacking one carbon atom); homo- (possessing one additional carbon atom); cyclo- (with a bond between two carbons that are normally not united); and seco- (with a carbon–carbon bond of the nucleus broken).

Polarity

Depending upon the number and character of their functional groups, steroid molecules may show diverse reactivities. Moreover, the reactivity of a functional group varies according to its location within the molecule (*e.g.*, esters are formed readily by 3-OH groups but only with difficulty by the 11*β*-OH group). An important property of steroids is polarity; *i.e.*, their solubility in oxygen-containing solvents (water, alcohols) rather than hydrocarbon solvents (hexane, benzene). Hydroxyl, ketonic, or ionizable (*i.e.*, capable of dissociating to form electrically charged particles) groups in a steroid molecule increase its polarity to an extent that is strongly influenced by the spatial arrangement of the atoms within the molecule.

Methods of isolation. Procedures for isolation of steroids differ according to the chemical nature of the steroids and the scale and purpose of the isolation. Steroids are isolated from natural sources by extraction with organic solvents, in which they usually dissolve more readily than in the aqueous tissue fluids. The source material often is treated initially with an alcoholic solvent, which dehydrates it, denatures (renders insoluble) proteins associated with the steroids, and dissolves many steroids. Saponification (treatment with aqueous alkali) either of whole tissues or of substances extracted from them by alcohol splits the molecules of sterol esters, triglycerides, and other fatty esters and permits the extraction of the sterols by means of water-immiscible solvents, such as hexane or ether, with considerable purification. Intact sterol esters or hormonal steroids and their metabolites (compounds produced by biological transformation) that are sensitive to strong acids or alkalies, however, require essentially neutral conditions for isolation, and, although some procedures for analysis of urinary steroids employ acid treatment, milder hydrolysis, as by enzymes, is preferred. The acidity of some steroids allows them to be held in alkaline solution while nonacidic impurities are extracted with organic solvents.

Commercially, abundant steroids usually are purified by repeated crystallization from solvents. Small-scale laboratory isolations for investigative or assay purposes usually exploit differing polarities of the steroid and of its impurities, which may be separated by partition between solvents differing in polarity or by chromatography (see below). Occasionally, special reagents may selectively precipitate or otherwise sequester the desired steroid. A classical example is the precipitation of 3*β*-hydroxy sterols such as cholesterol by the natural steroid derivative digitonin. New steroids of great physiological interest often are isolated from tissue only with extreme difficulty because they are usually trace constituents. For example, 500 kilograms (1,100 pounds) of silkworm pupae yielded 25 milligrams (0.0008 ounce) of pure molting hormone, the steroid ecdysone (*i.e.*, 20×10^6-fold purification). In such cases each isolation step is followed by an assay for the relevant physiological activity to ensure that the desired material is being purified. The percentage recovery of known steroid hormones during their assay in small biological samples usually is assessed by adding a trace of the same steroid in radioactive form to the initial sample, followed by radioassay (analysis based on radioactivity) after purification is complete. The efficiency of recovery of the radioactive steroid is assumed to be the same as that of the natural substance.

Determination of structure and methods of analysis. The systematic, stepwise breakdown by chemical methods of the steroid ring systems, used in early investigations of structure, is now mainly of historical interest. The small number of different nuclear structures found in steroids often has permitted establishment of the structure of a new steroid by conversion to related compounds of known structure. Structure elucidation in the steroid field, as in all areas of organic chemistry, now depends heavily upon physical methods, particularly nuclear magnetic resonance, infrared spectroscopy, optical rotatory dispersion, mass spectrometry, and X-ray crystallography. Data obtained by these methods reinforce and often replace the classical criteria of characterization of steroids: melting point, optical rotation, elemental analysis, and ultraviolet absorption at a fixed wavelength.

Chromatography

Chromatography is a crucial technique in steroid chemistry. The behaviour of a steroid in selected chromatographic systems often identifies it with a high degree of probability. The identification may be made virtually certain by the conversion of the material to derivatives that in turn are examined chromatographically. Abundant data for the behaviour of steroids in paper chromatography, thin-layer chromatography, and gas–liquid chromatography show that individual features of molecular structure determine the chromatographic properties of steroids in a predictable manner. Because gas-liquid chromatography is the most precisely controllable technique, it provides the most valuable data for structural identification. The gas–liquid chromatograph linked directly to the mass spectrometer permits characteristic mass-spectral fragmentation patterns and critical gas–liquid chromatographic data to be obtained simultaneously, using a sample containing less than a microgram of a steroid. This powerful technique is of growing importance in the structural analysis of steroids in extracts of such body fluids as blood and urine.

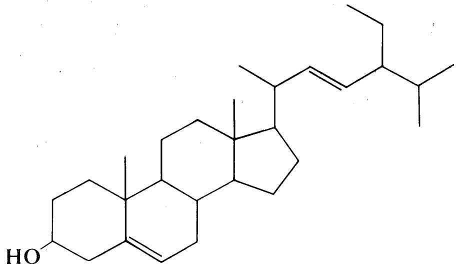
Synthesis of steroids. *Total synthesis.* The total synthesis of any steroid (*i.e.*, synthesis from simple organic chemicals by reactions that follow known pathways) is formally the final proof of its chemical structure. To reproduce all stereochemical details of the naturally occurring material, however, is an exacting intellectual and technical challenge that has been met with extraordinary ingenuity and originality by several chemists.

In most total syntheses of steroids, a monocyclic starting material such as a quinone provides one ring upon which the other rings of the nucleus are elaborated, step by step, by condensation reactions with smaller molecules to give the desired stereochemistry in successive ring fusions. Each new ring closure must also provide functional groups that can be used in building up the next ring. In a quite different approach, stereochemical control of ring fusions is achieved by using the fact that, under acidic conditions, open-chain molecules containing suitably located double bonds cyclize to multi-ring structures that have the necessary stereochemistry and that can be relatively easily converted to steroids. From its analogy with the cyclization of squalene 2,3-oxide to lanosterol in the biosynthesis of cholesterol (see below), this method is said to involve "biogenetic-type cyclization."

Partial synthesis. Although total synthesis of steroids has proved commercially feasible, it is often more practical to prepare them by partial synthesis; that is, by modification of other steroids that are naturally abundant. To be useful as a starting material for partial synthesis, the naturally occurring steroid must possess a molecular structure that can be easily converted to that of the desired product. For the synthesis of cortisol, cortisone, and their analogues, which carry an oxygen function at C-11, a pre-existing oxygen function at this position or at the adjacent C-12 is highly desirable. Indeed, prior to the advent of methods for microbiological oxidation, this was a crucial requirement, since the introduction of any functional group at C-11 of most steroids was extremely difficult.

Commercial synthesis

In the early commercial synthesis of androgenic steroids, cholesterol was the main starting material. Cholic acid and deoxycholic acid, inexpensive by-products from slaughterhouses, were starting materials for production of cortisone. The bulk of steroid drugs now is manufactured from the abundant steroids of plant origin, notably the sapogenins. Diosgenin, obtainable from several varieties of *Dioscorea,* a Mexican yam, is used in the commercial manufacture of progesterone, which can be converted to androgenic and estrogenic hormones and to the more complex adrenal steroid hormones, such as cortisone and cortisol. A most important advance in this field was the discovery that microorganisms such as *Rhizopus nigricans* introduce hydroxyl groups into a variety of steroids at C-11 and elsewhere: they are used in the commercial synthesis of a large number of steroid hormone analogues. A sapogenin, hecogenin, obtainable in quantity from the waste of sisal plants, is used for synthesis of cortisol. Stigmasterol, which is readily obtainable from soybean oil, can be transformed easily to progesterone and to other hormones, and commercial processes based on this sterol have been developed.

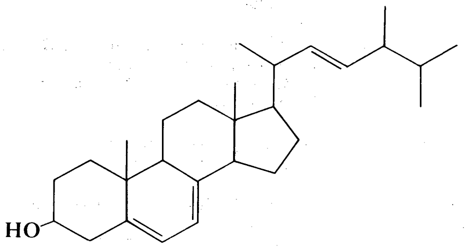


stigmasterol (7)

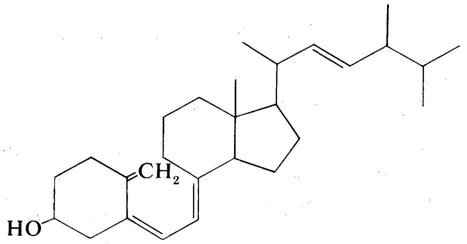
NATURAL DISTRIBUTION AND FUNCTIONS

Sterols and bile acids. The most generally abundant steroids are sterols, which occur in all tissues of animals, green plants, fungi, and yeasts. Evidence for the presence of steroids in bacteria and in primitive blue-green algae is conflicting. The major sterols (Table 47) of most tissues are accompanied by traces of their precursors—lanosterol in animals and cycloartenol in plants—and of intermediates between these compounds and their major sterol products. In mammalian skin, one precursor of cholesterol, 7-dehydrocholesterol, is converted by solar ultraviolet light to cholecalciferol, vitamin D_3, which controls calcification of bone by regulating intestinal absorption of calcium. The disease rickets, which results from lack of exposure to sunlight, can be treated by administration of the vitamin or of the corresponding derivative of ergosterol, ergocalciferol (vitamin D_2).

Rickets and atherosclerosis



ergosterol (8)



ergocalciferol (9)

Sterols are present in tissues in both the non-esterified (free) form and as esters of aliphatic fatty acids. In the disease atherosclerosis, fatty materials containing cholesterol form deposits (plaques), especially in the walls of the major blood vessels, and vascular function may be fatally impaired. The disease has many contributory factors but typically is associated with elevated concentrations of cholesterol in the blood plasma. One aim of medical treatment is to lower the plasma cholesterol level.

Free sterols appear to stabilize the structures of cellular and intracellular membranes. Because the sheath of nerve fibres is a deposit of many layers of the membranes of neighbouring cells, mature mammalian nerve tissue (*e.g.,* beef brain) is the richest source of cholesterol. Cholesterol also is converted in animals to steroids that have a variety of essential functions, and in plants to steroids the functions of which are less clearly understood. The bile acids

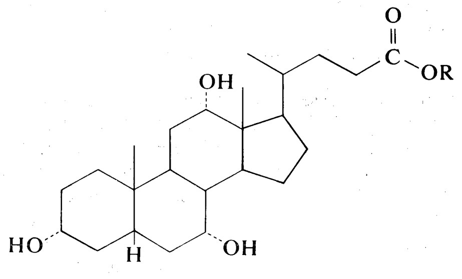
Table 47: Some Important Sterols and Their Sources

common name	systematic name	occurrence
Cholesterol	5-cholesten-3β-ol	principal sterol of most animals and all vertebrate tissues
Coprostanol	5β-cholestan-3α-ol	feces of vertebrates
Cholestanol	5α-cholestan-3β-ol	minor vertebrate sterol: guinea pig and rabbit adrenal
Lathosterol	5α-cholest-7-en-3β-ol	vertebrate skin, intestine
7-Dehydrocholesterol	5,7-cholestadien-3β-ol	mammalian skin, intestine
Desmosterol	5,24-cholestadien-3β-ol	chick embryo, barnacle (*Balanus glandula*)
Zymosterol	5α-cholesta-8,24-dien-3β-ol	minor sterol of yeasts
Ergosterol	5,7,22-ergostatrien-3β-ol	principal sterol of yeasts, ergot (*Claviceps purpurea*), and other fungi
Stigmasterol	5,22-stigmastadien-3β-ol	most green plants, soy beans
Sitosterol	5-stigmasten-3β-ol	most green plants, wheat germ
Fucosterol	5,24(28)-stigmastadien-3β-ol	principal sterol of marine brown algae (*Fucus* species)
Lanosterol	8,24-lanostadien-3β-ol	skin, sheep wool fat, yeasts
Lophenol	4α-methyl-5α-cholest-7-en-3β-ol	skin, intestine, feces, cactus (*Lophocerus schotti*)
Cycloartenol	9,19-cyclo-24-lanosten-3β-ol	generally minor sterol of green plants (*Artocarpus* species)

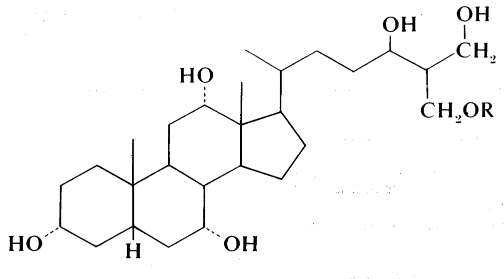
Table 48: Evolutionary Relationships of Bile Alcohols and Bile Acids

species	bile alcohol or bile acid (trivial name)
Elasmobranch fish	
Myxine glutinosa (hagfish)	5α-cholestane-3β,7α,16α,26-tetrol (myxinol)
Mustelus manazo (dogfish)	5β-cholestane-3α,7α,12α,24,26,27-hexol (scymnol)
Teleostian fish	
Latimeria chalumnae (coelacanth)	5α-cholestane-3β,7α,12α,26,27-pentol (latimerol)
Cyprinus carpio (carp)	5α-cholestane-3α,7α,12α,26,27-pentol (5α-cyprinol)
Amphibians	
Rana temporaria (frog)	5α,27-norcholestane-3α,7α,12α,24,26-pentol (5α-ranol)
Bufo vulgaris japonica (toad)	5β-cholestane-3α,7α,12α,25,26-pentol (5β-bufol)
Reptiles	
Alligator mississippiensis (alligator)	3α,7α,12α-trihydroxy-5β-cholestan-27-oic acid (trihydroxycoprostanoic acid)
Bitis arietans (puff adder)	3α,12α,23-trihydroxy-5α-cholanoic acid (bitocholic acid)
Bird	
Anser domesticus (goose)	3α,7α-dihydroxy-5β-cholanoic acid (chenodeoxycholic acid)
Mammals	
Man and most (but not all) species	3α,7α,12α-trihydroxy-5β-cholanoic acid (cholic acid) 3α,12α-dihydroxy-5β-cholanoic acid (deoxycholic acid) 3α-hydroxy-5β-cholanoic acid (lithocholic acid)

(cholanoic acids, earlier called cholanic acids) of higher vertebrates form conjugates with the amino acids taurine and glycine, and the bile alcohols (cholane derivatives) of lower animals form esters with sulfuric acid (sulfates; Table 48). These conjugates and sulfates enter the intestine as sodium salts and assist in the emulsification and absorption of dietary fat, processes that may be impaired when bile acid secretion is reduced, as in some liver diseases and in obstructive jaundice. The mixture of bile acids found in feces reflects the actions of intestinal microorganisms upon the primary bile acid secretory products (*e.g.*, deoxycholic acid arises by bacterial transformation of cholic acid).



cholic acid (10a; R = H) and sodium glycocholate (10b; R = $NHCH_2COO^-Na^+$)



scymnol (11a; R = H) and sodium scymnol sulfate (11b; R = $SO_3^-Na^+$)

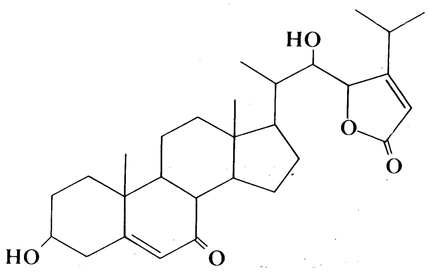
Sex hormones. Steroids that have a phenolic ring *A* (that is, those in which ring *A* is aromatic and bears a hydroxyl group) are ubiquitous products of the ovary of vertebrate animals. These are the estrogens, of which estradiol is the most potent. They maintain the female reproductive tissues in a fully functional condition, promote the estrous state of preparedness for mating, and stimulate development of the mammary glands and of other feminine characteristics. Estrogenic steroids have been isolated from urines of pregnant female mammals of many species including man, from placental and adrenal tissues, and, unexpectedly, from the testes and urines of stallions.

Estrogens and androgens

The corpus luteum, a modification of vertebrate ovarian tissue that forms following ovulation, produces the gestogens, which include progesterone and its derivatives. Gestogens also are secreted by the adrenals and placenta in some species. These compounds, in combination with the estrogens, regulate the metabolism of the uterus to permit implantation and subsequent development of the fertilized ovum in mammals. In birds, estrogens and gestogens stimulate the development of the oviduct and its secretion of albumin. Estrogens and gestogens suppress ovulation (release of the mature egg cell from the ovary); this fact is the basis of action of steroid anti-fertility drugs (see below). Estrogens and gestogens occur in primitive invertebrates, but their functions in those animals are obscure.

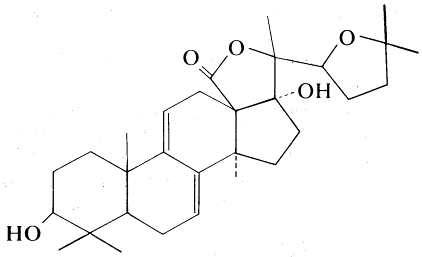
In male vertebrates, the androgens—steroids secreted by the testes—maintain spermatogenesis and the tissues of the reproductive tract. They promote male sexual behaviour and aggressiveness, muscular development, and, in man, the growth of facial and body hair and deepening of the voice. Testosterone and androstenedione are the principal androgens of the testes. Testosterone is more potent than androstenedione, but in the sexual tissues it appears to be converted to 5α-dihydrotestosterone, an even more potent androgen.

Adrenal hormones. The adrenal cortex of vertebrates synthesizes oxygenated progesterone derivatives. These compounds are hormones that are vital to survival and are classified according to their biological activity. The glucocorticoids promote deposition of glycogen in the liver and the breakdown of body proteins. Mineralocorticoids stimulate retention of sodium in the extracellular body fluids. Cortisol is the principal glucocorticoid in many species including man; in most rodents, this role is filled by corticosterone. The most potent mineralocorticoid of all species is aldosterone. Aldosterone has about 20 percent of the glucocorticoid activity of cortisol, which, conversely, has about 0.1 percent of the mineralocorticoid activity of aldosterone. Either steroid can maintain life in an animal from which the adrenal glands have been removed. The secretion of glucocorticoids is exquisitely responsive to injury and fear in animals and is primarily responsible for metabolic adaptation to stressful conditions. Failure of the adrenal cortex in man gives rise to Addison's disease, a formerly fatal condition that can now be successfully treated with synthetic adrenal steroids.



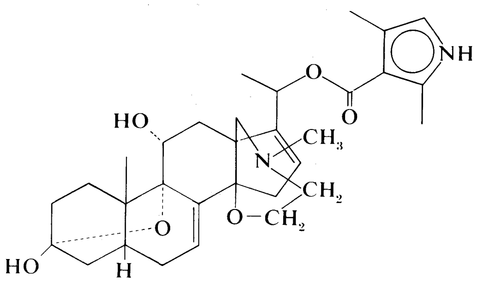
antheridiol (12)

Steroids of lower organisms. An area of increasing interest is the role of steroids in the reproduction, development, and self-defense of lower organisms. In an aquatic fungus, *Achlya bisexualis,* the steroid antheridiol (12) of the female stimulates male gamete formation. Insects and crustaceans produce the ecdysones, steroid hormones that promote molting and the development of adult characteristics (Table 49). Many plants, especially ferns and conifers, contain steroids that may protect them against some predatory insects, although this function is not established. Progesterone, 11-deoxycorticosterone, and related steroids with no known endocrine function in insects are released into the water by several species of water beetles to repel predatory fish, and the sea cucumbers (Holothuroideae) produce the holothurinogenins, a group of lanosterol derivatives toxic to nervous tissue.

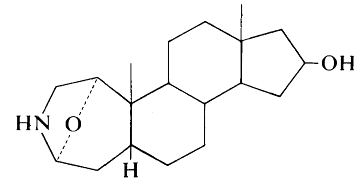


22,25-oxidoholothurinogenin (13)

Cardanolide and bufanolide derivatives, found in many plants and in the skin of toads, cause vomiting, visual disturbances, and slowing of the heart in vertebrates and are strong deterrents to predators. Birds and other predators avoid certain grasshoppers and butterflies that store cardenolides of the plants upon which they feed. The skin of the Colombian frog, *Phyllobates aurotaenia,* produces a deadly alkaloid, batrachotoxin, which is used by tribal peoples as an arrow poison. The skin of salamanders secretes a comparably poisonous alkaloid—samandarin.



batrachotoxin (14)



samandarin (15)

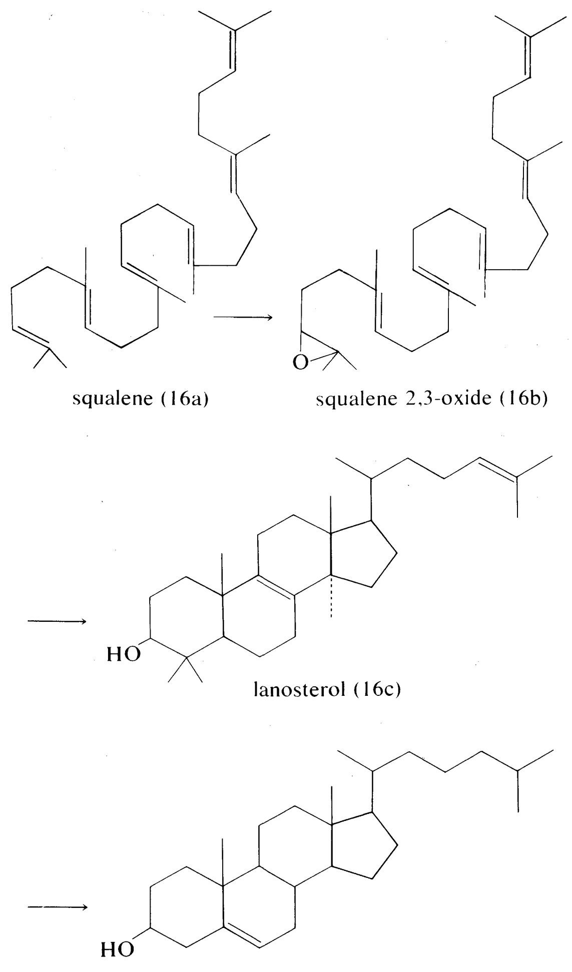
Many steroid alkaloids occur in plants, but their functions, like those of the steroid saponins, are unknown. It is possible that the taste of many of these compounds deters grazing animals or that they attract certain insect species to the plant.

BIOSYNTHESIS AND METABOLISM OF STERIODS

Cholesterol. Steroids are probably synthesized in all vertebrates and in many invertebrates by the same pathway, which includes cholesterol. Biosynthesis (formation in intact organisms) of cholesterol is especially vigorous in the liver of vertebrates but also occurs in the intestine, gonads, skin, and immature brain. It is barely detectable in the adult brain. The insects, certain mollusks, annelids, and some protozoa do not synthesize cholesterol but must obtain it, or a related sterol, in their diet.

Squalene and lanosterol

Cholesterol and other steroids are biosynthesized by extension of the enzyme pathway by which terpenoids are synthesized (see above *Isoprenoids*). Acetate fragments derived from common nutrient materials are converted into mevalonic acid, from which the terpenoid hydrocarbon squalene is formed. One end of the squalene molecule is then oxidized, giving squalene 2,3-oxide, which, by an intramolecular reaction (cyclization) and structural rearrangement, yields the steroid lanosterol. This enzyme-controlled reaction may be initiated by introduction of a positive charge into the oxide ring because it is remarkably similar to the nonenzymic, acid-catalyzed cyclizations of certain unsaturated hydrocarbons similar in structure to squalene. Cholesterol is formed from lanosterol by further structural changes.



squalene (16a) squalene 2,3-oxide (16b)

cholesterol (16d)

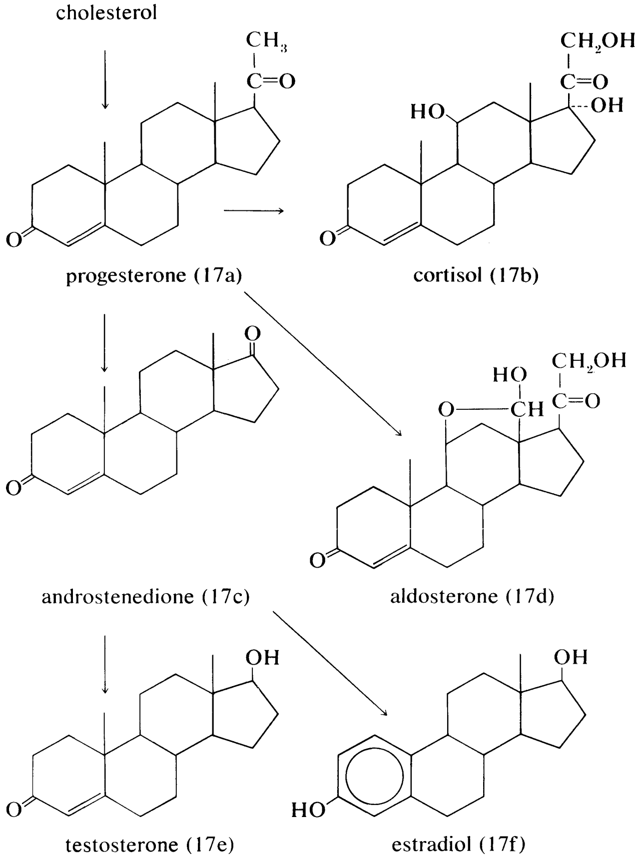
biogenesis of cholesterol

The principal forms in which cholesterol is excreted by vertebrates are the bile acids, which are synthesized in the liver. Their formation involves specific modifications of the steroid nucleus and formation of a carboxylic acid group that is linked to the amino acids taurine or glycine to give the forms in which the bile acids are secreted into the bile. The biosynthesis of cholesterol is influenced by feedback mechanisms that suppress the formation of mevalonic acid and, consequently, of cholesterol when levels of cholesterol and bile acids in the tissues are elevated.

Steroid hormones. In vertebrates, cholesterol is the central precursor of all steroid hormones secreted by the testes of the male, the ovaries of the female, and the adrenals of both sexes. These tissues share an embryonic tissue of origin and, in consequence, many enzymes for the transformation of cholesterol. A major (though not exclusive) common pathway involves conversion to progesterone. Progesterone is secreted by the corpus luteum of the ovary, but in the adrenal cortex it is further metabolized to steroid hormones (corticosteroids) such as cortisol and aldosterone. In both ovary and testis, progesterone is transformed further to the androgenic steroid androstenedione, which, together with its derivative testosterone, is secreted by the testis. In the ovary, androstenedione is modified to the estrogen estradiol. Normally, each organ secretes its own characteristic pattern of hormones, but in some disease states (*e.g.,* genetic defects and some tu-

Progesterone

mours of these endocrine glands) these patterns may be profoundly distorted.



biogenetic relationships of principal vertebrate steroid hormones

Many tissues, but mainly the liver, metabolize the steroid hormones to physiologically inactive products that are voided mainly in the urine, though some are also eliminated via the bile and, ultimately, the feces. Diagnosis of endocrine abnormalities may be assisted by analysis of urinary steroids. Urinary 17-ketosteroids (androstane derivatives with a >C=O function at C-17) arise principally through oxidation of adrenal steroid hormones in the liver and thus gauge secretion by the adrenal rather than by the testis. In pregnancy, the urinary excretion of pregnanediol, the principal metabolite of progesterone, measures placental progesterone output. Its decline before term may forewarn of abortion, which may be averted by administration of progestational hormones.

Steroid metabolism in plants. The early steps in the biosynthesis of steroids of both plants and animals are the same, except that in plants lanosterol is replaced by the related compound cycloartenol, which contains a three-membered ring (C-9, C-10, C-19) in lieu of the nuclear double bond of lanosterol. The side chains of the phytosterols, such as stigmasterol, and of the sterol ergosterol of yeasts and fungi contain extra carbon atoms that are incorporated in reactions involving *S*-adenosylmethionine, which donates methyl (CH_3) groups in numerous biological processes. Although most plant tissues contain only traces of cholesterol, this sterol is the biogenetic precursor of such important plant steroids as the sapogenins, cardiac glycosides, and steroid alkaloids. Because pregnane derivatives are intermediates in some of these transformations, plants and animals appear to have important features of steroid metabolism in common.

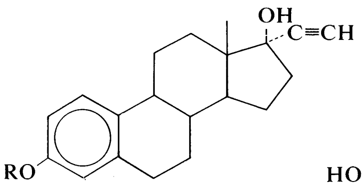
STRUCTURAL RELATIONSHIPS OF THE PRINCIPAL CATEGORIES OF STEROIDS

Sterols. A large group, the sterols, comprises the common 3-monohydroxy steroids of the cholestane, ergostane, and stigmastane series and their "methyl sterol" biogenetic precursors: lanosterol, cycloartenol, and certain derivatives of these sterols, such as lophenol (Table 47). Most sterols have a 3β-hydroxyl group, and many (though not the 4-methyl sterols) have a double bond between carbon atoms 5 and 6. Various sterols have double bonds at other positions in the nucleus corresponding to stages in the biosynthesis of cholesterol and other steroids that resemble it in the structure of ring *A*. Animal sterols, especially in embryonic tissues and skin, and phytosterols (*e.g.*, stigmasterol) also may have a double bond in the side chain. Sterols of feces (*e.g.*, coprostanol) have a 3α-hydroxyl group and *cis*- (5β) linked rings *A* and *B;* they are formed by metabolism of other sterols by intestinal bacteria. Certain sterols are transformed to calciferols (D vitamins) by ultraviolet light; this process occurs naturally in the skin and is used commercially in the manufacture of vitamin D_2 (ergocalciferol) from ergosterol and of vitamin D_3 (cholecalciferol) from synthetic 7-dehydrocholesterol.

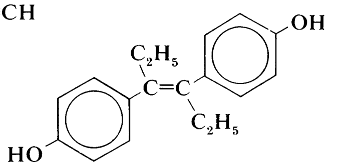
Bile acids and alcohols. The molecular structures of metabolites of cholesterol form an evolutionary series from the bile alcohols, such as myxinol and scymnol of the elasmobranch fishes and the related alcohols of some bony fishes and frogs, through the 5β-cholestanoic acids of crocodiles and alligators, to the 5β-cholanoic acids of the birds and mammals. This evolutionary trend is illustrated by the selected compounds in Table 48. They are not exclusively confined to the species indicated; for example, chenodeoxycholic acid is a major bile acid in man and many other mammals, and cholic acid is found in many nonmammalian species, together with primitive bile acids or alcohols that are not found in the mammals.

Estradiol

Estrogens. The estrogens of the ovary of vertebrates are steroids that are abundant in the urines of pregnant mares and of stallions. The most potent natural estrogen is estradiol; the less potent estrogens—estrone, estriol, and other oxygenated phenolic steroids—are metabolites of estradiol. Some species, notably the Equidae, secrete the less active estrogen equilenin. Estrone, synthesized from diosgenin, has been used as a starting material for synthesis of androgenic and progestational steroids lacking a C-19 methyl group (19-nor steroids). Synthetic estrogens, as estranol or mestranol, commonly used in oral contraceptives and for other therapeutic purposes, have acetylenic (containing triple bonds between carbon atoms) substituents. Nonsteroidal synthetic estrogens—*e.g.*, diethylstilbestrol and related compounds—are used clinically and also in animal husbandry to promote fattening of livestock and poultry and to improve the quality of their meat.



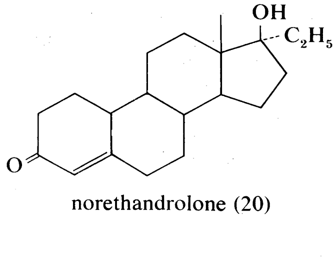
estranol (18a; R = H) and mestranol (18b; R = CH_3)



diethylstilbestrol (19)

Progestational steroids (gestogens, progestins). Three naturally occurring steroids of the corpus luteum and placenta have progestational action; these are progesterone and two of its metabolites. All possess an unsaturated ketonic structure in ring *A*. Pregnanediol, the main metabolite of progesterone, lacks both this structural feature and progestational activity.

Synthetic progestational steroids that are used in oral contraceptives and for other therapeutic purposes (see below) are derivatives of progesterone or of 19-nortestosterone. Among the latter is norethandrolone.



norethandrolone (20)

Table 49: Representative Ecdysones of Arthropods and Plants

compounds	variant of ecdysone structure	occurrence
C_{27} steroids

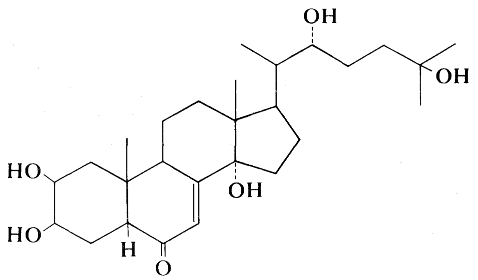
Makisterone B	20, 26-dihydroxy-, 24-methyl-25-deoxy-	*Podocarpus macrophyllus*
C_{29} steroids		
Makisterone C	20-hydroxy-, 24-ethyl-	*Podocarpus macrophyllus*
Cyasterone	20, 22-dihydroxystigmasteno-26, 28-lactone side chain	*Cyathula capitata* and several *Ajuga* species

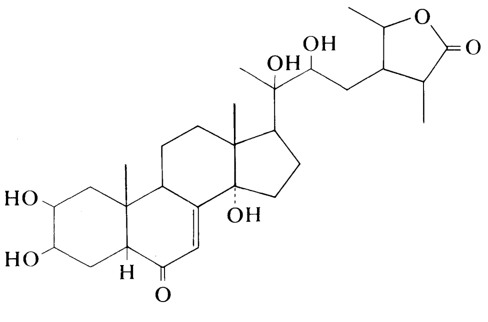
Androgens. Testosterone and androstenedione are the major testicular androgens. Several other less active androgens occur naturally. Major metabolites of testosterone are androsterone and etiocholanolone. The latter compound is androgenically inactive, but it is a pyrogen (*e.g.*, a fever-producing agent) that has been associated clinically with some febrile conditions. Various carboxylic acid esters and a number of synthetic analogues of testosterone are used therapeutically (see below).

Adrenal cortical hormones. The steroids of the adrenal cortex are progesterone derivatives that bear hydroxyl groups at positions 11, 17α, or 21. The potent mineralocortoid aldosterone carries an aldehyde function in place of the more usual C-18 methyl group. Glucocorticoid potency is higher in the trihydroxy derivative cortisol of man, monkeys, and dogs than in the dihydroxy steroid corticosterone of rats and mice. Every adrenal steroid hormone has a ketone group at C-3 and a double bond between C-4 and C-5. In the liver their physiological activities are lost when ring *A* is reduced, and they are partially inactivated when the 11β-hydroxyl is oxidized to a ketone group (as in cortisone and 11-dehydrocorticosterone). The adrenal corticoids are among the most chemically reactive of the steroid hormones; they are sensitive to strong acids and alkalies and to elevated temperatures.

In many synthetic analogues of cortisol and cortisone, physiological activity is modified. Derivatives with enhanced anti-inflammatory activity are especially valuable therapeutically and are discussed below.



α-ecdysone (21)



cyasterone (22), a phytoecdysone

Molting hormones

Ecdysones. The molting hormones (zooecdysones) of insects and crustaceans are generally derivatives of cholestane (Table 49). All possess a ketone group at position 6, a double bond between positions 7 and 8, and 2β, 3β, and 14α-hydroxyl groups. The side chain is hydroxylated at C-22 and variously at C-20, C-25, and C-26. Some of these compounds occur in plants, many of which also contain potent ecdysone analogues (phytoecdysones) with ergostane and stigmastane side chains.

The ecdysones show cross-species activity—that is, the ecdysone of one species induces molting in another species. The preponderance of ecdysones related to cholestane even in phytophagous insects probably reflects their capacity to convert dietary phytosterols to cholestane derivatives.

Cardiac glycosides and aglycones. Many species of plants contain toxic (specifically, heart-arresting) steroids of the cardanolide type as glycosides (compounds that contain structural groups derived from sugars) of up to four sugar residues, which may include glucose, rhamnose, and 10 other sugars peculiar to this group of natural products. Typically, these compounds (Table 50) are 5β-steroids and have 3β- and 14β-hydroxyl groups, but hydroxyl groups may occur in many other positions. In all cases, the aglycone (the steroid that results when the sugar groups are removed) is less active than its glycosides, but generally, activity declines with increasing numbers of sugar residues after the first. The structures of the sugars have important but not predictable effects on activity.

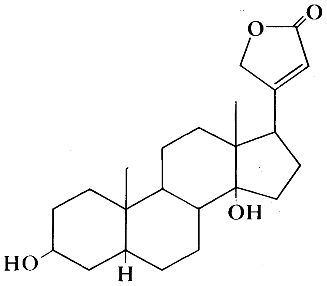
Table 50: Some Cardiac Glycosides and Their Cardenolide Aglycones

glycoside	aglycone	systematic name of aglycone
Digitoxin	digitoxigenin	$3\beta,14\beta$-dihydroxy-5β-card-20(22)-enolide
Gitoxin	gitoxigenin	$3\beta,14\beta,16\beta$-trihydroxy-5β-card-20(22)-enolide
Digoxin	digoxigenin	$3\beta,12\beta,14\beta$-trihydroxy-5β-card-20(22)-enolide
Periplocin	periplogenin	$3\beta,5\beta,14\beta$-trihydroxy-5β-card-20(22)-enolide
Sarmentocymarin	sarmentogenin	$3\beta,11\alpha,14\beta$-trihydroxy-5β-card-20(22)-enolide
k-Strophanthin	strophanthidin	$3\beta,5\beta,14\beta$-trihydroxy-19-oxo-5β-card-20(22)-enolide
Ouabain	ouabagenin	$1\beta,3\beta,5\beta,11\alpha,14\beta$,19-hexahydroxycard-20(22)-enolide

The most important cardiac glycosides, medicinally, are those occurring in foxglove (*Digitalis*): digitoxin, gitoxin, and digoxin. Each of these contains a specific aglycone (*e.g.*, digitoxigenin is the aglycone of digitoxin) linked to three molecules of the sugar digitoxose and is derived from a more complex glycoside (digilanides A, B, and C, respectively) from which glucose and acetic acid are removed during the isolation procedures.

Toxic glycosides

The squill, or sea onion, *Scilla maritima*, a seashore plant, contains several toxic glycosides of which the aglycones are bufadienolides more typical of the toad poisons than of plant products. (In a bufadienolide, two double bonds are present in the bufanolide side chain.) A white form of the squill produces the glycoside scillaren A, which contains the aglycone scillarenin, while a red form

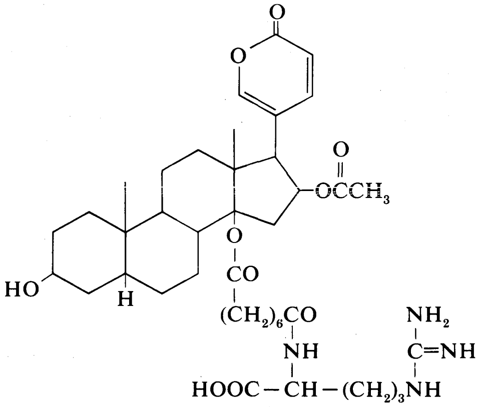


digitoxigenin (23)

produces scilliroside, which is specifically toxic to rodents and has long been used as a rat poison. The contribution of the side chain to cardiac activity differs little between the bufanolides and the cardanolides.

Toad poisons. Defensive venoms secreted by skin glands (principally the parotid glands) of the toad owe their high toxicity to bufadienolides that occur both free (bufogenins) and combined (bufotoxins). These compounds have digitalis-like properties and have been used medicinally in a traditional Chinese preparation, Ch'an Su. The best characterized is bufotoxin, from the European toad *Bufo vulgaris* and the Oriental toad *Bufo gargarizans,* of which the bufogenin is bufotalin, a close structural relative of gitoxin.

Sapogenins and saponins. Sapogenins are steroids of the spirostan type that occur widely and in great variety in plants. They are linked to sugars as glycosides, usually through a 3β-hydroxyl group. The glycosides are saponins, so called because they form soapy solutions and have other surface active (*e.g.,* hemolytic) properties. Since saponins are difficult to purify, the complete structures of only a few are known. Among these is dioscin (from certain yams, *Dioscorea* species, and yuccas, *Trillium* species); the steroid portion of this saponin is diosgenin.



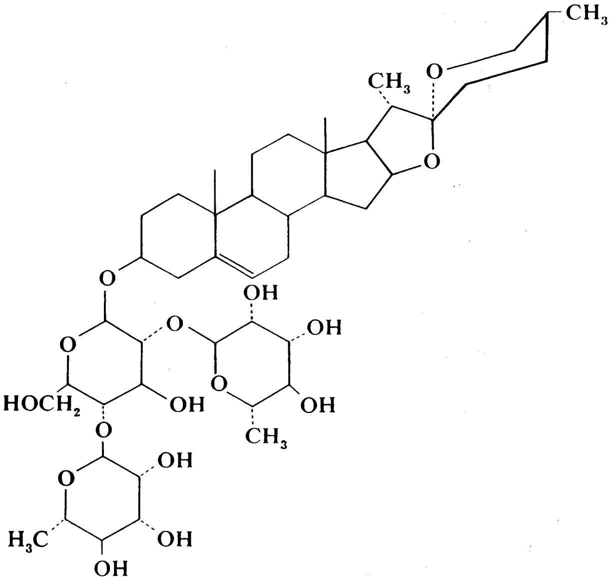
bufotoxin (24)

The nature and number of sugar residues per molecule are known for many saponins. These include the common sugars glucose, xylose, galactose, rhamnose, and arabinose. In most cases, however, only the structure of the sapogenin, which can be released from the saponin by acid hydrolysis, is known with certainty. Linkage of rings *A* and *B* may be *cis-* (5β) or *trans-* (5α) or may involve unsaturation at C-5. A hydroxyl group is nearly always present at position 3, and hydroxyl or ketonic groups may be present at positions 1, 2, 4, 5, 6, 11, 12, or 15. Many pairs of natural sapogenins differ only in configuration at C-25. Their structural features and abundance make diosgenin and hecogenin useful as starting materials for steroid hormone manufacture.

PHARMACOLOGICAL ACTIONS OF STEROIDS

ide
ffects

Aside from their principal physiological effects, all steroid hormones have generalized influences upon metabolic systems throughout the body. These are sometimes seen as powerful pharmacological side effects when, either during hormone therapy or through some endocrine abnormality, the body is exposed to excessive amounts of a naturally occurring steroid hormone. In some synthetic analogues of the natural hormones, a desired activity is accentuated while others are minimized. Furthermore, just as naturally occurring steroid hormones of differing biological activity (estrogens, androgens, glucocorticoids, mineralocorticoids) often act antagonistically, the many steroid analogues include a number of inhibitors of the natural hormones. Details of the effects of steroids upon living organisms, including pharmacological applications, are more fully covered in other articles (see BIOCHEMICAL COMPONENTS OF ORGANISMS; ENDOCRINE SYSTEMS).



dioscin (25), a saponin of diosgenin

Androgens and anabolic steroids. Androgens secreted or administered in abnormally large amounts can cause development of male characteristics in the female and precocious sexual development in the male. Conversely, hypogonadism of the male (inadequate testicular function) leads to retarded sexual development and retention of feminine bodily characteristics (eunuchoidism), which can sometimes be remedied by administration of androgenic steroids. Several esters of testosterone are commonly used by injection for this purpose. Many orally active analogues of testosterone are also available (Table 51) in which activity is greatly enhanced, and often the ratio of androgenic activity to anabolic activity is shifted markedly in favour of the latter. This ratio primarily determines the therapeutic value of these compounds as anabolic agents. They are used together with growth hormone to promote growth in children in whom growth is retarded. They are also used to promote physical recovery from debilitating diseases. Their alleged use by some athletic competitors in sports has been decried.

Use as
anabolic
agents

The psychic effects of androgens have been exploited in their use to correct frigidity in women and lack of self-esteem in adolescents. Androgens are also used in the treatment of estrogen-dependent tumours, such as breast cancer in women.

thetic gestogens, such as medroxyprogesterone acetate and chlormadinone acetate (Table 52), have anti-androgenic properties that are the basis for their use against benign or malignant hyperplasia of androgen-dependent tissues such as the prostate. Other anti-androgens are A-nortestosterone and A-norprogesterone and their derivatives. The anti-androgens cyproterone and medroxyprogesterone acetate have been used successfully to control sexually violent patients.

The Pill

Synthetic estrogens and gestogens: steroid contraceptives. The most effective currently available method of contraception uses combinations of synthetic estrogens and gestogens that prevent ovulation and render the uterine environment inimical to conception and to the development of the ovum. Unlike the natural hormones, these synthetic steroids are highly active when taken orally, as tablets, and as contraceptives they are popularly referred to as the Pill. Ovulation is suppressed because release of the pituitary hormone that stimulates it is inhibited, primarily by the estrogenic component. The gestogens are also anti-ovulatory, but their principal function in oral contraceptives is to control the uterine bleeding (menstruation) that follows withdrawal of the estrogen. The tablets are taken according to schedules that simulate a 28-day menstrual cycle. Most frequently, a combination of the two types of steroid is taken daily during 21 or 22 days and is then interrupted for the remainder of the 28-day period. During the nonmedication days, the menstrual flow occurs. An alternative sequential schedule aims to approximate more closely to the endocrine events of the normal menstrual cycle by the use of tablets of estrogen alone for 14–15 days followed by tablets of combined estrogen and gestogen for 5–7 days prior to interruption to permit menstruation. The combination method is somewhat more reliable, probably because the gestogens in the combination regime influence the uterine environment to prevent implantation of the ovum in those few cycles in which ovulation is not inhibited.

The contraceptive steroids, which were brought into popular use in the early 1960s, have proved remarkably safe. Their discontinuance is usually followed by a prompt return of fertility. Some individuals suffer unpleasant symptoms (nausea, water retention, tiredness) in the use of certain preparations, but a variety of alternative types have become available (Table 52), among which a satisfactory one usually may be found. Estrogens that have been used in oral contraceptives include estranol, which has about the same potency as estradiol, and mestranol, which is less potent. The main differences between preparations are the character of the gestogens and the quantities and ratios of the steroids that they contain.

Other uses of estrogens and gestogens

Besides their use in birth control, the contraceptive steroid preparations and synthetic gestogens are used to correct irregularities of the menstrual cycle and its frequent physical and psychological symptoms. The gestogens are used to maintain pregnancy in cases of threatened abortion, some as anti-androgens, and others as anti-estrogens. Contraceptive steroid preparations are also used for control of breeding cycles and synchronization of estrus in farm animals. The synthetic estrogens are used to alleviate the unpleasant physical and psychic symptoms of the menopause in women and for the treatment of some cancers of the prostate in men and of the breast in women. They are also used in some cases to suppress the plasma cholesterol concentrations in sufferers from advanced atherosclerosis, a disease that is markedly more prevalent in men and postmenopausal women than in younger women with intact ovaries.

Anti-estrogens. Androgenic steroids are anti-estrogenic and are often used to suppress the growth of estrogen-dependent cancers. Methyltestosterone and fluoxymesterone (Table 51), and norethindrone (norethisterone) and norgestrel (Table 52) are anti-estrogens. Since estrogens block the release of the pituitary hormone responsible for ovulation, a potent anti-estrogen can stimulate ovulation by inhibiting this action of estrogens.

Adrenal hormones. The anti-inflammatory and glucocorticoid activities of cortisol are enhanced, in some cases with relative reduction of its mineralocorticoid activity, by various structural modifications (Table 53). A 9α-fluorine

atom enhances the glucocorticoid activity of cortisol about 10-fold, but its salt-retaining activity about 50-fold. On the other hand, unsaturation at C-1 increases glucocorticoid, but not mineralocorticoid, activity, and 6α-fluorine or methyl and 16-methyl or hydroxyl groups (and especially 16α,17α-acetonides—*i.e.,* compounds formed from 16α,17α-dihydroxy compounds and acetone) enhance anti-inflammatory activity while reducing salt activity. These groupings, therefore, appear in various combinations in anti-inflammatory steroids, many of which, however, lack the salt-retaining activity necessary for total adrenal replacement therapy. Cortisol analogues, such as dexamethasone, are used to treat many inflammatory and rheumatic diseases, to suppress the immune response in allergies and in organ transplantation, and to delay the progress of leukemia. They are also widely used for the treatment of local inflammatory reactions. A synthetic steroid of a quite different type, spironolactone (Aldactone A), is used as an antagonist to the action of aldosterone in certain cases of hypertension.

Cardiotonic steroids. Preparations in which cardiotonic steroids of both vegetable and animal origin are the active principles have been used as emetics, diuretics, and arrow poisons since ancient times. The use of digitalis, ouabain, and strophanthin glycosides to slow the rate and strengthen the contractility of the failing heart is one of the most important methods of treatment of this condition. Of these agents, the digitalis glycosides are the most widely used. The therapeutic effects of these agents are related to their influence upon muscle cells, but knowledge of their mechanism of action is incomplete and their use in medicine remains essentially empirical.

Conclusion: The general biological significance of steroids. That such diverse physiological functions and effects should be shown by steroids, all of which are synthesized by essentially the same central biosynthetic pathway, is a remarkable example of biological economy. Most of these functions, especially those of a hormonal type, involve the transmission of biologically essential information. The specific information content of the steroid resides in the character and arrangement of its substituent groups and in other subtle structural modifications. The mechanism of action of no steroid hormone at the molecular level is as yet known, nor is it known why the steroid nucleus is so highly appropriate as a carrier of informational signals in systems of biological control. But that it is, is beyond doubt, and it seems reasonable to expect that many further regulatory functions of steroids, especially in lower life forms, remain to be discovered.

(R.B.C./Ed.)

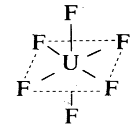
COORDINATION COMPOUNDS

Coordination compounds are substances with characteristic chemical structures in which a central metal atom is surrounded by nonmetallic atoms (or groups of atoms), called ligands, joined to it by chemical bonds. The class includes a number of important biological materials, such as vitamin B$_{12}$ and hemoglobin, the red colouring matter of blood. It also includes a number of industrially important materials used as dyestuffs and pigments; as agents for extracting, purifying, and analyzing metals; and as catalysts for preparing such useful organic substances as the polyethylene plastics. Coordination compounds have been much studied because of what they reveal about molecular structure and chemical bonding, as well as because of the unusual chemical nature and the useful properties of certain coordination compounds.

The general class of coordination compounds—or complexes, as they are sometimes called—is extensive and diverse. The substances in the class may be composed of electrically neutral molecules or of positively or negatively charged species (ions).

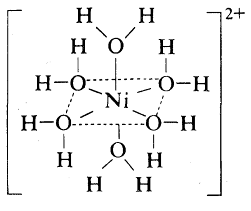
eutral
oordina-
ion com-
ounds

Among the many coordination compounds having neutral molecules is uranium hexafluoride. The molecular formula of this compound, UF$_6$, indicates that six atoms of fluorine (F) are joined to one atom of uranium (U). The structural formula of the compound represents the actual arrangement of atoms in the molecules:



In this formula the solid lines, which represent bonds between atoms, show that four of the fluorine atoms are bonded to the single atom of uranium and lie in a plane with it, the plane being indicated by dotted lines (which do not represent bonds); whereas the remaining two fluorine atoms (also bonded to the uranium atom) lie above and below the plane, respectively.

An example of an ionic coordination complex is the hydrated (water-containing, with formula H$_2$O) ion of nickel, symbol Ni, molecular formula [Ni(H$_2$O)$_6$]$^{2+}$, the structure of which is

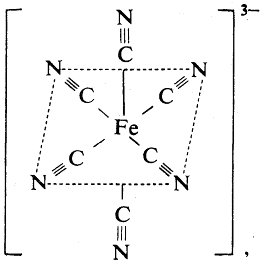


in which the symbols and lines are used as above and the brackets and the "two plus" (2+) sign show that the double positive charge goes with the whole unit.

The central metal atom in a coordination compound itself may be neutral or charged (ionic). The coordinated groups—or ligands, as they are usually called—may be neutral molecules such as water (in the above example), ammonia, or carbon monoxide; negatively charged ions (anions) such as fluoride (in the first example above) or cyanide ion; or, occasionally, positively charged ions (cations) such as hydrazinium or nitrosonium ion.

Complex ions

Complex ions—that is, the ionic members of the family of coordination substances—may exist as free ions in solution, or they may be incorporated into crystalline materials (salts) with other ions of opposite charge. In such salts, the complex ion may be either the cationic (positively charged) or the anionic (negatively charged) component (or, on occasion, both). The hydrated nickel ion (above) is an example of a cationic complex. An anionic complex is the hexacyanide of ferric (symbol Fe) ion, $[Fe(CN)_6]^{3-}$, or



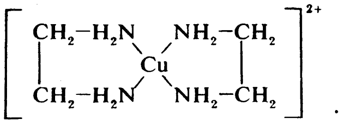
in which the symbols have the same general meaning as in the above examples. Crystalline salts containing these ions are potassium ferricyanide $K_3[Fe(CN)_6]$, and the hexahydrate of nickel chloride, $[Ni(H_2O)_6]Cl_2$, in each case the charge on the complex ion being neutralized by appropriate numbers of ions of opposite charge. In the case of potassium ferricyanide, three positively charged potassium ions, K^+, neutralize the charge on the complex, and in the nickel complex the charges are neutralized by negative chloride ions, Cl^-.

Chelates and chelation

Each molecule or ion of a coordination compound includes a number of ligands, and, in any given substance, the ligands may be all alike or they may be different. Attachment of the ligands to the metal atom may be through only one bond or it may be through several bonds. When only one bond is involved, the ligand is said to be unidentate; when two are involved, it is bidentate; and so on. In general, ligands utilizing more than one bond are said to be multidentate. Because a multidentate ligand is joined to the metal atom in more than one place, the resulting complex is said to be cyclic—*i.e.,* to contain a ring of atoms. Coordination compounds containing multidentate ligands are called chelates (Greek *chele,* "claw"), and their formation is termed chelation. Chelates are particularly stable and useful (see below *Multidentate*). An example of a typical chelate is the complex formed between cupric ion (Cu^{2+}) and the organic compound ethylenediamine (formula $NH_2CH_2CH_2NH_2$). The formula of the complex is

$$[Cu(NH_2CH_2CH_2NH_2)_2]^{2+},$$

the structural formula is



The total number of bonds from the ligands to the metal atom is called the coordination number; generally, coordination numbers range between 2 and 12, with 4 and 6 being the most common. The ligands surrounding the central atom often are referred to collectively as the coordination sphere.

The distinction between coordination compounds and other substances is, in fact, somewhat arbitrary. The designation coordination compound, however, is generally restricted to substances the molecules or ions of which are discrete entities and in which the central atom is metallic. Accordingly, molecules such as sulfur hexafluoride and carbon tetrafluoride are not normally considered to be coordination compounds because sulfur and carbon are nonmetallic elements. Yet there is no great difference between these compounds and, say, uranium hexafluoride. Furthermore, such simple ionic salts as sodium chloride or nickel difluoride are not considered to be coordination compounds because they consist of continuous ionic lattices rather than discrete molecules. Nevertheless, the arrangement (and bonding) of the anions surrounding the metal ions in these salts is similar to that in coordination compounds. Coordination compounds generally are characterized by a variety of distinctive physical and chemical properties, such as colour, magnetic susceptibility, solubility and volatility, an ability to undergo oxidation-reduction reactions, and catalytic activity (see below).

GENERAL ASPECTS

History. Among the earliest recorded examples of a coordination compound is the substance Prussian blue, with formula $Fe_4[Fe(CN)_6]_3$, which has been used as an artist's pigment since the beginning of the 18th century. Another early example of the preparation of a coordination compound is the use of a sparingly soluble compound, potassium hexachloroplatinate, formula $K_2[PtCl_6]$, in 1760 to refine the element platinum.

The sustained and systematic development of modern coordination chemistry, however, usually is considered to have begun with the discovery in 1798 that ammoniacal solutions of a cobalt chloride, $CoCl_3$, on standing overnight, deposited orange crystals with the composition $CoCl_3 \cdot 6NH_3$, the correct formulation of which is now recognized to be $[Co(NH_3)_6]Cl_3$; this shows that the six ammonia groups are associated with the cobalt atom and the whole is neutralized by three chlorine atoms. The feature of this observation that was particularly significant was the recognition that two independently stable compounds (*i.e.,* cobalt chloride and ammonia) could combine to form a new chemical compound with properties quite different from those of the constituent compounds.

Formulations of Werner

Discoveries of further cobaltammine complexes and many other coordination compounds were made in the 19th century, but it was not until 1893 that Alfred Werner, a Swiss chemist, proposed the first essentially correct formulation of such compounds and provided the first insight into the nature of their bonding. Werner reformulated a series of platinum complexes and showed that their dissociation into ions in solution took place as shown in Table 54. In each case, the number of ions formed was determined by measurements of the electrical conductivity of the solutions and by analytical determinations of the free chloride ions (where these were formed). It is noteworthy that in Werner's formulations the coordination number of platinum retains the constant value of 6. This constancy of coordination number of metal atoms occurs frequently, though not invariably.

Table 54: Platinum Complexes as Formulated by Werner

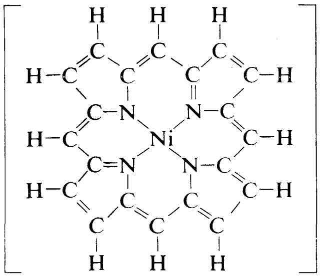
old formulation	Werner formulation	dissociation
$PtCl_4 \cdot 6NH_3$	$[Pt(NH_3)_6]Cl_4$	$\rightarrow [Pt(NH_3)_6]^{4+} + 4Cl^-$
$PtCl_4 \cdot 5NH_3$	$[Pt(NH_3)_5Cl]Cl_3$	$\rightarrow [Pt(NH_3)_5Cl]^{3+} + 3Cl^-$
$PtCl_4 \cdot 4NH_3$	$[Pt(NH_3)_4Cl_2]Cl_2$	$\rightarrow [Pt(NH_3)_4Cl_2]^{2+} + 2Cl^-$
$PtCl_4 \cdot 3NH_3$	$[Pt(NH_3)_3Cl_3]Cl$	$\rightarrow [Pt(NH_3)_3Cl_3]^+ + Cl^-$
$PtCl_4 \cdot 2NH_3$	$[Pt(NH_3)_2Cl_4]$	→ none
$PtCl_4 \cdot NH_3 \cdot KCl$	$K[Pt(NH_3)Cl_5]$	$\rightarrow K^+ + [Pt(NH_3)Cl_5]^-$
$PtCl_4 \cdot 2KCl$	$K_2[PtCl_6]$	$\rightarrow 2K^+ + [PtCl_6]^{2-}$

Classification. A coordination compound is characterized by the nature of the central metal atom or ion; the oxidation state of the latter (that is, the gain or loss of electrons in passing from the neutral atom to the charged ion); and by the number, kind, and arrangement of the ligands. Because virtually all metallic elements form coordination compounds, sometimes in several oxidation states and usually with many different ligands, a large number of coordination compounds is known.

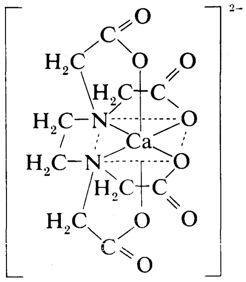
Mononuclear, unidentate. The simplest types of coordination compounds are those containing a single metal atom or ion (mononuclear compounds), surrounded by unidentate ligands. Most of the coordination compounds already cited, such as the platinum complexes of Werner, belong to this class. Among the ligands forming such complexes are a wide variety of neutral molecules, such as ammonia, water, carbon monoxide, and nitrogen, as well as monoatomic and polyatomic anions, such as the hydride, fluoride, chloride, oxide, hydroxide, nitrite, thiocyanate, carbonate, sulfate, and phosphate ions. Coordination of such ligands to the metal virtually always occurs through an atom possessing an unshared pair of electrons, which it donates to the metal to form a coordinate bond with the latter. Among the atoms that are known to coordinate to metals are those of virtually all the nonmetallic elements (such as hydrogen, carbon, oxygen, nitrogen, and sulfur), with the exception of the noble gases (helium, neon, argon, krypton, and xenon).

Coordination via unshared electron pair

Multidentate. The chelate complex of a copper ion and ethylenediamine mentioned above is an example of a compound formed between a metal ion and a bidentate ligand. Two further examples of chelate complexes are shown below. These are a nickel complex with a tetradentate large-ring ligand, known as a porphyrin, and a calcium complex with a hexadentate ligand, ethylenediaminetetraacetate. Because metal-ligand attachment in such chelate complexes is through several bonds, such complexes tend to be very stable.

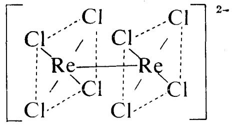


nickel-porphyrin complex

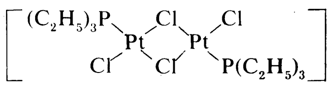


calcium-ethylenediamine-tetraacetate complex

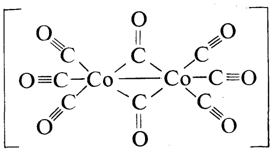
Certain ligands may be either unidentate or multidentate, depending on the particular compound in which they occur. The carbonate ion, formula $(CO_3)^{2-}$, for example, is coordinated to the cobalt ions in two cobalt compounds, $[Co(NH_3)_5(CO_3)]^+$ and $[Co(NH_3)_4(CO_3)]^+$, through one and two oxygen atoms, respectively.



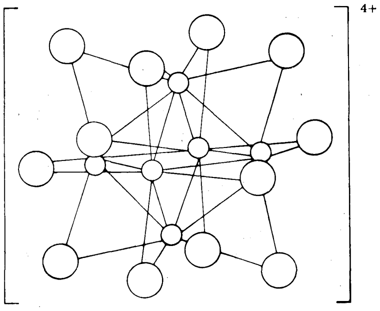
complex with metal-metal bond (Re is rhenium)



complex with bridging ligands (C_2H_5 is ethyl radical, Pt is platinum, P is phosphorus, and Cl is chlorine)



complex with metal-metal bond and bridging ligands



complex with metal-cluster nucleus

○ = molybdenum atoms

◯ = chlorine atoms

Polynuclear. Polynuclear complexes are coordination compounds containing two or more metal atoms, or ions, in a single coordination sphere. The two atoms may be held together through direct metal–metal bonds, through bridging ligands, or both. Examples of each are shown below, along with a unique metal-cluster complex having six metal atoms in its nucleus.

Nomenclature. Generally, the systematic naming of coordination compounds is carried out by rules recommended by the International Union of Pure and Applied Chemistry (IUPAC). Among the more important of these are the following:

IUPAC rules of nomenclature

1. Neutral and cationic complexes are named by first identifying the ligands, followed by the metal and its oxidation number (in Roman numerals enclosed within parentheses). Anionic ligands are cited ahead of neutral ones, and inorganic ligands ahead of organic ones. When the complex contains more than one ligand of a given kind, the number of such ligands is designated by one of the prefixes di-, tri-, tetra-, penta-, and so on, or, in the case of complex ligands, bis-, tris-, tetrakis-, pentakis-, and so on. The oxidation number of the metal is defined in the customary way as the residual charge on the metal if all the ligands were removed together with the electron pairs involved in coordination to the metal. The following examples are illustrative:

$[Co(NH_3)_5Cl]^{2+}$	chloropentaamminecobalt(III)
$[Ni(NH_2CH_2CH_2NH_2)_3]^{2+}$	tris(ethylenediamine)nickel(II)
$[Fe(CO)_5]$	pentacarbonyliron(0)
$[Al(H_2O)_5(OH)]^{2+}$	hydroxopentaaquo-aluminum(III)
$[RhH(CO)(P[C_6H_5]_3)_3]$	hydridocarbonyltris(triphenyl-phosphine)rhodium(I).

2. Anionic complexes are similarly named, except that the name is terminated by the suffix -ate; *e.g.,*

$[PtCl_4]^{2-}$	tetrachloroplatinate(II)
$[Ag(S_2O_3)_2]^{3-}$	bis(thiosulfato)argentate(I)
$[OsNCl_5]^{2-}$	nitridopentachloroosmate(VI)
$[Cr(SCN)_4(NH_3)_2]^-$	tetrathiocyanatodiammine-chromate(III).

3. In the case of salts, the cation is named first, then the anion; *e.g.,*

$[Pt(NH_3)_3Cl]Cl$	chlorotriammineplatinum(II) chloride
$K_3[Fe(CN)_6]$	potassium hexacyanoferrate(III)
$[Cr(NH_3)_6][Co(CN)_6]$	hexaamminechromium(III) hexacyanocobaltate(III).

4. Polynuclear complexes are named as follows, bridging ligands being identified by a prefix consisting of the Greek letter mu (μ-):

$[(CO)_5Mn-Mn(CO)_5]$	decacarbonyldimanganese (0) *or* bis(pentacarbonyl-manganese)
$[(NH_3)_5Cr-OH-Cr(NH_3)_5]Cl_5$	μ-hydroxo-bis[pentaamminechromium(III)] chloride

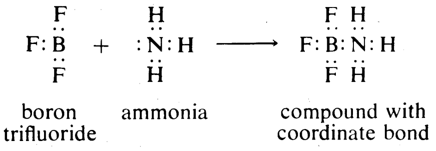
In addition to their systematic designations, many coordination compounds are also known by names reflecting their discoverers or colours. Examples are:

$K[PtCl_3(C_2H_4)]$	Zeise's salt
$NH_4[Cr(NH_3)_2(SCN)_4] \cdot H_2O$	Reinecke's salt
$[Co(NH_3)_5(H_2O)]Cl_3$	roseocobaltic chloride (red)
$Fe_4[Fe(CN)_6]_3$	Prussian blue

Coordinate bonding. Werner originally postulated that coordination compounds could be formed because the central atoms carried the capacity to form secondary or

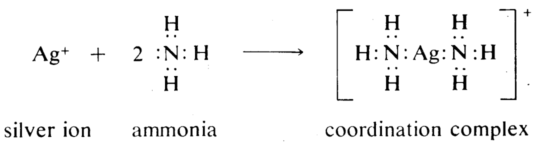
Electron pair theory of bonding

coordinate bonds, in addition to the normal or valence bonds. A more complete description of coordinate bonding, in terms of electron pairs, became possible in the 1920s following the introduction of the concept that all covalent (nonionic) bonds consist of electron pairs shared between atoms, a concept advanced chiefly by the U.S. chemist Gilbert N. Lewis. In Lewis' formulation, when both electrons are contributed by one of the atoms, as in the boron–nitrogen bond, which is formed when the substance boron trifluoride combines with ammonia, the bond is called a coordinate bond:



In these formulas, the valence (or bonding) electrons are indicated by dots, each pair of dots between two atomic symbols representing a bond between the corresponding atoms.

Following Lewis' ideas, the suggestion was made that the bonds between metals and ligands were of this same type, with the ligands acting as electron donors and the metal ions as electron acceptors. This suggestion provided the first electronic interpretation of bonding in coordination compounds. The coordination reaction between silver ions and ammonia illustrates the resemblance of coordination compounds to the situation in the boron–nitrogen compound. According to this view, the metal ion can be regarded as a so-called Lewis acid and the ligands as Lewis bases:



In the above formulas, the dots again represent valence electrons.

Considerable success in understanding certain coordination compounds also has been achieved by treating them as examples of simple ionic or electrostatic bonding. This view attributes the bonding in coordination compounds to electrostatic forces between the positively charged metal ions and negatively charged ligands or, alternatively, in the case of neutral ligands (*e.g.,* water and ammonia), charge separations (dipoles) that appear within the molecules. Although this approach meets with considerable success for complexes of metal ions with small electronegative ligands, such as fluoride or chloride ions or water molecules, it breaks down for ligands of low polarity (charge separation), such as carbon monoxide. It also requires modification to explain why the spectral (light absorption) and magnetic properties of coordinated metal ions generally differ from those of the free ions and, for a given metal ion, depend on the nature of the ligands. Thus, the complex ion hexafluoroferrate(III) (FeF_6^{3-}), has magnetic properties to be expected from a substance with five unpaired electrons, as does the free iron(III) ion (Fe^{3+}), whereas the magnetic properties of the closely related hexacyanoferrate(III) $[Fe(CN)_6]^{3-}$ correspond to only one unpaired electron.

The ligand-field theory

Since 1950 it has been apparent that a more complete theory, which incorporates contributions from both ionic and covalent bonding, is necessary to give an adequate account of the properties of coordination compounds. Such a theory is the so-called ligand-field theory, which has its origin in the more general theory of chemical bonding called the molecular-orbital theory (molecular orbitals describing the spatial distributions of electrons in molecules, just as atomic orbitals describe the distributions in atoms). This theory accounts with remarkable success for most properties of coordination compounds.

An important conclusion from ligand field theory is that two types of bonds, called sigma bonds and pi bonds, occur in coordination compounds just as they do in ordinary covalent (organic) compounds. Sigma bonds are the more usual of the two, and they are symmetrical about the axis of the bond; pi bonds, which are less common, are unsymmetrical with regard to the bond axis. In coordination compounds, pi bonding may result from donation of electrons from ligands, such as fluorine or oxygen atoms, to empty *d* orbitals of the metal atoms (the designation *d* merely being a way of indicating the particular orbitals involved). An example of this type of bonding is the chromate ion, $(CrO_4)^{2-}$, in which the oxygen atoms donate electrons to the central chromium ion. Alternatively, electrons from *d* orbitals of the metal atom may be donated to empty orbitals of the ligand. This is the case in the compound tetracarbonylnickel, in which empty pi orbitals in the carbon monoxide molecules accept *d*-orbital electrons from the nickel atom.

Coordination number and geometry. Among the essential properties of coordination compounds are the number and arrangement of the ligands attached to the central metal atom or ion—that is, the coordination number and the coordination geometry, respectively. The coordination number of a particular complex is determined by the relative sizes of the metal atom and the ligands, by spatial (steric) constraints governing the shapes (conformations) of multidentate ligands, and by electronic factors, most notably the electronic configuration of the metal ion. The influence of the latter is illustrated by the examples in Table 55. The numbers labelled "total number of valence electrons" in this table comprise the *d* electrons of the metal ion together with the pair of electrons donated by each of the ligands.

Table 55: Coordination Numbers and Geometries of Metal Cyanide Complexes

electron configuration*	metal ion	cyanide complex	geometry	total number of valence electrons
d^2	Mo^{4+}	$[Mo(CN)_8]^{4-}$	dodecahedral	18
d^3	Cr^{3+}	$[Cr(CN)_6]^{3-}$	octahedral	15
d^4	Mn^{3+}	$[Mn(CN)_6]^{3-}$	octahedral	16
d^5	Fe^{3+}	$[Fe(CN)_6]^{3-}$	octahedral	17
d^6	Co^{3+}	$[Co(CN)_6]^{3-}$	octahedral	18
d^7	Co^{2+}	$[Co(CN)_5]^{3-}$	square pyramidal	17
d^8	Ni^{2+}	$[Ni(CN)_4]^{2-}$	square planar	16
d^8	Ni^{2+}	$[Ni(CN)_5]^{3-}$	square pyramidal or trigonal bipyramidal	18
d^{10}	Cd^{2+}	$[Cd(CN)_4]^{2-}$	tetrahedral	18
d^{10}	Ag^+	$[Ag(CN)_2]^-$	linear	14

*Number of *d* electrons indicated by superscript.

The 18-electron rule

Contributing to the pattern of coordination numbers in Table 55 is the 18-electron rule (sometimes called the noble gas rule), which states that coordination compounds in which the total number of valence electrons approaches but does not exceed 18 (the number of electrons in the valence shells of the noble gases) are most stable. The stabilities of 18-electron valence shell's are also reflected in the coordination numbers of the stable mononuclear carbonyls of different metals—*e.g.,* tetracarbonylnickel, pentacarbonyliron, and hexacarbonylchromium (each of which has a valence shell of 18).

The 18-electron rule applies particularly to covalent complexes, such as the cyanides, carbonyls, and phosphines. For more ionic (also called outer-orbital) complexes, such as fluoro or aquo complexes, electronic factors are less important in determining coordination numbers, and configurations corresponding to more than 18 valence shell electrons are not uncommon. Several nickel complexes, for example, including the hexafluoro, hexaaquo, and hexaammine complexes, each have 20 valence shell electrons.

Any one metal ion tends to have the same coordination number in different complexes—*e.g.,* generally 6 for chromium(III)—but this is not invariably so. Differences in coordination number, for example, may result from difference in the sizes of the ligands. The iron(III) ion, for example, is able to accommodate six fluoride ions in the hexafluoride complex, but only four of the larger chloride ions in the tetrachloride. In some cases, a metal ion and ligand form two or more complexes with different coordination numbers—*e.g.*, tetracyanonickelate(II) and pentacyanonickelate(II).

Isomerism. Coordination compounds often exist as isomers—*i.e.*, as compounds with the same chemical composition but different structural formulas. Many different kinds of isomerism occur among coordination compounds. The following are some of the more common types.

Ionization isomerism. Certain isomeric pairs occur that differ only in that two ionic groups exchange positions within (and without) the primary coordination sphere. These are called ionization isomers and are exemplified by the two compounds $[Co(NH_3)_5Br]SO_4$ and $[Co(NH_3)_5(SO_4)]Br$, in the first of which the bromide ion is coordinated to the cobalt ion, and the sulfate ion is outside the coordination sphere; and in the second of which the sulfate ion occurs within the coordination sphere, and the bromide ion is outside it.

Coordination isomerism. Ionic coordination compounds in which both the positive and negative ions are ionic can exist as isomers if the ligands associated with the two metal atoms are exchanged, as in the pair of compounds shown by the formulas $[Co(NH_3)_6][Cr(CN)_6]$ and $[Cr(NH_3)_6][Co(CN)_6]$. Such compounds are called coordination isomers, as are the isomeric pairs obtained by redistributing the ligands between the two metal atoms, as in the doubly coordinated pair, $[Pt(NH_3)_4][PtCl_6]$ and $[Pt(NH_3)_4Cl_2][PtCl_4]$.

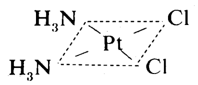
Ligand isomerism. Isomeric coordination compounds are known in which the overall isomerism results from isomerism solely within the ligand groups. An example of such isomerism is shown by the ions

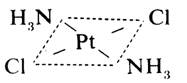
$[Pt(NH_2CH_2CH_2CH_2NH_2)_2]^{2+}$ and

$$[Pt(NH_2\underset{\displaystyle CH_3}{\underset{|}{C}}HCH_2NH_2)_2]^{2+}.$$

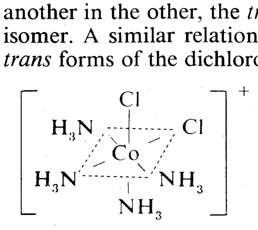
Linkage isomerism. Isomerism also results when a given ligand is joined to the central atom through different atoms of the ligand. Such isomerism is called linkage isomerism. A pair of linkage isomers are the ions $[Co(NH_3)_5(NO_2)]^{2+}$ and $[Co(NH_3)_5(ONO)]^{2+}$, in which the nitro group is joined to the cobalt atom through nitrogen and oxygen atoms, as shown by designating the nitro group by the formulas NO_2^- and ONO^-, respectively. Another example of this variety of isomerism is given by the pair of ions $[Co(CN)_5(NCS)]^{3-}$ and $[Co(CN)_5(SCN)]^{3-}$, in which an isothiocyanate $(NCS)^-$, and a thiocyanate group $(SCN)^-$, are bound to the cobalt ion through a nitrogen and a sulfur atom, respectively.

Geometrical isomerism. Geometrical isomers of coordination compounds differ from one another only in the manner in which the ligands are distributed; for example, in the isomeric pair of dichlorodiammineplatinum(II) compounds

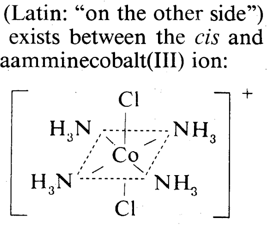




the two ammonia molecules and the two chlorine atoms are situated next to another in one isomer, called the *cis* (Latin: "on this side") isomer, and across from one another in the other, the *trans* (Latin: "on the other side") isomer. A similar relationship exists between the *cis* and *trans* forms of the dichlorotetraamminecobalt(III) ion:

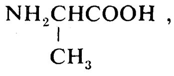


cis



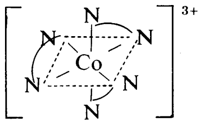
trans

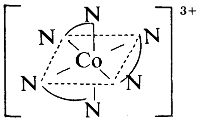
Optical isomerism. Optical isomers possess the ability to rotate plane-polarized light in opposite directions (a property determined with an instrument called a polarimeter). Optical isomers exist when the molecules of the substances are mirror images but are not superimposable upon one other. In coordination compounds, optical isomerism can arise either from the presence of an asymmetric ligand, such as one isomer of an amino acid,



$$NH_2\underset{\displaystyle CH_3}{\underset{|}{C}}HCOOH\ ,$$

or from an asymmetric arrangement of the ligands. Familiar examples of the latter variety are octahedral complexes carrying three bidentate ligands, such as ethylenediamine, $NH_2CH_2CH_2NH_2$. The two optical isomers corresponding to such a complex are depicted by the structures below:





For convenience, the ethylenediamine ligands above are indicated merely by a curved line between the symbols for the nitrogen (N) atoms.

PRINCIPAL CLASSES

The tendency for complexes to form between a metal ion and a particular combination of ligands and the properties of the resulting complexes depend on a variety of properties of both the metal ion and the ligands. Among the pertinent properties of the metal ion are its size, charge, and electron configuration. Relevant properties of the ligand include its size and charge, the number and kinds of atoms available for coordination, the sizes of the resulting chelate rings formed (if any), and a variety of other geometrical (steric) and electronic factors.

Stabilization of oxidation states

Many elements, notably certain of the metals, exhibit a range of oxidation states—that is, they are able to gain or lose varying numbers of electrons. The relative stabilities of these oxidation states are markedly affected by coordination of different ligands. The highest oxidation states correspond to empty or nearly empty *d* subshells (as the patterns of *d* orbitals are called). These states are generally stabilized most effectively by small negative ligands, such as fluorine and oxygen atoms, which possess unshared electron pairs. Such stabilization reflects, in part, the contribution of pi bonding caused by electron donation from the ligands to empty *d* orbitals of the metal ions in the complexes. Conversely, neutral ligands, such as carbon monoxide and unsaturated hydrocarbons, which are relatively poor electron donors but which can accept pi electrons from filled *d* orbitals of the metal, tend to stabilize the lowest oxidation states of metals. Intermediate oxidation states are most effectively stabilized by ligands such as water, ammonia, and cyanide ion, which are moderately good sigma electron donors but relatively poor pi electron donors or acceptors (see above *Coordinate bonding*). These trends are illustrated in Table 56, in which the complexes formed by chromium with various ligands are related to the oxidation states and electron configurations.

Table 56: Chromium Complexes of Various Oxidation States

oxidation state	electron configuration*	coordination complex
+6	d^0	$[CrF_6]$, $[CrO_4]^{2-}$
+5	d^1	$[CrO_4]^{3-}$
+4	d^2	$[CrO_4]^{4-}$, $[Cr(OR)_4]$†
+3	d^3	$[Cr(H_2O)_6]^{3+}$, $[Cr(NH_3)_6]^{3+}$
+2	d^4	$[Cr(H_2O)_6]^{2+}$
0	d^6	$[Cr(CO)_6]$, $[Cr(C_6H_6)_2]$

*Number of *d* electrons indicated by superscript.
†Capital R symbolizes an organic alkyl radical.

Aquo complexes. There are few ligands that equal water in respect to the number and variety of metal ions with which they form complexes. Nearly all metallic elements form aquo complexes, frequently in more than one oxidation state. Such aquo complexes include hydrated ions in aqueous solution as well as hydrated salts such as hexaaquochromium(III) chloride, $[Cr(H_2O)_6]Cl_3$. For metal ions with partially filled *d* subshells (*i.e.*, transition metals), the coordination numbers and geometries of the hydrated ions in solution can be inferred from their light-absorption spectra, which are generally consistent with octahedral coordination by six water molecules. Higher coordination numbers probably occur for the hydrated rare-earth ions such as lanthanum(III).

Complex ions in aqueous solution

When other ligands are added to an aqueous solution of a metal ion, replacement of water molecules in the coordination shell may occur, with the resultant formation of other complexes. Such replacement is generally a stepwise process, as illustrated by the following series of reactions that results from the progressive addition of ammonia to an aqueous solution of nickel(II) salt:

$$[Ni(H_2O)_6]^{2+} + NH_3 \rightleftharpoons [Ni(H_2O)_5(NH_3)]^{2+} + H_2O$$

$$[Ni(H_2O)(NH_3)_5]^{2+} + NH_3 \rightleftharpoons [Ni(NH_3)_6]^{2+} + H_2O$$

With increasing additions of ammonia, the equilibria are shifted toward the higher ammine complexes (those with more ammonia and less water) until ultimately the hexaamminenickel(II) ion predominates.

The tendency of metal ions in aqueous solution to form complexes with ammonia as well as with organic amines (derivatives of ammonia, carrying chains of carbon atoms attached to the nitrogen atom) is widespread. The stabilities of such complexes exhibit a considerable range of dependence on the nature of the metal ion as well as on that of the amine. The marked enhancement of stability that results from chelation is reflected in the equilibrium constants of the reactions—values that indicate the relative proportions of the starting materials and the products at equilibrium. Table 57, for example, shows the equilibrium constants for the formation of complexes of hexaaquonickel(II) ions with a series of polyamines—*i.e.,* for a series of reactions of the type

Equilibrium constants

Table 57: Equilibrium Constants for the Formation of Various Nickel Amine Complexes

n	amine (L)	equilibrium constant K_L, M^{-1}*
1	$\underline{N}H_3$	5×10^2
2	$\underline{N}H_2CH_2CH_2\underline{N}H_2$	4×10^7
3	$\underline{N}H_2CH_2CH_2\underline{N}HCH_2CH_2\underline{N}H_2$	5×10^{10}
4	$\underline{N}H_2CH_2CH_2\underline{N}HCH_2CH_2\underline{N}HCH_2CH_2\underline{N}H_2$	1×10^{14}

*M is molar concentrations.

$$[Ni(H_2O)_6]^{2+} + nL \rightleftharpoons [Ni(H_2O)_{6-n}L_n]^{2+} + nH_2O,$$

in which L is the ligand and n the number of water molecules displaced from the complex. In the table it can be seen that the equilibrium constants, K_L, increase dramatically as the possibilities for chelation increase—that is, as the number of nitrogen atoms (N) available for bonding to the metal atom increases.

It should be noted that in the particular examples cited above the coordination number of the metal ion is invariant throughout the substitution process, but this is not always the case. Thus, the ultimate products of the addition of the cyanide ion to an aqueous solution of hexaaquonickel(II) ion are tetracyanonickelate(II) and pentacyanonickelate (II). Similarly, addition of the chloride ion to a solution of hexaaquoiron(III) yields tetrachloroferrate(III).

Halide complexes. Probably the most widespread class of complexes involving anionic ligands is that of the complexes of the halide ions—*i.e.,* the fluoride, chloride, bromide, and iodide ions. In addition to forming simple halide salts, such as sodium chloride and nickel difluoride (in which the metal ions are surrounded by halide ions, these in a sense being regarded as coordinated to them), many metals form complex halide salts, such as potassium tetrachloroplatinate(II), $K_2[PtCl_4]$, that contain discrete complex ions. Most metal ions also form halide complexes in aqueous solution. The stabilities of such complexes span an enormous range—from the alkali-metal ions (lithium, sodium, potassium, and so on), the formation of whose halide complexes in aqueous solution can barely be detected, to extremely stable halide complexes, such as the tetraiodomercurate(II), tetrachlorothallate(III), and tetrachloropalladate(II) ions, the extent of whose dissociation is extremely small.

Hard and soft ions

The stabilities of halide complexes reflect a pattern in which metal ions can be divided into two general classes, designated as A and B or, alternatively, as hard and soft, respectively. (Generally, the electrons in the atoms of the hard elements are considered to form a compact and not easily deformable group, whereas those in the atoms of the soft elements form a looser group—that is, one more easily deformed.) For the former class, which includes beryllium, magnesium, scandium, chromium, iron, nickel, copper, indium, and tin, the order of increasing stability of the halide complexes in aqueous solution is iodides, bromides, chlorides, and fluorides. Conversely, for the class B (or soft) ions, such as platinum, silver, cadmium, mercury, thallium, and lead, the order of increasing stability of the halide complexes is fluorides, chlorides, bromides, and iodides. In contrast to class A metals, those of class B also tend to form more stable complexes with sulfur-containing ligands than with oxygen-containing ligands and more stable complexes with phosphorus ligands than with nitrogen ligands.

Metal carbonyls. Following the discovery of the first metal carbonyl complex, tetracarbonylnickel, in 1890, many compounds containing carbon monoxide coordinated to transition metals have been prepared and characterized. For reasons already discussed, such compounds generally contain metal atoms or ions in low oxidation states. The following are some of the more common types of metal carbonyl compounds: (1) simple mononuclear carbonyls of zero-valent metals, such as tetracarbonylnickel, pentacarbonyliron, and hexacarbonylchromium—highly toxic, volatile compounds, the most stable of which have filled valence shells of 18 electrons; (2) salts of anionic and cationic carbonyls, such as tetracarbonylcobaltate(I) and hexacarbonylmanganese(I); (3) binuclear and polynuclear carbonyls, such as bis(tetracarbonylcobalt), the structural formula of which was shown earlier (see above *Classification: Polynuclear*); and (4) mixed complexes containing other ligands additional to CO: chloropentacarbonylmanganese, hydridotetracarbonylcobalt(I), and tricarbonylnitrosylcobalt.

Complexes of molecular nitrogen

Although molecular nitrogen, N_2, is isoelectronic with carbon monoxide (that is, has the same arrangement of electrons), its tendency to form complexes with metals is much smaller. The first complex containing molecular nitrogen as a ligand—*i.e.,* pentaamminenitrogenruthenium(II), $[Ru(NH_3)_5(N_2)]^{2+}$—was prepared in 1965, and many others have been discovered subsequently. Such complexes have attracted considerable interest because of their possible roles in the chemical and biological fixation of nitrogen.

Organometallic complexes. Organometallic complexes, complexes formed between organic (carbon-containing) groups and metal atoms, can be divided into two general classes: (1) complexes containing metal–carbon sigma bonds and (2) pi-bonded metal complexes of unsaturated hydrocarbons—that is, compounds with multiple bonds between carbon atoms. These substances are covered above in *Organometallic compounds.*

GENERAL METHODS OF PREPARATION

The great variety of coordination compounds is matched by the diversity of methods through which such compounds can be synthesized. Complex halides, for example, may be prepared by direct combination of two halide salts (either in the molten state or in a suitable solvent). Palladium chloride and potassium chloride, for example, react to give the complex potassium tetrachloropalladate(II), as shown in the following equation:

$$PdCl_2 + 2KCl \longrightarrow K_2[PdCl_4].$$

Another widely used route to coordination compounds is through the direct combination of a metal ion and appropriate ligands in solution. Thus, the addition of a sufficiently high concentration of ammonia to an aqueous solution of a nickel(II) salt leads, through a series of reactions (see above *Aquo complexes*) to the formation of the hexaamminenickel(II) ion, which can be precipitated, for example, as the sulfate salt, $[Ni(NH_3)_6]SO_4$.

Complexes of metal ions in high oxidation states are sometimes more readily formed by adding the ligands to a solution of the metal ion in a lower oxidation state in the presence of an oxidizing agent. Thus, addition of ammonia to an aqueous solution of a cobalt(II) salt in the presence of air or oxygen leads to the formation of cobalt(III) ammine complexes such as hexaamminecobalt(III), $[Co(NH_3)_6]^{3+}$, and aquopentaamminecobalt(III), $[Co(NH_3)_5(H_2O)]^{3+}$, ions.

Complexes of metals in low oxidation states, such as the carbonyls of zero-valent metals, can sometimes be prepared by direct combination of the metal with the ligand as, for example, in the reaction of nickel metal with carbon monoxide:

$$\mathrm{Ni(solid)} + 4CO \xrightarrow[1\ \mathrm{atm}]{25^\circ} Ni(CO)_4.$$

More commonly, a salt of the metal is reduced in the presence of the ligand. An example of this type of synthesis is the reduction of cobalt carbonate with hydrogen in the presence of carbon monoxide to give bis(tetracarbonylcobalt):

$$2CoCO_3 + 2H_2 + 8CO \xrightarrow[250-300\ \mathrm{atm}]{120-200^\circ} Co_2(CO)_8 + 2CO_2 + 2H_2O.$$

Similar procedures are applicable to the synthesis of metal sandwich compounds containing cyclopentadienyl and benzene ligands. Dibenzenechromium, for example, can be prepared from chromic chloride, benzene, and aluminum, as shown in the following equation:

$$CrCl_3 + 2C_6H_6 + Al \longrightarrow Cr(C_6H_6)_2 + AlCl_3.$$

Hydrido complexes of transition metals can be prepared by reactions of suitable precursors either with molecular hydrogen or with suitable reducing agents such as hydrazine or sodium borohydride; for example,

$$2[Co(CN)_5]^{3-} + H_2 \longrightarrow 2[CoH(CN)_5]^{3-}$$

Transition metal complexes containing metal–carbon bonds can be prepared by a variety of routes, some of the more important of which are illustrated by the following examples:

$$Mn(CO)_5Br + LiCH_3 \longrightarrow Mn(CO)_5(CH_3) + LiBr,$$

$$[Mn(CO)_5]^- + CH_3Br \longrightarrow Mn(CO)_5(CH_3) + Br^-,$$

$$PtHCl[P(CH_3CH_2)_3]_2 + CH_2{=}CH_2 \longrightarrow Pt(CH_2CH_3)Cl[P(CH_3CH_2)_3]_2,\ \text{and}$$

$$2[Co(CN)_5]^{3-} + CH_3I \longrightarrow [Co(CN)_5(CH_3)]^{3-} + [Co(CN)_5I]^{3-}$$

PRINCIPAL REACTIONS

Acid–base. Coordination to a positive metal ion usually enhances the acidity (*i.e.*, the tendency to lose protons) of hydrogen-containing ligands, such as water and ammonia. Thus, metal ions in aqueous solution commonly exhibit acidic behaviour. Such behaviour is exemplified by hydrolysis reactions of the type shown in the following equilibrium:

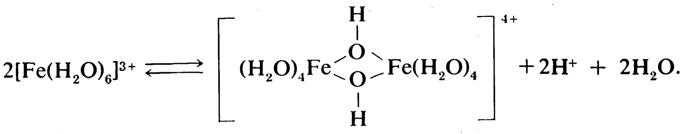
$$[M(H_2O)_x]^{n+} \rightleftharpoons [M(H_2O)_{x-1}(OH)]^{(n-1)+} + H^+,$$

in which M represents the metal ion, n its charge, and x the number of coordinated water molecules.

Acid–base equilibria

The acidities of such aquo ions depend upon the charge, size, and electronic configuration of the metal ion. This dependence is reflected in the values of acid dissociation constants, which range from about 10^{-14} (a value only slightly larger than for pure water, for which the dissociation constant = $10^{-15.7}$) for the hydrated lithium ion, to about 10^{-2} (a value equivalent to that of a fairly strong acid) for the hydrated uranium(IV) ion. Acid–base equilibria are rapidly established in solution, generally within a fraction of a second (see CHEMICAL REACTIONS).

In some cases, hydrolysis of a metal ion may be accompanied by polymerization to form dinuclear or polynuclear hydroxo- or oxygen-bridged complexes:



$$2[Fe(H_2O)_6]^{3+} \rightleftharpoons \left[(H_2O)_4Fe\overset{\overset{H}{|}}{\underset{\underset{H}{|}}{\genfrac{}{}{0pt}{}{O}{O}}}Fe(H_2O)_4 \right]^{4+} + 2H^+ + 2H_2O.$$

Even very weakly acidic ligands, such as ammonia, can acquire appreciable acidity through coordination to a metal ion. Thus, the hexaammineplatinum(IV) ion dissociates according to the equilibrium

$$[Pt(NH_3)_6]^{4+} \rightleftharpoons [Pt(NH_3)_5(NH_2)]^{3+} + H^+.$$

Substitution. One of the most general reactions exhibited by coordination compounds is that of substitution, or replacement, of one ligand by another. This process is depicted in a generalized manner by the equation $ML_{x-1}Y + Z \rightarrow ML_{x-1}Z + Y$ for a metal complex of coordination number x. The ligands L, Y, and Z may be chemically similar or different. (Charges have been omitted here for simplicity.)

Replacement of water

A class of substitution reactions that affords the widest possible comparison of different metal ions is the replacement of water in the coordination shells of metal-aquo complexes in aqueous solution. The substitution may be by another water molecule (which can be labelled with the isotope oxygen-18 to permit the reaction to be followed) or by a different ligand, such as the chloride ion. Reactions of both sorts occur as shown below (oxygen-18 is indicated by the symbol $\overset{*}{O}$):

$$[M(H_2O)_x]^{n+} + H_2\overset{*}{O} \longrightarrow [M(H_2O)_{x-1}(H_2\overset{*}{O})]^{n+} + H_2O$$

$$[M(H_2O)_x]^{n+} + Cl^- \longrightarrow [M(H_2O)_{x-1}Cl]^{(n-1)+} + H_2O.$$

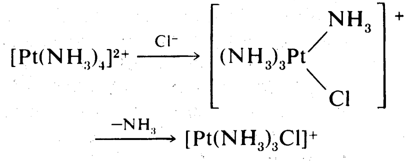
Many such reactions are extremely fast, and it has been only since 1950, following the development of appropriate experimental methods (including stopped flow, nuclear magnetic resonance, and relaxation spectrometry), that the kinetics and mechanisms of this class of reactions have been extensively investigated. Rates of substitution of metal-aquo ions have been found to span a wide range, the characteristic times required for substitution ranging from less than 10^{-9} second for monopositive ions, such as hydrated potassium ions, to several days for certain more highly charged ions, such as hexaaquochromium(III) and hexaaquorhodium(III). The rate of substitution parallels the ease of loss of a water molecule from the coordination shell of the aquo complex and thus increases with increasing size and with decreasing charge of the metal ion. For transition metal ions, electronic factors also have an important influence on rates of substitution.

Dissociative and associative mechanisms

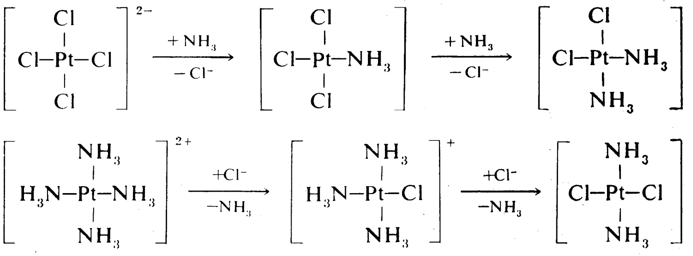
There are two limiting mechanisms (or pathways) through which substitution may occur; namely, dissociative and associative mechanisms. In the dissociative mechanism, a ligand is lost from the complex to give an intermediate compound of lower coordination number. This type of reaction path is typical of octahedral complexes, many aquo complexes, and metal carbonyls such as tetracarbonylnickel. An example of a dissociative reaction pathway for an octahedral complex of cobalt is as follows:

$$[Co(CN)_5(H_2O)]^{2-} \xrightarrow{-H_2O} [Co(CN)_5]^{2-} \xrightarrow{+I^-} [Co(CN)_5I]^{3-}.$$

The associative mechanism for substitution reactions, on the other hand, involves association of an extra ligand with the complex to give an intermediate of higher coordination number; then one of the original ligands is lost to restore the initial coordination number. Substitution reactions of square planar complexes, such as those of the nickel(II), palladium(II), and platinum(II) ions, usually proceed through associative pathways involving intermediates with coordination number 5. An example of a reaction following such a pathway is



A characteristic feature of this class of reactions is the sensitivity of the rate of substitution of a given ligand to the nature of the ligand in the *trans* position (that is, on the opposite side of the metal atom). The *trans* ligand activates a ligand for replacement as follows, in decreasing order: carbon monoxide, cyanide ion, or ethylene, greater than phosphines, or hydride, nitrite, iodide, or thiocyanate ion, greater than bromide or chloride ion, greater than ammonia or water. The *trans* effect may be utilized for synthetic purposes; thus, the reaction of the tetrachloroplatinate(II) ion with ammonia yields *cis*-dichlorodiammineplatinum (II); whereas the reaction of the tetraammineplatinum(II) ion with the chloride ion gives the *trans* isomer, *trans*-dichlorodiammineplatinum(II). The reactions are shown below. In both reactions the *trans* effect causes introduction of the ligand *trans* to chloride rather than *trans* to ammonia:



$$\left[\begin{array}{c}\text{Cl}\\ | \\ \text{Cl–Pt–Cl}\\ | \\ \text{Cl}\end{array}\right]^{2-} \xrightarrow[-\text{Cl}^-]{+\text{NH}_3} \left[\begin{array}{c}\text{Cl}\\ | \\ \text{Cl–Pt–NH}_3\\ | \\ \text{Cl}\end{array}\right] \xrightarrow[-\text{Cl}^-]{+\text{NH}_3} \left[\begin{array}{c}\text{Cl}\\ | \\ \text{Cl–Pt–NH}_3\\ | \\ \text{NH}_3\end{array}\right]$$

$$\left[\begin{array}{c}\text{NH}_3\\ | \\ \text{H}_3\text{N–Pt–NH}_3\\ | \\ \text{NH}_3\end{array}\right]^{2+} \xrightarrow[-\text{NH}_3]{+\text{Cl}^-} \left[\begin{array}{c}\text{NH}_3\\ | \\ \text{H}_3\text{N–Pt–Cl}\\ | \\ \text{NH}_3\end{array}\right]^{+} \xrightarrow[-\text{NH}_3]{+\text{Cl}^-} \left[\begin{array}{c}\text{NH}_3\\ | \\ \text{Cl–Pt–Cl}\\ | \\ \text{NH}_3\end{array}\right]$$

Isomerization. Coordination compounds that exist in two or more isomeric forms (see above *Isomerism*) may undergo reactions that convert one isomer to another. Examples are the linkage isomerization and *cis-trans* isomerization reactions depicted below. The first of these has been shown to proceed intramolecularly (*i.e.*, without dissociation of the nitrite ligand), whereas the second probably occurs through dissociation of one of the water-molecule ligands:

$$[\text{Co(NH}_3)_5(\text{ONO})]^{2+} \longrightarrow [\text{Co(NH}_3)_5(\text{NO}_2)]^{2+}$$

$$cis\text{-}[\text{Co(NH}_2\text{CH}_2\text{CH}_2\text{NH}_2)_2(\text{H}_2\text{O})_2]^{3+} \longrightarrow trans\text{-}[\text{Co(NH}_2\text{CH}_2\text{CH}_2\text{NH}_2)_2(\text{H}_2\text{O})_2]^{3+}.$$

Oxidation–reduction. Transition metals commonly exhibit two or more stable oxidation states, and their complexes accordingly are able to undergo oxidation–reduction reactions. The simplest such reactions involve electron transfer between two complexes, with little if any accompanying rearrangement or chemical change. An example is shown below:

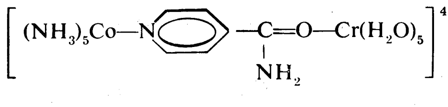
$$[\text{Fe(CN)}_6]^{4-} + [\text{IrCl}_6]^{2-} \longrightarrow [\text{Fe(CN)}_6]^{3-} + [\text{IrCl}_6]^{3-}.$$

In other cases, oxidatinn–reduction is accompanied by significant chemical rearrangement. An example is

$$[\text{Co(NH}_3)_5\text{Cl}]^{2+} + [\text{Cr(H}_2\text{O})_6]^{2+} + 5[\text{H}_3\text{O}]^+ \longrightarrow [\text{Co(H}_2\text{O})_6]^{2+} + [\text{Cr(H}_2\text{O})_5\text{Cl}]^{2+} + 5[\text{NH}_4]^+.$$

Outer-sphere and inner-sphere mechanisms

Two limiting mechanisms of electron transfer, commonly designated outer-sphere and inner-sphere mechanisms, have been recognized. Outer-sphere electron transfer occurs without dissociation or disruption of the coordination shell of either complex; *i.e.*, through both intact coordination shells. The first reaction above is of this type. On the other hand, inner-sphere electron transfer—*e.g.*, the second reaction above—proceeds by formation of a binuclear complex in which the two metal ions are joined by a common bridging ligand (in this case the chloride ion) through which the electron is transferred. Such electron transfer also may occur through polyatomic bridging ligands to which the two metal ions are attached at different sites separated by several atoms; for example, the reduction of pentaammine(isonicotinamide)cobalt(III) by chromium(II) ion through a bridged intermediate,



Strikingly large differences in rates of electron transfer are observed even among closely related reactions. Thus, the rate of reduction of the bromopentaamminecobalt(III) ion by the hexaaquochromium(II) ion is about 10^7 times higher than that of the acetatopentaamminecobalt(III) ion by the same chromium ion.

Oxidative addition. The oxidations of certain complexes, notably those of metal ions with nearly filled *d* shells, are accompanied by increases in their preferred coordination numbers in accord with the patterns shown in Table 55. Such complexes are particularly effective in reducing saturated molecules, such as chlorine, hydrogen peroxide, methyl iodide, and hydrogen, with accompanying incorporation of the fragments of reductive cleavage (the chloride ion, hydroxide ion, methyl carbanion, and hydride ion, respectively) into the coordination shells to achieve the necessary expansions of the coordination numbers. Three such classes of reactions, namely those characteristic of five-coordinate (d^7), four-coordinate (d^8), and two-coordinate (d^{10}) complexes, are illustrated by the equations below:

$$2[\text{Co(CN)}_5]^{3-} + \text{H}_2\text{O}_2 \longrightarrow 2[\text{Co(CN)}_5(\text{OH})]^{3-}$$

$$\text{IrCl(CO)[P(C}_6\text{H}_5)_3]_2 + \text{H}_2 \longrightarrow \text{IrH}_2\text{Cl(CO)[P(C}_6\text{H}_5)_3]_2$$

$$\text{Pt[P(C}_6\text{H}_5)_3]_2 + \text{CH}_3\text{I} \longrightarrow \text{PtI(CH}_3)[\text{P(C}_6\text{H}_5)_3]_2$$

Interest in the synthetic and catalytic applications of such oxidative addition reactions has prompted intensive study of these reactions since about 1960, which has resulted in the discovery of new reactions of this type, and in the elucidation of certain aspects of the mechanisms by which they occur.

SIGNIFICANCE AND APPLICATIONS

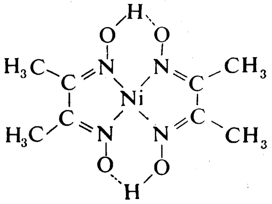
The applications of coordination compounds in chemistry and technology are many and diverse. Naturally occurring coordination compounds are vitally important to living organisms.

Important industrial uses

Dyes and pigments. The brilliant and intense colours of many coordination compounds render them of great value as dyes and pigments. The early use of Prussian blue as a pigment has already been mentioned. Phthalocyanine complexes—for example, copper phthalocyanine—containing large-ring ligands closely related to the porphyrins, constitute an important class of dyes for fabrics.

Extraction and separation of metals. Several important hydrometallurgical processes utilize metal complexes. Nickel, cobalt, and copper can be extracted from their ores as ammine complexes using aqueous ammonia. Differences in the stabilities and solubilities of the ammine complexes can be utilized in selective precipitation procedures that bring about separation of the metals. The purification of nickel can be effected by reaction with carbon monoxide to form the volatile tetracarbonylnickel complex, which can be distilled and thermally decomposed to deposit the pure metal. Aqueous cyanide solutions usually are employed to separate gold from its ores in the form of the very stable dicyanoaurate(I) complex. Cyanide complexes also find application in electroplating.

Chemical analysis. There are a number of ways in which coordination compounds are used in the analysis of various substances. These include (1) the selective precipitation of metal ions as complexes, for example, nickel(II) ion as the dimethylglyoxime complex (shown below); (2) the formation of coloured complexes, such as the tetrachlorocobaltate(II) ion, that can be determined spectrophotometrically—that is, by means of their light absorption properties; and (3) the preparation of complexes, such as metal acetylacetonates, that can be separated from aqueous solution by extraction with organic solvents:



Sequestering. In certain circumstances the presence of metal ions is undesirable, as for example in water, in which calcium and magnesium ions cause hardness. In such cases the undesirable effects of the metal ions frequently can be eliminated by "sequestering" the ions as harmless complexes through the addition of an appropriate complexing reagent. Ethylenediaminetetraacetic acid (EDTA) forms very stable complexes and is widely used for this purpose. Its applications include water softening (by tying up calcium and magnesium ions) and the preservation of organic substances, such as vegetable oils and rubber, in which case it combines with traces of transition metal ions that would catalyze oxidation of the organic substances.

Catalysis. A technological and scientific development of major significance was the discovery in 1954 that certain complex metal catalysts, viz., a combination of titanium trichloride and triethylaluminum bring about the polymerizations (or joining together of the molecules) of organic compounds with carbon–carbon double bonds under mild conditions to form polymers of high molecular weight and highly ordered (stereoregular) structures. Certain of these polymers are of great commercial importance because they are used to make fibres, films, and plastic articles of many kinds. Other technologically important processes based on metal complex catalysts include the catalysis by metal carbonyls, such as hydridotetracarbonylcobalt(I), of the so-called hydroformylation of olefins—*i.e.,* of their reactions with hydrogen and carbon monoxide to form aldehydes—and the catalysis by tetrachloropalladate(II) ions of the oxidation of ethylene in aqueous solution to acetaldehyde (see also CHEMICAL REACTIONS: *Catalysis*).

Biology. Metal complexes play a variety of important roles in biological systems. Many enzymes, the naturally occurring catalysts that regulate biological processes, are metal complexes (metalloenzymes); for example, a hydrolytic enzyme important in digestion, carboxypeptidase, contains a zinc ion coordinated to several amino acid residues of the protein. Another enzyme, catalase, which is a very efficient catalyst for the decomposition of hydrogen peroxide, contains iron–porphyrin complexes. In both cases the coordinated metal ions are probably the sites of catalytic activity. Hemoglobin also contains iron–porphyrin complexes, its role as an oxygen carrier being related to the ability of the iron atoms to coordinate oxygen molecules reversibly. Other biologically important coordination compounds include chlorophyll (a magnesium–porphyrin complex) and vitamin B_{12}, a complex of cobalt with a macrocyclic ligand known as corrin.

(J.Ha.)

ORGANOMETALLIC COMPOUNDS

Organometallic compounds are those substances that contain chemical bonds between carbon atoms and metal atoms; this definition excludes such inorganic salts as the metal carbonates, which show quite different properties. Organometallic compounds constitute an immense group of chemical substances of importance to the history, theory, laboratory practice, and technology of chemistry. In a very general way it may be said that organometallic substances have unique properties that set them apart from both the inorganic and the organic families of compounds.

The metals n organometallic compounds

The metals involved in organometallic compounds may be from any of three categories: (1) the so-called main-group metals of the periodic table of the elements, which include such chemically active metals as lithium and magnesium; (2) the transition series of metals, which include those elements commonly thought of as metallic in character, such as iron, titanium, and platinum; and (3) the metalloids, or partly metal elements, such as silicon and boron. The carbon-containing groups in organometallic compounds also may be of several different varieties, including simple hydrocarbons (groups comprised solely of carbon and hydrogen atoms), unsaturated hydrocarbons (groupings with multiple bonds between carbon atoms), aromatic hydrocarbons (groupings with especially stable multiple bonds), and groups containing atoms other than carbon and hydrogen (oxygen or nitrogen, for example). Metal carbonyls, substances containing metal atoms and units of carbon monoxide, and metal isocyanides, substances containing metals and multiply bonded nitrogen-carbon groups, are classed as organometallic compounds and also as coordination compounds (compounds formed with metal atoms using bonds over and above those normally employed in bonding), revealing the close relationship between organometallic and coordination chemistry.

The carbon–metal bonds in organometallic compounds are of a number of different types: (1) ordinary covalent bonds, or σ-bonds, characterized by pairs of electrons shared between atoms, as, for example, in tetraethyllead, $(C_2H_5)_4Pb$, a gasoline additive; (2) ionic bonds, characterized by complete association of a bonding electron pair with one atom only, resulting in a separation of electrical charge, as in ethylpotassium, $(K^+C_2H_5^-)$; (3) unusual, multicentre covalent bonds, in which bonding extends over a group of atoms (in contrast with the usual two atoms), as in certain polymeric derivatives of light metals, such as ethyllithium, $(C_2H_5Li)_6$; and (4) donor–acceptor bonds, which involve association of a metal atom with an extended system of unsaturation, or overlapping π-orbitals (special electron pathways), as are found in ferrocene, bis(π-cyclopentadienyl) iron, $(\pi\text{-}C_5H_5)_2Fe$.

Physical and chemical properties

A group of compounds as varied as those in the organometallic series naturally includes substances exhibiting a wide range of physical and chemical properties. With regard to stability to heat and to air oxidation they range from alkylpotassium and alkylaluminum compounds, many of which are spontaneously inflammable in air, to ferrocene and the tetraalkyl derivatives of tin, which are very stable. Ferrocene, for example, survives heating to over 470° C (878° F) in the absence of air. The covalent organometallics vary from crystalline solids, often volatile and usually soluble in organic solvents, to liquids—or even, occasionally, to gases at room temperature; for example, trimethylboron, $(CH_3)_3B$, which boils at $-22°$ C ($-7.6°$F). Many organometallic compounds are highly toxic, particularly those that are volatile.

The first references to organometallic compounds appeared in the early 19th century. In 1827, for example, the Danish chemist W.C. Zeise reported that when platinum chloride was boiled with ethanol, and potassium chloride was added to the solution, a salt was obtained having the composition $KCl \cdot PtCl_2 \cdot C_2H_4 \cdot H_2O$. More than 100 years later it was realized that Zeise's salt should be formulated as a coordination compound of platinum, viz., $K[C_2H_4PtCl_3] \cdot H_2O$, with carbon–metal bonding. A reasonable theory to account for the bonding of the ethylene molecule (the C_2H_4 unit) to the platinum ion in this compound was not suggested until 1953.

Early historical landmarks in organometallic chemistry were the synthesis of the arsenic compound cacodyl, $(CH_3)_2AsAs(CH_3)_2$, in 1842 by the German chemist Robert Bunsen; the preparation of alkylzinc compounds in 1849 by the English chemist Sir Edward Frankland; the synthesis of nickel carbonyl in 1890 in England by Ludwig Mond, a German-born chemist; and the discovery of organomagnesium compounds in 1900 by the French chemist Victor Grignard. Although organometallic compounds had been studied for over a century, it was not until 1951, when the highly stable substance called ferrocene was discovered and its unusual π-bonded structure became known, that organometallic compounds in themselves became the subject of truly intensive research. Up to that time organometallic compounds had been of importance chiefly as substances that were useful in the synthesis of organic compounds of various types. This situation was particularly true of the organomagnesium compounds which are called, after their discoverer, Grignard reagents.

BONDING IN ORGANOMETALLIC COMPOUNDS

Polar and nonpolar bonding

Metals are electropositive elements—that is, their atoms tend to lose electrons to the atoms of other elements with which they combine. The atoms of nonmetals, on the other hand, generally attract electrons in chemical compounds. The concept of electronegativity (the power of an atom in a compound to attract electrons to itself) is useful in understanding the nature of chemical bonds. Thus, all metals have electronegativities less than that of carbon, with the result that in every carbon–metal bond the bonding electrons are attracted somewhat more to the carbon atom than to the metal atom, and the bond is polar (shows a separation of electrical charges) to some degree. Differences in electronegativity may be sufficient to produce compounds containing discrete positive and negative ions (atoms that have gained or lost electrons) held together by electrostatic forces. The electronegativity of a carbon atom is enhanced when it is part of an unsaturated system or when halogen atoms, particularly those of fluorine, are joined to it. These charge-transfer, or electrostatic, effects brought about by unsaturation or halogen substitution are responsible for the compound sodium cyclopentadienide having a structure with discrete Na^+ and $C_5H_5^-$ ions, and for the compound bis(trifluoromethyl)mercury, $(CF_3)_2Hg$, resembling more the ionic substance mercuric chloride, $HgCl_2$, than the covalent dimethylmercury, $(CH_3)_2Hg$. The latter substance, unlike its fluorocarbon analogue, is a typically organic, volatile liquid (boiling point 96° C [204.8° F]), immiscible with water. More organometallic compounds are covalent in nature than are truly ionic, because electronegativity differences between the organic groups and the metal atoms are not sufficiently pronounced to do other than impart a degree of polarity to a covalent bond. Indeed, with the least electropositive metals, such as tin or lead, their organic derivatives provide excellent examples of covalent compounds, with classical two-electron σ-bonds (bonds formed from ordinary σ-orbitals, as opposed to those from π-orbitals). Consequently, like hydrocarbons (compounds of carbon and hydrogen), these compounds are unaffected by oxygen and water at room temperature.

Organometallic compounds formed from the lighter metals (for example, lithium, beryllium, or aluminum) show somewhat different behaviour. In these compounds the carbon–metal bonds are readily decomposed by oxygen or water, affording metal–oxygen bonds and releasing the organic groups as hydrocarbons. The high reactivity of these covalent carbon–metal bonds is due to their considerable polarity, coupled with the ability of the metals to coordinate (form "secondary" bonds) with reactant molecules as a prelude to decomposition. Indeed, the availability of vacant metal orbitals to accept electron pairs is reflected in the polymeric nature of many of the organic derivatives of lithium, beryllium, and aluminum—*e.g.*, the dimethylberyllium compound, $[(CH_3)_2Be]_x$; the alkyl groups in these compounds link the metal atoms together, and to account for this it is assumed that the electron pairs occupy bonding orbitals embracing more than two atoms. These compounds, in which the number of bonding orbitals exceeds the number of electron pairs, are termed electron-deficient; they represent a bonding akin to that found in the metals, where the electrons are delocalized over many atoms in the structure.

Organometallic compounds of the transition elements

The transition metal–organic compounds include a number of metal alkyls, such as bis(triphenylphosphine)dimethylplatinum $[(C_6H_5)_3P]_2Pt(CH_3)_2$, which contain covalent carbon–metal σ-bonds similar to those found in organometallic compounds of the main-group elements, such as tin. Unless other groups are simultaneously coordinated to the metal atoms, however, most compounds of this class are of low thermal or oxidative stability. Occupation of all coordination sites (typically six) of a metal atom has an important influence on stability. Vacant sites allow coordination of oxygen and water molecules, circumstances that lead to decomposition by paths requiring low activation energies (energies required to initiate reactions). Thus, dimethylmanganese, $Mn(CH_3)_2$, is a bright-yellow powder that readily detonates and reacts instantaneously with air, whereas pentacarbonylmethylmanganese, $CH_3Mn(CO)_5$, is a volatile white solid, mp 95° C (203° F), stable to air for long periods in the solid state, and decomposing only slowly in solution.

The effective atomic number rule

In addition to the purely σ-complexes, the transition metals also form a large number of coordination compounds in which an unsaturated organic system is associated with the metal. In addition to Zeise's salt and ferrocene (see above), examples include allylpalladium chloride, tricarbonyl (cyclobutadiene) iron, and bis(benzene)chromium. These compounds are called π-complexes because the π-electrons of the hydrocarbon moieties (combining units) are involved in bonding to the metal atoms. The bonding in these cases is thought to involve reciprocal electron transfers between vacant and occupied π-orbitals of the organic group and filled and unfilled orbitals (electron pathways not involved in ordinary valence bonding) of the metal atom. Generally the metals are in their lower formal valence state—that is, fewer of their *d* electrons are involved in direct bonding—because this condition allows an energetically more favourable interaction of the *d* orbitals with the organic moieties. Many organic derivatives of the transition metals obey the so-called effective-atomic-number rule (a method for determining the degree of electronic saturation), with the result that the final electronic configuration of a fully coordinated metal is that of the next noble gas of higher atomic number. Thus, in the complex $\pi\text{-}C_5H_5Fe(CO)_2CH_3$, the iron atom acquires an additional 10 electrons to reach the configuration of the noble gas krypton, which has 18 more electrons than the preceding noble gas, argon; these electrons are supplied by the two CO groups (four electrons), the π-cyclopentadienyl group (five electrons), and the methyl group (one electron).

Many organo-transition metal complexes show fluxional behaviour—that is, the molecules exist in several chemically equivalent structures and are able to pass from one to another rapidly, a process that may be detected by the technique of nuclear magnetic resonance spectroscopy, which measures certain magnetic phenomena associated with the atomic nuclei.

ORGANOMETALLIC COMPOUNDS OF THE MAIN-GROUP ELEMENTS

Organic compounds of the main-group metals are generally named as a combination of the organic group and the metal; *e.g.*, $Si(C_2H_5)_4$, tetraethylsilicon; C_6H_5HgCl, phenylmercuric chloride; and $Na[B(C_6H_5)_4]$, sodium tetraphenylborate. Occasionally, compounds are named by adapting the name of the metal hydride, in the manner of organic compounds; *e.g.*, $(CH_3)_3SnH$ is called trimethylstannane.

Certain regularities in the trends of properties in the various families of organometallic compounds can be observed. For example, within a family, boiling points increase with increasing atomic weight of the metal atom; thus the boiling points for the tetramethyl derivatives of Group IVa elements (other than carbon) are as follows: silicon, 26.5° C (79.7° F); germanium, 43.4° C (110° F); tin, 78° C (172.4° F); and lead, 110° C (230° F). Chemical reactivities of organometallic compounds also vary in regular patterns. The small size of the lithium atom causes organolithium compounds to have covalent properties, but the other Group Ia organometallics show a steadily increasing reactivity from sodium to cesium.

Methods of preparation. The formation of these compounds may be achieved by three main methods: (1) reaction of a free metal with an organic halide or an unsaturated organic compound; (2) displacement of one metal in an organometallic compound by another, by reaction with a halide of the second metal; and (3) the addition of metal hydrides to unsaturated organic compounds.

1. Reactive main-group metals, such as lithium, sodium, and magnesium, react with organic halides to give either the organometallic compound or an organometallic halide. Examples are:

$$n\text{-}C_4H_9Br + 2Li \longrightarrow n\text{-}C_4H_9Li + LiBr$$

$$(C_6H_5)_3CCl + 2Na \longrightarrow (C_6H_5)_3CNa + NaCl$$

$$CH_3I + Mg \longrightarrow CH_3MgI\,.$$

Some hydrocarbons—*e.g.*, acetylene and cyclopentadiene—are sufficiently acidic to react directly with a metal, the reaction being accompanied by evolution of hydrogen:

$$C_6H_5C{\equiv}CH + Na \longrightarrow C_6H_5C{\equiv}CNa + \tfrac{1}{2}H_2$$

$$C_5H_6 + K \longrightarrow C_5H_5K + \tfrac{1}{2}H_2\,.$$

2. Treatment of a metal halide with an organic derivative of a different metal often leads to the substitution of one metal for the other. This is the most common synthetic method, and it is one of wide scope. A variety of examples are shown:

$$3(C_2H_5)_3Al + GaBr_3 \longrightarrow (C_2H_5)_3Ga + 3(C_2H_5)_2AlBr$$

$$(C_6H_5)_4Sn + 2BCl_3 \longrightarrow 2C_6H_5BCl_2 + (C_6H_5)_2SnCl_2$$

3. The readily available hydrides of metals of Groups IIIa and IVa add across carbon–carbon double and triple bonds, on heating or on exposure to ultraviolet light, often in the presence of a catalyst:

$$(C_6H_5)_3SnH + CH_2{=}CHCN \longrightarrow (C_6H_5)_3SnCH_2CH_2CN$$

$$Cl_3SiH + CH{\equiv}CH \longrightarrow Cl_3SiCH{=}CH_2$$

$$6n\text{-}C_4H_9CH{=}CH_2 + B_2H_6 \longrightarrow 2(C_6H_{13})_3B\,.$$

In an extensively used industrial process, olefins with terminal methylene, $=CH_2$, groups (1-olefins) react with aluminum and hydrogen under pressure to give the alkyls directly:

$$Al + \tfrac{3}{2}H_2 + 3(\text{1-olefin}) \longrightarrow (\text{alkyl})_3Al.$$

Specific synthetic procedures

The syntheses of many specific organometallics are dictated by the particular properties or reactions of a single compound or group of compounds. Thus, cyclopentadienylthallium is insoluble in water, and it may be prepared from cyclopentadiene and thallium hydroxide in aqueous solution because it readily separates from the solution. A large number of organomercury compounds are available by unique reactions: (1) mercuration of aromatic compounds with mercuric acetate, (2) reaction of aryldiazonium salts with mercury, and (3) interaction of arylsulfinic acids with mercuric chloride:

$$C_6H_6 + Hg(O_2CCH_3)_2 \longrightarrow C_6H_5HgO_2CCH_3 + CH_3CO_2H$$

$$ArN_2Cl + Hg \longrightarrow ArHgCl + N_2$$

$$ArSO_2H + HgCl_2 \longrightarrow ArHgCl + SO_2 + HCl,$$

where Ar is an aryl group.

The organosilicon halides, which are technologically important because they are precursors to the silicones, are prepared by a special reaction using copper as catalyst:

$$2CH_3Cl + Si \xrightarrow[300°]{Cu} (CH_3)_2SiCl_2$$

Organogermanium and organotin halides may be prepared similarly.

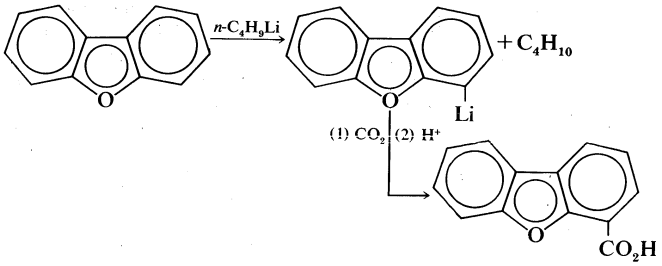
Many organoboron compounds have compact molecular structures based on cages of boron atoms and carbon atoms ("carboranes"). The most easily prepared carborane is $C_2B_{10}H_{12}$, which has a structure based on an icosahedron (a polyhedron with 20 faces), with 10 boron and two adjacent carbon atoms at the apexes and one hydrogen atom attached to each of these. This carborane can be prepared as follows:

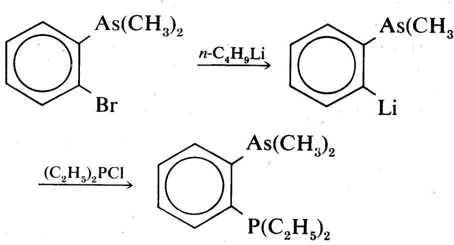
$$B_{10}H_{14} + HC{\equiv}CH \xrightarrow[C_6H_6]{2(C_2H_5)_2S} C_2B_{10}H_{12} + 2H_2.$$

The compound is high melting (294.5–295.5° C [562.1–563.9° F]) and is very resistant to oxidation and hydrolysis. Substitution at the carbon atoms may be effected by treatment with butyllithium to give $Li_2C_2B_{10}H_{10}$, followed by reaction with reactive halides.

Principal reactions. The reactions of main-group organometallic compounds are extremely varied, and certain classes of compound—*e.g.*, lithium, boron, and aluminum compounds, and the Grignard reagents—are very useful synthetically.

Organolithium compounds often are not isolated but are used as soon as they are formed, and a frequently employed sequence of reactions is metalation of an organic compound with *n*-butyllithium (a commercially available product) followed by reaction with a selected reagent that reacts with the organometallic intermediate.





A useful reaction occurs with alkyltriphenylphosphonium salts to give phosphinemethylenes. These intermediates react with carbonyl compounds to give olefins, a reaction known as the Wittig reaction.

$$(C_6H_5)_3P \xrightarrow{CH_3Br} (C_6H_5)_3P(CH_3)^+Br^- \xrightarrow{C_6H_5Li}$$

$$(C_6H_5)P = CH_2 \xrightarrow{R_2CO} (C_6H_5)_3PO + R_2C = CH_2$$

The most important reactions of organoboron compounds, R_3B, are cleavage of the C–B bonds in various ways to give alkanes, alcohols, ketones, and other compounds. The addition of B–H bonds to carbon–carbon double bonds is called hydroboration; the reaction proceeds rapidly in ethers (as solvents) affording diverse species, R_3B, in which the R groups can be complex organic moieties. Many syntheses of purely organic compounds depend on the addition of diborane (B_2H_6), often generated *in situ,* to olefins using a polyether—*e.g.*, diglyme, $(CH_3OCH_2CH_2)_2O$—as solvent.

Hydroboration

$$12RCH{=}CH_2 + 3NaBH_4 + 4(C_2H_5)_2OBF_3 \longrightarrow 4(RCH_2CH_2)_3B + 3NaBF_4 + 4(C_2H_5)_2O$$

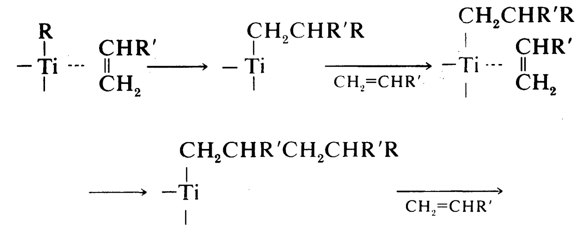
The resulting organoboron compounds undergo a variety of reactions. For example, treatment with alkaline hydrogen peroxide yields an alcohol RCH_2CH_2OH, whereas protonation (addition of a hydrogen ion) gives RCH_2CH_3; *i.e.*, effects hydrogenation of the starting olefin. Oxidation of $(RCH_2CH_2)_3B$ with chromic acid gives ketones or acids, while treatment with diethylchloramine, $(C_2H_5)_2NCl$, gives RCH_2CH_2Cl (corresponding to an overall addition of hydrogen chloride to the olefin in a manner opposite to that normally observed). Thus, a family of related organic syntheses depends on hydroboration.

The industrial availability of triorganoaluminum compounds has resulted in their becoming reagents of great utility. In the preparation of alkyl derivatives of other metals their use avoids the employment of ethers, which are necessary with Grignard reagents. Aluminum alkyls also cause dimerization, oligomerization, or polymerization of olefins—that is, joining of two olefin molecules, several olefin molecules, or many, respectively. The reactions are of use in the manufacture of detergents, which often are made from long-chain alcohols, as follows:

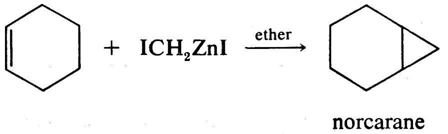
$$(C_2H_5)_3Al \xrightarrow[\substack{\sim 100^\circ \\ \sim 100\ \text{atm}}]{C_2H_4} [C_2H_5(C_2H_4)_n]_3Al \xrightarrow[\text{oxidation}]{\text{controlled}} H(C_2H_4)_{n+1}OH.$$

Olefin polymerization

If a compound $[CH_3(CH_2)_n]_3$ Al is heated under pressure, the alkyl chain becomes detached in the form of a medium-to-high-molecular-weight linear polyethylene. Such polymers, however, are better obtained by using aluminum–transition metal catalysts (Ziegler–Natta catalysts). For example, treatment of titanium tetrachloride, ($TiCl_4$), with triethylaluminum $(C_2H_5)_3Al$, in heptane solvent gives a complex that reacts with such olefins as ethylene or propylene. The polymers produced by this reaction are isotactic (sterically regular) solids with desirable properties, as opposed to disordered (atactic) polymers that are oils at room temperature. The mechanism of this industrially important process is a matter of some controversy but probably involves an initial reduction and alkylation of the titanium by the aluminum alkyl, followed by coordination and insertion of olefin molecules in a stereoregular way.



A mixture of zinc and copper reacts with di-iodomethane to give iodomethylzinc iodide (stable in solution only). This compound is useful in reacting with olefins to give cyclopropanes:



norcarane
(bicyclo [4.1.0] heptane)

Organozinc compounds also are formed as transient intermediates in a standard reaction for producing highly substituted esters (the Reformatsky reaction):

$$BrCH_2CO_2C_2H_5 \xrightarrow{Zn} [BrZnCH_2CO_2C_2H_5] \xrightarrow[H_2O]{R'_2CO} R'_2C(OH)CH_2CO_2C_2H_5.$$

The most important reaction of organocadmium compounds is the reaction with acid chlorides to give ketones:

$$2RCOCl + R'_2Cd \longrightarrow 2RCOR' + CdCl_2.$$

This method is preferred to the use of Grignard reagents, since the latter react rapidly with the ketone produced.

Analytical chemistry. Organic derivatives of main-group metals may be analyzed by combustion analysis, in which the compound is burned and the carbon and hydrogen present are determined as carbon dioxide and water (the residual metal oxide may be weighed directly). Spectroscopic methods—*e.g.*, infrared and nuclear magnetic resonance spectroscopy—provide a great deal of information, especially about the nature of the organic groups present. Mass spectrometry also is extensively used, often yielding precise molecular-weight measurements.

Tetraethyllead

Industrial applications. Aluminum alkyls are employed industrially in olefin polymerization and in the synthesis of long-chain alcohols (see above). Tetraethyllead was formerly used on a large scale as an additive (antiknock agent) in gasoline, since it is a combustion catalyst that permits higher compression ratios in the engine. The commercial process for manufacture of tetraethyllead is as follows:

$$4NaPb + 4C_2H_5Cl \longrightarrow (C_2H_5)_4Pb + 4NaCl + 3Pb.$$

In gasoline, tetraethyllead is mixed with dibromoethane and dichloroethane; these substances act as "scavengers" within the engine by converting the resulting lead oxide into volatile halides, which are emitted in the exhaust. Volatile lead compounds, however, are highly toxic, and their expulsion into the atmosphere is undesirable. Hence the use of lead alkyls in motor fuels is declining, and other methods are being sought for the production of fuels with superior combustion characteristics (higher "octane number").

Controlled hydrolysis of organosilicon halides produces polymers containing silicon–oxygen and silicon–carbon bonds. The silicones have unusual properties and are widely used for a number of purposes. Organotin compounds are used to stabilize polyvinyl chloride, a polymer used in many common plastic articles. They are also used as fungicides in agriculture and in treating plant diseases that infect potatoes, sugar beets, cacao, groundnuts (peanuts), and other crops. Tricyclohexyltin hydroxide also is used in agriculture, to kill mites. Tributyltin oxide is important as an industrial biocide and surface disinfectant; thus, it is used in preserving wood and in keeping clean the recirculating water of cooling towers.

Certain organomercury compounds have been widely used in pharmacy, for example, as diuretics, but have now been largely replaced by more specific organic compounds. Mercurochrome (2,7-dibromo-4-hydroxymercurifluorescein) is a familiar antiseptic.

ORGANOMETALLIC COMPOUNDS OF THE TRANSITION ELEMENTS

Organic compounds of transition metals are generally named as a combination of the organic group and the metal; *e.g.*, $Mn(CH_3)_2$, dimethylmanganese. When other donor ligands are present, their names precede that of the organic group; *e.g.*, $[(C_6H_5)_3P]_2Pt(C_6H_5)I$, iodobis(triphenylphosphine)phenylplatinum. Similarly, the names of π-bonded organic groups precede those of σ-bonded groups; *e.g.*, $(\pi\text{-}C_5H_5)Fe(CO)_2CH_3$, dicarbonyl-$\pi$-cyclopentadienyl-$\sigma$-methyliron. As these names tend to be cumbersome, many of the commonly encountered compounds have acquired simpler names; *e.g.*, $Fe(\pi\text{-}C_5H_5)_2$, ferrocene or bis(π-cyclopentadienyl)iron; $(\pi\text{-}C_5H_5)Mn(CO)_3$, cymantrene or π-cyclopentadienyltricarbonylmanganese. Organic complexes of the transition elements may be classified according to the number of electrons donated by the organic ligand (that is, the substance complexed with the metal atom; see Table 58). A great many separate compounds are known because many members of each particular class of organic molecule can bond to a given metal. There are, for example, a vast number of complexes of formula diene-$Fe(CO)_3$ because the $Fe(CO)_3$ group shows great affinity for any 4π-electron system based on two conjugated double bonds, of which there are many. Moreover, a particular metal may form complexes with all types of ligand; for example, in the series $CH_3Mn(CO)_5$,

$$[(\pi\text{-}C_2H_4)Mn(CO)_5]^+,\ (\pi\text{-}C_3H_5)Mn(CO)_4,$$
$$(\pi\text{-}C_6H_8)Mn(CO)_3H,\ (\pi\text{-}C_5H_5)Mn(CO)_3,\text{ and}$$

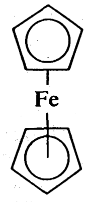
$[(\pi\text{-}C_6H_6)Mn(CO)_3]^+$, manganese is associated with organic groups that donate—in order—from one to six electrons to its valence shell. In each case the effective atomic number rule is obeyed, the manganese atom having 18 electrons in its outermost shell.

Table 58: Representative Ligands in Organotransition-Metal Complexes

number of electrons	class	examples of complexes
1	yl	$CH_3Re(CO)_5$, white, mp 120°
2	alkene	$[(\pi\text{-}C_2H_4)_2RhCl]_2$, orange red, decomp. > 100°
	carbene	$CH_3(CH_3O)CCr(CO)_5$, white, mp 34°
3	enyl*	$[(\pi\text{-}C_3H_5)PdCl]_2$, yellow, mp 145°
4	diene	$(\pi\text{-}C_4H_6)Fe(CO)_3$,† yellow oil
5	dienyl	$(\pi\text{-}C_5H_5)_2Ni$, green, mp 173°
	ollyl	$[(CH_3)_4N][\{\pi\text{-}1,2\text{-}B_9H_9C_2(CH_3)_2\}_2Fe]$‡, red, mp 247°
6	arene	$(\pi\text{-}C_6H_6)_2W$, green, decomposes 110°
	triene	$(\pi\text{-}C_7H_8)Mo(CO)_3$,§ orange red, mp 101°
7	trienyl	$(\pi\text{-}C_7H_7)V(CO)_3$, dark green, decomposes 134°

*Also called "π-allylic" ligands. †C_4H_6 is buta-1,3-diene. ‡The ligand $\{1,2\text{-}B_9H_9C_2(CH_3)_2\}^{2-}$ is an 11-atom B_9C_2 species (an icosahedron with an apex removed) having a face comprising five atoms (B_3C_2) with π-type molecular orbitals similar to those of $\pi\text{-}C_5H_5$. In forming the complex the metal atom completes the icosahedron. §C_7H_8 is cycloheptatriene.

Although this rule is very useful, it is not followed invariably; the exceptions may be rationalized by considering the relative energies of the *s, p,* and *d* orbitals (designations for electron pathways within the various shells). For metals of the scandium and titanium groups of the periodic table, the 3*d* orbitals have a relatively high energy compared with the other orbitals (4*s* and 4*p*) in the same valence band, and their importance in bonding, therefore, is less. At the other end of the transition series (in the neighbourhood of copper and zinc), the *d* orbitals are of relatively low energy and cannot easily be regarded as valence orbitals. Across the series vanadium, chromium, manganese, iron, cobalt, and nickel, the 3*d* orbitals decrease in energy more rapidly than do the 4*s* and 4*p* orbitals, but all three orbital types are generally sufficiently close in energy to be suitable for metal–ligand bonding. Under these conditions, maximum bonding—with associated stability—occurs when all orbitals are filled with electron pairs. This occurs when the metal atom has an 18-electron configuration; *i.e.,* the five *nd,* one $(n+1)s$, and three $(n+1)p$ orbitals ($n = 3$, 4, or 5) are all occupied by metal and ligand electrons. Nowhere is this better exemplified than in the case of ferrocene, a compound of exceptional stability and one in which the iron atom (eight electrons) is located symmetrically between two $\pi\text{-}C_5H_5$ groups (ten electrons), forming a classical "sandwich" molecular structure.



Exceptions to the effective-atomic-number rule

It follows from this reasoning that exceptions to the effective-atomic-number rule are found at both ends of the transition series, in which cases the 3*d* orbitals are too high (as with titanium) or too low (copper) in energy. Sixteen-electron environments are prevalent with organotitanium compounds—*e.g.,* $(\pi\text{-}C_5H_5)_2Ti(C_6H_5)_2$—and 14 with the metals of the copper group [*e.g.,* $(C_6H_5)_3PAuCH_3$]. With the latter, not only have the *d* electrons become low-energy (core) electrons but the *p* orbitals have become relatively high in energy compared with the *s* orbitals; consequently only one *p* orbital is used in bonding, in combination with the *s* orbital. A similar effect is responsible for the existence of numerous 16-electron complexes of nickel, palladium, and platinum, in which the relative energies of the *nd,* the $(n+1)s$, and the $(n+1)p$ orbitals are such as to lead to the use of one of the *d,* the *s,* and two of the *p* orbitals in bonding—*e.g.,* $[(C_2H_5)_3P]_2Pd(CH_3)I$.

Methods of preparation. It is convenient to consider separately the methods for preparing the π-complexes and the σ-compounds of the transition metals.

π-Complexes. Treatment of a suitable metal halide with an organic derivative of an alkali metal or a Grignard reagent using an ether (often tetrahydrofuran) as solvent is often a method for preparing π-complexes of transition elements.

$$2CH_2{=}CHCH_2MgBr + NiCl_2 \longrightarrow (\pi\text{-}C_3H_5)_2Ni + 2MgClBr$$

$$2C_5H_5Na + FeCl_2 \longrightarrow (\pi\text{-}C_5H_5)_2Fe + 2NaCl$$

$$2C_8H_8K_2 + UCl_4 \longrightarrow (\pi\text{-}C_8H_8)_2U + 4KCl$$

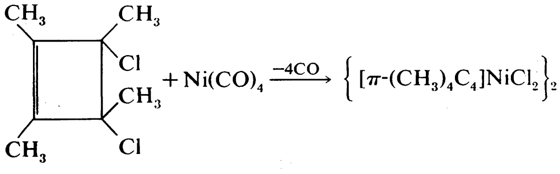
Reactions with olefins

The reaction between a metal complex and an unsaturated hydrocarbon is the most generally useful method of preparing π-complexes; it has several modifications. In one of the simplest forms of this reaction, carbonyls are displaced from metal carbonyl complexes by unsaturated hydrocarbons. The reaction is carried out by heating the reactants together or by exposing them to ultraviolet irradiation in a suitable solvent (often a saturated hydrocarbon).

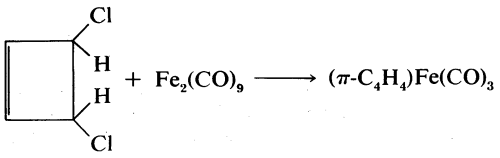
$$Fe(CO)_5 + CH_2{=}CHCH{=}CH_2 \xrightarrow{-2CO} (\pi\text{-}C_4H_6)Fe(CO)_3$$

$$CO_2(CO)_8 + 2C_5H_6 \longrightarrow 2(\pi\text{-}C_5H_5)Co(CO)_2 + 4CO + H_2$$

The more reactive metal carbonyls abstract chlorine atoms from carbon–chlorine bonds with concomitant oxidation of the metal to a metal chloride. This property has been used to isolate organic molecules that are not normally stable in the free state but that can be stabilized by coordination with a metal atom. Cyclobutadiene and its derivatives, sought by chemists for over 80 years, were finally prepared by being stabilized in this way.



$$+ Ni(CO)_4 \xrightarrow{-4CO} \left\{[\pi\text{-}(CH_3)_4C_4]NiCl_2\right\}_2$$



$$+ Fe_2(CO)_9 \longrightarrow (\pi\text{-}C_4H_4)Fe(CO)_3$$

Another example of this type of stabilization is found in the preparation of the trimethylenemethane group:

$$CH_2{=}C(CH_2Cl)_2 + Fe_2(CO)_9 \longrightarrow [\pi\text{-}(CH_2)_3C]Fe(CO)_3.$$

Reactions with acetylenes

Reactions between acetylenes and metal carbonyls (or their derivatives) can be a fruitful source of unusual organometallic compounds. A variety of reactions is possible, including coordination of the triple bond, di- or trimerization of the acetylene, and formation of ligands containing carbonyl groups, with the result that highly complex mixtures of products are obtained. For example, the mixture that results from treatment of iron carbonyls with acetylenes has given complexes of nearly 30 different types, containing such diverse ligands as cyclobutadienes, cyclopentadienones, and quinones.

The preparation of many π-complexes depends upon an initial reduction of a transition-metal compound in the presence of an unsaturated hydrocarbon to serve as the ligand. The synthesis of bis(benzene)chromium depends upon this technique:

$$3CrCl_3 + 2Al + AlCl_3 + 6C_6H_6 \longrightarrow 3[(\pi\text{-}C_6H_6)_2Cr]^+[AlCl_4]^-$$

$$2[(\pi\text{-}C_6H_6)_2Cr]^+ + S_2O_4^{2-} + 4OH^- \longrightarrow 2(\pi\text{-}C_6H_6)_2Cr + 2H_2O + 2SO_3^{2-}.$$

With this procedure, or modifications of it, arene complexes of many of the transition metals have been prepared. Aromatics other than benzene also may be used.

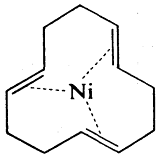
Reduction of nickel acetylacetonate with aluminum alkyls in the presence of triphenylphosphine and ethylene produces a yellow crystalline compound,

$$(\pi\text{-}C_2H_4)Ni[P(C_6H_5)_3]_2.$$

With cycloocta-1,5-diene, rather than ethylene and triphenylphosphine, the same method produces

$$(\pi\text{-}C_8H_{12})_2Ni,$$

a yellow solid of melting point 142° C (287.6° F) that is unstable in air but is reasonably stable to heat. An unusual complex that is prepared by a similar method is all-*trans*-1,5,9-cyclododecatrienenickel,



in which the metal atom is coordinated only to three double bonds. Many olefin complexes of nickel are used in further syntheses. Thus, $(\pi\text{-}C_{12}H_{18})Ni$ catalyzes the trimerization of butadiene, giving isomers of cyclododecatriene. In some syntheses the hydrocarbon itself functions as the reducing agent. Thus, treatment of rhodium trichloride with butadiene gives bis(butadiene)rhodium(I) chloride, $(\pi\text{-}C_4H_6)_2RhCl$.

Ligand-exchange reactions

Ligand-exchange reactions, those in which an organic group is transferred from one metal to another, also are used to prepare π-complexes. For example, treatment of $(C_6H_5CN)_2PdCl_2$ with diphenylacetylene, followed by reaction with hydrogen halides, gives dimeric tetraphenyl-cyclobutadienepalladium halides $\{[\pi\text{-}(C_6H_5)_4C_4]PdX_2\}_2$ (X = Cl or Br). The tetraphenylcyclobutadiene group then may be readily transferred to other metals. Thus, reaction of one of the above palladium complexes with $(\pi\text{-}C_5H_5)_2Co$ gives $[\pi\text{-}(C_6H_5)_4C_4]Co(\pi\text{-}C_5H_5)$, and reaction with $Fe(CO)_5$ gives $[\pi\text{-}(C_6H_5)_4C_4]Fe(CO)_3$.

σ-Compounds. Although simple alkyls and aryls of the transition metals are generally very unstable—*e.g.*, $(CH_3)_2Ni$ decomposes above −110° C (−166° F)—derivatives containing such ligands as carbon monoxide, phosphines, and π-bonded hydrocarbons are often reasonably robust chemically. A number of synthetic routes to these compounds are known.

Treatment of transition-metal-complex halides with Grignard reagents or with organolithium compounds frequently leads to replacement of the halogen with alkyl or aryl groups.

$$(C_6H_5)_3PAuCl + CH_3Li \longrightarrow (C_6H_5)_3PAuCH_3 + LiCl$$

Reactions between complex metal anions and organic halides yield organometallic compounds in which the anion has replaced the halide.

$$Na^+[Mn(CO)_5]^- + CH_3I \longrightarrow CH_3Mn(CO)_5 + NaI$$

The utility of this method is enhanced by the fact that acyl complexes, prepared by reaction of the anions with acid halides, can often be decarbonylated, either thermally or on ultraviolet irradiation, to give the corresponding alkyl compounds:

$$Na^+[Fe(CO)_2(\pi\text{-}C_5H_5)]^- + C_6H_5COCl \longrightarrow C_6H_5COFe(CO)_2(\pi\text{-}C_5H_5) + NaCl \xrightarrow{h\nu} C_6H_5Fe(CO)_2(\pi\text{-}C_5H_5) + CO.$$

Insertion reactions

Insertion of unsaturated groups into metal–hydrogen or metal–alkyl σ-bonds produces organometallic compounds with more extended alkyl chains.

$$(\pi\text{-}C_5H_5)Fe(CO)_2H + CH_2{=}CHCH{=}CH_2 \longrightarrow CH_3CH{=}CHCH_2Fe(CO)_2(\pi\text{-}C_5H_5)$$

A useful synthesis depends on the so-called oxidative-addition or oxidative-elimination reactions. Many transition-metal complexes, in which the metal atom is of low valence and which are not so fully coordinated as they might be, react with electron-acceptor (electrophilic) molecules to form compounds in which the valence state of the metal can be regarded formally as having increased by two units. The reacting molecule, which contains a bond designated A—B, may be cleaved by the metal atom to form in its coordination sphere two separate bonds, M—A and M—B; or, if the bond between A and B is a multiple one, the product may contain an A—B unit coordinated to the metal atom. The following reactions exemplify the utility of these kinds of processes in organometallic syntheses:

$$Fe(CO)_5 + C_3F_7I \longrightarrow C_3F_7Fe(CO)_4I + CO$$

$$[(C_6H_5)_3P]_3RhCl + C_2H_4 \longrightarrow (\pi\text{-}C_2H_4)Rh[P(C_6H_5)_3]_2Cl + (C_6H_5)_3P$$

$$[(C_6H_5)_3P]_2Ir(CO)Cl + CH_3I \longrightarrow CH_3Ir[P(C_6H_5)_3]_2(CO)(Cl)(I)$$

$$[(C_6H_5)_3P]_3Pt + CH_3C{\equiv}CCH_3 \longrightarrow [\pi\text{-}(CH_3)_2C_2]Pt[P(C_6H_5)_3]_2 + (C_6H_5)_3P.$$

Principal reactions. Each class of organometallic complex (see Table 58) has its own characteristic chemical and physical properties associated with the presence of a particular type of organic group. The degree to which group properties are shown, however, depends on the firmness with which the ligand is attached to the metal atom. Consequently, there are no reactions generally applicable to all those compounds, and even for a particular class large gradations in reactivity are observed.

Many organometallics are endothermic compounds; that is, their formation from the constituent elements involves an increase in free energy. Hence there is an inherent thermal instability with respect to decomposition into the metals and the hydrocarbons that make them up. Nevertheless, many hundreds of these compounds can be prepared, and in some cases they show considerable resistance to thermal decomposition, because it is necessary for a favourable free-energy change to be accompanied by a reaction path of sufficiently low energy if decomposition is to occur at a measurable rate. In many cases, decomposition may be kinetically rather than thermodynamically controlled—that is, it may not be observed normally because the rate is too slow, even though the energy requirements are favourable. The limiting process may be the initial breaking of an M—C bond to form M· and R· radicals (homolytic dissociation) or M^+ and R^- ions (heterolytic dissociation). Such bond dissociations are likely to be facilitated when empty low-lying orbitals are present in the metal atom, since electrons can temporarily reside in these. In both homolytic and heterolytic processes, the carbon fragments are generally reactive and rapidly form stable products; for example, by dimerization. It is the formation of these more stable products that makes the decomposition irreversible; but if there is a high activation energy (energy needed to initiate the process) for the dissociation, decomposition will not occur.

All organometallic compounds are thermodynamically unstable to oxidation because of the large favourable free-energy change in the conversion into metal oxide, carbon dioxide, and water. In this respect organometallic compounds are no different from purely organic compounds except that with the former an additional product (metal oxide) is involved. Again, however, kinetic factors (considerations of reaction rate) are often decisive both in enhancing stability toward oxygen and in lowering resistance to oxidative attack. In this case also instability can be associated generally with the presence of empty low-lying orbitals. Similar considerations apply to hydrolytic stability. Hydrolysis often involves an initial bonding with a water molecule, a process facilitated by an empty metal orbital. The M—C bond polarity, however, also is an important factor in hydrolysis because a further step in the process is the elimination of R^- as a hydrocarbon RH.

The existence of a closed-shell (18-electron) configuration has a bearing on the reactivity of a complex (see above). For complexes in which the metal atom already follows the effective-atomic-number rule, reaction may require displacement of one or more ligand molecules in order to provide a vacant coordination site or sites for a reactant molecule. This situation may lead only to the exchange of one ligand for another, but often a molecular rearrangement follows, affording an entirely new structure.

Cleavage reactions

Cleavage and insertion reactions are the hallmark of σ-bonds between transition metals and alkyl or aryl groups. Cleavage reactions are those in which the C—M bond is split, with attendant formation of a new bond to an inorganic atom. Typical reagents that may effect cleavage are acids, hydrogen, halogens, and metal halides.

$$(CH_3)_2Pt[P(C_2H_5)_3]_2 + HCl \longrightarrow CH_3Pt[P(C_2H_5)_3]_2Cl + CH_3Cl$$

$$C_6H_5Pt[P(C_2H_5)_3]_2Cl + H_2 \longrightarrow HPt[P(C_2H_5)_3]_2Cl + C_6H_6$$

$$(C_6H_5)_2Ti(\pi\text{-}C_5H_5)_2 + 2Cl_2 \longrightarrow Cl_2Ti(\pi\text{-}C_5H_5)_2 + 2C_6H_5Cl$$

$$(C_6H_5)_3Cr(THF)_3 + 3HgCl_2 \longrightarrow 3C_6H_5HgCl + CrCl_3 + 3THF$$

The term insertion designates a reaction in which a C—M bond is broken, with the reactant molecule's being placed between the two parts and joined to both. This process is the basis of the Ziegler–Natta olefin polymerizations (see above), but it also is known in many simpler forms.

$$C_6H_5Fe(CO)_2(\pi\text{-}C_5H_5) + (C_6H_5)_3P \longrightarrow C_6H_5COFe(CO)[P(C_6H_5)_3](\pi\text{-}C_5H_5)$$

$$CH_3Mn(CO)_5 + SO_2 \longrightarrow CH_3SO_2Mn(CO)_5$$

Conversion of σ- to π-complexes

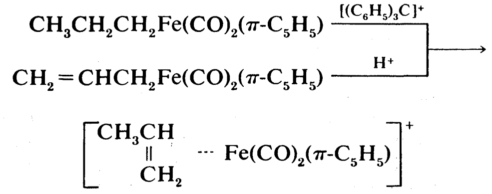
In many reactions, a σ-bonded organic group is converted into a π-complexed group. A simple example involves the complex $\sigma\text{-}CH_2{=}CHCH_2Mn(CO)_5$, which on heating or exposure to ultraviolet light releases carbon monoxide and forms $(\pi\text{-}C_3H_5)Mn(CO)_4$. Similar decarbonylations (loss of carbonyl groups) have been observed with σ-allyl carbonyl derivatives of cobalt, iron, chromium, molybdenum, and tungsten, in each case π-allyl complexes of these metals being formed.

In 1919 and afterward many polyphenylchromium compounds were prepared by treating chromium chloride ($CrCl_3$) with phenylmagnesium bromide. In 1954 it was shown that several of these compounds were cationic arene–chromium π-complexes; *e.g.*,

$$[(\pi\text{-}C_6H_6)Cr(\pi\text{-}C_6H_5C_6H_5)]^+,$$

which had been formed by rearrangement of $\sigma\text{-}C_6H_5Cr$ groups either in a hydrolysis step or thermally. Most of these transformations are exceedingly complex, and a multitude of products is formed. The history of the polyphenylchromium complexes is an example of the failure to recognize the true nature of a series of compounds because of the lack of sufficiently sophisticated analytical techniques.

Several σ-alkyl complexes have been converted to cationic olefin π-complexes by hydride abstraction (removal of H^-) or by protonation (addition of H^+).



$$CH_3CH_2CH_2Fe(CO)_2(\pi\text{-}C_5H_5) \xrightarrow{[(C_6H_5)_3C]^+}$$
$$CH_2{=}CHCH_2Fe(CO)_2(\pi\text{-}C_5H_5) \xrightarrow{H^+}$$
$$\longrightarrow \left[\begin{matrix} CH_3CH \\ \| \\ CH_2 \end{matrix} \cdots Fe(CO)_2(\pi\text{-}C_5H_5) \right]^+$$

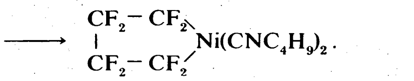
An unusual group of compounds contains a fluorocarbon group (chemical unit of only carbon and fluorine atoms) σ-bonded to a transition metal. These complexes are more stable chemically than their alkyl or aryl counterparts—*e.g.*, $C_2F_5Mn(CO)_5$ decomposes at 150° C (302° F), whereas $C_2H_5Mn(CO)_5$ decomposes at 25° (77° F); $C_6F_5Mn(CO)_5$ decomposes at 170° C (338° F), whereas $C_6H_5Mn(CO)_5$ decomposes at 100° C (212° F). Thermodynamic and kinetic factors both are thought to be responsible for the enhanced stability of the fluorocarbon compounds. The fluorocarbon–metal bonds are more ionic than hydrocarbon–metal bonds; that is, they show more complete association of the shared electron pair with the carbon atom of the bond. This effect is due to the strongly electron-withdrawing character of the fluorocarbon groups, which tend to pull the electron pair farther from the metal atom. Moreover, alkyl–metal bonds frequently decompose by a reaction that is the reverse of an insertion reaction, $M{-}C_2H_5 \rightarrow M{-}H + C_2H_4$. The analogous reaction involving elimination of a fluoroolefin and formation of a metal fluoride, although thermodynamically favoured, requires more activation energy in order to proceed at a measurable rate. Because of their stability, bonds between fluorocarbon groups and transition metals show little or no tendency to undergo insertion reactions. More than 500 complexes of this type are known, produced by reactions such as

$$HMn(CO)_5 + CF_2{=}CF_2 \longrightarrow HCF_2CF_2Mn(CO)_5$$

$$NaRe(CO)_5 + C_6F_6 \longrightarrow C_6F_5Re(CO)_5 + NaF$$

$$(\pi\text{-}C_5H_5)_2ZrCl_2 + 2C_6F_5Li \longrightarrow (C_6F_5)_2Zr(\pi\text{-}C_5H_5)_2 + 2LiCl$$

$$(C_4H_9NC)_4Ni + 2CF_2{=}CF_2$$



$$\longrightarrow \begin{matrix} CF_2-CF_2 \\ | \\ CF_2-CF_2 \end{matrix} \!\!\!>\! Ni(CNC_4H_9)_2 .$$

Reactions of π-complexes

The reactions of π-complexes are extremely extensive; it has been said that the cyclopentadienyl group forms more complexes than any other organic ligand. Whether or not this is strictly true, the range of complexes formed by this five-membered ring is certainly great. Simple cyclopentadienyl derivatives, $(\pi\text{-}C_5H_5)_2M$, of the first row transition elements, from vanadium through nickel, all have the same structure, consisting of a metal atom sandwiched between two five-membered rings. This situation gives rise to a fairly constant melting point (173° C [343° F]), although the differing electronic configurations result in markedly different reactivities. Thus, in marked contrast with the highly stable ferrocene, chromocene bursts into flame spontaneously in air.

One of the main factors responsible for the many ramifications of coordination chemistry is the ability of a metal atom to bond more than one type of ligand within its coordination sphere at the same time. Moreover, certain ligands stabilize the bonding of others, and this is especially true of the $\pi\text{-}C_5H_5$ group, as illustrated by the existence of the following compounds of metals of the first transition series:

$$(\pi\text{-}C_5H_5)_2Ti(C_6F_5)_2,$$

$$(\pi\text{-}C_5H_5)V(\pi\text{-}C_7H_7),$$

$$(\pi\text{-}C_5H_5)Cr(NO)_2Cl,$$

$$(\pi\text{-}C_5H_5)Mn(\pi\text{-}C_6H_6),$$

$$(\pi\text{-}C_5H_5)Fe(\pi\text{-}C_4H_4N),$$

$$(\pi\text{-}C_5H_5)Co(\pi\text{-}C_5H_6),$$

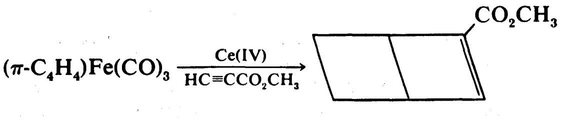
$$(\pi\text{-}C_5H_5)Ni(CO)CF=CFCF=CF_2.$$

The cyclopentadienylmetal carbonyls undergo a number of chemical reactions and show several resemblances to the metal carbonyls. For example, the $(\pi\text{-}C_5H_5)M$ group is isoelectronic with (*i.e.,* has the same number of electrons as) the $M'(CO)_3$ group, where M′ is the element preceding M in the periodic table. Many complexes containing the $Fe(CO)_3$ group thus have counterparts containing the $(\pi\text{-}C_5H_5)Co$ group; similarly, the chemistry of $[(\pi\text{-}C_5H_5)Fe(CO)_2]_2$ bears many resemblances to that of $[Mn(CO)_5]_2$, and that of $(\pi\text{-}C_5H_5)Mn(CO)_3$ to $Cr(CO)_6$. The cyclopentadienylmetal carbonyls also resemble the metal carbonyls in that in both cases there are numerous polynuclear complexes containing metal–metal bonds; *e.g.,* $[(\pi\text{-}C_5H_5)Ni]_3(CO)_2$, $[(\pi\text{-}C_5H_5)RhCO]_3$, or $[(\pi\text{-}C_5H_5)FeCO]_4$.

Aromatic reactions of π-complexes

A striking feature of the chemistry of certain cyclopentadienyl complexes is the ability of the five-membered ring to undergo reactions typical of aromatic systems. Such chemisty was first demonstrated for ferrocene, which can be acylated (substituted with an acyl group) under Friedel-Crafts conditions—that is, with aluminum choloride as catalyst. Furthermore, one of the hydrogen atoms can be replaced by a lithium atom or a mercuriacetate group, using butyllithium or mercuric acetate, respectively. Introduction of these and other functional groups has allowed the synthesis of hundreds of ring-substituted ferrocene compounds. Many other cyclopentadienylmetal compounds, on the other hand, do not undergo substitution reactions for either of several reasons: (1) the metal atom interferes with the reaction—*e.g.,* becomes oxidized; or (2) the complex does not survive the reaction conditions. Aromatic behaviour also has been shown by $(\pi\text{-}C_5H_5)_2M$, M=Ru, Os; $(\pi\text{-}C_5H_5)Mn(CO)_3$, termed "cymantrene"; $(\pi\text{-}C_5H_5)Cr(CO)_2NO$; $(\pi\text{-}C_5H_5)_2ReH$; and certain other compounds.

In tricarbonyl(cyclobutadiene)iron, the metal–ligand bonding is sufficiently strong to allow the cyclobutadiene group to show aromaticity. For example, CH_3CO and HgCl groups may be substituted for H atoms of the ring to give useful intermediates for further syntheses. On the other hand, $(\pi\text{-}C_4H_4)Fe(CO)_3$ can be oxidized, releasing cyclobutadiene, which may be characterized by the reactions it undergoes immediately.



When this reaction is carried out with $C_6H_5C{\equiv}CH$, the organic compound produced is in the unusual situation of having a classical benzene ring bonded to its valence isomer, Dewar benzene (named for the Scottish chemist who proposed this structure for ordinary benzene), the structure shown in the above formula.

Analytical chemistry. Analytical methods for the organic derivatives of the transition metals are generally similar to those for the organic derivatives of the main-group metals. Spectroscopic techniques are an important source of information, and with metal carbonyl derivatives, infrared spectroscopy is extremely valuable in determining the number of carbonyl groups and their arrangement around the metal. Proton magnetic resonance spectra are of help in interpreting the nature of the bonded hydrocarbon groups, although the number of fluxional systems discovered means that care must be exercised in the interpretation of apparently simple spectra. Other spectroscopic methods—*e.g.,* Mössbauer, and electronspin resonance techniques—have been used where appropriate.

The increasing complexity of the compounds discovered makes X-ray crystallographic methods the final arbiter of structures; hundreds of new structures are determined by this method each year. This analytical technique has been greatly facilitated by computer processing of data.

Industrial applications. Relatively few organometallic compounds of the transition metals find direct practical application. On the other hand, their value as reaction intermediates is almost inestimable.

Use in the petroleum industry

As already indicated, organometallics are widely employed in the petroleum-based industries. Certain industrial-scale syntheses depend upon the transient existence of catalysts in the form of metallo-organic complexes, which are constantly regenerated. Hydroformylation, or the conversion of olefins into aldehydes or ketones using carbon monoxide and hydrogen under pressure (100°–300° C [212°–572°F]; 100 atm), is catalyzed by cobalt carbonyl and related complexes, including those of rhodium. The catalytic material in the system is thought to be a hydridocarbonyl—such as $HCo(CO)_3$—derived from $Co_2(CO)_8$, and the various reaction steps include insertion reactions (olefin inserted into metal–hydrogen bonds and CO into metal–alkyl bonds) as well as oxidative-addition and reductive-elimination reactions. The overall process clearly depends upon organometallic intermediates and their cleavage reactions.

$$Co_2(CO)_8 + H_2 \rightleftharpoons 2HCo(CO)_3 + 2CO$$

$$\xrightarrow[\pi\text{-complex formation}]{RCH=CH_2} (\pi\text{-}RCH=CH_2)Co(CO)_3H$$

$$\xrightarrow{\text{insertion}} RCH_2CH_2Co(CO)_3$$

$$\xrightarrow[\text{insertion}]{CO} RCH_2CH_2COCo(CO)_3 \xrightarrow[\text{oxidative addition}]{H_2} RCH_2CH_2COCo(CO)_3H_2$$

$$\xrightarrow[\text{elimination}]{\text{reductive}} \underset{\text{product}}{RCH_2CH_2CHO} + \underset{\textit{catalyst}}{HCo(CO)_3}$$

The mechanisms of such reactions are related to the mechanisms of catalytic hydrogenation of olefins or acetylenes by certain metal complexes. In both cases, the catalyst carries out three basic reactions: (1) activation of molecular hydrogen by breaking of the H—H bond and generation of two M—H bonds; (2) activation of the olefin by formation of a π-complex; and (3) transfer of hydrogen to the olefin (by insertion to form a σ-metal–alkyl group, followed by cleavage of this group by hydrogen). It is apparent that conversion of a π-complex into a σ-complex represents a key step in the overall process.

Use in hydrolysis reactions

Another useful synthesis depends in part for its success on the fact that coordinated olefins become susceptible to a hydrolysis reaction that leads to oxidation. In this way ethylene is converted to acetaldehyde; propylene, to acetone; and ethylene and acetic acid to vinyl acetate (which serves as a monomer for polymerization). In one variation of this basic reaction, ethylene and oxygen are passed together through an aqueous solution of palladium and cupric salts. The overall reaction ($C_2H_4 + {}^1/_2O_2 \rightarrow CH_3CHO$) results from a combination of three steps:

$$(1)\quad C_2H_4 + PdCl_2 + H_2O \longrightarrow CH_3CHO + Pd + 2HCl$$

$$(2)\quad Pd + 2CuCl_2 \longrightarrow PdCl_2 + 2CuCl$$

$$(3)\quad 2CuCl + 2HCl + \tfrac{1}{2}O_2 \longrightarrow 2CuCl_2 + H_2O.$$

Reaction (1), the reaction that forms the product, is itself composed of several steps, including formation of the

π-complex anion $[(\pi\text{-}C_2H_4)PdCl_3]^-$ (related to the anion of Zeise's salt) and its rearrangement after hydrolysis to a σ-complex $[CH_2OHCH_2PdCl_3]^{2-}$.

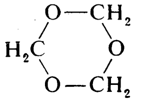
Other industrial reactions catalyzed by transition-metal complexes include the isomerization, dimerization, and polymerization of olefins, the trimerization of acetylenes, the tetramerization of acetylene (to cyclooctatetraene), and the dismutation (conversion to products with both larger and smaller carbon skeletons) of olefins (*e.g.,* the conversion of propene into ethylene and 2-butene). In each of these reactions the making and breaking of carbon–metal bonds are essential steps. (M.I.B./F.G.A.S.)

POLYMERS

Polymers are essential to the existence of man and his civilization. The human body, all animal and plant tissues, and most structural substances of organic nature—such as proteins, wood, resin, and chitin, the hard coating of insects—consist of polymeric (macromolecular) materials. Many minerals, such as diamond, quartz, and feldspar, are inorganic polymers, and numerous products of ancient and modern industry, such as concrete, porcelain, glass, textiles, paper, rubbers, and plastics, are either entirely or substantially polymeric. Only in the first half of the 20th century, however, was it clearly recognized that these substances all possess one essential common feature, namely, that they consist of very large (macro) molecules.

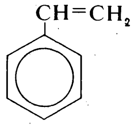
Definition

A polymer (Greek *polys,* "many"; *meros,* "part" or "unit") is a substance the molecules of which are multiples of low-molecular-weight units, molecular weight being, as the name suggests, a measure of the weight of a molecule relative to a chosen standard (for practical purposes, the weight of an atom of hydrogen). The low-molecular-weight unit making up the polymer is referred to as the monomer. As long as a polymer is strictly uniform in molecular weight and molecular structure, its degree of polymerization is indicated by the Greek word for the number of monomers it contains; thus, for example, dimers, trimers, tetramers, and pentamers indicate twofold, threefold, fourfold, and fivefold polymers. The term polymer, however, is used to designate a combination of an unspecified number of monomer units. Trioxymethylene, for example, is a (cyclic) trimer of formaldehyde (CH_2O):

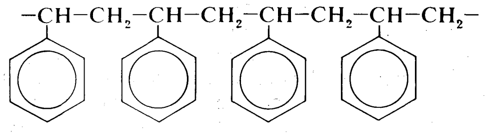


trioxymethylene

and polystyrene is the polymer prepared from the monomer styrene:



styrene



polystyrene

If the number of monomer units in a polymer becomes very large, the latter is sometimes called a high polymer. According to present-day usage, a polymer or high polymer need not consist of individual molecules all having exactly the same molecular weight or precisely the same chemical composition and molecular structure.

In the case of some natural polymers, such as the proteins, the individual molecules all have the same molecular weight and molecular structure. This identity of the polymer molecules results from highly specific cellular processes that produce them according to fixed patterns. With most synthetic and natural polymers, however, significant differences occur in the molecular weight of the individual macromolecules, with the result that the material itself is a mixture of homologous polymeric constituents—that is, of individual molecules differing in the number of monomer units they contain. Methods are not available for preparing synthetic polymers of fixed molecular weight, nor can the prepared mixture be separated completely into fractions with uniform molecular weights. Variability in the composition and molecular structures of polymers results from the presence of different end groups that terminate the chains, occasional branches in the chain, variations in the arrangement of the monomeric units, and irregularity in the sequence of monomeric units of different types if more than one type is present.

A completely rigorous system of classifying and naming polymers, conforming to the practice in naming ordinary organic and inorganic molecules, is impossible because of the common variations in structure between individual molecules of most polymer types—variations that cannot be eliminated, or even determined quantitatively in nature or amount by available methods. Nevertheless, it is convenient to treat a particular type of polymer as a single molecular species for purposes of discussion because these variations in structure do not significantly affect the physical and chemical properties of the substance and do not affect its practical application.

NATURAL POLYMERS

All living beings—animals and plants alike—are composed to a very large extent of organic polymers, which not only provide structural materials for the maintenance of life functions but also participate in carrying out the life functions themselves. The solid portions of all plants consist of several polymers, the most important of which are cellulose, lignin, and various resins.

Cellulose and lignin

Cellulose in wood is intimately connected with lignin; but in other parts of plants, it is found in relatively pure form as fibres such as cotton and flax. Cellulose itself is a polysaccharide, that is to say, a polymer whose monomer units are individual sugar molecules. In cellulose the sugar glucose comprises the monomer units, and they are joined to give molecular weights of up to several millions. In most fibres the polymer chains are combined to give laterally ordered crystalline units that, in turn, are separated by disordered or amorphous areas. This two-phase structure gives cellulose fibres their strength and, at the same time, their softness and pliability.

In all types of wood cellulose is accompanied by lignin, a second polymer, which shows much less regularity than cellulose. Lignin molecules consist of a complicated three-dimensional network of phenolic residues joined chemically by means of short hydrocarbon chains. Because of this molecular complexity, the molecular weight of lignin is not exactly known, but in any event it is very high. Wood also contains several types of resins, which are polymers of the simple hydrocarbon isoprene and have molecular weights ranging from a few thousand to several hundred thousand.

The most important terpene, as the isoprene polymers are called, is rubber, present in the sap of many tropical trees, especially of the genus *Hevea.* Rubber is a polyhydrocarbon and consists, in the native state, of long chains of isoprene, which have molecular weights around 500,000. Balata, another natural, rubberlike resin, also is a polyisoprene; it differs from hevea rubber chiefly in the geometry of double bonds, or linkages, between carbon atoms in the molecular chains.

Life on Earth is based largely on the existence, properties, and reactions of two classes of polymers—the proteins and the nucleic acids. The monomeric units of proteins

Proteins and nucleic acids

are amino acids, relatively small molecules containing amino ($-NH_2$) and carboxylic acid ($-COOH$) groups. The twenty amino acids that occur normally in proteins are always arranged in precise, but different, orders in different protein molecules. Certain proteins have molecular weights around 50,000; in others the molecular weight reaches several millions. All fibres and membranes of animal tissues consist of high-molecular-weight proteins; the processes of life—such as metabolism, vision, and respiration—are based on the protein materials known as enzymes, which act as catalysts for biochemical reactions. Generally, the exterior parts of the animal body—fur, hair, nails, horn, and skin—consist of proteins with molecular structures of three-dimensional networks of very high molecular weight (*e.g.,* keratin).

Other important natural polymers are the starches, which—like cellulose—are polymers of glucose. Starches are widely distributed in plants and play an important role as a food for animals of all kind. Starches differ from cellulose chiefly in the way the individual monomeric units are joined in the molecules; some varieties—amylose, for example—are simple chains with molecular weights around 100,000; others—called amylopectins—are three-dimensional networks (like lignin) with very high molecular weights. All hard, tough, and strong parts of insects and crustacea—shells, wings, and claws, for example—consist of a nitrogen-containing polysaccharide called chitin. Chitin is composed of long chains of glucose molecules that have been modified by acetylated amino groups; the molecular weights of typical chitin polymer chains are around 100,000.

Diamond, graphite, and silica

Many inorganic polymers also are found in nature; these are characterized by their hardness, high melting range, and great mechanical strength. Some inorganic polymers are formed by atoms of the element alone; in others the monomeric units are inorganic compounds. Diamonds are a good example of the first class; this substance consists of a three-dimensional network of carbon atoms that are combined with each other exclusively by single bonds. In fact, diamond is the simplest crystalline, three-dimensional polymer that exists. Another polymeric form of the element carbon is graphite, the writing material in a lead pencil. Graphite consists of two-dimensional polymeric layers of carbon atoms joined together alternately by single and double bonds. Between these layers of densely packed carbon atoms are relatively large distances, a factor that causes the typical lamellar (layer-like) character of all graphitic materials. Elemental sulfur and selenium exist generally in crystalline modifications but also in a polymeric form consisting of long chains with molecular weights around 100,000.

The most important inorganic polymer is silica, or silicon dioxide, which exists in several crystalline modifications and in a glossy amorphous form; they are all three-dimensional networks—partly regular, partly random—held together by chemical bonds between silicon and oxygen. The strength of the silicon–oxygen bonds is responsible for the high softening range and the extreme hardness of these compounds.

The three-dimensional silica networks are capable of accepting electrons; in the process they are converted into polymeric ions that can be neutralized and stabilized by positively charged metal ions, such as those of sodium, potassium, magnesium, calcium, and aluminum. The result is a large and important family of silicates that, together with other metals, form most of the hard and high-melting natural rocks—including granite, feldspar, and agate.

SYNTHETIC POLYMERS

Organic. In the course of their studies, organic chemists of the 19th century frequently encountered materials that were neither ordinary liquids nor crystalline solids but of an amorphous semisolid or glassy character. These materials generally defied the classical methods of purification, isolation, and identification. As a consequence, most of these substances were only referred to in passing in scientific writings but were not further investigated. In a few instances, however, the yield of such a material was so considerable and its properties were so attractive for practical use that its preparation was more thoroughly studied, and a larger scale development of the product was carried out. Of these developments, probably the most important stemmed from the discovery in 1909 by Leo Baekeland, a Belgian-born U.S. chemist, of a viscous product from the reaction of phenol with formaldehyde. Baekeland discovered that many species of useful plastics could be prepared by varying the proportions of the components and the conditions of the reaction. This discovery led to the development of the Bakelite resins, which occupy an important position in the plastics industry. In the 1920s, when the structure and character of the most important natural polymers—cellulose, proteins, and rubber—were elucidated, a new, broadly based series of systematic studies of polymer formation was undertaken. These studies led to the production of a large number of synthetic polymers, which in turn permitted an amazing variety of industrial applications of polymers as fibres, plastics, synthetic rubbers, coatings, and adhesives.

This rapid development in the chemistry of synthetic polymers was aided by the fact that most building units for the preparation of synthetic polymers are products of the petroleum-refining industry, which also was undergoing rapid development at the same time.

It is convenient to classify the synthetic organic polymers according to the chemical character of their monomers, beginning with the simplest variety, the hydrocarbons.

Polyhydrocarbons. Many simple and inexpensive unsaturated hydrocarbons, such as ethylene, propylene, butadiene, and styrene, can be readily transformed into polymeric materials by simple addition polymerization, the repeated addition of one monomer unit after another to the growing polymer chain. In this way important thermoplastic and elastomeric (polymers with elastic properties) products are obtained.

Polyethylenes and polypropylenes

There are two ways to prepare polyethylene on an industrial scale: (1) polymerization with oxygen as catalyst at high pressure (1,000–2,000 atmospheres) and high temperatures (190°–210° C [374°–410° F]) and (2) polymerization with organometallic catalysts at ordinary pressure and ordinary temperatures. The high-pressure polyethylenes have specific gravities between 0.92 and 0.93 (water = 1.000), melting points around 110° C (230° F), and molecular weights from 20,000 to 40,000. They represent relatively soft, but tough, thermoplastic materials with excellent electrical and mechanical properties and with outstanding resistance against most acids, bases, and solvents. Such high-pressure polyethylenes are widely used for the production of synthetic fibres and for the preparation of bottles and small containers. The low-pressure polyethylenes have specific gravities between 0.95 and 0.97, melting points around 134° C (273° F), and molecular weights up to many hundred thousands. They represent hard, tough, strong thermoplastic materials with excellent electrical, mechanical, and chemical properties. They are widely used for the production of larger bottles, containers, pails, and trash cans.

There are two varieties of polypropylene: a soft, rubbery type of minor importance and a hard, crystalline, high-melting type, which is a valuable thermoplastic material of wide applications in certain areas of the textile industry and also used to make molded objects. The second type of polypropylene has crystalline character, melts at around 178° C (352° F), and has a density of about 0.90, and a molecular weight ranging from 50,000 to 200,000.

Polybutadines and polystyrenes

Most polybutadienes are typical elastomers; they have many valuable properties. Butadiene can be polymerized in solution, suspension, or emulsion with different types of catalysts. Some of the products are crystalline, others are amorphous. All of them remain soft and resilient down to low temperatures and can be cured into elastomers of great strength and excellent abrasion resistance. The molecular weights range from 80,000 to 200,000. Most polybutadienes are soluble in aromatic solvents, such as benzene.

Styrene polymerizes readily in pure form or in solution, suspension, or emulsion—usually under the influence of peroxide catalysts. The polymer is a colourless, transparent, thermoplastic resin (polymer product used to make objects of plastic with the application of heat), which has a specific gravity around 1.08 and a molecular weight range from 50,000 to 200,000. Commercially produced polystyrene is amorphous, has useful electrical and mechanical properties, and softens around 90° C (194° F). It is highly resistant to moisture, acids, and bases but is easily attacked by organic solvents. Polystyrene and closely related polymers are the most popular resins for certain molding and extrusion procedures in the forming of plastic objects.

Particularly important are copolymers (polymers composed of several monomer units) of butadiene and styrene, which are made in emulsion with the aid of peroxide catalysts. During the 1940s and 1950s these amorphous elastomeric materials were the most important synthetic rubbers and, subsequent to that time, continued to be valuable and useful products. They can be compounded and used like natural rubber, and they exhibit excellent resistance to abrasion and deterioration caused by oxygen, heat, and light.

Polyvinyls and polyacrylics. Many derivatives of ethylene still retain the double bond and are able to polymerize. Among the materials produced in this way are several important families of polymers, the polyvinyls and polyacrylics.

Polyvinyl
hlorides
nd
olyvinyl
sters

The replacement of one hydrogen atom in ethylene by chlorine leads to vinyl chloride, which polymerizes readily under the influence of peroxide catalysts in suspension or emulsion. The product, polyvinyl chloride, is a colourless, hard, tough thermoplastic material, which softens only at a high temperature. Its specific gravity is around 1.55; it is substantially amorphous and resistant to most destructive chemical agents, including hot organic solvents. The molecular weight ranges from 50,000 to 150,000. It is a very useful material prepared as sheets and as extruded or molded products.

Vinyl acetate and vinyl butyrate are liquid esters of vinyl alcohol (the hydroxide equivalent of vinyl chloride). They polymerize with peroxide catalysts in solution, suspension, and emulsion to give amorphous, soft resins with molecular weights between 30,000 and 100,000. The products find many uses as coatings and adhesives. Both vinyl acetate and vinyl butyrate copolymerize readily with vinyl chloride to give a large family of thermoplastic materials. In these substances the vinyl chloride contributes hardness and high-melting characteristics, whereas the vinyl esters act as internal (*i.e.,* chemically bonded) plasticizers, additives that impart favourable qualities to plastics. These copolymers exhibit a wide range of properties; hence they find many applications, such as for coatings, cohesives, films, and extruded or molded articles of many kinds.

oly-
crylics

The basic units for the large and important family of polymeric materials known as polyacrylics are acrylic acid (propenoic acid) and methacrylic acid (a methylacrylic acid with the methyl and carboxyl groups joined to the same carbon atom). The methyl esters of these acids are readily polymerized with the aid of peroxide catalysts in the pure material or in solution, suspension, or emulsion. Polymethyl methacrylate is a hard, colourless, brilliantly transparent thermoplastic material that is widely used to manufacture extruded and molded articles. Equally important is the polymer of acrylonitrile (vinyl cyanide) that is usually made in suspension or emulsion with the aid of peroxide catalysts. The product has a molecular weight in the range 70,000 to 120,000; it represents a white, hard, moderately crystalline, material, which softens at a high temperature and is soluble only in a few selected high-boiling organic liquids, such as *N,N*-dimethylformamide and dimethyl sulfoxide. Copolymers of acrylonitrile (80–90 percent) and methyl acrylate or vinyl acetate occupy an important place in the man-made fibre industry. Copolymers of acrylonitrile (10–15 percent) and styrene represent thermoplastics for extrusion and molding. The products possess superior hardness, higher softening ranges, and better impact resistance than the polymers prepared from either monomer alone. Finally, copolymers of acrylonitrile (20–30 percent) and butadiene, prepared in emulsion, represent a valuable species of synthetic elastomer. These so-called nitrile rubbers have excellent resistance to hot oils, oxygen, ozone, light, and heat; therefore, they find important applications in the construction of airplanes, automobiles, and electrical equipment.

Polyacetals and polyethers. In addition to the polymers whose backbone chains consist of a continuous sequence of carbon–carbon bonds, there are many important polymers with oxygen or nitrogen atoms in the backbone chain along with carbon atoms. Among those with oxygen atoms in the backbone are the polyacetals and polyethers. One of the simplest polyacetals is polyformaldehyde, a hard, high-melting, crystalline material with excellent resistance against abrasion and against the action of solvents. It is prepared by polymerization of formaldehyde—a very simple and inexpensive monomer—in the gaseous state with anionic catalysts. It is used for making machine parts in place of, or in conjunction with, certain metals. Polyoxyethylene, a polyether, is prepared in bulk or in solution from ethylene oxide with cationic catalysts. The product is a white, crystalline, water-soluble material with a melting point of about 75° C (167° F); it is a particularly useful thickener of aqueous solutions and a material used for coatings for textiles and paper.

Polyesters. When a bifunctional carboxylic acid, such as adipic acid, $HO_2C(CH_2)_4CO_2H$, reacts with a bifunctional alcohol, such as ethylene glycol, $HO(CH_2)_2OH$, under conditions that lead to the elimination of water, a linear macromolecule is formed that is characterized by a repetition of ester groups ($-COO-$) along the chain and is called, therefore, a polyester. Each combination of a specific dicarboxylic acid and a specific glycol leads to a particular polyester.

Nomen-
clature
of linear
polymers

In a convenient naming system for linear polyesters, the number of carbon atoms in the glycol and in the dicarboxylic acid are used after the word polyester. For example, hexamethylene glycol, $HO(CH_2)_6OH$, with six carbon atoms, and adipic acid, $HOOC(CH_2)_4COOH$, also with six carbon atoms, give a polyhexamethylene glycol adipate commonly referred to as polyester-6,6. Similarly, polydecamethylene succinate is polyester-10,4. Polyesters can also be formed by the self-condensation of hydroxycarboxylic acids, such as hydroxyundecanoic acid, $HO(CH_2)_{10}COOH$. The resulting polymers need only one figure to characterize them; in this case, the product polymer is called polyester-11.

All linear polyesters made with bifunctional open-chain glycols and dicarboxylic acids are colourless, crystalline, thermoplastic materials. Their melting points and solubilities vary over a wide range and depend on the length of the methylenic ($-CH_2-$) segments between the ester bonds in the chain. Because of the polarity (separation of electrical charge) of these bonds, they are mainly responsible for the intermolecular attraction between the chains, and hence for their softening and solubility behaviour. The closer the ester bonds, the higher is the melting point of the polyester and the less is its solubility. Polyethylene glycol oxalate, polyester-2,2, melts around 200° C (392° F), whereas polyester-6,6 melts around 80° C (176° F). The former is soluble in only a few selected organic liquids; the latter dissolves readily in most ordinary organic solvents, such as benzene, ethyl methyl ketone, and butyl acetate.

Low-molecular-weight polyesters (molecular weight up to 5,000) are excellent plasticizers for many natural and synthetic resins; the high-molecular-weight species (above 10,000–15,000) are valuable thermoplastics themselves and are used for the manufacture of films and molded objects. Polyesters with high melting points (250° C [482° F] and above) are obtained from aromatic (cyclic) constituents. Examples are the polymer made from ethylene glycol and terephthalic acid (benzene-1,4-dicarboxylic acid)—the so-called polyester-2T—and the material made by the self-esterification of 4-hydroxybenzoic acid—the HOB-polyester—both of which melt above 250° C and do not dissolve in most organic solvents. Because of their high melting points and insolubility, they represent valuable materials for the formation of films used in electrical insulation, photography, and packaging, and also for fibres used in fabrics and tire cord. When the polyesterification is carried out in the presence of a polyfunctional component—such as pentaerythritol, a tetrahydroxy compound, or a tricarboxylic acid—the product is not a linear macromolecule but a highly branched species that, after sufficient removal of water, is converted into a three-dimensional network. Unlike the thermoplastic linear polyesters, systems of this kind are thermosetting—that is, the original material softens on heating, but once set in a new shape it is extremely resistant to further heating. The thermoset polyesters are insoluble, hard, and tough materials of extremely high molecular weight. They are widely used as coatings, laminating agents, and in making molded objects. They are usually applied as thermosetting compositions that are cured into the thermoset state.

Nylons

Polyamides. When a bifunctional amine (two $-NH_2$ groups) reacts with a bifunctional acid (two $-CO_2H$ groups) with elimination of water, a linear macromolecule is formed that contains in the chain a regular repetition of amide groups ($-CO-NH-$) and is therefore called a polyamide. More commonly, these materials are known as nylons. The same nomenclature is used for polyester as for polyamides. Thus, the nylon made of hexamethylenediamine, $H_2N(CH_2)_6NH_2$, and adipic acid, $HOOC(CH_2)_4COOH$, is nylon-6,6; the polymer made from the same diamine and sebacic acid, $HOOC(CH_2)_8COOH$, is nylon-6,10; and the material made by the self-polymerization of aminocaproic acid, $H_2N(CH_2)_5COOH$, is nylon-6. All polyamides consisting of linear, bifunctional components are hard, tough, colourless, crystalline, thermoplastic materials. Their softening and solubility behaviour is controlled by the magnitude of the intermolecular forces between the individual chains; the major contribution to these forces comes from the amide bonds ($-CO-NH-$), which are polar themselves and also capable of establishing hydrogen bridges ($\gt C{=}O \cdots H{-}N\lt$) between adjacent macromolecular chains. The closer the amide groups are in the chain, the stronger is the cohesion between chains, and the stronger the cohesion, the higher the melting point, and the greater the insolubility. For example, the polyamide of ethylenediamine and oxalic acid, nylon-2,2, melts above 300° C, or 572° F (with decomposition), whereas nylon-6,6 melts around 260° C (500° F) and nylon-6,10 at 215° C (419° F). An interesting contrast exists between the polyester series and the polyamide series: corresponding members—such as the polyester-6,6 and the polyamide-6,6—differ substantially in softening temperature and solubility, the nylons having much higher melting points and much lower solubilities than the esters. This difference is usually attributed to the fact that the polyamides can develop hydrogen bridges whereas the polyesters cannot.

Although nylons find many important applications in the field of extrusion and molding, their outstanding use is in the man-made fibre industry. Nylons dominate all other synthetic fibres in quantity and quality and find successful use in fabrics, tire cords, and many industrial fibres.

Polyurethanes. Another important family of synthetic organic polymers is obtained by the reaction of bifunctional isocyanates (containing two $-NCO$ groups) with bifunctional alcohols (two $-OH$ groups). Again, one obtains linear macromolecules that, in this case, are characterized by the regular repetition of the urethane groups ($-O-CO-NH-$). The presence of the urethane groups permits the buildup of a three-dimensional network because of the reaction of the hydrogen of the $-NH-$ group with the terminal isocyanate group of a chain. These networks are either elastomeric or rigid; they are used with great success in the field of elastomeric fibres (spandex) and in making both soft and rigid foams.

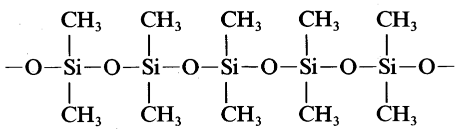
Synthetic polysilicates

Inorganic. Although the synthetic organic polymers are a very large family of useful materials, are the product of a very large industry, and although annual world production is measured in millions of tons, synthetic inorganic polymers have not found any large-scale industrial applications. Synthetic polysilicates (in the form of colloidal particles) are used as fillers and reinforcing agents for plastics used as dentures as well as in synthetic rubbers. Certain polyphosphates with medium molecular weight find some use as flameproofing agents.

The only linear inorganic polymer of known structure and molecular weight is made by the interaction of phosphorus pentachloride (PCl_5) and ammonia (NH_3), with the elimination of hydrogen chloride (HCl). The product is known as polyphosphonitrile chloride; the molecular chains, which have a molecular weight of about 100,000, are composed of repeating $PNCl_2$ units. The substance is a yellow, amorphous, soft, rubbery material that dissolves in many organic solvents and, if stretched to a few times its original length, shows a distinct fibre X-ray diagram, an indication of a regular pattern in the structure of the fibres. Because the material is easily hydrolyzed (broken apart with water), it has found little use as a structural elastomer, but it does have potential use as a polymeric flameproofing agent.

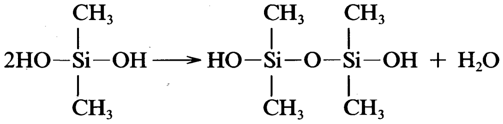
Silicones

Mixed organic–inorganic. Considerable progress was made during the 1950s and 1960s in the synthesis, characterization, and use of linear polymers containing substantial amounts of inorganic elements in the backbone of the chain, together with organic groups attached to the backbone. The most important representatives of this relatively young family of polymers are the polysiloxanes—or silicones, as they are generally called—which have a backbone chain of alternating silicon and oxygen atoms. Also attached to each of the silicon atoms are two monovalent organic groups, such as the methyl ($-CH_3$), or phenyl ($-C_6H_5$) groups. The structure of polydimethyl siloxane is as follows:



$$-\mathrm{O}-\underset{\mathrm{CH_3}}{\overset{\mathrm{CH_3}}{\mathrm{Si}}}-\mathrm{O}-\underset{\mathrm{CH_3}}{\overset{\mathrm{CH_3}}{\mathrm{Si}}}-\mathrm{O}-\underset{\mathrm{CH_3}}{\overset{\mathrm{CH_3}}{\mathrm{Si}}}-\mathrm{O}-\underset{\mathrm{CH_3}}{\overset{\mathrm{CH_3}}{\mathrm{Si}}}-\mathrm{O}-\underset{\mathrm{CH_3}}{\overset{\mathrm{CH_3}}{\mathrm{Si}}}-\mathrm{O}-$$

Polymers of this type are prepared from monomeric dialkylsilanediols by removal of water between molecules. Preparation of the dimer of dimethylsilanediol demonstrates how the process occurs.



$$2\mathrm{HO}-\underset{\mathrm{CH_3}}{\overset{\mathrm{CH_3}}{\mathrm{Si}}}-\mathrm{OH} \longrightarrow \mathrm{HO}-\underset{\mathrm{CH_3}}{\overset{\mathrm{CH_3}}{\mathrm{Si}}}-\mathrm{O}-\underset{\mathrm{CH_3}}{\overset{\mathrm{CH_3}}{\mathrm{Si}}}-\mathrm{OH} + \mathrm{H_2O}$$

Polysiloxanes of low molecular weight, which sometimes have a closed-ring instead of an open-chain structure, are oils and greases. Higher-molecular-weight types are versatile elastomeric materials; they remain soft and rubbery even at temperatures as low as −80° C (−112° F) and, at the same time, are more stable at high temperatures (300° C [570° F] and above) than most conventional plastics and rubbers. Similar polymer chains, in which oxygen atoms alternate with boron, phosphorus, or aluminum atoms, also have been studied, but generally their molecular weights are too low (not higher than 2,000) to provide useful mechanical strength.

STRUCTURE OF POLYMERS

The fundamental consideration in the chemical study of polymers, as of any molecular substance, is the composition of the material in terms of its content of the various kinds of atoms and its structure or arrangement of the atoms in the molecules. Determining the composition is substantially a matter of elemental analysis and does not differ from the procedures used in the study of ordinary inorganic and organic compounds. Furthermore, the composition of the polymer follows simply from the compositions of the monomer, or monomers, used to build it up—with due consideration for such additives as catalysts, activators, modifiers, and stabilizers, some of which may become incorporated in the polymer molecules.

Molecular structure

It is much more complicated, however, to define and, consequently, to establish what is generally called the structure of a polymeric or macromolecular system. The term structure refers, first, to all of the information that can be collected concerning a representative, isolated macromolecule of the material, and second, to the manner in which the individual polymer molecules are geometrically arranged and physically bonded to one another in a macroscopic sample of the material. The former aspect of the structure may be called the molecular, or intramolecular, structure; whereas the latter is the supermolecular, or intermolecular, structure—also referred to as the texture, or morphology.

Molecular weights. In considering the molecular structure, it must always be borne in mind that, with the exception of proteins and certain nucleic acids, all natural and synthetic polymers are heteromolecular, or polymolecular, in character—*i.e.,* they do not consist of a single species of large molecules, but rather of a mixture of many species, which have different molecular weights but substantially the same chemical composition. The best characterization of a given polymer is, therefore, its molecular-weight distribution, which is a representation of the percentages of each molecular weight species in the sample. Determining such a distribution requires a delicate and, sometimes, difficult study of the system; this can always be achieved in a satisfactory manner, however, as long as it is possible to prepare a dilute solution (0.1–2.0 percent) of the polymer in an appropriate solvent and to reprecipitate the polymer from the solution without chemical changes. The procedures for establishing molecular weight distributions can be divided into analytical and preparative methods, depending upon whether one obtains information only about the distribution or whether one actually obtains the individual fractions with different molecular weights.

Methods of analysis

The oldest of the analytical methods is ultracentrifugation, a high-speed centrifugation process that separates molecules in solution according to their molecular weights. Analysis of the distribution of the polymer molecules after centrifugation makes it possible to arrive at a complete description of the spread of molecular weights in the original polymer material. Refinements of this method have increased its applicability to complicated polymeric systems and may make it possible to accomplish a physical separation of the different molecular species in this way.

Gel-permeation chromatography—*i.e.,* separation of molecular mixtures by filtration of a solution through a jellylike material—is a more recently discovered practical way to arrive at the molecular-weight distribution of soluble polymers and may, with further improvements, make it possible to obtain the individual fractions.

Extraction and precipitation are the standard preparation methods, which actually furnish more or less uniform fractions of a polymer, each of which is composed of a narrower molecular-weight distribution than is the original material. With the aid of repeated, careful extraction or precipitation steps or both, it is possible to obtain relatively large amounts of materials that are substantially more uniform than the raw polymer.

The systematic application of these methods has shown that all natural and synthetic polymers, such as cellulose, rubber, polyethylene, nylon, and polyvinyl chloride, have rather broad distribution functions; *i.e.,* they represent mixtures of molecules that differ considerably in their molecular weight. In nylon, for example, the 10 percent of the molecules with largest molecular weight have on the average about 10 times the molecular weight of the 10 percent of lowest molecular weight. For many purposes, it is satisfactory to approximate the molecular-weight distribution by a numerical average: doing this means that a mathematical function is replaced by a single number.

Number and weight averages

In statistical approaches to any subject it is customary to use different averages, which are characterized by the type of quantity averaged. If a polymer is divided into a number of fractions on the basis of molecular weight, two kinds of average molecular weight can be obtained: number-average and weight-average molecular weights. The number-average molecular weight is obtained by adding together the molecular weights of each fraction (*i.e.,* the number of molecules in each fraction times the molecular weight of that fraction) and dividing the total by the number of all molecules in the system. The number-average molecular weight can be measured experimentally by end-group analysis (detection of the ends of the polymer chains) or by measurements of the vapour pressure or osmotic pressure of solutions of the polymer, both effects depending on the numbers of molecules in the solution.

On the other hand, the weight-average molecular weight is obtained by adding together the actual weights of all molecular weight fractions (*i.e.,* the weight of each fraction times its molecular weight) and dividing this sum by the total weight of all molecules in the system. The weight-average molecular weight can be experimentally determined by light scattering, ultracentrifugation, or viscosity measurements of very dilute solutions, all of which are influenced by the weight of material present in the sample.

Separate determinations of the number- and weight-average molecular weights give an idea of the relative uniformity, or nonuniformity, of a given polymer sample. In an ideal case, in which all molecules have a single molecular weight, the number and weight averages are the same. When the polymer sample contains many molecular classes, however, each with a different molecular weight, the two averages are likely to be quite different. When experimental studies show that the number- and weight-average molecular weights are very similar, the polymer itself is relatively uniform—that is, its molecules all have about the same molecular weights. On the other hand, when the two averages are found to be quite different, then the polymer sample has a broad distribution function and the material is polymolecular and nonuniform.

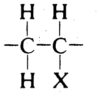
Arrangement of monomer units. The second step in the description of the molecular structure of a polymeric material is the determination of the overall shape of the polymer molecules, or the arrangement of the individual units in the polymer. Clearly, the polymers with the simplest structures are the linear polymers. In such macromolecules the individual structural units, or monomers, are joined to one another in linear sequence. Each terminal unit is connected to only one other unit; each chain is connected to two others. At no point in the chain is any unit connected with three or more other units. Linear macromolecules invariably have only two end groups. Systems composed solely of polymers of this kind show reversible melting and solubility behaviour.

Linear and nonlinear systems

Nonlinear polymeric systems, such as branched macromolecules in which certain of the monomer units are connected with three or four neighbours, are also known. If the number of monomers joined to multiple neighbours is small, the shape of the molecule is essentially that of a linear backbone carrying a number of relatively short branches. In a system of this kind, the individual branched molecules can still be separated from one another without breaking chemical bonds and, as a consequence, materials consisting of branched macromolecules in most cases melt and dissolve reversibly. If, however, the number of multifunctional units in the individual chains becomes relatively large, each develops into a branch and the branches of different backbone chains join together to create a three-dimensional network in which backbone chains are no longer distinguishable from branches and in which all existing units are joined to a number of others by chemical bonds. Systems of this type are called polymeric networks, or cross-linked polymers. Materials in which this type of molecular bonding is preponderant are nonmelting and insoluble, although they may soften and swell to a certain extent when heated or exposed to certain solvents.

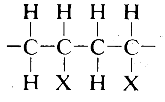
The third step in the description of the molecular structure of a polymeric material is the elucidation of the chain structure or the method of joining of the individual units, or monomers, within the chain.

Depending on the chemical character of the repeating unit, many different types of chain formation are possible even in the case of a linear chain.



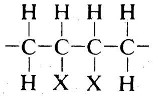
$-\overset{\text{H}}{\underset{\text{H}}{\text{C}}}-\overset{\text{H}}{\underset{\text{X}}{\text{C}}}-$

(1)



$-\overset{\text{H}}{\underset{\text{H}}{\text{C}}}-\overset{\text{H}}{\underset{\text{X}}{\text{C}}}-\overset{\text{H}}{\underset{\text{H}}{\text{C}}}-\overset{\text{H}}{\underset{\text{X}}{\text{C}}}-$

(2)



$-\overset{\text{H}}{\underset{\text{H}}{\text{C}}}-\overset{\text{H}}{\underset{\text{X}}{\text{C}}}-\overset{\text{H}}{\underset{\text{X}}{\text{C}}}-\overset{\text{H}}{\underset{\text{H}}{\text{C}}}-$

(3)

A repeating unit of structure (1) (in which X is any constituent) may, for instance, be joined in two ways to give the structures (2) or (3). Structure (2) represents a "head-to-tail" juncture of the two units, whereas (3) is a "head-to-head" union. Most of the better known vinyltype polymers have molecular chains composed substantially of units joined in head-to-tail fashion. It also is possible, however, for polymer chains to be composed exclusively or in part of units joined head-to-head.

Spatial arrangement in single carbon chains

In a single chain of carbon atoms joined by single bonds, each carbon atom that carries a substituent X is asymmetric—that is, it can exist in either of two forms, or configurations, termed *d* and *l,* which are mirror images of one another (like right and left hand gloves). The various forms of polymer chains that exist depend on the relative configurations of the asymmetric carbons in the chains. If all carbons in a head-to-tail chain, as in structure (2), have the same configuration, the polymer is called isotactic; if the configuration alternates regularly along the chain from *d* to *l,* the molecule is called syndiotactic; and finally, if there is random alternation between the two possible configurations, it is called atactic. (For a discussion of tacticity see below *Classification and nomenclature.*)

Although the structural unit (1) is derived from a particularly simple type of monomer, $H_2C{=}CHX$, it leads to the various possible structures just described. Even more possibilities arise from such monomers as $H_2C{=}CX-CH{=}CH_2$ or $XHC{=}CHY$. Polymer stereochemistry, the discipline that deals with these subjects, is of considerable practical importance, because polymers of different chain structures have distinctly different properties, even when they are derived from the same monomer.

Polymer morphology. Experience also has shown that the ultimate, practical properties of all polymeric materials depend not only on their molecular design—size, shape, and chain structure—but also to a considerable extent on the supermolecular character of the system. This quality, also known as texture, or morphology, of the polymer, is influenced chiefly by the fact that all macromolecules can assume a large number of conformations or spatial shapes, which result from free rotation about single bonds in the chains. These conformations include various helical (spiral) forms, as well as random tangles or coils.

To analyze the supermolecular structure of polymeric systems, it is necessary to focus attention not on any individual macromolecule but on a unit of volume within the investigated object—fibre, film, or molded structure—which contains many macromolecules. In general, a cube with 200-angstrom edges contains many hundreds of polymer molecules and, as a consequence, many thousands of molecular segments. Experience shows that these segments can have several characteristic mutual relationships inside a volume element: (1) they can be randomly distributed in regard to their spatial orientation regardless of whether they belong to the same molecular chain or to different chains; (2) they can possess a degree of lateral (side-by-side) order through the folding of the individual chains; and (3) they can possess lateral order through the parallel arrangement of extended chains.

If all volume elements in the material belong to group (1), the material is an amorphous solid, or glass, which is homogeneous and isotropic (structurally uniform in all directions). It also is noncrystalline and unoriented. Systems of this type usually are obtained when a polymer melt is solidified rapidly by quenching (cooling by sudden immersion).

Orientation and crystallinity

If all volume elements in a sample belong to group (2), the polymer is composed of single crystals, which can be either randomly distributed in space or in a preferred arrangement with respect to a fixed axis or plane. In the first case, the system is unoriented; in the second case, it has a definite orientation. Systems of this type are obtained when a polymer is precipitated slowly from a dilute solution or solidified slowly from a melt.

If all volume elements belong to group (3), the sample consists of extended chain crystallites—that is, crystalline areas or domains—which, again, may be unoriented or may possess particular spatial orientations. Systems of this type are obtained when concentrated solutions or melts are solidified while under the influence of mechanical forces, such as shear or stress.

In practice, any actual polymeric material—in the form of a fibre, film, sheet, or tube—represents a mixture of the three types of volume elements, and its macroscopic character is defined empirically by such expressions as "degree of orientation," "degree of crystallinity," or "later order." It is often difficult to decide whether any given sample has its segments laterally ordered in an intramolecular fashion by means of chain folding, or intermolecularly by way of extended chain crystallization. Extensive experimentation with different methods often is required to discriminate between the two. The degree of orientation is determined quantitatively by optical birefringence (splitting of light waves) or by the measurement of Young's modulus (a measure of elasticity), both properties being dependent on the relative degree of orientation of the chain. The degree of crystallinity, or lateral order, is determined qualitatively by such methods as X-ray and electron diffraction (interference effects observed with X-rays and with beams of electrons) and density, swelling volume, and isotope exchange, all properties influenced by the arrangement of the molecular chains.

Determining the degree of crystallinity

Polymeric materials produced by spinning and related processes, with subsequent mechanical drawing or rolling of the product, consist of more or less oriented mixtures (50–90 percent orientation) of both amorphous and extended-chain crystalline domains (25–85 percent crystallinity). Larger pieces, made by extrusion, injection, or compression, have a typical spherulitic (composed of small spheres) texture containing all three possible segment organizations; the overall degree of orientation is usually low (less than 20 percent), the content of laterally ordered domains is high (up to 95 percent), and chainfolding crystallization is the predominant mode.

CLASSIFICATION AND NOMENCLATURE

A homopolymer consists of macromolecules formed either by a single type of unit or by two or more chemically different types in regular sequence. Homopolymers may, and frequently do, contain irregularities in minor amounts, especially at the ends of the chains and at junctions leading to branches.

Copolymers are macromolecules containing two or more chemically different monomeric units in a more-or-less irregular sequence. Normally, the relative numbers of the different types of units are not the same in different molecules, nor even in different portions of a single molecule. A mixture of different macromolecules is called a polyblend. A block copolymer is a type of copolymer in which distinct groups of monomeric units of each type are linked together by chemical bonds and then interspersed along the chain. If, for example, the monomer units are designated A and B, a block copolymer of them might have the following structure:

$$-\mathrm{A}-\mathrm{A}-\mathrm{A}-\mathrm{A}-\mathrm{A}-\mathrm{B}-\mathrm{B}-\mathrm{B}-\mathrm{B}-\mathrm{A}-\mathrm{A}-\mathrm{A}-\mathrm{A}-$$

A graft copolymer, on the other hand, contains branches of varying length composed of monomer units of one type joined to a backbone chain made up of monomer units of a second type. Such a copolymer might be composed as follows:

$$-\mathrm{A}-\mathrm{A}-\overset{\overset{\mathrm{B-B-B-B-B-B-B-B-B-B-}}{|}}{\mathrm{A}}-\mathrm{A}-\mathrm{A}-\mathrm{A}-\mathrm{A}-\mathrm{A}-\mathrm{A}-\mathrm{A}-\mathrm{A}-\mathrm{A}-\mathrm{A}-\overset{\overset{\mathrm{B-B-B-}}{|}}{\mathrm{A}}-\mathrm{A}-$$

In their structure and in their properties, graft and block copolymers represent an intermediate form partway between normal copolymers and polyblends.

Tacticity

A tactic polymer consists of macromolecules whose monomeric units follow one another along the chain with their steric configurations (spatial orientations) ordered according to some pattern. The pattern, or tacticity, of the polymer, may consist of one or more simple rules. A eutactic polymer is a tactic polymer whose monomeric units are completely ordered, so that it is devoid of any element of structural disorder. An atactic polymer, on the other hand, is one in whose molecules the spatial configuration of the units is purely random. By way of example, a vinyl polymer prepared by conventional processes is generally atactic; it may possess a regular head-to-tail arrangement, but it is disordered with regard to the steric configurations of the tertiary carbon atoms that follow each other along chains. In isotactic polymers the asymmetric units are ordered in such a way that there is a continual, exact repetition of the unit configuration along the chain. A syndiotactic polymer consists of macromolecules whose monomeric units are asymmetric and ordered in such a way that there is a continual inversion of steric configuration from one monomeric unit to the next down the chain.

Polyelectrolytes are substances that dissociate in water (or other ionizing solvents) to give a polymeric material bearing a great many ionic, or electrically charged, groups, together with an equivalent number of counterions (ions of small charge and opposite sign). Polyelectrolytes can be polyacids (if they release hydrogen ions), polybases (if they release hydroxide ions), polysalts (if they release small cations or anions), or polyampholytes (if they release both hydrogen and hydroxide ions).

Cross-links

Under certain conditions chemical bonds may form between growing polymer chains. Such bonds, called cross-links, form whenever the monomeric units contain functional groups capable of reacting with one another, over and above those consumed in the initial polymerization reaction. The initial result of cross-linking is the formation of small domains, within which the macromolecules consist of random three-dimensional networks of chemically linked chains; such domains are called microgels. If a cross-linking reaction extends over macroscopic dimensions, and if the polymerizing system is taken up by a liquid solvent (or liquid monomer), the result is a gel, or jelly-like material. Drying converts such a gel into an insoluble and nonmelting material, composed entirely of a three-dimensional network at the molecular level. Such thermosetting resins as phenol–formaldehyde and urea–formaldehyde resins and copolymers of styrene and divinylbenzene fall into this category. Similar insoluble and infusible systems are obtained under certain conditions when a vinyl derivative is polymerized in the presence of a small amount of a divinyl compound. The materials thus obtained are called "popcorn" polymers; their exact structure has not been completely elucidated.

POLYMERIZATION PROCESSES

There are many processes by which small molecules can be bonded together to form large ones. Classification of these processes usually is based either on the chemical mechanisms by which the monomeric units are joined together or on the experimental conditions that exist during the reaction. Classifications by reaction mechanism distinguishes between polymerization by addition and polymerization by condensation.

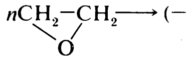
Polymerization mechanisms. *Addition.* Typical cases of addition polymerization are:

Vinyl-type polymerization

1. The addition of small molecules of one type to one another, accomplished by the opening of a multiple bond and without elimination of any part of the molecule, also called vinyl-type polymerization (in the following equations *n* is any number):

$$nH_2C{=}CHX \longrightarrow (-CHX-CH_2-)_n$$

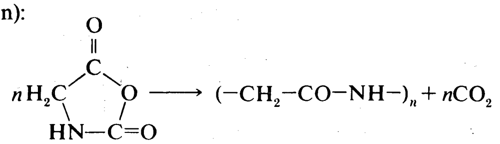
2. The addition of small molecules of one type to one another by the opening of a ring and without elimination of any part of the molecule (epoxide-type polymerization):



3. The addition of small molecules, all of one type, to one another by opening of a multiple bond with elimination of part of the molecule (aliphatic diazo-type polymerization):

$$nRCH = N_2 \longrightarrow (-CHR-)_n + nN_2$$

4. The addition of small molecules of one type to one another by opening of a ring with elimination of part of the molecule (*a*-aminocarboxyanhydride-type polymerization):



5. The addition of small molecules of one type to those of another type by opening of a multiple bond (polyurethane, polyurea, and polyamide formation):

$$nHOCH_2CH_2OH + nOCN(CH_2)_6NCO$$
$$\longrightarrow [-OCH_2CH_2OCONH(CH_2)_6NHCO-]_n$$

6. The addition to one another of biradicals of a single type formed by dehydrogenation (poly-*p*-xylylene polymerization):

$$n(\cdot H_2C-C_6H_4-CH_2\cdot) \longrightarrow (-CH_2-C_6H_4-CH_2-)_n$$

Polyester and polyamide formation

Condensation. A number of possible forms of condensation polymerization are also observed. Typical cases are as follows:

1. The formation of polyesters, polyamides (nylon), and polyethers by elimination of water, or alcohols, from single bifunctional molecules, such as ω-hydroxy- or ω-aminocarboxylic acids or from such combinations as glycols or diamines with diesters or dicarboxylic acids. The reaction of a glycol with a dicarboxylic acid, for example, proceeds as follows:

$$nHO(CH_2)_xOH + nHOOC(CH_2)_yCOOH$$
$$\longrightarrow [-O(CH_2)_xOOC(CH_2)_yCO-]_n + nH_2O$$

2. The formation of polyhydrocarbons by the elimination of halogen or hydrogen halides with the aid of metal and metal halide catalysts:

$$nClH_2C(CH_2)_xCH_2Cl \longrightarrow [-H_2C(CH_2)_xCH_2-]_n + nCl_2$$

3. The formation of polysulfides by the elimination of sodium chloride from bifunctional alkyl or aryl halides with alkali sulfides or by the oxidation of dimercaptans (a type of organic sulfur compound). The former proceeds as follows:

$$nClH_2C(CH_2)_xCH_2Cl + nNa_2S_4$$
$$\longrightarrow [-H_2C(CH_2)_xCH_2S_4-]_n + 2nNaCl$$

Experimental conditions. In actual practice the experimental conditions under which polymerization reactions occur are more commonly used to classify the reactions. Commonly, then, polymerization processes are classified according to whether they occur in the gaseous phase, in the pure liquid phase, or as dispersions, solutions, or emulsions.

Gaseous phase polymerization

1. Polymerization in the gaseous phase may occur at normal, reduced, or elevated pressures. The most important process of this type is the polymerization of ethylene, which is usually carried out at pressures of about 1,500 atmospheres in the temperature range between 190° and 210° C (374° and 410° F). Poly-*p*-xylylene is prepared at reduced pressure by cooling the pyrolyzed monomer from 900° C (1,652° F) to room temperature.

2. Polymerization of single or of several monomer types frequently takes place in the pure liquid phase (bulk polymerization). Many vinyl-type polymerizations are carried out in this manner, particularly when large, transparent pieces (such as plates, rods, lenses) of the final product are desired. Polyester and polyamide formation are carried out almost exclusively in the bulk phase, as is the polycondensation of alkylsilanediols and the formation of phenol–, urea–, and melamine–formaldehyde resins.

3. Polymerization of one or more monomers frequently is carried out by dispersion in the form of small droplets in a liquid that does not dissolve the monomer. (This process also is referred to as suspension, bead, or pearl polymerization.) Styrene, methyl methacrylate, vinyl chloride, and other monomers are polymerized in this manner to give beads of very uniform size and quality for use in certain molding techniques.

4. Polymerization of one or more monomers may take place in solution. If the polymer is soluble in its own

monomer and in the solvent selected for the reaction, the system thickens increasingly as the reaction proceeds. If the polymer is insoluble in the liquid constituents, a slurry forms as the reaction proceeds, and the polymer settles as a more or less swollen powdery mass. Vinyl chloride, acrylonitrile, vinyl acetate, and other monomers usually are polymerized and copolymerized by this technique.

Emulsion polymerization

5. Polymerization of one or more monomers often is conducted in emulsion. It has been found that polymerization frequently takes place in a particularly favourable manner if the monomers are brought together in the form of an aqueous emulsion with the aid of emulsifying agents such as soaps. The polymer or copolymer is then obtained in the form of a latex, or milky liquid, which either can be used as such or can be coagulated by the addition of acids to form agglomerates of the product polymer. Studies of the mechanism of emulsion polymerization indicate that several important steps in the process occur in the micelles (little particles) of the emulsifying agent. The final growth of the macromolecules takes place in polymer particles swollen by monomers transferred by diffusion from the monomer droplets. Most rubbery polymers and copolymers, and some plastics, are produced on a very large scale by emulsion polymerization.

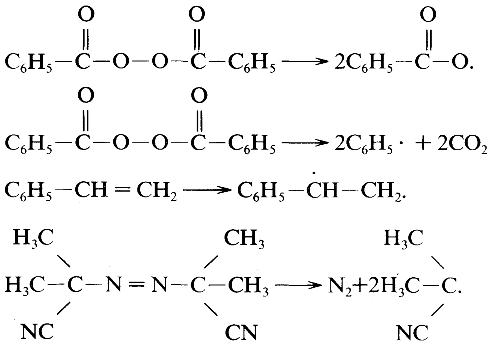
Several other polymerization methods, such as polymerization in the solid state, in a fine powder, or in a foam of small bubble size, have been studied in the laboratory but have not been employed on a large scale for commercial use.

Most polymerization techniques can be carried out in separate batches or as continuous processes. Batch processing still prevails in most large-scale operations, but there is a tendency toward the development of continuous methods for all polymerization processes. Continuous processes have been developed for production of acrylonitrile, nylon, polyester, and certain synthetic rubbers.

Catalysts basic to polymerization reactions

Catalysis. Catalysts, substances that promote chemical reactions without being consumed in the reactions, play an important role in most polymerization reactions. Addition polymerization can be accelerated by three different types of catalysts: free-radical, cationic, and anionic.

Free radical catalysis. Initiation of a polymerization reaction may take place through the initial formation of a free radical, which either is produced by decomposition of a labile (*i.e.,* easily reactive) molecule or is formed in the course of a chemical reaction. Typical cases of free-radical-forming catalysts are peroxides, hydroperoxides, and azo compounds. Various ways of forming free radicals are indicated by equations 1–5:

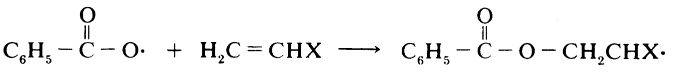


$$C_6H_5-\overset{O}{\overset{\|}{C}}-O-O-\overset{O}{\overset{\|}{C}}-C_6H_5 \longrightarrow 2C_6H_5-\overset{O}{\overset{\|}{C}}-O.$$

$$C_6H_5-\overset{O}{\overset{\|}{C}}-O-O-\overset{O}{\overset{\|}{C}}-C_6H_5 \longrightarrow 2C_6H_5\cdot + 2CO_2$$

$$C_6H_5-CH=CH_2 \longrightarrow C_6H_5-\dot{C}H-CH_2.$$

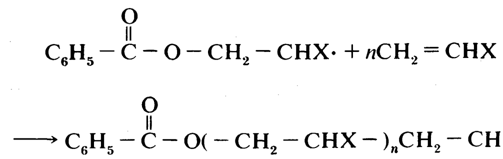
The initiator decomposes either by thermal action at a sufficiently high temperature or at low temperatures under the influence of a photon (packet of light energy) or an electron. The activation energy required to break the critical bond in the molecule of the initiator, usually a O—O, C—N, or C—O bond, amounts to only about 15–30 kilocalories. Some initiators, such as certain hydroperoxides and aliphatic azodinitriles, act at relatively low temperatures (40°–50° C [104°–122° F]); whereas others, such as peroxides or aliphatic azodiesters, require temperatures as high as 150°–175° C (302°–347° F). The free-radical initiator (produced in reactions such as those shown in equations 1–5) attacks the double bond of the monomer, attaches itself to it, and reproduces the free radical at the other end of the adduct:



$$C_6H_5-\overset{O}{\overset{\|}{C}}-O\cdot + H_2C=CHX \longrightarrow C_6H_5-\overset{O}{\overset{\|}{C}}-O-CH_2CHX\cdot$$

The propagation reaction

This process is called the propagation reaction; as it is repeated again and again, it consumes the molecules of the monomer to form macromolecules:



$$C_6H_5-\overset{O}{\overset{\|}{C}}-O-CH_2-CHX\cdot + nCH_2=CHX$$

$$\longrightarrow C_6H_5-\overset{O}{\overset{\|}{C}}-O(-CH_2-CHX-)_nCH_2-CHX\cdot$$

The activation energies of typical propagation reactions have been found to be 5–10 kilocalories.

A free radical at the end of a growing chain can also react with a monomer molecule in such a way that it abstracts a hydrogen atom from the latter and transfers the free radical character from the growing chain to the monomer:

$$R-CH_2-CHX\cdot + CH_2=CHX$$

$$\longrightarrow R-CH_2-CH_2X + CH_2=CX\cdot$$

Such processes are called chain-transfer reactions; they occur between the growing chains and molecules of the monomer or of the already formed polymer. If two free-radical chain ends react with each other, there results a pairing of the lone electrons either by recombination or by disproportionation. Either process leads to the termination of the propagation step and finishes the polymerization reaction by the formation of stable macromolecules. Examples of both are:

$$\ldots CH_2-CHX\cdot + \cdot XCH-CH_2\ldots$$

$$\xrightarrow{\text{recombination}} \ldots CH_2-CHX-CHX-CH_2\ldots$$

$$\xrightarrow{\text{disproportionation}} \ldots CH_2CH_2X + XCH=CH\ldots$$

The interplay of initiation, propagation, and termination reactions leads to average lifetimes for the free radical-type chain ends of 0.1 to 10 seconds and to steady-state free-radical concentrations of 10^{-6}–10^{-8} mole per litre.

To produce free radicals at lower temperatures, such as room temperature or below, the interaction of electron donors, such as iron(II) ions, Fe^{2+}, with electron acceptors, such as hydrogen peroxide, H_2O_2, is utilized. In this way, an oxidation–reduction system is set up, which acts as a permanent source of free radicals:

$$H_2O_2 + Fe^{2+} \longrightarrow Fe^{3+} + HO^- + HO\cdot$$

Such systems are capable of initiating polymerization reactions at temperatures as low as −20° C (−4° F). This reaction activation is of great practical importance in emulsion polymerization, where many undesirable complications can be avoided, or at least suppressed, by working at low temperatures.

Free-radical initiation is employed in the bulk polymerization of styrene and methyl methacrylate, in the solution copolymerization of vinyl chloride–vinyl acetate, in the suspension polymerization of acrylonitrile and vinyl chloride, in the emulsion copolymerization of butadiene–styrene and butadiene–acrylonitrile, and in many other vinyl-type addition polymerizations.

Cationic catalysis. Certain vinyl-type monomers, such as propylene, isobutylene, and most vinyl ethers, do not respond to free-radical initiation but can be initiated by catalysts that produce protons by interaction with a cocatalyst. The protons attack the monomer to form a carbonium ion (a molecular fragment with a positive charge on a carbon atom), which then acts as the carrier for the propagation. A typical example of cationic polymerization

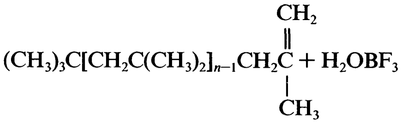
Boron trifluoride as catalyst

is the formation of polyisobutylene from isobutylene under the influence of boron trifluoride as catalyst and water as cocatalyst. The process can be represented by a series of equations:

$$BF_3 + H_2O \rightleftharpoons H_2OBF_3 \rightleftharpoons H^+ + HOBF_3^- \quad (1)$$

$$H^+ + CH_2 = C(CH_3)_2 \longrightarrow (CH_3)_3C^+ \quad (2)$$

$$(CH_3)_3\overset{+}{C} + nCH_2 = C(CH_3)_2 \longrightarrow (CH_3)_3C[CH_2C(CH_3)_2]_{n-1}CH_2\overset{+}{C}(CH_3)_2 \quad (3)$$



$$(CH_3)_3C[CH_2C(CH_3)_2]_{n-1}CH_2\overset{+}{C}(CH_3)_2 + HOBF_3^- \longrightarrow (CH_3)_3C[CH_2C(CH_3)_2]_{n-1}CH_2\underset{\displaystyle CH_3}{\overset{\displaystyle CH_2}{\overset{\|}{\underset{|}{C}}}} + H_2OBF_3 \quad (4)$$

The interaction of catalyst and cocatalyst produces protons (1), the concentration of which is controlled by an equilibrium that depends upon the concentration of the reactants and on the temperature. Other catalysts of this type are aluminum chloride and stannic chloride; other cocatalysts are ethers and amines. The proton adds to the monomer to form a carbonium ion (2), which propagates the chain by subsequent addition to other monomers (3). No formation of free radicals by splitting of an electron pair is necessary; instead, the displacement of an electron pair within the interacting particles suffices to bring about the chemical changes required to combine the monomeric units into macromolecules. As a consequence, the activation energies for initiation and propagation by cationic initiation are much lower than by the free-radical mechanism, and cationic polymerization leads to rapid formation of large molecules even at temperatures as low as −80° C (−112° F).

The termination of cationic polymerization takes place by the reaction of the negatively charged complex ion with the carbonium-ion chain end, a reaction that results in the formation of a terminal hydroxyl group or a terminal double bond (4). Essentially this reaction restores the molecule of the catalyst to its original state so that it can attack another monomer and begin another reaction cycle.

Anionic catalysis. Anions, or negative ions, such as hydroxide (OH^-), amide ion ($NH^-{}_2$, and various carbanions designated R^-, can also initiate vinyl-type addition polymerization under certain conditions. The reaction proceeds by conversion of the monomer to a carbanion, which then undergoes propagation reactions with further monomers. This mechanism is of great importance, and it has been established that most polymerizations initiated by alkali metals or alkali-metal alkyls are of this type. In certain cases the lifetime of the carbanions is very long, so that there is essentially no termination reaction. Polymers formed under such conditions are called living polymers.

Living polymers

Most addition polymerizations involving ring opening are subject to catalytic influence by positively or negatively charged ions. Thus the polymerization of ethylene oxide and other epoxides is strongly accelerated by bases, and the polymerization of α-aminocarboxyanhydrides by acids. Both types are initiated by water, alcohols, or amines.

Coordination-complex catalysis. A very important group of ionic initiators is formed when compounds of transition metals—such as titanium, zirconium, and vanadium—are mixed with metal alkyls—butyllithium, $LiCH_2CH_2CH_2CH_3$, diethylzinc, $Zn(CH_3CH_2)_2$, and triethylaluminum $Al(CH_3CH_2)_3$, for example. In such cases the result is a solid precipitate, that is able to polymerize ethylenic compounds by a suspension type process. Polymerizations of this type take place very rapidly under mild conditions and lead to many products of great importance; *e.g.,* linear polyethylene, isotactic polypropylene, *cis*-1,4-polybutadiene, and ethylene–propylene copolymers.

Condensation catalysis. Most polycondensation reactions also are influenced by acids and bases. In these cases it is important to distinguish between equilibrium and rate effects. Certain materials, such as catalysts, influence the rate, or speed, of chemical reactions without affecting the relative amount of product formed; other substances affect primarily the amount of product present at equilibrium. With many condensation reactions, water-binding agents, such as phosphoric anhydride, sulfuric acid, or trifluoroacetic anhydride, very markedly increase the overall formation of polymer, but they do so by shifting the equilibrium in the direction of polycondensation rather than by a catalytic influence on the elementary process of chain propagation. As most polycondensation reactions are carried out at rather elevated temperatures (200° C [392° F] or higher), it is necessary to employ acids and bases of very low volatility, such as antimony(III) oxide, Sb_2O_3, lead dioxide, PbO_2, calcium hydride, CaH_2, or potassium hydroxide, KOH.

PROPERTIES AND USES OF POLYMERS

Mechanical strength of polymers. The most important property of organic polymers, as compared with ordinary organic substances, is that they exhibit considerable mechanical strength in the solid state. Hence polymers are used to make fibres, films, plastics, rubbers, coatings, and adhesives of commercially valuable properties. The degree to which favourable mechanical properties are exhibited depends upon several factors, the interaction of which determines the most appropriate use of a given polymer and characterizes it as a typical material to form a fibre, plastic, or coating.

Degree of polymerization. One decisive factor for mechanical resistance is the degree of polymerization, or the molecular weight, of the material under consideration. Extensive experiments with many polymers have shown that for each polymer there exists a certain critical molecular weight below which the material shows only poor mechanical strength. Above this critical value, mechanical strength is rapidly developed with increasing molecular weight up to a second level, above which the increase of mechanical resistance with increasing molecular weight becomes less pronounced. An industrially useful material must have, therefore, a certain molecular-weight value above which only a diminishing return of strength is gained. As a matter of safety, it is advisable to choose a molecular weight well above this point, but it has been found that materials with too high a degree of polymerization exhibit exorbitant viscosities in solution or in the molten state, which render such important processes as filtration, spinning, casting, and molding unduly difficult. A proper compromise between easy processing ability and desirable ultimate properties must therefore be established by choosing an optimum molecular-weight range in each individual case.

Optimum molecular weight

Intermolecular forces. Another important factor for the development of characteristic mechanical properties is the magnitude of the intermolecular forces between individual macromolecules in a given material, as well as the structural regularity of the macromolecules themselves. If the intermolecular attraction is small and the chains are difficult to fit laterally into a lattice-like arrangement, then at a particular temperature and stress material that has been stretched shows a distinct tendency to return to a relaxed state in which the macromolecules are again curled rather than laterally ordered. Such behaviour is typical of rubbers (elastomers). On the other hand, if the molecular cohesion is strong and the fine structure of the chains provides for easy lateral fitting into lattice-like aggregates, a state of substantial crystallinity is favoured and the material is a typical fibre. In intermediate cases, in which the forces are moderate and the geometry of the chains is not very favourable for crystallization, the behaviour of the material will depend greatly upon external conditions such as temperature and pressure. Such systems are typical plastics.

These qualitative considerations show that rubbers, plastics, and fibres are not intrinsically different materials. Their differences are rather a matter of degree and result from the combined effect of the intermolecular forces between the long chains and the general tendency of the chains themselves to curl and fold, which leads to a mixture of crystallized and disordered portions in a given sample of the material. In general, it can be said that under given conditions, such as temperature and external forces applied to the sample, the tendency to crystallize is brought about by two different factors, which to a certain extent conflict with each other:

Intermolecular forces versus molecular geometry

1. Forces between the individual macromolecules: if these forces are strong, then at ordinary temperatures they chiefly determine the behaviour of the material, and it can be expected to behave like a hard plastic or like a typical fibre. This condition appears to be true for cellulose, certain proteins, nylon, polyesters, and polyacrylics.
2. The microgeometry of the molecular chains themselves: If the chains fit easily into a crystal-like lattice, as polyethylene, nylon, and certain other substances do, the material crystallizes under the influence of comparatively weak forces and hence, in general, has a tendency to appear more fibre-like than would be expected if the intermolecular forces alone were considered. On the other hand, materials with bulky and irregular macromolecular chains do not crystallize even if the intermolecular forces are quite strong. These are soft plastics and elastomers, and they behave more like rubber than would be expected on the basis of the intermolecular forces alone.

Commercially important polymers. From the practical point of view, classification and application of organic polymers is dominated by the raw materials (monomers) from which they are derived, because the monomeric units are responsible not only for the intermolecular forces and the structure of the individual polymer molecules but, in most cases, also for the cost of the final product.

Polyhydrocarbons. Chemically the simplest class of commercial polymers is the polyhydrocarbons. These are very widely used and cover the entire range from very soft and resilient rubbers, through plastics of all kinds, to strong, tough, and high-melting fibres.

Uses of polyethylene, polypropylene, and polystyrene

The most important commercial hydrocarbon polymer is polyethylene, which exists in two types: a lower density material, which is made by high-pressure polymerization, and a high-density type, which is made with the aid of special catalysts at normal pressure. Both are processed by various molding, extrusion, and casting techniques and are widely used to produce such products as trash cans, pails, containers for milk and most household liquids, shopping bags, and wrapping films for many dry goods. Polypropylene is somewhat stiffer and has a higher melting point and a more brilliant and transparent appearance. It is used for the same purposes as polyethylene but also, because of its higher melting point, as a fibre for carpets, upholstery, drapings, and, mixed with wool or acrylic fibres, for blankets. Polystyrene is brilliantly transparent and excellently moldable, but it has a somewhat lower softening point and it is more likely to swell in organic solvents than polyethylene or polypropylene. It is widely used for many household goods, as well as toys, pens, pencils, and decorative molded items. These three polyhydrocarbons all have relatively regular, easily orientable molecular chains, which can be readily brought into laterally ordered bundles resembling a crystal-like structure. They are used, therefore, as plastics and fibres, in spite of the fact that the intermolecular forces between the hydrocarbon chains are low. Other important polyhydrocarbons, however, with more bulky chains, which show more resistance to lateral order, have the properties of a typical rubber. Natural rubber—*cis*-polyisoprene—is the classical representative of these substances. Others are the principle synthetic elastomers, such as polybutadiene and copolymers of butadiene or isoprene with styrene and with each other. It is interesting that random copolymers of ethylene and propylene are also typical elastomers, because the irregular sequence of the two monomers along the chain reduces their capacity for the formation of laterally ordered semicrystalline domains.

Uses of polyvinyl chlorides and polyacrylonitrile

Chlorinated and cyanated polyhydrocarbons. Commercially important classes of polymers are the chlorinated and cyanated polyhydrocarbons. In these, the presence of a chlorine atom or cyano-group increases intermolecular attraction and has the consequence that regularly built chains of these materials behave like fibres or plastics. Outstanding examples are the successful synthetic fibres made of polyvinylidene chloride, polyvinyl chloride, and polyacrylonitrile. If irregularity is introduced into the molecular chains by copolymerization or by the use of bulky monomers, elastomeric materials are obtained. Examples are neoprene—a polychloroprene rubber—and the copolymers of butadiene with acrylonitrile, which form a large and important class of synthetic elastomers.

Polyesters. Intermolecular forces between adjacent macromolecular chains can also be increased by the introduction of an ester bond into the backbone of the chain; this addition leads to the large and important family of polyesters. If the chains are regularly built and easy to align, typical fibre-forming polymers are obtained, such as polyethylene glycol terephthalate, which is today one of the most successful synthetic fibres. Polyesters with less regular chains form a large variety of plastics that are reversibly softening and behave like typical thermoplastics; such polyesters can be cross-linked and thereby made into hard, insoluble, and nonmelting thermoset materials.

Uses of nylons

Polyamides. Still larger intermolecular forces are obtained when an amide bond is introduced into the backbone of linear macromolecules, producing the large and important family of polyamides, or nylons. These have the distinction of being superior fibre-forming materials, and in the late 1930s they initiated the introduction of synthetic fibres into the textile industry. Polyamides with reduced chain regularity produce excellent plastics, which are used in molding and extrusion processes. Polyacrylic compositions excel by their weather resistance, scratch resistance, high gloss, and capacity to accommodate pigments and other fillers. As a consequence, they represent an extremely successful class of materials for synthetic paints and coatings, widely used on products ranging from furniture to automobiles and airplanes.

Other polymers. Other polymers of some practical importance are: the polyurethanes as rubbers, foams, and adhesives; the polyfluorocarbons and the silicones because of their exceptional chemical inertness; the epoxy resins as coatings and adhesives; and several linear macromolecules composed of aromatic rings, because of their useful behaviour at temperatures as high as 600° C (1,112° F).

(H.F.M.)

PRINCIPLES OF CHEMICAL SYNTHESIS

Chemical synthesis is concerned with the construction of complex chemical compounds from simpler ones. Several million compounds have been synthesized, and their number is being added to at the rate of some hundreds of thousands every year.

GENERAL CONSIDERATIONS

A synthesis usually is undertaken for one of three reasons: first, to meet an industrial demand for a product. For example, ammonia is synthesized from nitrogen and hydrogen and used to make, among other things, ammonium sulfate, employed as a fertilizer; vinyl chloride is made from ethylene and used in the production of polyvinyl chloride (PVC) plastic. In general, a vast range of chemical compounds is synthesized for applications as fibres and plastics, pharmaceuticals, dyestuffs, herbicides, insecticides, and other products.

Second, an enormous number of compounds of considerable molecular complexity occur naturally, in both living organisms and their degradation products; examples are proteins (in animals) and alkaloids (alkaline materials found in plants). The syntheses of these natural products have usually been undertaken in the context of the determination of the structures of the compounds; if a material is deduced to have a particular structure on the basis of its chemical reactions and physical properties, then the finding that a compound synthesized by an unambiguous method for this structure is identical to the natural product provides confirmation of the validity of the assigned structure.

Third, a synthesis may be carried out to obtain a compound of specific structure that does not occur naturally and has not previously been made, in order to examine the properties of the compound and thereby test theories of chemical structure and reactivity.

GENERAL APPROACH TO SYNTHESIS

There is, then, an essentially limitless range of compounds that are capable of being synthesized. In practice, the synthesis of a preselected compound is made possible by particular chemical groupings undergoing transformations that, while they are dependent upon the conditions applied to the compound, are largely independent of the structure of the remaining part of the molecule. Thus, the combination of a knowledge of the structure of the compound to be synthesized and the general types of transformation that compounds undergo enables a synthesis to be planned. The general approach, cut to its barest essentials, is to examine the structure of the desired end product—for example, *Z*—and to deduce the structure of some (slightly simpler) compound—for example, *Y*—that should be capable of transformation into *Z* by a reaction of known type. A possible precursor of *Y* is sought in similar manner, and in this way the chain of compounds is extended until a compound, *A*, is reached that is available for the work; the necessary transformations, beginning with *A* and ending with *Z*, are then carried out. Most individual steps in the sequence result in a change in only one bond; some result in changes in two bonds at a time, but it is rare for more extensive changes to occur.

Evaluation of a synthetic method. Three factors must be borne in mind when evaluating a particular synthetic plan. The first is cost, of far greater importance in industrial, large-scale synthesis than in laboratory work in which a particular synthesis may be carried out only once, as in the total synthesis of a naturally occurring compound, and which in any case is likely to be on a relatively small scale.

Importance of yield

Second, the yield in each step must be considered. A step in a synthesis may be theoretically possible but in practice almost impossible to achieve. For example, a proportion of the reactant may be converted into a different product by an alternative process that competes with the desired one, some of the product may undergo a subsequent reaction, or some of the product may be lost in the separation processes required for its isolation in a pure state. The yield is usually defined, on a percentage basis, as the number of molecules of product obtained when 100 could in principle have been formed. A yield of about 80 percent or more is generally considered good, but some transformations can prove so difficult to achieve that even a yield of 10 or 20 percent may have to be accepted.

Naturally, the yield of a process affects the cost of the product, because the shortfall from a 100 percent yield represents wasted material. In addition, yield can be of the utmost importance in determining whether or not a synthesis is a practicable possibility, because the overall yield of a synthesis is the product of the yields of the individual steps. If these intermediate yields are mostly low, the ultimate product may not be obtainable in the necessary amount from the available starting material.

Finally, consideration must be given to the rate at which each step in the planned sequence occurs. In many instances, a desired reaction is possible in principle but in practice takes place so slowly as to be ineffective. It is then necessary to investigate whether the rate can be increased to a practicable level by altering the conditions of the reaction—for example, by raising the temperature or by adding an extra species that increases the rate without altering the nature of the reaction.

The factors that have been briefly mentioned above as important in determining the course of a synthesis will now be considered in detail.

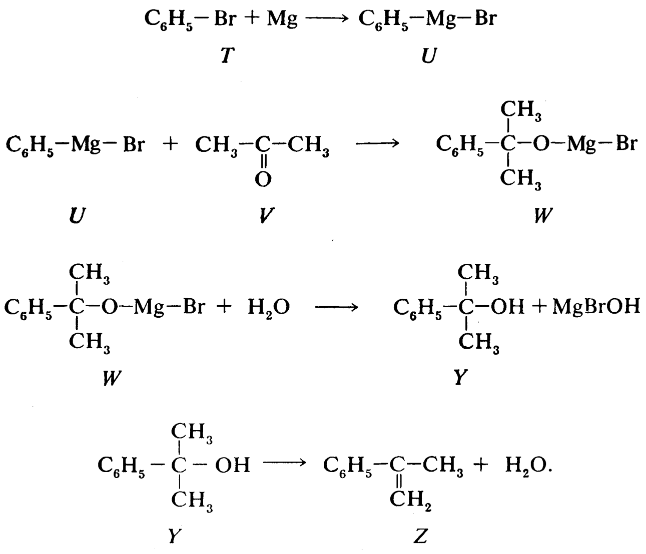
Sources of starting materials

Availability of starting materials. All syntheses must be planned so as to start with available materials. A few elements occur naturally and require only a simple separation process for their isolation; examples are oxygen and nitrogen in the atmosphere and the metals gold and silver. Most metals occur, however, as minerals, in combined form, and an appropriate chemical extraction process must be applied if the element itself is required.

The main source of organic compounds is now petroleum, which has superseded coal. Petroleum consists mainly of straight-chain alkanes (hydrocarbons of general formula C_nH_{2n+2}, such as methane, CH_4, ethane, CH_3CH_3, propane, $CH_3CH_2CH_3$, etc.) with up to about 125 carbon atoms in the chain, together with smaller quantities of cyclic alkanes and aromatic hydrocarbons such as benzene; the proportions vary from one oil field to another. The mixture is separated by fractional distillation, based on the fact that the compounds in the mixture have different boiling points. From the resulting compounds, others are formed by chemical processes; for example, the compounds containing 16–20 carbon atoms are passed through a catalyst, a fine powder made of silica and aluminum oxide, and heated at 450°–500° C (850°–950° F), resulting in the formation of smaller compounds including olefins (compounds containing the unit $>C{=}C<$) such as ethylene, a process called catalytic cracking. From such processes a large number of compounds is available on an industrial scale, at prices that range upward from a few cents per pound.

Planning the synthesis. *Possible synthetic routes.* As has been noted, the usual approach is to work backward in a stepwise fashion until an available starting material is reached.

If, for example, the compound sought, again labelled *Z*, is an olefin, a possible precursor is an alcohol because it is known that olefins can be obtained (among other ways) from alcohols by removal of water (dehydration). One route to an alcohol is by reaction of one of a group of compounds called Grignard reagents with a compound containing the carbonyl group $>C{=}O$; an appropriate combination in this case would be the compounds *U* + *V*, the Grignard reagent *U* being available from the compound *T*. As the materials *T* and *V* are available in most laboratories, one possible scheme for synthesizing *Z* is now complete:



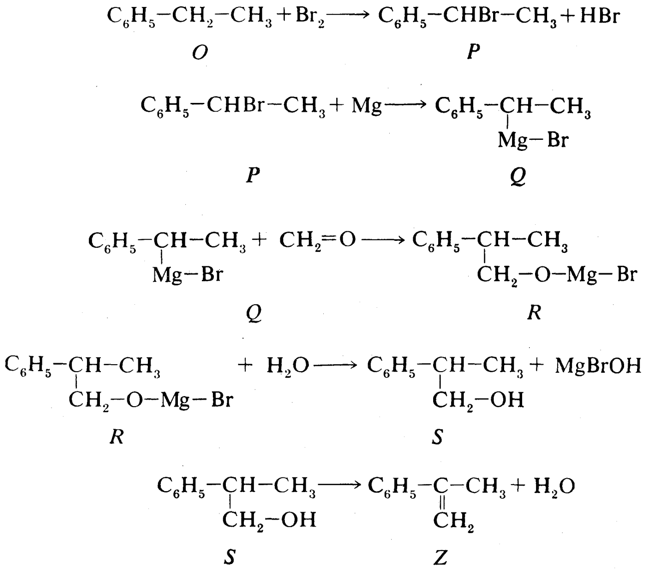
$$\underset{T}{C_6H_5{-}Br} + Mg \longrightarrow \underset{U}{C_6H_5{-}Mg{-}Br}$$

$$\underset{U}{C_6H_5{-}Mg{-}Br} + \underset{V}{CH_3{-}\underset{\underset{O}{\|}}{C}{-}CH_3} \longrightarrow \underset{W}{C_6H_5{-}\overset{\overset{CH_3}{|}}{\underset{\underset{CH_3}{|}}{C}}{-}O{-}Mg{-}Br}$$

$$\underset{W}{C_6H_5{-}\overset{\overset{CH_3}{|}}{\underset{\underset{CH_3}{|}}{C}}{-}O{-}Mg{-}Br} + H_2O \longrightarrow \underset{Y}{C_6H_5{-}\overset{\overset{CH_3}{|}}{\underset{\underset{CH_3}{|}}{C}}{-}OH} + MgBrOH$$

$$\underset{Y}{C_6H_5-\overset{\overset{CH_3}{|}}{\underset{\underset{CH_3}{|}}{C}}-OH} \longrightarrow \underset{Z}{C_6H_5{-}\underset{\underset{CH_2}{\|}}{C}{-}CH_3} + H_2O.$$

Other possibilities would certainly be considered. First, there is an alternative alcohol, *S*, from which the product could be derived; working backward from *S*, by way of the appropriate Grignard reagent, gives a possible route from *P*. *P* is unlikely to be available in the laboratory, however; if it is not, it requires synthesis, for example, from *O*. At this stage it is realized that the planned synthesis is longer than that from *T* and *V*, and, unless some specific advantage can be seen—for example, much better yields, which are unlikely in this case—it is discarded.



$$\underset{O}{C_6H_5{-}CH_2{-}CH_3} + Br_2 \longrightarrow \underset{P}{C_6H_5{-}CHBr{-}CH_3} + HBr$$

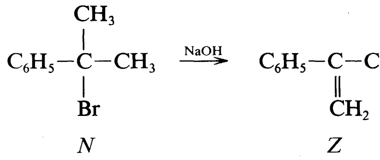
$$\underset{P}{C_6H_5{-}CHBr{-}CH_3} + Mg \longrightarrow \underset{Q}{C_6H_5{-}\underset{\substack{|\\ Mg{-}Br}}{CH}{-}CH_3}$$

$$\underset{Q}{C_6H_5{-}\underset{\substack{|\\ Mg{-}Br}}{CH}{-}CH_3} + CH_2{=}O \longrightarrow \underset{R}{C_6H_5{-}\underset{\substack{|\\ CH_2{-}O{-}Mg{-}Br}}{CH}{-}CH_3}$$

$$\underset{R}{C_6H_5{-}\underset{\substack{|\\ CH_2{-}O{-}Mg{-}Br}}{CH}{-}CH_3} + H_2O \longrightarrow \underset{S}{C_6H_5{-}\underset{\substack{|\\ CH_2{-}OH}}{CH}{-}CH_3} + MgBrOH$$

$$\underset{S}{C_6H_5{-}\underset{\substack{|\\ CH_2{-}OH}}{CH}{-}CH_3} \longrightarrow \underset{Z}{C_6H_5{-}\underset{\substack{\|\\ CH_2}}{C}{-}CH_3} + H_2O$$

Second, a precursor to *Z* other than the alcohols *Y* and *S* would be considered. For example, a possibility is *N*. The most obvious route to *N*, however, is from the alcohol *Y*, so that this method would simply involve an extra, unnecessary step compared with the route involving the conversion of *Y* into *Z* directly.



$$\underset{N}{C_6H_5{-}\overset{\substack{CH_3\\ |}}{\underset{\substack{|\\ Br}}{C}}{-}CH_3} \xrightarrow{NaOH} \underset{Z}{C_6H_5{-}\underset{\substack{\|\\ CH_2}}{C}{-}CH_3}$$

Evaluation of alternatives. Once a scheme with the minimum number of transformations in it has been selected, attention must be given to three other questions for each of the individual steps.

The first of these is whether the step will succeed as planned in this particular case. For example, reaction with the Grignard reagent was chosen because it is known that normally a Grignard reagent reacts with a compound containing the carbonyl group to give an alcohol. Some exceptions to this are also known, however; if, for example, the carbon atom in the carbonyl group is attached to two very bulky groups, the Grignard reagent can be prevented from reaction. Therefore, an examination must be made of any grounds for suspecting that the reaction might fail.

The second question is whether any unwanted transformation will occur at the same time. It frequently happens that there are two or more positions in a compound with which a particular agent can react. In such cases, unless that position at which reaction is desired is much more reactive than the others, it is necessary to modify the other positions to prevent them from reacting. This technique, called protection, is described in more detail later.

The third question is whether the operations required are practicable in the laboratory. For example, some reactions require very high pressures, and the necessary equipment is not widely available; others involve hazards that can be adequately dealt with only in highly specialized laboratories, as in the case of radioactive materials.

The problems in planning a synthesis increase rapidly with the degree of complexity of the target molecule for two reasons: first, the number of possible combinations of steps that must be considered in reaching a decision as to the best route quickly multiplies; for example, if there were two ways in which the final step could be effected, two for the preceding step, and so on, then the number of possibilities to consider is 32 for a five-step synthesis, over 1,000 for a 10-step synthesis, and so on. Second, as the molecule becomes more complex, the possibility of finding a reagent that will effect a desired transformation without bringing about unwanted processes is reduced. Even the most thoughtfully conceived scheme can founder because there was no hint from any previous observation that a particular step would fail as a result of a combination of factors specific to the target molecule in question and never previously encountered. It can be readily appreciated that some of the more complex compounds that have been synthesized—for example, the steroid cholesterol, the alkaloid strychnine, and the plant material chlorophyll—have each taken many man-years of highly skilled effort for their achievement. The failure of a step in a synthesis, perhaps formation of a product different from the one intended, can sometimes be turned to advantage in revealing a new aspect of reaction mechanism that can be applied in later syntheses.

The protection of reactive positions. A plan to effect reaction at a particular position in a compound with a specific reagent can be thwarted if in the molecule there is another position or group that preferentially reacts with that reagent. In such cases it is sometimes possible to block this more reactive position temporarily, while the planned reaction is carried out. The technique is to introduce another reagent that converts the more reactive grouping into a derivative that is inert to the desired reagent; the latter can then be introduced so as to react at the intended position, and finally a third reaction is used to reconvert the blocked position to its original form.

Factors affecting reaction rate. Some reactions take place instantaneously at room temperature simply on mixing the reagents. This is especially true of reactions between inorganic salts; for example, when an aqueous solution of silver nitrate is mixed with one of sodium chloride, silver chloride immediately precipitates from the solution. The underlying reason for this rapidity is that these compounds both contain ions that move freely in solution and collide frequently with each other; collision between a silver ion and a chloride ion can result in the two particles staying together and gradually coagulating with other such pairs as a precipitate, because silver chloride is insoluble in water.

Reactions of covalent compounds

In contrast, the reactions of covalently bonded compounds usually occur slowly at room temperature. The reason is that one or more of these bonds generally has to be broken, and energy is required for that process; the energy is normally supplied in the form of heat but in some circumstances can be supplied as visible or ultraviolet light. The reaction of iodomethane, CH_3I, with sodium hydroxide, NaOH, in solution, to give methanol, CH_3OH, and sodium iodide, NaI, is exemplary. Sodium hydroxide is an ionic compound containing Na^+ and OH^- ions, and its reaction with iodomethane consists of the formation of a covalent bond between the oxygen atom of OH^- and the carbon atom of CH_3I while at the same time the C—I bond breaks, the two electrons in the bond remaining with the iodine atom, which consequently becomes an iodide ion. The first requirement for reaction to occur is a collision between the OH^- ion and CH_3I, but it is also necessary that the molecules possess enough kinetic energy on collision in order to supply the amount necessary for bond breaking. At room temperature only a small proportion possess the required amount of energy, but as the temperature is raised the average amount of kinetic energy of the particles increases and, with it, the proportion of molecules that possess enough energy for reaction. The critical amount of energy—*i.e.*, the activation energy—varies from reaction to reaction, and so does the dependence of the rate on temperature, but, as a rough guide, for many reactions the rate doubles for each 10° C (18° F) rise in temperature.

Reactions in liquids

The physical state of the reactants also has to be considered. Two solids do not react at a significant rate because when they are put in contact the rate at which the molecules diffuse from one into the other and thereby collide with each other is negligible. In both gases and liquids, however, collisions occur millions or billions of times a second; consequently, a solid reactant is usually brought into the liquid state by heating, or, if its melting point is undesirably high, it is dissolved in a solvent. A commonly employed method is to dissolve the reactants in a solvent, such as water or benzene, and then to heat the solution at its boiling point.

Reactions in the gas phase, which are mostly of industrial concern, can be carried out in temperature-controlled furnaces. For example, in the Haber process for the manufacture of ammonia, a mixture of nitrogen and hydrogen is heated at a pressure of 300 atmospheres and a temperature of about 500° C (950° F).

Catalysis. Many reactions occur too slowly even at elevated temperatures to be practicable procedures, but their rates can sometimes be enormously increased by the addition of a catalyst (defined broadly as a material that speeds a reaction but is unchanged at the end of it).

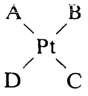
Catalysts can be divided into two categories—heterogeneous and homogeneous; the former group are solids suspended in a solution of the reactants or over which gaseous reactants are passed, and the latter are materials that are soluble in the reaction medium.

A simplified interpretation of the ability of a heterogeneous catalyst, usually a metal, to increase the rate of a reaction is that molecules of each reactant become adsorbed on its surface in close proximity, and their internal bonds become weakened somewhat so that reaction is facilitated. Homogeneous catalysts, on the other hand, almost always take part chemically in the reactions they catalyze but are regenerated at the end of the process. Metallic compounds have proved valuable as catalysts for organic reactions, including those of industrial importance. The key to success with these catalysts lies in the transient formation of an intermediate compound.

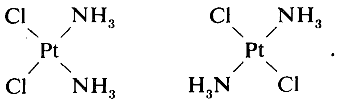
Metallic compounds as catalysts

Activation. Closely akin to catalysis is the activation of a compound by a slight modification of one of its groups.

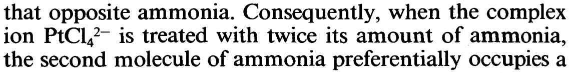
An activating influence of a different type occurs in reactions of inorganic complexes of platinum, and it is useful to consider this behaviour in detail. Platinum exists in salts as the ion Pt^{2+}, usually bonded to four molecules or ions located at the corners of a hypothetical square of which platinum is the centre:



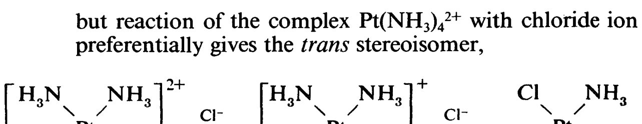
The ease with which a particular group, A, for example, is replaced by another group is much more strongly dependent upon the nature of the group opposite (*trans*) to it, C, than on those adjacent to it, B and D. This *trans* effect can be exploited in synthesis, as, for example, in the preparation of the two stereoisomers of the compound $PtCl_2(NH_3)_2$:



Here, use is made of the fact that a chloride ion, Cl^-, exerts a greater *trans* effect than does ammonia, NH_3; that is, the group *trans* to chloride is more readily replaced than is that opposite ammonia. Consequently, when the complex ion $PtCl_4^{2-}$ is treated with twice its amount of ammonia, the second molecule of ammonia preferentially occupies a position adjacent to the first, giving the *cis* stereoisomer,



but reaction of the complex $Pt(NH_3)_4^{2+}$ with chloride ion preferentially gives the *trans* stereoisomer,



Isolation and purification of products. The product of a synthesis is normally contaminated with reagents used in the synthesis, by-products, and possibly some unchanged starting material; these contaminants must be removed in order for a pure sample to be obtained. In a multistep synthesis, it is normally desirable to purify the product from each step before proceeding to the next. Various techniques for isolation and purification are discussed in the article ANALYSIS AND MEASUREMENT: *Chemical separations and purifications.*

RECENT DEVELOPMENTS IN SYNTHETIC METHODS

The art of chemical synthesis is a constantly evolving one in which new approaches and techniques are developed to meet new challenges. There are two recent developments of a novel kind that are likely to become of increasing importance.

First, it has been shown that synthetic schemes can be efficiently planned with the aid of a computer. The input consists of the various methods for transforming particular types of grouping into others, together with the known information as to the suitability of each process in particular structural situations. For any particular target molecule, the computer can then select various synthetic schemes and can choose between these on the basis of such factors as ease of handling, likely yields, or other considerations.

Automated synthesis

Second, the practicability of the automation of synthesis has been proved for the case of polypeptides. Briefly, polypeptides and proteins are polymers that occur in living systems, and they are best synthesized from amino acids, species that contain both carboxylic acid groups and amino groups. In the laboratory, however, problems arise. First, amino acids do not react together readily; it is necessary to activate the carboxylic acid group of one molecule by converting it into some suitable function that will react readily with the amino group of the second molecule. Second, the activated group is approximately as likely to react with the amino group of another molecule of the same type as with that of a molecule of the second amino acid. To obviate this problem, the amino group of the first molecule is first protected by the application of a suitable reagent. The sequence of operations, then, is to protect one amino acid at its amino end, activate it at its carboxylic acid end, and treat it with the second amino acid; the protecting group is then removed, and a third amino acid, likewise protected at its amino end and activated at its carboxylic end, is introduced; the synthesis continues with repetition of this cycle. The outstanding problem has been that, after each chemical operation, it has been necessary to purify the intermediate product so as to prepare it for the next operation, and this has not only been considerably time-consuming but has also resulted in the loss of material at each step; since dozens or even hundreds of steps are needed, the procedure has proved impracticable for very large molecules. The advance, simple in concept and remarkably effective in practice, has been to attach the first amino acid in the sequence, by means of a reaction generating a covalent bond, to an insoluble solid. The second amino acid, duly protected and activated, is introduced, and, after reaction, soluble reagents and by-products are simply removed by washing the solid, the protecting group is removed by chemical reaction and washing, and the next amino acid is introduced. No purifications other than washing are necessary until the final polypeptide, having been removed from the solid by chemical reaction, is purified. The losses normally sustained during conventional purification methods are thereby avoided, so that yields are high, and each of the individual steps can be carried out in quick succession.

Moreover, apparatus can be designed so that the fairly small number of reagents needed, including each amino acid in its protected and activated form, can be automatically delivered into the reaction vessel at the appropriate time, according to a predetermined program based on the particular polypeptide required. (R.O.C.N./Ed.)

BIBLIOGRAPHY

Classification: Three typical sources, written at different levels, are: R.W. PARRY *et al., Chemistry: Experimental Foundations* (1970), a secondary-school text; D.B. MURPHY and V. ROUSSEAU,

Foundations of College Chemistry (1969), a college-level text; and R.B. HESLOP and P.L. ROBINSON, *Inorganic Chemistry*, 3rd ed. (1967), an advanced treatise. Later full-sized monographs include WILLIAM L. JOLLY, *Modern Inorganic Chemistry* (1984); JAMES E. HUHEEY, *Inorganic Chemistry: Principles of Structure and Reactivity*, 3rd ed. (1983); JOHN MCMURRY, *Organic Chemistry* (1984); HARLAND D. EMBREE, *Organic Chemistry: Brief Course* (1983); *Dictionary of Organic Compounds*, 5th ed., 5 vol. (1982).

(W.F.K.)

Inorganic compounds: Comprehensive works: F.A. COTTON and G. WILKSON, *Advanced Inorganic Chemistry: A Comprehensive Text*, 2nd ed. (1966), the standard text; N.V. SIDGWICK, *The Chemical Elements and Their Compounds*, 2 vol. (1950), the classic compilation; C.S.G. PHILLIPS and R.J.P. WILLIAMS, *Inorganic Chemistry*, 2 vol. (1965–66), a sound and extensive survey of the field; P.J. and B. DURRANT, *Introduction to Advanced Inorganic Chemistry*, 2nd ed. (1970), a relatively thorough presentation of the subject; H.J. EMELEUS and A.G. SHARPE (eds.), *Advances in Inorganic Chemistry and Radiochemistry*, vol. 1 (1959–), annual reviews on specific aspects of inorganic chemistry; INTERNATIONAL UNION OF PURE AND APPLIED CHEMISTRY, *Nomenclature of Inorganic Chemistry* (1959), commission report on internationally accepted methods of naming inorganic compounds. See also WILLIAM H. PORTERFIELD, *Inorganic Chemistry: A Unified Approach* (1984); BODIE E. DOUGLAS, DARL H. MCDANIEL, and JOHN J. ALEXANDER, *Concepts and Models of Inorganic Chemistry*, 2nd ed. (1983); DAVID B. RORABACHER and JOHN F ENDICOTT (eds.), *Mechanistic Aspects of Inorganic Reactions* (1982); D.T. BURNS, A. TOWNSEND, and A.G. CATCHPOLE, *Inorganic Reaction Chemistry: Systematic Chemical Separation*, 2 vol. in 3 (1980–81); STEPHEN J. LIPPARD (ed.), *Progress in Inorganic Chemistry* (1983).

(D.H.B.)

Studies on water: Theoretical and experimental investigations of the structure and properties of water and aqueous solutions form the subject of a number of recent books including J.L. KAVANAU, *Water and Solute-Water Interactions* (1964); O.Y. SAMOILOV, *The Structure of Aqueous Electrolyte Solutions and the Hydration of Ions* (1965; orig. pub. in Russian, 1957); and D. EISENBERG and W. KAUZMANN, *The Structure and Properties of Water* (1969). Collections of papers by various authors treating in detail topics related to water include A.K. COVINGTON and P. JONES (eds.), *Hydrogen-Bonded Solvent Systems* (1968); and R.A. HORNE (ed.), *Water and Aqueous Solutions: Structure, Thermodynamics and Transport Processes* (1972). N.E. DORSEY, *Properties of Ordinary Water Substance in All Its Phases* (1940), although old, contains a most complete and detailed compilation of water properties. A number of journals and volume series are devoted in whole or in part to water chemistry, water pollution, water management, and oceanography. These include *Advances in Hydroscience, Water Resources Research, Limnology and Oceanography, Environmental Science and Technology, Geochimica et Cosmochimica Acta, Journal of Geophysical Research, Journal of the Water Pollution Control Federation,* and the *Journal of Solution Chemistry.* In the past much of the fundamental research on water appeared in either the *Journal of Physical Chemistry* or the *Journal of Chemical Physics.* For later research see JON C. VAN LOON, *Chemical Analysis of Inorganic Constituents of Water* (1982); ROLF K. FREIER, *Wasseranalyse: Physiko-chemische Untersuchungsverfahren wichtiger Inhaltsstoffe* (1964); OLOF ALEXANDERSSON, *Living Water* (1982); AMERICAN WATER WORKS ASSOCIATION, *Introduction to Water Quality Analyses* (1982).

(R.A.Ho./Ed.)

Organic compounds: E.H. RODD (ed.), *Chemistry of Carbon Compounds*, 10 vol. (1951–62; 2nd ed. by S. COFFEY, 1964–), is the most extensive general text on organic chemistry in English. *Beilsteins Handbuch der organischen Chemie* is the only source in any language that attempts to cover the chemical and physical properties of all organic compounds with references to the original literature. The fourth edition of 27 volumes published during the years 1918–37 covers all known organic compounds through 1909. Publication of the first supplement of 31 volumes covering the years 1910–19 began in 1928 and was completed in 1938. The second supplement of 31 volumes covers 1920–29. It was published between 1941 and 1957. General indexes cover all of the literature through 1929. The third supplement covering 1930–49, published 1958–73, consists of 49 volumes. Until a general index is published for this supplement, the indexes to each volume must be used. Publication of the fourth supplement, covering 1950–59, began in 1973. *Chemical Abstracts*, published by the AMERICAN CHEMICAL SOCIETY, Washington D.C., is a weekly journal that summarizes world literature in all branches of chemistry. A collective formula index was published covering the years 1920–46. It was followed by supplementary indexes for 1947–56, 1957–61, 1962–66, and 1967–71. For data from 1972 to date, there are semiannual indexes. R.C. WEAST (ed.), *Handbook of Chemistry and Physics*, 63rd ed. (1982–83), lists the common physical properties for more than 15,000 organic compounds. The *Nomenclature of Organic Chemistry*, 2nd ed. (1966), published by the INTERNATIONAL UNION OF PURE AND APPLIED CHEMISTRY, provides the internationally approved rules of nomenclature. The introduction to the index of *Chemical Abstracts*, vol. 56 (1962), discusses the naming of organic compounds followed for indexing purposes. See also R.S. CAHN, *An Introduction to Chemical Nomenclature* (1959); and the UNITED STATES TARIFF COMMISSION, *Synthetic Organic Chemicals* (1970), for production information. For discussion of specific compounds see WILHELM KEIM (ed.), *Catalysis in C_1 Chemistry* (1983); DONALD L. WISE (ed.), *Organic Chemicals from Biomass* (1983); K.L. CHENG, KEIHEI UENO, and TOSHIAKI IMAMURA (eds.), *CRC Handbook of Organic Analytical Reagents* (1982); A. BENNINGHOVEN (ed.), *Ion Formation from Organic Solids: Proceedings of the Second International Conference, Münster, Federal Republic of Germany, September 7–9, 1982* (1983). T.W. GRAHAM SOLOMONS, *Organic Chemistry*, 3rd ed. (1984), is a comprehensive survey.

(C.R.No.)

Hydrocarbons: Brief discussions of the structure, nomenclature, properties, preparation, and reactions of hydrocarbons are presented in all introductory organic chemistry texts. The following are recommended: J.B. HENDRICKSON, D.J. CRAM, and G.S. HAMMOND, *Organic Chemistry*, 3rd ed. (1970); C.R. NOLLER, *Chemistry of Organic Compounds*, 3rd ed. (1965); J.D. ROBERTS and M.C. CASERIO, *Basic Principles of Organic Chemistry* (1964); and L.F. and M.A. FIESER, *Advanced Organic Chemistry* (1961). Special classes of hydrocarbons are discussed in these more advanced treatises: F.D. ROSSINI, B.J. MAIR, and A.J. STREIFF, *Hydrocarbons from Petroleum* (1953), a classic work that describes the isolation of pure hydrocarbons from petroleum; B.T. BROOKS *et al.* (eds.), *The Chemistry of Petroleum Hydrocarbons*, 3 vol. (1954–55); S. PATAI (ed.), *The Chemistry of Alkenes* (1964; H.G. VIEHE (ed.), *Chemistry of Acetylenes* (1969); E.J. CLAR, *Polycyclic Hydrocarbons*, 2 vol. (1964), mainly on compounds with fused six-membered rings (vol. 1 includes a chapter by R. SCHOENTAL on the cancer-producing properties of certain hydrocarbons). Later research is reflected in LOUIS SCHMERLING, *Organic and Petroleum Chemistry for Nonchemists* (1981); K.E. STERIN, V.I. ALEKSANYAN, and G.N. ZHIZHIN, *Raman Spectra of Hydrocarbons* (1980; trans. from the Russian); ALF BJØRSETH (ed.), *Handbook of Polycyclic Aromatic Hydrocarbons* (1983); CLARENCE D. CHENG, *Hydrocarbons from Methanol* (1983); S.O. SCHLANGER and M.B. CITA (eds.), *Nature and Origin of Cretaceous Carbon-Rich Facies* (1982); JOSEPH J. GAJEWSKI, *Hydrocarbon Thermal Isomerizations* (1981).

(H.Ha./Ed.)

Alcohols, phenols, and ethers: UNION CARBIDE CORP., *Alcohols* (1969); R.L. BENT, "Alcohols," in *Encyclopedia of Chemical Technology*, 2nd ed., vol. 1, pp. 531–541 (1963); J.A. MONICK, *Alcohols* (1968); E.H. RODD (ed.), *Chemistry of Carbon Compounds*, 2nd ed., vol. 1A–2D (1965–70).

L.F. and M. FIESER, *Advanced Organic Chemistry*, ch. 22 (1961); F.M. KONRAD, "Phenols," in *Encyclopedia of Polymer Science and Technology*, vol. 10, pp. 73–92 (1969); S.J. LEDERMAN and N. POFFENBERGER, "Phenol," in *Encyclopedia of Chemical Technology*, 2nd ed., vol. 15, pp. 147–159 (1968); E.H. RODD (ed.), *Chemistry of Carbon Compounds*, vol. 3, pt. A, ch. 8 (1954).

UNION CARBIDE CORP., *Ethers* (1960); L.F. and M. FIESER, *Advanced Organic Chemistry*, pp. 303–314 (1961); A.P. LURIE, "Ethers," in *Encyclopedia of Chemical Technology*, 2nd ed., vol. 8, pp. 470–498 (1965). See also TOSHIHIKO HANAI, GUNTER ZWEIG, and JOSEPH SHERMA (eds.), *Phenols and Organic Acids* (1982); H.K. MANGOLD and F. PALTAUF (eds.), *Ether Lipids: Biochemical and Biomedical Aspects* (1983); LON J. MATHIAS and CHARLES E. CARRAHER (eds.), *Crown Ethers and Phase Transfer Catalysis in Polymer Science* (1984).

(J.A.Mo.)

Aldehydes and ketones: C.D. GUTSCHE, *The Chemistry of Carbonyl Compounds* (1967), a short treatise, written for the student in undergraduate organic chemistry, covering the structure, the properties, the mechanism of reactions, and the synthetic utility of carbonyl compounds; C.R. NOLLER, *Chemistry of Organic Compounds*, 3rd ed. (1965), a textbook, designed for a high-level first-year course in organic chemistry, that includes material relating to aldehydes and ketones; R.C. FUSON, *Reactions of Organic Compounds* (1962), a textbook for the advanced student that includes material relating to aldehydes and ketones; E.S. GOULD, *Mechanism and Structure in Organic Chemistry* (1959); J.S. HINE, *Physical Organic Chemistry*, 2nd ed. (1962); J. MARCH, *Advanced Organic Chemistry: Reactions, Mechanisms, and Structure* (1968); and E.E. ROYALS, "The Chemistry of Carbonyl Compounds," in *Advanced Organic Chemistry*, pt. 2 (1954), advanced textbooks including material relating to the mechanisms of the reactions of carbonyl compounds; W.P. Jencks, "Carbonyl- and Acyl-group Reactions," in *Catalysis in Chemistry and Enzymology,* pp. 463–554 (1969), a detailed discussion of the mechanism of various types of carbonyl reactions; S. Patai (ed.), *The Chemistry of the Carbonyl Group* (1966) and *The Chemistry of Carboxylic Acids and Esters* (1969), collections of detailed essays covering various aspects of carbonyl chemistry. Later monographs on the topic include Anthony C. Wilbraham and Michael S. Matta, *Introduction to Organic and Biological Chemistry* (1984); Walter W. Linstromberg and Henry E. Baumgarten, *Organic Chemistry,* 5th ed. (1983); Henry Weiner and Bendicht Wermuth (eds), *Enzymology of Carbonyl Metabolism* (1982); Junji Furukawa and Takeo Saegusa, *Polymerization of Aldehydes and Oxydes* (1963); Mackenzie Walser and John R. Williamson (eds.), *Metabolism and Clinical Implications of Branched Chain Amino and Ketoacids: Proceedings of a Symposium* (1981). (C.D.G.)

Carboxylic acids: Several monographs devoted exclusively to carboxylic acids and their derivatives are: S. Patai (ed.), *The Chemistry of Carboxylic Acids and Esters* (1969); and F.D. Gunstone, *An Introduction to the Chemistry and Biochemistry of Fatty Acids and Their Glycerides,* 2nd ed. (1968). Additional material may be found in selected chapters in the following review series: R.T. Holman (ed.), *Progress in the Chemistry of Fats and Other Lipids;* R. Paoletti and D. Kritchevsky (eds.), *Advances in Lipid Research;* and F.D. Gunstone (ed.), *Topics in Lipid Chemistry.* Specific research is reported in Frank D. Gunstone and Frank A. Norris, *Lipids in Foods: Chemistry, Biochemistry, and Technology* (1983); Michael J. Gibney and David Kritchevsky (eds.), *Animal and Vegetable Proteins in Lipid Metabolism and Atherosclerosis* (1983); T.E. Mittler and R.H. Dadd (eds.), *Metabolic Aspects of Lipid Nutrition in Insects* (1983); William W. Christie, *Lipid Analysis: Isolation, Separation, Identification, and Structural Analysis of Lipids,* 2nd ed. (1982). (F.D.G.)

Organic halogen compounds: W.K.R. Musgrave, "Halogen Derivatives of the Aliphatic Hydrocarbons," in S. Coffey (ed.), *Rodd's Chemistry of Carbon Compounds,* 2nd rev. ed., vol. 1A, ch. 3 (1964); W.J. Feast, "Halogen Derivatives of the Aliphatic Hydrocarbons," *ibid.,* vol. 1A, ch. 3 suppl. (1971); W.J. Feast and W.K.R. Musgrave, "Halogen Derivatives of Benzene and Its Homologues," *ibid.,* vol. 3A, ch. 3 (1971)—together these chapters describe the preparation and reactions of halogenated aliphatic and benzenoid hydrocarbons, including some theoretical interpretation of the chemistry involved. W.A. Sheppard and C.M. Sharts, *Organic Fluorine Chemistry* (1969), describes the chemistry of aliphatic, aromatic, and heterocyclic fluorine-containing compounds and their commercial application; R.O.C. Norman and R. Taylor, *Electrophilic Substitution in Benzenoid Compounds* (1965), and L.M. Stock, *Aromatic Substitution Reactions* (1968), describe in detail theories concerning nucleophilic and electrophilic substitution in aromatic compounds. Environmental aspects are discussed in F. Moriarty (ed.), *Organochlorine Insecticides: Persistent Organic Pollutants* (1975); Milos Hudlicky, *Chemistry of Organic Fluorine Compounds,* 2nd rev. ed. (1976); Peter B.D. de la Mare, *Electrophilic Halogenation* (1976); National Research Council. Committee on Impacts of Stratospheric Change, *Halocarbons: Environmental Effects of Chlorofluoromethane Release* (1976); T.M. Sugden and T.F. West (eds.), *Chlorofluorocarbons in the Environment* (1978); William J. Nicholson and John A. Moore (eds.), *Health Effects of Halogenated Aromatic Hydrocarbons* (1979); M.A.G. Kahn and R.H. Stanton (eds.), *Toxicology of Halogenated Hydrocarbons* (1981). (W.K.R.M.)

Organic nitrogen compounds: N.V. Sidgwick, *The Organic Chemistry of Nitrogen,* 3rd ed. rev. by I.T. Miller and H.D. Springall (1966), a comprehensive account of the subject for readers who have at least the equivalent of college-level organic chemistry; P.A.S. Smith, *The Chemistry of Open-Chain Organic Nitrogen Compounds,* 2 vol. (1965–66), more detailed but narrower coverage of the subject and with more references; C.A. Streuli and P.R. Averell, *The Analytical Chemistry of Nitrogen and Compounds,* 2 vol. (1970), comprehensive treatment of this subject; *Kirk-Othmer Encyclopedia of Chemical Technology,* 2nd ed., 22 vol. (1963–70), presents industrial and technological aspects of nitrogen compounds under many individual headings throughout the various volumes; S. Patai, *The Chemistry of the Amino Group* (1968); J.Z. Zabicky (ed.), *The Chemistry of Amides* (1970); Z. Rappoport, *The Chemistry of the Cyano Group* (1971); and H. Feuer (ed.), *The Chemistry of the Nitro and Nitroso Groups,* 2 vol. (1969–70), highly detailed presentations at an advanced level. See also Melvin J. Astle, *Industrial Organic Nitrogen Compounds* (1961); Peter A.S. Smith, *Derivatives of Hydrazine and Other Hydronitrogens Having N—N Bonds* (1983); Frederich R. Benson, *The High Nitrogen Compounds* (1984). (P.A.S.S.)

Organic phosphorus compounds: R.F. Hudson, *Structure and Mechanism in Organophosphorus Chemistry* (1965); A.J. Kirby and S.G. Warren, *The Organic Chemistry of Phosphorus* (1967), modern mechanistic treatments of the subject, far from comprehensive in their compound coverage; G.M. Kosolapoff, *Organophosphorus Compounds* (1950), deals almost exclusively with compound synthesis, now out of date but the only work of its kind; K. Sasse, *Organische Phosphorverbindungen,* vol. 12/1 and 12/2 of E. Mueller (gen. ed.), *Methoden der organischen Chemie* (1963–64), a comprehensive and indispensable source book for the preparation and properties of organic phosphorus compounds. C. Fest and K.-J. Schmidt, *The Chemistry of Organophosphorous Pesticides,* 2nd rev. ed. (1982), is an informative treatment. (A.J.K.)

Organic sulfur compounds: Ralph Connor, "Organic Sulfur Compounds," in Henry Gilman (ed.), *Organic Chemistry: An Advanced Treatise,* 2nd ed., vol. 1 (1943), is comprehensive but now somewhat dated. W.A. Pryor, *Mechanisms of Sulfur Reactions* (1962), focusses on reactions of elemental sulfur but contains valuable sections on its organic compounds. Norman Kharasch (ed.), *Organic Sulfur Compounds,* vol. 1 (1961) and Norman Kharasch and C.Y. Meyers (eds.), *The Chemistry of Organic Sulfur Compounds,* vol. 2 (1966), are collections of chapters on specialized topics. Frederick Challenger, *Aspects of the Organic Chemistry of Sulphur* (1959), emphasizes natural products. H. Goldwhite treats aliphatic compounds in S. Coffey (ed.), *Rodd's Chemistry of Carbon Compounds,* 2nd ed., vol. 1, pt. B, ch. 5 (1965); and A.R. Forrester and J.L. Wardell and D.R. Hogg, treat aromatic compounds in the same work, vol. 3, pt. A, ch. 5–6 (1971). Individual groups of organic sulfur compounds are the subject of articles in the 2nd ed. of the *Kirk-Othmer Encyclopedia of Chemical Technology:* M.B. Berenbaum and R.N. Johnson, "Polymers Containing Sulfur," vol. 16, pp. 253–281 (1968); Julius Fuchs, "Sulfuric and Sulfurous Esters," vol. 19, pp. 483–498 (1969); W.S. MacGregor, "Sulfoxides," vol. 19, pp. 320–337; E.E. Gilbert, "Sulfonic Acids," vol. 19, pp. 311–319; Leonard Doub, "Sulfonamides," vol. 19, pp. 255–279; S.D. Turk, "Thiols," vol. 20, pp. 205–218, 1969). Specialized research is discussed in Barry M. Trost and Lawrence S. Melvin, *Sulfur Ylides: Emerging Synthetic Intermediates* (1975); and Eric Block, *Reactions of Organosulfur Compounds* (1978). (J.V.K.)

Heterocyclic compounds: Modern textbooks of heterocyclic chemistry include: A.R. Katritzky and J.M. Lagowski, *The Principles of Heterocyclic Chemistry* (1967), also available in French, German, Spanish, Italian, Japanese, Russian, and Polish translation, which offers a concise comparative account; R.M. Acheson, *An Introduction to the Chemistry of Heterocyclic Compounds,* 2nd ed. (1967), which places more emphasis on the division of the subject into compound classes; and A. Albert, *Heterocyclic Chemistry,* 2nd ed. (1968), a more detailed treatment. Of the numerous more specialized works available, K. Schofield, *Hetero-Aromatic Nitrogen Compounds: Pyrroles and Pyridines* (1967), treats the fundamental chemistry of two parent classes of compounds; *Advances in Heterocyclic Chemistry,* 16 vol., ed. by A.R. Katritzky and A.J. Boulton (1963–73); and the *Chemistry of Heterocyclic Compounds,* ed. by A. Weissberger and E.C. Taylor (1950–73), are continuing series of reviews. Later monographs include George R. Newkome and William W. Paudler, *Contemporary Heterocyclic Chemistry: Syntheses, Reactions, and Applications* (1982); Alfred Hassner (ed.), *Small Ring Heterocycles* (1983); H.C. van der Plas, *Ring Transformations of Heterocycles,* 2 vol. (1973). (A.R.K.)

Dyestuffs and pigments: Society of Dyers and Colourists, *The Colour Index,* 3rd ed., 4 vol. (1971). F.W. Gibbs, "Invention in Chemical Industries," in Charles Singer *et al.* (eds.), *A History of Technology,* vol. 3, ch. 25 (1957); E.J. Koch, *Rezeptbuch für Faserstoff-Laboratorien* (1960; Eng. trans., *Microscopic and Chemical Testing of Textiles: A Practical Manual,* 1963); Walter Garner, *Textile Laboratory Manual,* 3rd ed., 6 vol. (1966–67); Hans Meier, *Die Photochemie der organischen Farbstoffe*

(1963); FRANCES M. HAMER, *The Cyanine Dyes and Related Compounds* (1964); G. BRITTON, *The Biochemistry of Natural Pigments* (1983); D.H. SOLOMON and D.G. HAWTHORNE, *Chemistry of Pigments and Fillers* (1983). (C.H.Gi./Ed.)

Alkaloids: R.H.F. MANSKE and H.L. HOLMES (eds.), *The Alkaloids: Chemistry and Physiology,* 14 vol. (1950–73), a comprehensive series by authorities in the many fields of alkaloid chemistry, updated at intervals; T. KAMETANI, *The Isoquinoline Alkaloids* (1968), a study of 23 classes of isoquinoline alkaloids with physical properties, structures, and references to discovery and syntheses in tabular form; T. SWAIN (ed.), *Chemical Plant Taxonomy,* ch. 14 (1963), taxonomy from the point of view of molecular relations; R.E. ALSTON and B.L. TURNER, *Biochemical Systematics* (1963), chemical taxonomy from the botanical point of view; R. GOUTAREL, *Les alcaloïdes stéroïdiques des apocynacées* (1964), on isolation, structure, and synthesis; I.D. SPENSER, "The Biosynthesis of Alkaloids and Other Nitrogenous Secondary Metabolites," in M. FLORKIN and E.H. STOTZ (eds.), *Comprehensive Biochemistry,* vol. 20 (1968). See also MAURICE SHAMMA, *The Isoquinoline Alkaloids: Chemistry and Pharmacology* (1972); JOHN S. GLASBY, *Encyclopedia of the Alkaloids,* 4 vol. (1975–83); TREVOR ROBINSON, *The Biochemistry of Alkaloids,* 2nd ed. (1981); S. WILLIAM PELLETIER (ed.), *Alkaloids: Chemical and Biological Perspectives* (1983); A. BAERHEIM SVENDSEN and R. VERPOORTE, *Chromatography of Alkaloids* (1983). (R.H.M.)

Isoprenoids: ERNEST GUENTHER, *The Essential Oils,* 6 vol. (1948–52), a compendium for the general reader of the history, sources, isolation, properties, uses, and analyses of the more volatile isoprenoids; SIR JOHN SIMONSEN *et al., The Terpenes,* 5 vol. (1947–57), an authoritative work on the properties, chemistry, and structures of isoprenoids; WILLIAM TEMPLETON, *An Introduction to the Chemistry of the Terpenoids and Steroids* (1969), a text that requires some knowledge of organic chemistry; L. RUZICKA, "History of the Isoprene Rule," *Proc. Chem. Soc.,* pp. 341–360 (1959), a historical account of the application of the isoprene rule to the structures of terpenoids; J.W. CORNFORTH, "Terpenoid Biosynthesis," *Chem. Brit.* 4:102–106 (1968), a good summary for the nonchemist; JOHN H. RICHARDS and JAMES B. HENDRICKSON, *The Biosynthesis of Steroids, Terpenes and Acetogenins* (1964), details of the biosynthesis of isoprenoids (for the chemist). An interested reader will find the following informative: JOHN S. GLASBY, *Encyclopedia of the Terpenoids,* 2 vol. (1982); FROST & SULLIVAN, *Flavor and Fragrance Market in the U.S.* (1982); UNITED NATIONS INDUSTRIAL DEVELOPMENT ORGANIZATION, VIENNA, *Information Sources on Essential Oils* (1979). (R.H.E.)

Steroids: The chemistry of steroids is comprehensively treated in L.F. and M. FIESER, *Steroids* (1959); more recent information appears in several chapters in S. COFFEY (ed.), *Rodd's Chemistry of Carbon Compounds,* 2nd ed., vol. 2, *Steroids,* 2 pt. (1970–71); for biochemical aspects, see M. FLORKIN and E.H. STOTZ (eds.), *Sterols, Bile Acids and Steroids* (1963); or D.M. GREENBERG, *Metabolic Pathways,* vol. 2 (1968); for comprehensive coverage of the biology and chemistry of the Pill, see D. LEDNICER (ed.), *Contraception: The Chemical Control of Fertility* (1969). For contemporary research see AFANASII A. AKHREM and YURII A. TITOV, *Total Steroid Synthesis* (1970; trans. from the Russian); ROBERT T. BLICKENSTAFF, ANIL C. GHOSH, and GORDON C. WOLF, *Total Synthesis of Steroids* (1974); S. GOROG, *Quantitative Analysis of Steroids* (1983). (R.B.C.)

Coordination compounds: J.C. BAILAR (ed.), *Chemistry of the Coordination Compounds* (1956), a comprehensive monograph containing a historical account and detailed chapters on various specialized topics, such as stereochemistry and applications; F. BASOLO and R.C. JOHNSON, *Coordination Chemistry* (1964), an introductory account with emphasis on reactions of coordination compounds; M.M. JONES, *Elementary Coordination Chemistry* (1964), the most complete elementary account of the subject including nomenclature, descriptive chemistry, bonding, structures, stabilities, and applications; L.E. ORGEL, *An Introduction to Transition-Metal Chemistry: Ligand-Field Theory,* 2nd ed. (1966), a qualitative, highly readable account of coordination and organometallic compounds of transition metals; D.P. GRADDON, *An Introduction to Co-ordination Chemistry,* 2nd ed. (1968), an excellent concise account of the most important aspects of coordination compounds including stereochemistry and applications; J. HALPERN, "Homogeneous Catalysis by Coordination Compounds," *Adv. Chem. Ser.* 70:1–24 (1968), a review of catalysis of hydrogenation and related reactions of olefins; "Coordination Compounds in Homogeneous Catalysis," *Pure Appl. Chem.,* 20:59–75 (1969), a brief general review of the catalytic properties of coordination compounds. Later works include CHARLES C. PRICE and EDWIN J. VANDENBERG (eds.), *Coordination Polymerization* (1983); KENNETH D. KARLIN and JON ZUBIETA (eds.), *Copper Coordination Chemistry: Biochemical and Inorganic Perspectives* (1983); I. BERTINI, R.S. DRAGO, and C. LUCHINAT (eds.), *The Coordination Chemistry of Metalloenzymes: Proceedings of the NATO Advanced Study Institute held at San Miniato, Pisa, Italy, May 28–June 8, 1982* (1983); MILES P. HACKER, EVAN B. DOUPLE, and IRWIN H. KRAKOFF (eds.), *Platinum Coordination Complexes in Cancer Chemotherapy: Proceedings of a Symposium* (1984). (J.Ha.)

Organometallic compounds: E.G. ROCHOW, *Organometallic Chemistry* (1964), a highly readable, general introduction to the subject; G.E. COATES, M.L.H. GREEN, and K. WADE, *Organometallic Compounds,* 3rd ed., 2 vol. (1967–68), the most useful general introduction to the subject, with many illustrative examples. These two works treat both main group and transition-metal organometallics. More detailed books on these separate topics are: J.J. EISCH, *The Chemistry of Organometallic Compounds: The Main Group Elements* (1967); and R.B. KING, *Transition-Metal Organometallic Chemistry* (1969). A series of reviews of particular topics may be found in the serial publication *Advances in Organometallic Chemistry,* ed. by F.G.A. STONE and R. WEST (1964–). Volumes appear at approximately yearly intervals. Extensive coverage is given in M.V. TWIGG (ed.), *Mechanisms of Inorganic and Organometallic Reactions* (1983); STEPHEN G. DAVIES, *Organotransitional Metal Chemistry* (1982); ALAN H. COWLEY (ed.), *Rings, Clusters, and Polymers of the Main Group Elements* (1983); H.M. COLQUHOUN et.al., *New Pathways for Organic Synthesis: Practical Applications of Transition Metals* (1984); SIR GEOFFREY WILKINSON, F. GORDON A. STONE, and EDWARD W. ABLE (eds.), *Comprehensive Organometallic Chemistry: The Synthesis, Reactions, and Structures of Organometallic Compounds* (1982). (M.I.B./F.G.A.S.)

Polymers: Detailed information may be found in the multivolume *Encyclopedia of Polymer Science and Technology,* ed. by H.F. MARK, N.G. GAYLORD, and N.M. BIKALES (1964–). Textbooks on polymer science include: P.J. FLORY, *Principles of Polymer Chemistry* (1953); C.E.H. BAWN, *The Chemistry of High Polymers* (1948); F.W. BILLMEYER, *Textbook of Polymer Science* (1962); and J.K. STILLE, *Introduction to Polymer Chemistry* (1962). Important early technical works are K.H. MEYER and H.F. MARK, *Der Aufbau der hochpolymeren organischen Naturstoffe* (1930), and H. STAUDINGER, *Die hochmolekularen organischen Verbindungen* (1932), two works on high-molecular-weight compounds; H.F. MARK and G.S. WHITBY (eds.), *Collected Papers of Wallace Hume Carothers on High Polymeric Substances* (1940); and K.H. MEYER and H.F. MARK, *Hochpolymere chemie,* 2 vol. (1940; Eng. trans. of vol. 2, *Natural and Synthetic High Polymers,* 2nd ed., 1950). For current data, see the *Journal of Polymer Science* (irreg.); *Journal of Applied Polymer Science* (monthly); *Makromolekulare Chemie* (10–12/year); and *Macromolecules* (bimonthly). Later monographs report extensive research and practical applications: STANLEY R. SANDLER and WOLF KARO, *Polymer Syntheses,* 3 vol. (1974–80); GEORGE MATTHEWS, *Polymer Mixing Technology* (1982); A. CIFERRI, W.R. KRIGBAUM, and ROBERT B. MEYER (eds.), *Polymer Liquid Crystals* (1982); JOHN J. AKLONIS and WILLIAM J. MACKNIGHT, *Introduction to Polymer Viscoelasticity,* 2nd ed. (1983); NORIO ISE and IWAO TABUSHI (eds.), *An Introduction to Speciality Polymers* (1983); CHARLES G. GEBELEIN, DAVID J. WILLIAMS, and RUDOLPH D. DEANIN (eds.), *Polymers in Solar Energy Utilization* (1983); JOSEPH A. BIESENBERGER and DONALD H. SEBASTIAN, *Principles of Polymerization Engineering* (1983); GREGORY R. MOORE and D.E. KLINE, *Properties and Processing of Polymers for Engineers* (1984); BILL M. CULBERTSON and CHARLES U. PITTMAN, JR., *New Monomers and Polymers* (1984); JOSEF JANČA (ed.), *Steric Exclusion Liquid Chromatography of Polymers* (1984). (H.F.M.)

Chemical synthesis: J.B. HENDRICKSON, D.J. CRAM, and G.S. HAMMOND, *Organic Chemistry,* 3rd ed. (1970). ch. 23. "Organic Synthesis," deals with the strategy underlying synthesis; R.B. WOODWARD, "Synthesis," in *Perspectives in Organic Chemistry,* ed. by A.R. TODD (1956), illustrates the diversity of complex molecules that occur naturally and some general considerations pertaining to their synthesis; E.J. COREY, "General Methods for the Construction of Complex Molecules," *Pure Appl. Chem.,* 14:19–37 (1967), deals with the logic of synthesis and with methods of formulating practicable synthetic plans; R.B. MERRIFIELD, "Solid-Phase Peptide Syntheses," *Endeavour,* 24:3–7 (1965), describes a recent development, referred to in the article; E.J. COREY, "Computer-Assisted Analysis of Complex Synthetic Problems," *Q. Rev. Chem. Soc.,* 25:455–482 (1971). See also the following monographic treatments of the topic: RAYMOND K. MACKIE and DAVID M. SMITH, *Guidebook to Organic Synthesis* (1982); STUART WARREN, *Organic Synthesis: The Disconnection Approach* (1982); BRIAN ROBINSON, *The Fischer Indole Synthesis* (1982); RICHARD R. MUCCINO, *Organic Syntheses with Carbon-14* (1983); NITOSI NOZAKI (ed.), *Current Trends in Organic Synthesis: Proceedings of a Conference* (1983); WILLIAM P. WEBER, *Silicon Reagents for Organic Synthesis* (1983). (R.O.C.N.)

Chemical Elements

Chemical elements are the fundamental materials of which all matter is composed. From the modern viewpoint, a substance that cannot be decomposed into simpler substances by ordinary chemical processes is, by definition, an element.

This article considers the origin of the elements and their abundances throughout the universe. The geochemical distribution of these elementary substances in the Earth's crust and interior is treated in some detail, as is their occurrence in the hydrosphere and atmosphere. The article also discusses the periodic law and the tabular arrangement of the elements based on it. The various element groups of the periodic table are described with due attention given to the chief properties and applications of their members. For specific information about the compounds of the elements, see the articles CHEMICAL COMPOUNDS, MOLECULES, and CHEMICAL REACTIONS. Details concerning the structure and properties of matter are provided in ATOMS and MATTER. (Ed.)

This article is divided into the following sections:

General observations. At present there are 110 known chemical elements. (The discovery of element 110, reported in 1987 by Soviet scientists, remains unconfirmed, however, and is still considered extremely tentative.) Elements can combine with one another to form a wide variety of more complex substances called compounds. The number of possible compounds is almost infinite; perhaps a million are known, and more are being discovered every day. When two or more elements combine to form a compound, they lose their separate identities, and the product has characteristics quite different from those of the constituent elements. The gaseous elements hydrogen and oxygen, for example, with quite different properties, can combine to form the compound water, which has altogether different properties from either oxygen or hydrogen. Water clearly is not an element because it consists of, and actually can be decomposed chemically into, the two substances hydrogen and oxygen; these two substances, however, are elements because they cannot be decomposed into simpler substances by any known chemical process. Most samples of naturally occurring matter are physical mixtures of compounds. Seawater, for

Elements, compounds, and mixtures

example, is a mixture of water and a large number of other compounds, the most common of which is sodium chloride, or table salt. Mixtures differ from compounds in that they can be separated into their component parts by physical processes; for example, the simple process of evaporation separates water from the other compounds in seawater.

Historical development of the concept of element. The modern concept of an element is unambiguous, depending as it does on the use of chemical and physical processes as a means of discriminating elements from compounds and mixtures. The existence of fundamental substances from which all matter is made, however, has been the basis of much theoretical speculation since the dawn of history. The ancient Greek philosophers Thales, Anaximenes, and Heracleitus each suggested that all matter is composed of one essential principle—or element. Thales believed this element to be water; Anaximenes suggested air; and Heracleitus, fire. Another Greek philosopher, Empedocles, expressed a different belief—that all substances are composed of four elements: air, earth, fire, and water. Aristotle agreed and emphasized that these four elements are bearers of fundamental properties, dryness and heat being associated with fire, heat and moisture with air, moisture and cold with water, and cold and dryness with earth. In the thinking of these philosophers all other substances were supposed to be combinations of the four elements, and the properties of substances were thought to reflect their elemental compositions. Thus, Greek thought encompassed the idea that all matter could be understood in terms of elemental qualities; in this sense, the elements themselves were thought of as nonmaterial. The Greek concept of an element, which was accepted for nearly 2,000 years, contained only one aspect of the modern definition—namely, that elements have characteristic properties.

In the latter part of the Middle Ages, as alchemists became more sophisticated in their knowledge of chemical processes, the Greek concepts of the composition of matter became less satisfactory. Additional elemental qualities were introduced to accommodate newly discovered chemical transformations. Thus, sulfur came to represent the quality of combustibility, mercury that of volatility or fluidity, and salt that of fixity in fire (or incombustibility). These three alchemical elements, or principles, also represented abstractions of properties reflecting the nature of matter, not physical substances.

The important difference between a mixture and a chemical compound eventually was understood, and in 1661 the English chemist Robert Boyle recognized the fundamental nature of a chemical element. He argued that the four Greek elements could not be the real chemical elements because they cannot combine to form other substances nor can they be extracted from other substances. Boyle stressed the physical nature of elements and related them to the compounds they formed in the modern operational way.

Lavoisier's list of elements

In 1789 the French chemist Antoine-Laurent Lavoisier published what might be considered the first list of elemental substances based on Boyle's definition. Lavoisier's list of elements was established on the basis of a careful, quantitative study of decomposition and recombination reactions. Because he could not devise experiments to decompose certain substances, or to form them from known elements, Lavoisier included in his list of elements such substances as lime, alumina, and silica, which now are known to be very stable compounds. That Lavoisier still retained a measure of influence from the ancient Greek concept of the elements is indicated by his inclusion of light and heat (caloric) among the elements.

Seven substances recognized today as elements (*i.e.,* gold, silver, copper, iron, lead, tin, and mercury) were known to the ancients because they occur in nature in relatively pure form. They are mentioned in the Bible and in an early Hindu medical treatise, the *Caraka-saṃhitā*. Sixteen other elements were discovered in the second half of the 18th century, when methods of separating elements from their compounds became better understood. Eighty-two more followed, after the introduction of quantitative analytical methods.

The atomic nature of the elements. Paralleling the development of the concept of elements was an understanding of the nature of matter. At various times in history, matter has been considered to be either continuous or discontinuous. Continuous matter is postulated to be homogeneous and divisible without limit, each part exhibiting identical properties regardless of size. This was essentially the point of view taken by Aristotle when he associated his elemental qualities with continuous matter. Discontinuous matter, on the other hand, is conceived of as particulate—that is, divisible only up to a point, the point at which certain basic units called atoms are reached. According to this concept, also known as the atomic hypothesis, subdivision of the basic unit (atom) could give rise only to particles with profoundly different properties. Atoms, then, would be the ultimate carriers of the properties associated with bulk matter.

The atomic hypothesis

The atomic hypothesis is usually credited to the Greek philosopher Democritus, who considered all matter to be composed of atoms of the four elements—earth, air, fire, and water. But Aristotle's concept of continuous matter generally prevailed and influenced thought until experimental findings in the 16th century forced a return to the atomic theory. Two types of experimental evidence gave support to the atomic hypothesis: first, the detailed behaviour of gaseous substances and, second, the quantitative weight relationships observed with a variety of chemical reactions. The English chemist John Dalton was the first to explain the empirically derived laws of chemical combination by postulating the existence of atoms with unique sets of properties. At the time, chemical combining power (valence) and relative atomic weights were the properties of most interest. Subsequently numerous independent experimental verifications of the atomic hypothesis were carried out, and today it is universally accepted. Indeed, in 1969 individual uranium and thorium atoms were actually observed by means of an electron microscope.

The structure of atoms. Atoms of elemental substances are themselves complex structures composed of more fundamental particles called protons, neutrons, and electrons. Experimental evidence indicates that, within an atom, a small nucleus, which generally contains both protons and neutrons, is surrounded by a swarm, or cloud, of electrons. The fundamental properties of these subatomic particles are their weight and electrical charge. Whereas protons carry a positive charge and electrons a negative one, neutrons are electrically neutral. The diameter of an atom (about 10^{-8} centimetre) is 10,000 times larger than that of its nucleus. Neutrons and protons, which are collectively called nucleons, have relative weights of approximately one atomic mass unit, whereas an electron is only about $^1/_{2000}$ as heavy. Because neutrons and protons occur in the nucleus, virtually all of the mass of the atom is concentrated there. The number of protons in the nucleus is equivalent to the atomic number of the element. The total number of protons and neutrons is called the mass number because it equals the relative weight of that atom compared to other atoms. Because the atom itself is electrically neutral, the atomic number represents not only the number of protons, or positive charges, in the nucleus but also the number of electrons, or negative charges, in the extranuclear region of the atom.

Composition of atoms

The chemical characteristics of elements are intimately related to the number and arrangement of electrons in their atoms. Thus, elements are completely distinguishable from each other by their atomic numbers. The realization that such is the case leads to another definition of an element, namely, a substance, all atoms of which have the same atomic number.

The existence of isotopes. Careful experimental examination of naturally occurring samples of many pure elements shows that not all the atoms present have the same atomic weight, even though they all have the same atomic number. Such a situation can occur only if the atoms have different numbers of neutrons in their nuclei. Such groups of atoms—with the same atomic number, but with different relative weights—are called isotopes. The number of isotopic forms that a naturally occurring element possesses ranges from one (*e.g.*, fluorine) to as many as ten (*e.g.*, tin); most of the elements have at least two isotopes. The atomic weight of an element is usually determined on large numbers of atoms containing the natural distribution of isotopes, and, therefore, it represents the average isotopic weight of the atoms constituting the sample. More recently, precision mass-spectrometric methods have been used to determine the distribution and weights of isotopes in various naturally occurring samples of elements.

(J.J.L.)

ORIGIN OF THE ELEMENTS

Nuclear fusion

The fundamental reaction that produces the huge amounts of energy radiated by the Sun and most other stars is the fusion of the lightest element, hydrogen, its nucleus having a single proton, into helium, the second lightest and second most abundant, with a nucleus consisting of two protons and two neutrons. In many stars the production of helium is followed by the fusion of helium into heavier elements, up to iron. The still heavier elements cannot be made in energy-releasing fusion reactions; an input of energy is required to produce them (see below *Processes producing heavier elements*).

The proportion of different elements within a star—*i.e.*, its chemical composition—is gradually changed by nuclear fusion reactions. This change is initially concentrated in the central regions of the star where it cannot be directly observed, but it alters some observable properties of the star, such as brightness and surface temperature, and these alterations are taken as evidence of what is going on in the interior. Some stars become unstable and discharge some transmuted matter into interstellar space; this leads to a change in the chemical composition of the interstellar medium and of any stars subsequently formed. The main problem concerned with the origin of the chemical elements is to decide to what extent the chemical composition of the stars seen today differs from the initial chemical composition of the universe and to determine where the change in chemical composition has been produced. Reference is made below to the chemical composition of the universe, but most of the observations refer to our own and neighbouring galaxies.

Cosmic abundances of the elements

The relative numbers of atoms of the various elements are usually described as the abundances of the elements. The chief sources of data from which information is gained about present-day abundances of the elements are observations of the chemical composition of stars and gas clouds in the Galaxy, which contains the solar system and part of which is visible to the naked eye as the Milky Way; of neighbouring galaxies; of the Earth, Moon, and meteorites; and of the cosmic rays.

STARS AND GAS CLOUDS

Spectroscopic analysis

Atoms absorb and emit light, and the atoms of each element do so at specific and characteristic wavelengths; a spectroscope spreads out these wavelengths of light from any source into a spectrum of bright-coloured lines, a different pattern identifying each element; when light from an unknown source is analyzed in a spectroscope, the different patterns of bright lines in the spectrum reveal which elements emitted the light. Such a pattern is called an emission, or bright-line, spectrum. When light passes through a gas or cloud at a lower temperature than the light source, the gas absorbs at its identifying wavelengths and a dark-line, or absorption, spectrum will be formed.

Thus, absorption and emission lines in the spectrum of light from stars yield information concerning the chemical composition of the source of light and of the chemical composition of clouds through which the light has travelled. The absorption lines may be formed either by interstellar clouds or by the cool outer layers of the stars. The chemical composition of a star is obtained by a study of absorption lines formed in its atmosphere.

The presence of an element can, therefore, be detected easily, but it is more difficult to determine how much of it there is. The intensity of an absorption line depends not only on the total number of atoms of the element in the atmosphere of the star but also on the number of these atoms that are in a state capable of absorbing radiation of the relevant wavelength and the probability of absorption occurring. The absorption probability can, in principle, be measured in the laboratory, but the whole physical structure of the atmosphere must be calculated to determine the number of absorbing atoms. Naturally, it is easier to study the chemical composition of the Sun than of other stars, but, even for the Sun, after many decades of study, there are still significant uncertainties of chemical composition. The spectra of stars differ considerably, and originally it was believed that this indicated a wide variety of chemical composition. Subsequently, it was realized that it is the surface temperature of a star that largely determines which spectral lines are excited and that most stars have similar chemical compositions.

There are, however, differences in chemical composition among stars, and these differences are important in a study of the origin of the elements. Studies of the processes that operate during stellar evolution enable estimates to be made of the ages of stars. There is, for example, a clear tendency for very old stars to have smaller quantities of elements heavier than helium than do younger stars. This suggests that the Galaxy originally contained little of the so-called heavy elements (elements beyond helium in the periodic table); and the variation of chemical composition with age suggests that heavy elements must have been produced more rapidly in the Galaxy's early history than now. Observations are also beginning to indicate that chemical composition is dependent on position in the Galaxy as well as age, with a higher heavy-element content near the galactic centre.

In addition to stars, the Galaxy contains interstellar gas and dust. Some of the gas is very cold, but some forms hot clouds, the gaseous nebulae, the chemical composition of which can be studied in some detail. The chemical composition of the gas seems to resemble that of young stars. This is in agreement with the theory that young stars are formed from the interstellar gas.

COSMIC RAYS

High energy electrons and atomic nuclei known as cosmic rays reach the Earth from all directions in the Galaxy (see COSMOS: *Cosmic rays*). Their chemical composition can be observed only to a limited extent, but this can give some information about their place of origin and possibly about the origin of the chemical elements.

The cosmic rays are observed to be proportionately richer in heavy elements than are the stars, and they also contain more of the light elements lithium, beryllium, and boron, which are very rare in stars. One particularly interesting suggestion is that transuranium nuclei may have been detected in the cosmic rays. Uranium is element 92, the most massive naturally occurring on Earth; 13 elements beyond uranium (called the transuranium series) have been created artificially. All transuranium nuclei are highly unstable, which would seem to indicate that the cosmic rays must have been produced in the not too distant past.

(R.J.T.)

SOLAR SYSTEM

Direct observations of chemical composition can be made for the Earth, the Moon, and meteorites, although there are some problems of interpretation. The chemical composition of the Earth's crust, oceans, and atmosphere can be studied, but this is only a minute fraction of the mass of the Earth, and there are many composition differences even within this small sample. Some information about the chemical properties of the Earth's unobserved interior can be obtained by the study of the motion of earthquake

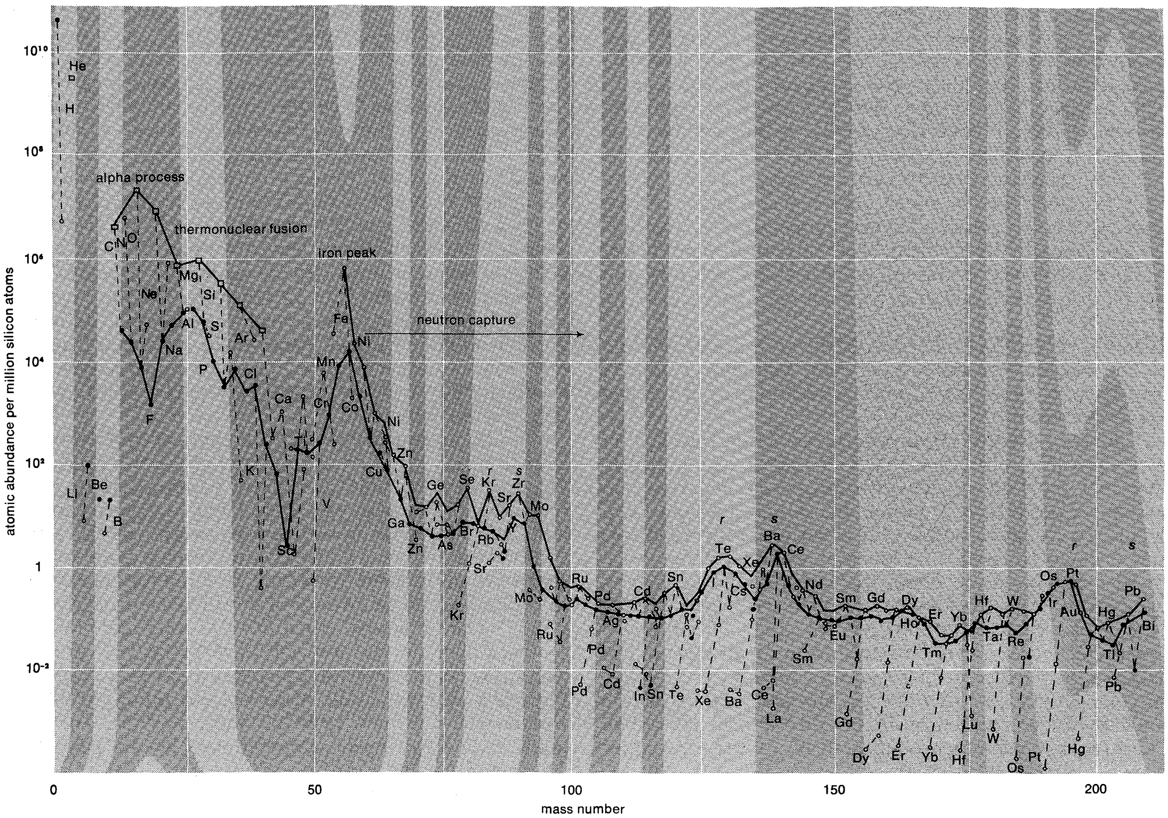


Figure 1: Nuclear abundances plotted against atomic mass number. Filled circles represent nuclei with odd mass numbers; open circles, even mass numbers; open squares, nuclei that can be reduced to helium nuclei (alpha particles). Broken lines join isotopes of given elements; upper solid line at left joins alpha-particle nuclei; upper solid line at right joins nuclei with even mass numbers; the lower solid line joins those with odd mass numbers. The letters *r*, *s* refer to elements formed by the rapid and slow neutron-capture processes.

This diagram first appeared in *New Scientist*, vol. 26, 1965, B. Pagel

waves and by the Earth's magnetic field, which originates in the interior (see below *Geochemical distribution of the elements*).

The Apollo data

Until recently, more was known about element abundances in distant stars than in the Earth's nearest neighbour, the Moon. The lunar landings have provided samples that have been intensively analyzed in many laboratories throughout the world. The data for the Apollo 11 material, collected in the Sea of Tranquility (Mare Tranquillitatis), are given in Table 3. Analyses of Apollo 12 collections are similar for most of the elements. Comparison of the analytical data with those for carbonaceous chondrites (a type of meteorite that provides a good average sample of nonvolatile solar system material) shows that the lunar material has undergone marked geochemical fractionation (segregation of elements). Meteorites suffer from heating in the Earth's atmosphere, so that what is found on Earth is not necessarily the original chemical composition of the meteorites, especially for the volatiles, light gases that are easily lost. When allowance is made for the loss of volatile light gases and for effects of chemical separation, it seems quite possible that the overall chemical composition of the Earth, Moon, Sun, and the meteorites is essentially the same and that they have a common origin.

If elemental abundances are the same in the Earth and stars, isotopic abundances are likely to be the same. Theories predict the relative production of the different isotopes, and it is desirable to be able to compare these with observation. The study of terrestrial abundances of radioactive elements yields information about the age of the solar system, which is discussed below. (R.J.T./Ed.)

SUMMARY OF OBSERVATIONS

The Suess–Urey abundance table

The chemical composition of all objects in the universe is not quite the same, and not all elements can be observed in any one object, even if they are present. Nevertheless, the compositions of many objects are sufficiently similar to make it worthwhile to try to construct a typical table of abundances. Such compilations have been made by several authors and the best known, the work of the American physicists Hans Suess and Harold Urey, is shown in Figure 1. Although this dates from 1956, and later compilations differ in some details, its general character is not in dispute.

The main properties shown in the abundance table (Figure 1) are quite clear. Hydrogen and helium are much more common than all of the other elements. There is a gradual decline toward higher atomic number with a great underabundance of lithium, beryllium, and boron. There is a significant peak in the region of iron, the element with the highest fractional binding energy, and the decline continues to higher atomic number with some subsidiary peaks. These peaks are associated with nuclei containing 50, 82, or 126 neutrons; the theory of nuclear structure predicts that these nuclei should be particularly stable, and these numbers are known as "magic" numbers.

Processes producing heavier elements

As mentioned above, energy can be released by either nuclear fusion or fission reactions and there will be a tendency for material to be gradually converted into elements with maximum binding energy. As observations suggest that hydrogen and helium are much more abundant than other elements, and there is an abundance peak near iron, it is generally supposed that heavy elements have been built up from light elements. In addition, some sites in which element transmutations can occur are known; for example, the interiors of stars tend to get hotter as they evolve, and a succession of nuclear reactions provides the energy that they radiate. Whether or not stars are the site of major nucleosynthesis, some nucleosynthesis certainly occurs there.

Atomic nuclei interact through two strong forces. Be-

Conditions for fusion

cause they have positive electric charges, they repel one another, but there is also a very short-range strong nuclear interaction that is attractive. This may cause fusion reactions to occur if the nuclei ever approach close enough for it to be operative. To overcome the electrical repulsion, the particles must be moving rapidly, as they will be if the material is at a high temperature. The overcoming of the electrical repulsion leads to what are known as thermonuclear reactions. Heavy nuclei have higher electric charges than light nuclei, and a higher temperature is required for reactions between them. The rate of thermonuclear reactions depends on density as well as temperature, but the temperature dependence is much more critical.

REACTION STAGES REFLECTING INCREASING TEMPERATURE

If one imagines a mixture of light elements gradually heated up, a succession of nuclear reactions occurs that is described below.

Hydrogen burning. Hydrogen is converted into helium by a succession of nuclear reactions that change four protons into a helium nucleus, two positrons, and two neutrinos. (A positron is a particle like an electron but with a positive charge; a neutrino is a particle with no charge and negligible mass.) Two different reaction chains exist. In the proton–proton chain the helium nucleus is built up directly from protons. In another series of reactions that involve carbon and nitrogen, called the carbon–nitrogen cycle, the nuclei of carbon and nitrogen are used as catalysts to transform hydrogen into helium; protons are successively added to carbon or nitrogen until a helium nucleus can be emitted by them and the original carbon or nitrogen nucleus reproduced. Both of these reactions occur at temperatures of about 10,000,000 to 20,000,000 K (10,000,000 K is approximately 18,000,000° F).

Helium burning. At temperatures of about 100,000,000 to 200,000,000 K (1 to 2×10^8 K), three helium nuclei can fuse to form carbon. This reaction takes place in the following way: two helium nuclei combine to form an unstable isotope of beryllium, which has an extremely short life; rarely, a third helium nucleus can be added to form carbon before the beryllium decays. Subsequently, a fourth helium nucleus may combine with carbon to give oxygen. The relative amounts of carbon and oxygen produced depend on the temperature and density at which helium is burned.

Carbon and oxygen burning. At temperatures between 5×10^8 K and 10^9 K, pairs of carbon and oxygen nuclei can fuse to produce such elements as magnesium, sodium, silicon, and sulfur.

Silicon burning. Further heating of the material leads to a complicated set of nuclear reactions whereby the elements produced in carbon and oxygen burning are gradually converted into the elements of maximum fractional binding energy; *e.g.,* chromium, manganese, iron, cobalt, and nickel. These reactions have collectively been given the name silicon burning because an important part of the process is the breaking down of silicon nuclei into helium nuclei, which are added in turn to other silicon nuclei to produce the elements noted above.

Reversible nuclear reaction equilibrium. Finally, at temperatures around 4×10^9 K, an approximation to nuclear statistical equilibrium may be reached. At this stage, although nuclear reactions continue to occur, each nuclear reaction and its inverse occur equally rapidly, and there is no further overall change of chemical composition. Thus, the gradual production of heavy elements by nuclear fusion reactions is balanced by disintegrations, and the buildup process effectively ceases once the material is predominantly in the form of iron and its neighbouring elements of the periodic table. Indeed, if further heating occurs, a conversion of heavy nuclei to light nuclei follows in much the same way as occurs in the ionization of atoms when they are heated up. The elements heavier than iron cannot be produced by fusion reactions between light elements; an input of energy is required to produce them.

NEUTRON CAPTURE

It is believed that these heavier elements, and some isotopes of lighter elements, have been produced by successive capture of neutrons. Two processes of neutron capture may be distinguished: the *r*-process, rapid neutron capture; and the *s*-process, slow neutron capture. If neutrons are added to a stable nucleus, it is not long before the product nucleus becomes unstable and the neutron is converted into a proton. Outside a nucleus, a neutron decays into a proton and an electron by a process called beta decay (β-decay). Inside a nucleus it can be stable if the nucleus does not contain too many neutrons. In slow neutron capture, neutrons are added at a rate such that whenever an unstable nucleus is formed, it beta-decays before another neutron can be added. If neutrons can be added more rapidly, as in the *r*-process, the unstable nuclei formed cannot decay before additional neutrons are added until a nucleus is eventually produced that will not accept a further neutron. This nucleus, however, will eventually be subject to beta decay, thus permitting further neutron capture.

Rapid and slow processes of neutron capture

It can be imagined that neutron capture could proceed at an arbitrary rate, giving a mixture of the two processes, but, when the possible sites where neutron-capture reactions could take place are considered, it appears that a fairly clean-cut division between the two processes can be made. If the neutron capture occurs during a quiet stage of stellar evolution, there will be ample time for beta decays to occur, and an *s*-process will result. If neutron capture occurs in an explosive situation, the time scale will be so short that the reaction will have to be an *r*-process. The *r*-process produces the most neutron-rich isotopes of the heavy elements, while those isotopes produced by the *s*-process tend to have relatively more protons. The naturally radioactive nuclei are produced by the *r*-process. The neutron-capture processes appear to give a simple explanation of the magic-number abundance peaks mentioned earlier.

Two small groups of nuclei are not readily fitted into either the sequence of nuclear fusion reactions or the neutron-capture processes. These are nuclei with very low relative abundances. One group consists of the light-nuclei lithium, beryllium, and boron, together with the heavy stable isotope of hydrogen, deuterium. These nuclei are destroyed by nuclear fusion reactions at temperatures lower than that needed to convert hydrogen into helium, and they are bypassed by the production of carbon from helium. The other group consists of the most proton-rich isotopes of some heavy elements, which cannot be produced by the addition of neutrons. Two rather rare or inefficient processes would suffice to produce these isotopes, but there is no complete agreement about what these processes are. It has been suggested that the heavy, proton-rich isotopes might be produced by a process of proton capture and that lithium, beryllium, and boron have been produced by the breakdown of heavier nuclei. A recent suggestion is that they are produced in interstellar space by collisions between cosmic-ray protons and interstellar carbon, nitrogen, and oxygen.

Regions of element synthesis

A discussion of how the present chemical composition of the universe has arisen brings to light two distinct questions: what was the initial chemical composition and what alterations have occurred since creation. Ideally, by working backwards, the initial composition can be deduced from the present composition and a life-history, but this approach is overambitious. The initial composition predicted by simple cosmological theory can then be tested for compatibility with present observations. Element production in the universe as a whole can be discussed first; production in stars and other objects in the Galaxy is treated in the sections that follow.

ELEMENT PRODUCTION IN THE UNIVERSE AS A WHOLE

Hydrogen and helium are overwhelmingly the most abundant elements in the objects of which there is direct knowledge, and, as some buildup of heavy elements occurs in stars, the working hypothesis is usually adopted that the initially created matter contained only light elements. Theories differ only as to whether the initial composition was pure hydrogen or whether there was also a substantial amount of helium.

It is usual to try to devise the simplest theory that can account for the small number of reliable observations of agreed cosmological significance. This need not imply that the universe is simple, but, rather, that it is easiest to work out the consequences of simple theories and there is a better chance of discovering contradictions before too much time has been wasted on detail. The simplest assumption, made in several theories, about the initial chemical composition is that it was pure hydrogen, the hope being that it can be shown that all other elements have been synthesized during the lifetime of the universe.

In the steady-state theory, in which matter is assumed to be continuously created, the initial composition is arbitrary, although supporters of the steady-state theory have always hoped that production of pure hydrogen would give a consistent picture of the universe. In the big-bang theory, which has received much attention in recent years, there is considerably less freedom of choice. Observations of distant galaxies suggest that the universe is expanding and, if this is so, that galaxies may have been very close together about 10,000,000,000 years ago. In the big-bang theory it is assumed that the universe was created at that time and, in the simplest version, that at its creation the universe was very hot as well as very dense. Nuclear reactions in the early stages of the expansion lead to a rather well-defined initial chemical composition for the universe.

Although there are more complicated big-bang theories than the one just mentioned, there is only one arbitrary quantity in the simplest theory, and assignment of some arbitrary specified value to any one of the unknowns will determine the others. If, for example, the density of the universe is specified at some temperature (perhaps 10^{10} K), the subsequent life history of the universe is, in principle, determined. For a wide range of values of this density, the chemical composition after the initial phase is a mixture of hydrogen and helium, with between 20 percent and 30 percent by mass in the form of helium. Most study in recent years has been concerned with trying to decide whether an initial chemical composition devoid of helium or one with 25 percent helium is most likely to be consistent with present observations.

Observed helium content

There are two particular reasons why interest in the big-bang theory has recently been stimulated. The first is concerned with the observed helium content of objects in the Galaxy. It is not always easy to estimate the helium abundance in a star or gas cloud, but most estimates have indicated helium abundances greater than 25 percent by mass. Such values would fit in well with most of the helium being primeval and a small admixture having been produced in stars in the galactic lifetime. The second reason for interest in the big-bang theory is the discovery that very short radio waves, microwaves, are observed to be reaching the Earth from all directions in space. According to the big-bang theory, the universe was filled with radiation in its early stages and most of this radiation has never subsequently been absorbed. As the universe has expanded, the radiation has been shifted toward longer wavelengths by the Doppler effect, a change in wavelength brought about by motion of the source with respect to the observer. As a result of this effect, the radiation created by the big bang would be expected to appear today as microwaves of just the type that have been observed.

The big-bang theory not only predicts that all objects, except those in which the helium can have been destroyed, should have a minimum of about 25 percent helium but that the microwave radiation should have a particular distribution with frequency known as the Planck form. The theory can be proved false either if objects are discovered with a substantially smaller amount of helium than 25 percent or if the microwave spectrum does not have the Planck form. Several observations have been made which suggest that the theory is false, but to date none of them appears to be conclusive.

ELEMENT PRODUCTION IN STARS

A substantial amount of nucleosynthesis must have occurred in stars. It was stated above that a succession of nuclear fusion reactions takes place as the temperature of the stellar material rises. Theories of stellar evolution indicate that the internal temperatures of stars first rise during their life history and eventually fall after reaching a maximum value. For very low-mass stars, the maximum temperature may be too low for any significant nuclear reactions to occur, but for stars as massive as the Sun or greater, most of the sequence of nuclear fusion reactions described above can occur. Moreover, a time scale for stellar evolution is derived in theories of stellar evolution that show that stars substantially more massive than the Sun can have completed their active life history in a time short compared with the age of the universe derived from the big-bang cosmological theory.

This result implies that stars more massive than the Sun, which were formed very early in the life history of the Galaxy, could have produced some of the heavy elements that are seen today but that stars much less massive than the Sun could have played no part in this production. Unless the Galaxy is very much older than is generally believed, such low mass stars, even if formed with the Galaxy, would still be at an early stage in their evolution because changes within them proceed at a relatively slow pace. If there has been substantial heavy-element production in stars, a sufficient fraction of the earliest stars formed must have been relatively massive.

Mass loss in stars

If substantial nucleosynthesis has occurred in stars, could such a process have produced all of the heavy elements that are observed today and possibly all of the helium inside the stars? A vital point is the following: if the heavy elements produced in stars are to influence what is observed, they must be expelled from the interiors of the stars in which they are produced and incorporated into future generations of stars, in which they can be observed subsequently. Unfortunately, direct knowledge of mass loss from stars is fragmentary; steady loss of mass is observed in some stars, and a few are observed to explode catastrophically, as in the explosion of a supernova. At present it is only possible for a very rough estimate to be made of the rate of exchange of matter between stars and the interstellar medium.

Supernovae are believed to be stars reaching the end of their evolution, and many astronomers believe that a supernova explosion is the main process whereby heavy elements produced inside stars are returned to the interstellar medium. In addition, because a supernova explosion is the most violent type of event regularly observed in galaxies, it is believed that cosmic rays must also be produced in the explosion. Some rough estimates follow. The mass of the Galaxy is believed to be between 10^{11} and 2×10^{11} solar masses, and perhaps 2×10^{9} solar masses are heavy elements. If these heavy elements were produced steadily in a galactic lifetime of about 10^{10} years, one-fifth of a solar mass of heavy elements must have been produced each year. Counts of supernovae in nearby galaxies suggest that there might be one supernova explosion per large galaxy about every 30 years. If all the heavy elements are produced in supernovae, about six solar masses are required from each explosion. Although these numbers are very uncertain, this amount seems too large, but it could be reduced if the frequency of supernovae is very much higher in young galaxies. The possibility remains that a significant quantity of heavy elements may be produced by a very large number of less spectacular stars or by much more massive objects that are mentioned below.

If there has been a gradual production of heavy elements, recently formed stars should contain more than old stars. It is possible to identify some stars which have formed quite recently. The light output of stars rises as a rather high power of their mass according to a mass–luminosity relation that is valid for the vast majority of stars whose masses are known, while their supply of nuclear energy is only directly proportional to the mass. This means that the more massive stars complete their life history much more rapidly than low-mass stars and that the brightest stars observed today cannot be more than a few million years old at the most. The heavy-element content of the young stars is greater than that of many old stars, perhaps because of a gradual increase in the heavy-element content of the interstellar medium from which stars are formed. Observations show that only the very oldest stars have an extremely small amount of very heavy elements in their visible layers, and it appears that element production must have been much more rapid when the Galaxy was young than it is now. There may indeed have been a much higher frequency of supernovae. Recent observations suggest also that chemical composition is a function of a star's place of origin as well as its age. In particular, the production of heavy elements may have been higher near the centre of the Galaxy than elsewhere (see below *Element production in massive objects*).

Although the first nuclear reaction to occur in stars is the conversion of hydrogen into helium, all of the helium that is observed today can hardly have been produced in ordinary stars, the more so if all objects contain more than about 25 percent helium by mass. Considering the relative amounts of helium and heavier elements, observations indicate that the total mass of helium may be ten times greater than that of the heavier elements; if all elements other than hydrogen have been produced in stars, the relative production of helium and heavier elements must have just this value. As stars evolve, however, the conversion of hydrogen into helium is followed by the conversion of helium into heavier elements. At all stages in a star's evolution there will be a region where the temperature is suitable for the conversion of hydrogen into helium, but it appears that there will be only a thin shell of helium separating the regions in which hydrogen has not yet been converted into helium and the region where helium has been burned into heavy elements. The possible chemical composition of a highly evolved star is a series of layers of different chemical composition. The central region would contain elements such as iron and nickel with layers of successively lighter elements surrounding it and the outermost layer containing essentially only hydrogen or hydrogen and helium. A very special type of mass loss would be required to expel 10 times as much helium as heavy elements from these different layers into interstellar space.

Layers of elements

It is also difficult to see how the full amount of helium could have been produced. If a quarter of the galactic mass, originally hydrogen, has been converted into helium, it can be shown that essentially all of the mass must have passed through at least one generation of massive stars. The total energy release under such a circumstance would imply that the Galaxy was very much more luminous in the past—one hundred times more luminous for the first 10 percent of its lifetime, for example.

ELEMENT PRODUCTION IN MASSIVE OBJECTS

Collapse in supermassive stars

Although there is no direct evidence for the existence of stars more than about 50 times as massive as the Sun, there is no obvious reason why much more massive objects should not exist. If they were sufficiently massive, they would not behave as ordinary stars because their gravitational attraction would be so strong that not even the energy released by conversion of hydrogen into helium would prevent such supermassive stars from continuing to collapse rapidly. According to present theoretical ideas, if such a collapse is spherically symmetrical, nothing can prevent the supermassive object from collapsing to an extremely high or infinite density; but, if it is asymmetrical—because it is, for example, rapidly rotating—there is some possibility that the catastrophic collapse, called an implosion, might be followed by explosion. At the high-density, high-temperature phase of such an object, some nucleosynthesis (manufacture of nuclei from smaller nuclei) would occur, primarily of helium but with a small amount of heavier elements according to the arguments given early in this article. Such objects have been suggested as a possible important source of helium.

There is some observational evidence that explosions on a very much greater scale than single supernovae are occurring in galaxies. In some peculiar galaxies that are strong emitters of radio waves, there is evidence that explosions have thrown a large quantity of gas hundreds of thousands of light-years into intergalactic space. Such galactic explosions may not be related to the theoretical supermassive objects mentioned above, but it is difficult to believe that some nucleosynthesis does not take place during the phases of extreme conditions that must occur in such objects. The suggestion that heavy-element abundances may be higher near the centre of the Galaxy could be related to a past explosion there.

Radioactive chronologies

Radioactive elements in the Earth, the Moon, and in meteorites can provide useful information about the ages of these objects and about the dates of formation of the heavy elements themselves. The elements uranium and thorium gradually decay into lead, different isotopes of lead arising from the various isotopes of uranium and thorium; some isotopes of lead are, however, not produced by any radioactive decay process. When the rocks of the Moon or the Earth's crust or the meteorites solidified, further chemical separation of the radioactive elements and their decay products was prevented. By studying the relative amounts of the radioactive isotopes and their decay products, it is possible to obtain an estimate of when the rocks solidified. Estimates can also be made using radioactive isotopes other than uranium and thorium.

The results of these discussions indicate that the meteorites, or at least the parent body of the meteorites, solidified between 4.5×10^9 and 4.6×10^9 years ago. It is possible to speak with such confidence of this age because two isotopes of uranium and one of thorium have very different decay times that bracket that value. There is no unique age for the rocks of the Earth's crust because there has been considerable volcanic activity during the Earth's history and rocks have solidified at all stages. All indications are that the oldest rocks have ages of the same order as the ages of the parent bodies of the meteorites. Only a very small region of the Moon's surface has been studied so far, but it has been found to have very old rocks of age up to about 4.5×10^9 years. No conclusions can be drawn about the date of solidification of the Moon from these few observations, as nothing is known about its past geological history, but they are certainly not inconsistent with the view that the Earth, the Moon, and meteorites have a similar age and origin.

Radioactive nuclei

It has also been found possible to obtain information about the time of formation of the radioactive elements. Assuming that both radioactive nuclei and their stable neighbours are produced by the neutron-capture process discussed earlier, theory predicts a relative production rate for all of the nuclei. The radioactive nuclei can be divided into three groups: short-lived, medium-lived, and long-lived, where short-lived means considerably less than the believed age of the universe and long-lived means comparable with that age. If radioactive nuclei are produced and decay steadily, then at some point in time the total amount of a short-lived isotope reaches a steady value. In meteorites, one can study the decay products of such short-lived nuclei and can discover their abundance when the meteorites were formed. This amount is lower than the expected value, suggesting that nucleosynthesis ceased in the solar system material about 2×10^8 years before the meteorites and planets solidified.

Study of the decay products of nuclei with medium decay rates indicates that their abundance is higher than if nucleosynthesis has occurred at a constant rate throughout galactic history. This suggests that the solar system material was significantly enriched in heavy elements shortly before the cessation of nucleosynthesis—that is, before the Sun and planets were formed. Finally, the very long-lived isotopes give information about the total time scale of nucleosynthesis that is not inconsistent with the galactic age estimated by other methods.

Although there is not unanimous agreement concerning these results, it appears that it is, in principle, possible to obtain a considerable amount of information about the past rate of nucleosynthesis and possibly about the types of objects in which it has occurred. In particular, it may eventually be possible to decide whether most element production has occurred in a large number of supernovae or in a much smaller number of massive objects.

(R.J.T.)

GEOCHEMICAL DISTRIBUTION OF THE ELEMENTS

Basic work of Clarke and Goldschmidt

Knowledge of the geochemical distribution of elements involves elucidation of the relative and absolute abundances of the chemical elements in the Earth and in its various parts—the crust, interior, atmosphere, and hydrosphere. This comprises a major part of the science of geochemistry, which is the study of the distribution of the chemical elements in space and time and the laws governing this distribution. Basic knowledge in this area was largely accumulated during the 19th century. As noted above, the concept of a limited number of chemical elements had been established by 1800, and the appearance of the periodic table, in 1869, provided a new insight into the limitations on the number of elements. Concurrent with these advances in chemical understanding, from about 1850 onward there was a steadily increasing output of analytical data on the Earth's rocks, minerals, and waters, mainly from laboratories in Europe and North America. The output from North America was materially increased following the establishment of the United States Geological Survey in 1879 and the appointment of Frank W. Clarke as chief chemist in 1884.

Clarke's name will always be linked with the study of the geochemical distribution of the elements—indeed, the term clarke was proposed as the unit for the average percentage of an element in the Earth's crust by Soviet scientists and has been generally adopted. In 1889 Clarke wrote the first of his many publications on the geochemical distribution of the elements. He assembled many chemical analyses of rocks from different continents, calculated average values, and showed that the overall chemical compositions of continental areas are remarkably similar. By combining these averages he obtained values for the abundances of the commoner elements in the continental crust of the Earth, values that have not been materially changed in spite of the vast increase of available data since that time. He also estimated abundances for many of the less common elements; these estimates were based in many instances on very limited and imprecise data and subsequently have been improved.

A further development of great significance was the assemblage of comprehensive data on the abundances of individual elements in terrestrial materials and in the Cosmos (based on solar and meteorite abundances) by the Norwegian geochemist Victor Moritz Goldschmidt during the 1930s. Goldschmidt's tables provided the basis for modern research on the geochemical distribution of the elements, and his compilation of data on cosmic abundances was the key to later theories on element synthesis in stars and supernovae.

Goldschmidt also contributed to the understanding of elemental distribution within the Earth through his geochemical classification of the elements into lithophile, siderophile, chalcophile, and atmophile. Lithophile elements are those with a strong affinity for oxygen; they are concentrated in the crust or lithosphere as silicate and oxide minerals. Siderophile elements are principally metals that alloy readily with iron; Goldschmidt explained their scarcity in the Earth's crust by their concentration in the nickel–iron core (the siderosphere). Chalcophile elements are those with strong affinity for sulfur; they occur mainly as sulfides. And atmophile elements are gases, such as nitrogen, argon, and other rare gases, which are unreactive and hence accumulate in the atmosphere. (Goldschmidt also proposed a group of biophile elements, for those that concentrate in living matter—essentially carbon, hydrogen, oxygen, nitrogen, sulfur, and phosphorus.)

Terrestrial distribution

The study of earthquake waves passing through the body of the Earth has shown that the interior is not uniform; it consists of distinct shells separated by concentric discontinuities at which the velocities of the passing waves change. The two major discontinuities that are universally recognized are the Mohorovičić Discontinuity, which divides the Earth's crust from its underlying mantle, and the Wiechert–Gutenberg Discontinuity, which separates the mantle from the core. The latter discontinuity exists at a depth of 2,900 kilometres (1,800 miles); it is marked by a sudden increase in density, from about 5.7 at the base of the mantle to 9.7 at the top of the core. The only reasonable interpretation of this discontinuity is that the mantle consists of silicates and oxides of the common elements (largely magnesium and iron), and the core consists of metallic iron alloyed with minor amounts of other elements (analogous to the nickel-iron in meteorites). The Mohorovičić Discontinuity varies in depth from place to place; it averages about 33 kilometres (20 miles) below the continents and about 8 kilometres (5 miles) below the bottom of the deep oceans. It too is marked by a density increase from crust to mantle—a comparatively small one, from about 3 to 3.3.

To the three spherical divisions—crust, mantle, and core—two more should be added: the hydrosphere, which is the discontinuous shell of fresh and salt water, on and within the crust; and the atmosphere, the ocean of air that surrounds the Earth, gradually thinning into the vacuum of outer space. The principal characteristics of these "geospheres" are set forth in Table 1.

Table 1: Volume and Masses of Earth Shells

	thickness (km)	volume ($\times 10^{27}$ cm^3)	mean density (g/cm^3)	mass ($\times 10^{27}$ g)	mass (percent)
Atmosphere	—	—	—	0.000005	0.00009
Hydrosphere	3.73 (mean)	0.00135	1.03	0.00139	0.024
Crust	20 (mean)	0.010	2.8	0.029	0.5
Mantle	2,880	0.897	4.5	4.010	67.1
Core	3,471	0.175	11.0	1.936	32.4
Whole Earth	6,371	1.083	5.52	5.976	100.00

THE EARTH'S CORE

The evidence for the composition of the core is all indirect because no means have yet been devised for directly sampling the deep interior of the Earth. The moment of inertia of the Earth indicates that there is a concentration of mass around the centre, and seismic data have shown that below the Wiechert–Gutenberg Discontinuity the density of the material is high, ranging upwards from 9.7. The only heavy element with high cosmic abundance is iron, and because an iron–nickel alloy is an important meteorite component, it is reasonable to conclude that the Earth's core consists largely of metallic iron with a minor admixture of other elements. This conclusion is supported by geophysical evidence that indicates that the mean atomic number of the material of the core is about 22. The atomic number of iron is 26, so this implies that the core also contains elements of lower atomic number. Sulfur, with atomic number 16, and carbon, 6, are relatively abundant in meteoritic matter, and the presence of minor amounts of these elements in the core would effectively reduce the mean atomic number. Some authorities have advocated silicon (atomic number 14) as the major alloying component in the core, but this seems less likely; if silicon were the sole alloying element, then the core would have to contain more than 30 percent silicon in order to reduce its mean atomic number to 22. In addition, free silicon requires extremely reducing conditions (lack of oxygen), and the presence of ferrous iron in the mantle is inconsistent with this requirement.

It is not possible to give definite figures for the abundances of the elements in the Earth's core. It is certainly made up largely of metallic iron, however, probably with some nickel, a little cobalt, and appreciable amounts of such lighter elements as carbon and sulfur.

THE EARTH'S MANTLE

The mantle comprises that part of the Earth between the Mohorovičić and the Wiechert–Gutenberg discontinuities.

It makes up 83 percent of the volume of the Earth and 67 percent of its mass and is thus of decisive importance in determining the bulk composition of the planet. In estimating elemental abundances in the mantle, however, the same difficulty as with the core arises: direct sampling is not feasible. Much more geophysical data are available for the mantle, however, and some volcanic eruptions have brought rock fragments to the surface that have certainly been derived from this zone. The most remarkable of these materials are the diamond-bearing inclusions found in the famous pipes, or volcanic necks, that are mined in South Africa and Siberia. The presence of diamond, the high-pressure form of carbon, implies a depth of origin of at least 100 kilometres (62 miles), but these inclusions are rare. The common type of mantle-derived inclusion is peridotite, a silicate rock consisting largely of olivine, $(Mg,Fe)_2SiO_4$, with minor amounts of orthopyroxene, $(Mg,Fe)SiO_3$, and diopside, $CaMg(Si_2O_6)$.

roperties

Geophysical information indicates that below a depth of about 1,000 kilometres (620 miles), the mantle behaves as an essentially homogeneous material, but above this level its physical properties are more varied, and there is evidence for second-order discontinuities. This region above 1,000 kilometres is frequently referred to as the upper mantle, and in recent years has been the object of a concentrated research effort by geologists and geophysicists all over the world. The significance of the upper mantle is that processes originating there have dramatic effects on the surface—in the form of volcanic eruptions and some earthquakes—and less dramatic but equally important effects within the crust, such as the introduction and concentration of some elements, possibly leading to the formation of ore deposits. Increased knowledge of the upper mantle thus has both scientific and economic appeal.

Geophysical data on the properties of the upper mantle suggest that it must consist essentially of magnesium-iron silicates, probably largely olivine in the region immediately below the crust. Olivine is not stable under very high pressures, however; it is converted to a different phase of about 10 percent higher density and with a structure like the mineral oxide spinel ($MgAl_2O_4$). This conversion would occur in the mantle at depths of around 400 kilometres, and a second-order discontinuity at that depth can plausibly be ascribed to this conversion. Pyroxenes also undergo transformations to phases of greater density at the high pressures within the mantle. Thus the mantle, although composed of material of familiar chemical composition, consists, in its lower part at least, of different minerals than those in the upper part.

mplica-
ions of
he occur-
ences of
iamond

Many estimates of the composition of the upper mantle have been made in recent years; some of these are presented in Table 2. On the whole, the similarities are more important than the differences. All agree that the principal components are oxides of silicon, magnesium, and iron. The differences are mainly in the minor components such as aluminum oxide, calcium oxide, and the alkalies, and are determined largely by theoretical considerations and the weight given to specific aspects of the geophysical and geochemical data.

Although fairly reliable estimates exist for the abundances of the major elements in the mantle, little is known of minor and trace elements. Knowledge of the crystal structure of possible mantle minerals indicates that many minor and trace elements will not be readily incorporated, however. They are therefore likely to concentrate in liquid material in the mantle and be carried upward in solution, eventually being transported into the crust. It is thus probable that the mantle is relatively depleted, and the crust relatively enriched, in minor and trace elements. This is certainly true for uranium and thorium, because the amount of these elements in the crust is almost sufficient to account for the total amount of heat flowing out of the Earth.

THE EARTH'S CRUST

The crust is a comparatively thin shell on the surface of the Earth and makes up less than 1 percent of its total mass. Its geochemical significance is only marginally related to its bulk, however. It has been subjected to extensive investigations, and it provides the raw materials on which civilization depends. It is the most diverse of the geospheres, being a complex mosaic of many rock types—igneous, sedimentary, and metamorphic—each with a wide variety of chemical and mineralogical compositions. The surface is veneered with soils, related in composition to the rocks from which they formed, but with important modifications because of the smaller grain size, the presence of organic matter, and an intricate complex of living organisms. Ultimately, man's welfare and indeed his survival depends on the wise utilization of the materials in the crust. Modern civilization has been erected upon the exploitation of fuels and ore deposits, which are simply geochemical concentrations of useful elements.

Igneous rocks. Clarke estimated that 95 percent of crustal rocks are of igneous origin (formed from molten silicate masses, or magmas). Sedimentary rocks occur as a thin veneer on an igneous or metamorphic basement, except where locally thickened in mountain belts. The primordial rocks of the crust must have been essentially igneous, and the first sedimentary rocks were derived from them by processes of weathering and erosion. Metamorphic rocks are formed from both sedimentary and igneous rocks by transformations due to heat and pressure at depth in the crust; unless very intense, these transformations do not totally obliterate the primary igneous or sedimentary features. Igneous rocks show a wide range of composition; the principal component, silica (SiO_2), ranges from about 35 percent to 80 percent among the commoner igneous rocks, and other components also show a wide variation. They thus illustrate some quite extensive geochemical fractionations of the elements, the fractionations that may have economic significance if they bring about the findings of workable ore deposits.

Chief components of the upper mantle

In 1924 a comprehensive review of igneous rock composition based on compilation of over 5,000 superior analyses was published. This was in many respects the ultimate refinement of Clarke's initial review of 1889. It confirmed that the averages of analyses from different

continental areas are essentially identical. It also revealed significant geochemical differences between the continental and oceanic crusts. The average of igneous rock analyses from the oceanic islands is notably lower in silica and alkalies, and higher in magnesium and calcium oxides, than the continental averages. This is simply a reflection of the fact that most oceanic islands, such as Hawaii, consist almost entirely of basalts (averaging about 50 percent silica), whereas continental areas include large granitic masses, with silica contents around 70 percent. In terms of volumes, igneous rocks consist predominantly of two great types, granitic and basaltic. The former essentially are confined to the continents and the latter occur in both continents and ocean basins. The other types of igneous rocks, while many and varied, are quantitatively insignificant and hardly affect the averages. Thus, for the major elements, the average of over 5,000 analyses of igneous rocks is not significantly different from the simple aver-

age of two individual rocks, a granite (G-1) and a basalt (W-1). This can be seen from Table 3, by comparing G-1 and W-1 values with those in the column headed "Earth's crust."

The figures for the specific granitic (G-1) and basaltic (W-1) rocks are included in Table 3 because they have been analyzed for practically all the elements in different geochemical laboratories throughout the world. The rock G-1 was a granite from Westerly, Rhode Island, and W-1 was a basaltic rock (specifically a diabase) from Centerville, Virginia. Several hundred kilograms of each of these rocks were crushed to a fine powder in the laboratories of the U.S. Geological Survey and samples distributed to analytical laboratories throughout the world, in order to obtain as many analyses as possible. The results were then critically examined, and the figures given in Table 3 are considered to be the best available in terms of accuracy and precision. G-1 and W-1 are undoubtedly the most thoroughly analyzed rocks and now serve as basic geochemical standards. It must be borne in mind that they are individual rocks, however, and cannot be considered to be averages of all granites and all basalts. Indeed, it is clear that G-1 is unusually rich in some trace elements (*e.g.*, thorium).

Geochemical distinction between oceanic and continental crust

Perhaps the most significant feature of the composition of the Earth's crust is that it is dominated by comparatively few elements. Only eight—oxygen, silicon, aluminum, iron, calcium, magnesium, sodium, and potassium—are present in amounts greater than 1 percent, and these eight make up almost 99 percent of the whole. Of these, oxygen comprises almost 50 percent by weight. The dominance of oxygen is even more marked when weight percentages are converted to atomic percentages, as follows: oxygen (weight percentage, 46.6; atomic percentage, 62.2), silicon (27.7; 21.2), aluminum (8.13; 6.47), iron (5.00; 1.92), calcium (3.63; 1.94), magnesium (2.09; 1.84), sodium (2.83; 2.64), potassium (2.59; 1.42). This comparison, of course, merely emphasizes the fact that the crust consists almost entirely of oxygen compounds, mostly silicates and aluminosilicates of iron, calcium, magnesium, and the alkali metals. As Goldschmidt remarked, the lithosphere may well be called the oxysphere. Clarke and his collaborators calculated that the average mineralogical composition of igneous rocks is: quartz 12.0 percent, feldspars 59.5 percent, pyroxene and hornblende 16.8 percent; biotite 3.8 percent, titanium minerals 1.5 percent, apatite 0.6 percent, and other accessory minerals 5.8 percent.

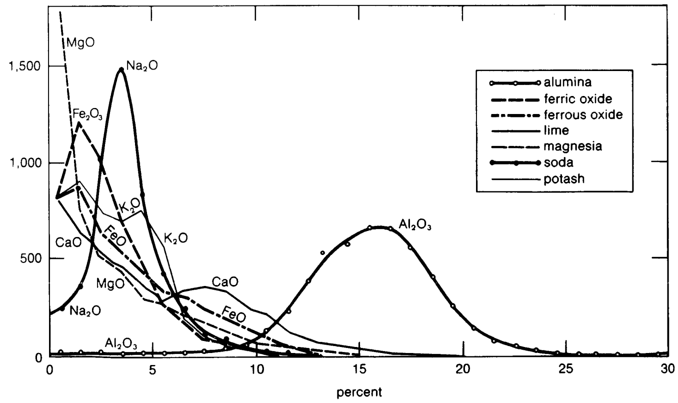

Figure 2: Frequency distribution of the major oxides in analyses of igneous rocks.

So far only the major elements have been discussed, those present in amounts greater than 1 percent by weight. Consideration must now be given to the minor and trace elements. The data are given in Table 3, and are presented diagramatically in Figure 3.

A cursory examination immediately reveals some intriguing features in the abundance pattern. The predominance of the even-numbered elements over the neighbouring odd-numbered ones is still apparent but not so regular as in the cosmic abundances. Chemical fractionations taking place during the evolution of igneous rocks from primordial matter have clearly modified this basic relationship. The odd–even relationship is most prominent in the rare-earth elements (atomic numbers 57–71), which are chemically so similar that they are little fractionated by geochemical processes.

The eight principal components of the crust

A particularly noteworthy feature is that some unfamiliar elements, such as rubidium, are relatively abundant, whereas others, such as most of the industrial metals except iron and aluminum, are actually of very low abundance. Thus boron, familiar to every homemaker in the form of borax cleansers and boric-acid antiseptics and well-known in the ancient world, is an element of extremely low abundance, much lower, for example, than zirconium, and lower even than hafnium, an element first discovered as late as 1923. Mercury, another element known to the ancient Greeks and Romans, is also of extremely low abundance. On the other hand, the so-called rare-earth elements are not extremely rare. Evidently one must make a clear distinction between abundance and availability. Some elements may be of low abundance but are readily available, because geochemical processes result in their concentration in specific deposits which can be commercially exploited. Other elements that are relatively abundant may be widely dispersed in small amounts and seldom or never occur in concentrated large deposits. A typical example is titanium, which is present in practically all igneous rocks in amounts ranging up to several percent, but which, in spite of its useful properties as a metal, is still not widely used. This is partly because of its dispersed nature and partly because of the technical difficulties in extracting the element from the minerals in which it occurs.

The distribution of minor and trace elements in igneous rocks, for those of lithophile affinity, is largely controlled by their ionic radii or size. Minor and trace elements with radii similar to those of major elements can substitute for these elements in the common minerals of the igneous rocks. The crystal structures of these minerals act as sorting mechanisms, accepting those atoms of appropriate size and rejecting others. Thus rubidium, with a radius of 1.47Å (one angstrom [Å] = 10^{-8} centimetres) is incorporated in potassium feldspar, $KAlSi_3O_8$, because its radius is close to that of potassium (1.33Å). The next higher alkali element, cesium, with a considerably larger radius (1.67Å), is not accepted into the feldspar structure; it remains in the igneous liquid during the crystallization of the major minerals until its concentration increases to such an extent that it can form the independent mineral pollucite ($CsAlSi_2O_6$).

The factor of ionic size, coupled with geochemical affinity (lithophile, chalcophile, or siderophile) is a key to the distinction between abundance and availability. Elements that are similar in size and geochemical affinity to major elements are dispersed in small amounts in common minerals; *i.e.*, rubidium in potassium feldspar, gallium in aluminum minerals, and germanium in silicate minerals. Elements that do not readily enter the common minerals of igneous rocks remain in the residual melt as crystallization proceeds. Fractional crystallization of magmas (igneous melts) normally results in a residual liquid of granitic composition. Under suitable conditions this residual liquid solidifies as a coarse-grained rock known as a pegmatite. Pegmatites are famous for their content of rare and unusual minerals, which contain many of the minor and trace elements. They are the commercial sources of lithium, beryllium, scandium, yttrium, the rare earths, cesium, niobium, and tantalum, all elements that concentrate in the residual liquid because of their specific geochemical properties.

Chalcophile elements are all of rather low abundance, and the minerals that they form, mainly sulfides and some arsenides, are not stable at the high temperatures of igneous crystallization. Sometimes these elements are found in granites and pegmatites—molybdenite (MoS_2) is a typical example. More frequently they are removed from the crystallizing magma as hot aqueous solutions and are deposited as metalliferous veins in the surrounding rock. Sometimes they may reach the surface as components in thermal springs; mercury has been deposited (as native mercury and as cinnabar, HgS) by some of these springs,

occasionally in sufficient amounts for profitable mining.

Minor and trace elements

Sedimentary rocks. The decomposition of pre-existing rocks by weathering, the transportation and deposition of the weathering products as sediments, and the eventual formation of sedimentary rocks might be expected to produce a gross mixture of materials, thereby working against further geochemical differentiation of the elements. This is not the case; sedimentary processes frequently produce remarkable concentrations of the elements, leading to almost pure deposits of certain minerals. Some sandstones, *e.g.,* contain over 99 percent quartz and some limestones over 99 percent calcium carbonate. The ultimate is reached in salt deposits, with extensive beds of anhydrite ($CaSO_4$), gypsum ($CaSO_4 \cdot 2H_2O$), halite (NaCl), and other compounds. Goldschmidt compared the sedimentary process with a quantitative chemical analysis, involving the successive separation of specific elements or groups of elements.

Quartz (SiO_2) is highly resistant to weathering and accumulates as deposits of sand. When consolidated these deposits form sandstones, an important group of sedimentary rocks. Under special conditions almost any mineral may be deposited in sand-sized grains, but most minerals are eventually decomposed by weathering. A few resistant ones may survive and be sufficiently concentrated to form economic deposits known as placers; the most familiar are probably the gold-bearing sands, important sources of this element, but sand deposits may have economic concentrations of zirconium (as the mineral zircon, $ZrSiO_4$), titanium (as rutile, TiO_2, and ilmenite, $FeTiO_3$), tin (as cassiterite, SnO_2), and others.

The aluminosilicates of igneous rocks, mainly the feldspars, $(K,Na)AlSi_3O_8$ and $(Na,Ca)(Al,Si)_4O_8$, are relatively easily decomposed by weathering. The alkali elements and calcium are largely carried away in solution, whereas the aluminum and silicon are quickly redeposited as insoluble clay minerals. When consolidated, these minerals form shales and mudstones. The ferromagnesian minerals undergo a more complex decomposition, sometimes leading to the deposition of iron-rich sediments consisting largely of hydrated ferric oxide; such sediments are valuable iron ores in many countries.

Calcium is carried away in solution mainly as calcium bicarbonate, $Ca(HCO_3)_2$. Most of it eventually reaches the sea, where it is utilized by a vast variety of organisms as skeletal material in the form of calcite and aragonite (polymorphs—different forms—of $CaCO_3$). Accumulation of skeletal materials after death of the organisms has formed extensive deposits of limestone throughout geological time. Magnesium in seawater can react with calcium carbonate to form dolomite, $CaMg(CO_3)_2$, and in this way some magnesium is removed from solution and deposited in sediments.

Much of the magnesium, however, remains in seawater, which is essentially a dilute solution of magnesium, calcium, sodium, and potassium chlorides and sulfates, with many other elements in small amounts (Table 3). Under special geological circumstances bodies of seawater can be cut off from the open ocean, and under arid conditions the water will evaporate and extensive salt beds be deposited. Such conditions have occurred in different regions throughout geological time, and the resulting salt deposits are economically important as sources of sodium, potassium, calcium, magnesium, chlorine, and sulfur (see MINERALS AND ROCKS: *Evaporites*).

The three major groups of sedimentary rocks are sandstones, shales, and the carbonate rocks (limestones and dolomites). Much less geochemical research has been devoted to sedimentary rocks than to igneous rocks, and the data for their contents of minor and trace elements are therefore less extensive. The figures in Table 3 show that the minor and trace elements generally tend to be more concentrated in shales than in the sandstones and carbonate rocks.

Concentration of elements by sedimentary processes

The problem of arriving at an average composition for all sedimentary rocks is still largely unresolved, largely because of uncertainty in the relative amounts of shales, sandstones, and carbonate rocks. From geochemical arguments Clarke estimated the relative percentages of these three groups as 80:15:5, respectively. Actual measurements of sedimentary rocks suggest that these figures overestimate the amount of shales and underestimate that of limestones, however. Thus, a compilation of the recorded amounts of shales, sandstones, and limestones in more than 213,000 metres (700,000 feet) of sedimentary rock formations gave relative percentages of 46:32:22, respectively. The identification of a formation as a limestone, a sandstone, or a shale, however, is likely to be gross; shales usually contain considerable sand, sandstones may carry much clay, and the term limestone is applied to many rocks with 50 percent or less of carbonate. It does appear that limestones are more prominent in the geological record than might be expected from geochemical calculations, however; this probably reflects the fact that shallow-water environments are the great places of carbonate deposition, whereas the ocean deeps are the repository primarily of clay-rich sediments.

Metamorphic rocks. Comparatively few investigations have been made of the elemental composition of metamorphic rocks. Many of these rocks retain the geochemical features of their parent igneous or sedimentary materials, and their bulk composition has been little changed despite complete recrystallization and the production of new minerals and structures in some instances. Some metamorphic rocks, however, have been markedly modified by the removal of some components and the addition of others.

Average composition of sedimentary rocks

The Geological Survey of Canada has performed a comprehensive study of a large area of the Canadian Shield, a region of complex geology largely made up of metamorphic rocks. From a collection of more than 8,000 bedrock samples, the average abundances of all the major elements and a number of minor and trace elements were determined; the figures are given in Table 3. As might be anticipated, the average composition is not very different from the average composition of igneous rocks. It does show a somewhat higher silicon content, probably reflecting a preponderance of granitic over basaltic rocks and a relative abundance of quartz-rich sedimentary rocks in the original makeup of the Canadian Shield. The general validity of these abundance figures for metamorphic rocks has been confirmed by a similar study of the average composition of metamorphic rocks in the U.S.S.R., which has given closely comparable results.

Ore deposits. An ore deposit, in its simplest terms, is a portion of the Earth's crust from which some industrial raw material can be extracted at a profit. As such, its characteristics are as much economic as geochemical. Nevertheless, its formation required the operation of geochemical processes to produce the concentration of a specific element or elements in a particular place. Economics decide whether this concentration is rated as an ore deposit or merely as a deposit of scientific interest. The economics may change with time, depending upon price, availability of transportation, cost of labour, and other factors.

Table 4: Concentration Factors for Ore Bodies of the Commoner Metals

metal	percent in Earth's crust	minimum percent profitably extracted	enrichment factor necessary for an ore body
Aluminum	8.13	30	4
Iron	5.00	30	6
Manganese	0.10	35	350
Chromium	0.02	30	1,500
Copper	0.007	1	140
Nickel	0.008	1.5	175
Zinc	0.013	4	300
Tin	0.004	1	250
Lead	0.0016	4	2,500
Uranium	0.0002	0.1	500

Some general principles can, however, be enunciated. Proceeding from the average abundance of an element in the crust, and the minimum abundance that can be profitably exploited under normal circumstances, a factor of enrichment necessary to produce an ore deposit can be derived (Table 4). The economic control is immediately evident in the approximate relation between the factor of enrichment and the price of the product sought. The most extreme example of this is in diamond mining, where the product sought may be present in the rock mined in as low a concentration as 1 part in 50,000,000. Ease of extraction, of course, plays an important role in this. Diamonds are readily separated from the great mass of waste rock by a relatively simple and inexpensive process. Magnesium is commercially extracted from seawater, where its concentration is 0.13 percent, rather than from the common rock dunite, where its concentration is about 25 percent, because of the ready availability of seawater and the cheapness of the extraction process.

Ore deposits may be found in all types of rocks—igneous, sedimentary, and metamorphic—and seawater is also a significant source of such elements as sodium, chlorine, magnesium, and bromine. There are many possible processes of geochemical enrichment leading to the formation of ore deposits, and they are often the end result of a complex series of such processes acting over a long period of time. The economic importance of ore deposits has ensured their thorough study by all techniques of geological and geochemical research, but much controversy still exists regarding the origin of many of the more complex deposits.

The most readily understood ore deposits are those of sedimentary origin. They have been formed at the surface of the Earth by processes that can usually be observed operating at the present time and that can readily be simulated in the laboratory. Salt deposits are one kind whose origin is clearly amenable to such an approach. As long ago as 1849 an Italian scientist initiated laboratory studies on the evaporation of seawater and elucidated the sequence of crystallization of the different salts. Comparison of the results with the mineralogy of salt deposits revealed gross similarities but also important differences; these differences can be explained by a variety of mild metamorphic reactions resulting from burial of these deposits under overlying sediments.

The Canadian Shield

Some sedimentary deposits are not readily explicable by such an approach, however. The most extensive and economically important are the vast Precambrian iron-ore deposits, which are a major source for the hundreds of millions of tons of steel produced annually. They occur on all the continents (except perhaps Antarctica) and are uniformly of great age (about 1,900,000,000 years or older). Probably the most extensive and best exposed of these are in the Hamersley Range of Western Australia, where individual beds of iron ore are continuous over hundreds of square miles in a horizontally bedded sequence of iron ore and quartzite thousands of feet thick. The conditions that gave rise to these deposits were apparently unique to this early period in Earth history, because similar deposits are not known in younger geological formations. It has been argued that the explanation lies in an oxygen-free reducing atmosphere in early geological times, under which iron could readily be transported in solution as ferrous compounds to the ocean or large lakes, where deposition eventually took place, perhaps through the agency of primitive organisms. As soon as free oxygen appeared in the atmosphere, 1,000,000,000 to 2,000,000,000 years ago, the geochemical cycle for iron was profoundly modified, and this type of transportation and deposition ended forever.

Processes other than fractional crystallization from igneous melts also give rise to magmatic ore deposits. Economic deposits of the oxide mineral chromite ($[Fe,Mg][Cr,Al]_2O_4$), for example, occur almost entirely as bands or lenses in magnesium-rich igneous rocks. Chromite evidently crystallizes early from a magma, and, being of higher density than the liquid, it sinks to the bottom of the magma chamber and becomes concentrated as almost pure bodies of this mineral. Some accessory minerals of igneous rocks are important sources of metallic elements, but the rocks cannot be mined directly because the grade is too low. If these minerals are chemically and mechanically resistant, weathering and transportation may eventually concentrate them into workable deposits. A large proportion of the world's zirconium, hafnium, rare earths, and thorium, and some iron and titanium, come from such deposits in river and beach sands.

A large number of important ore deposits occur in metamorphic rocks. The ultimate origin of these deposits is frequently obscured by the complex processes they have undergone. If it can be established that the enclosing metamorphic rocks were of sedimentary origin, the question then arises whether the ore material was deposited along with the sediments or was introduced by circulating solutions during the metamorphism or possibly at some later time. The answer is seldom clear-cut, and such deposits continue to excite lively controversy among geochemists and economic geologists.

Mineral fuels. The mineral fuels—coal, petroleum, and natural gas—may be described as a special type of economic deposit. Geochemically they represent the concentration of carbon and hydrogen by processes that were initially biological in nature. Coal is essentially the product of accumulation of land plants in large amounts, and petroleum and natural gas are the products of marine organisms (although the origin of some petroleum and natural gas under nonmarine conditions cannot be entirely excluded). The origin of petroleum and natural gas presents a more difficult problem than coal because they are fluids and thus are free to migrate from their place of origin.

Sedimentary iron-ore deposits

The formation of coal is a relatively straightforward geochemical process that can readily be traced through its successive stages. The first requirement is a geological one—the rapid accumulation of plant material under conditions that inhibit its decomposition, followed by its burial under inorganic sediments such as shales and sandstones. The great coal-forming period in the Northern Hemisphere followed the Devonian Period (345,000,000 to 395,000,000 years ago), when abundant land plants first appeared, and has been named the Carboniferous Period (280,000,000 to 345,000,000 years ago). During this period, large areas in North America and Europe were evidently low-lying swamps that supported a lush vegetation. This vegetation died, accumulated in successive layers, and was partly decomposed by bacteria and other organisms to form peat. Burial of peat deposits under inorganic sediments brought an end to the period of bacterial decomposition, and the further changes to coal were essentially a mild metamorphism caused by an increase in temperature and pressure.

Chemically, this mild metamorphism was in large part the expulsion of carbon dioxide and water from the coal-forming substance. The main trend in the change from peat through lignite to bituminous coal and anthracite is the decrease in oxygen content and the increase in carbon (Table 5). If carried to its ultimate conclusion the product would be pure carbon in the form of graphite. This occurs comparatively rarely, but evidence for it is the presence of small amounts of graphite in many metamorphic rocks.

Table 5: Average Composition of Fuels

	carbon	hydrogen	nitrogen	oxygen
Wood	49.65	6.23	0.92	43.20
Peat	55.44	6.28	1.72	36.56
Lignite	72.95	5.24	1.31	20.50
Bituminous coal	84.24	5.55	1.52	8.69
Anthracite coal	93.50	2.81	0.97	2.72

Source: Clarke, *The Data of Geochemistry.*

Formation of coal

Coal also contains inorganic material that appears as ash when it is burned, and some coal ashes show a remarkable concentration of unusual elements. This was demonstrated by Goldschmidt in 1933, when he found appreciable amounts of germanium in some coal ashes. The Hartley Seam of the Durham Coalfield in England contains so much germanium that the ash has a brilliant yellow colour because of the presence of the oxide (GeO_2).

The source of these minor and trace elements (Table 6) and their mode of incorporation in the coal are still not fully understood. There are three possibilities: (1) these elements were taken up by the plants during growth; (2) they were carried into the coal swamp as a component of the inorganic sediments; or (3) they were absorbed during or after the coal-forming processes from circulating solutions. The first possibility is not favoured, because growing plants seldom incorporate appreciable amounts of nonorganic elements. The second possibility also is unlikely, because there is no correlation, or rather an inverse correlation, between ash content and trace element concentrations. This leaves the third possibility as the most likely one. The presence of a large amount of carbonaceous matter means that the coal-forming environment is a highly reducing one, which will favour the precipitation of some elements; the presence of hydrogen sulfide and sulfide ions will cause the precipitation of chalcophile elements (with affinity for sulfur); and complex organic compounds are noted for their absorptive, or chelating, capacity for metallic ions. Thus several individual reactions are potentially available for the fixation of foreign elements in the coal substance.

Table 6: Rare Elements in Coal Ash

	average content in coal ash (g/ton)	average content in Earth's crust (g/ton)	factor of enrichment
Boron	600	10	60
Germanium	500	1.5	330
Arsenic	500	2	250
Bismuth	20	0.2	100
Beryllium	45	2.8	16
Cobalt	300	25	12
Nickel	700	75	9
Cadmium	5	0.2	25
Lead	100	13	8
Silver	2	0.1	20
Scandium	60	22	3
Gallium	100	15	7
Molybdenum	50	1.5	30
Uranium	400	2.7	150

As pointed out above, the origin of petroleum is not as readily elucidated as the origin of coal, because petroleum can migrate from the region in which it was formed. Indeed, the very occurrence of a commercial oil field probably implies the concentration of the petroleum from a large volume of source rocks into a relatively much smaller reservoir.

The fact that petroleum is almost always found in marine sedimentary rocks has long been a basic argument in favour of a marine origin for this material. It is certainly true that some oil has been found in igneous and metamorphic rocks, but migration from a sedimentary source bed is a reasonable explanation for these occurrences. Proof of a marine origin has been forthcoming in recent years by the sensitive analyses of recent marine sediments, which show that they contain small amounts of petroleum hydrocarbons, evidently generated either directly by marine organisms or by their subsequent decomposition.

Inorganic components of coal

Natural petroleum is a complex mixture of hundreds of different hydrocarbons, but its bulk composition is remarkably constant, about 85 percent carbon and 15 percent hydrogen. It may include small amounts of organic compounds containing oxygen, sulfur, and nitrogen. Its content of other elements is exceedingly small. Petroleum ash, unlike coal ash, is not noted for its trace element content. Some petroleum ash contains appreciable amounts of vanadium, however, and has been utilized as a source of this element. A class of nitrogen-bearing organic compounds known as porphyrins include a metal atom in their molecular structure; usually this atom is iron, but other elements in this region of the periodic table, especially vanadium, nickel, and copper, may play a similar role. The vanadium content of some petroleum ash probably originates as a vanadium porphyrin in some of the organisms involved in petroleum formation.

Petroleum is always accompanied by natural gas, but many natural gas fields have no petroleum associated with them. This can probably be ascribed to greater possibility for migration for a gas as compared to a liquid. It is also possible that some natural gas is generated from coal deposits. Natural gas consists largely of methane, but small amounts of more complex hydrocarbons may be present, and it may also contain unwanted components such as nitrogen, carbon dioxide, and hydrogen sulfide. Natural gas containing hydrogen sulfide is known as "sour gas" and for long was an undesirable material because of the noxious nature of this compound; recently, however, it has been found profitable to extract the hydrogen sulfide by converting it to sulfur and then utilize the hydrocarbons.

Composition of petroleum

Natural gas is the sole source of one element, helium, the industrial demand for which has steadily increased in recent years. Comparatively few occurrences of natural gas contain sufficient helium for the extraction to be commercially profitable. Currently, the Western world's need for helium is largely met by its extraction from wells in western Texas. The explanation for this local concentration of helium in some natural gas fields is still a matter for discussion; the only reasonable source is from the disintegration of radioactive elements in the crust, but the mechanism of concentration remains something of an enigma.

Soils. Soil is a thin veneer that forms a discontinuous cover on the land areas of the Earth. Its volume and its mass are small in comparison to the major geospheres, but it is of vast importance to man. Superficially it might be considered merely as comminuted (pulverized) and decomposed bedrock; however, this viewpoint takes into account only its inorganic components and completely neglects the complex of organic compounds, living organisms, water, and included gases that gives the soil its characteristic properties and its value as the abode of life. Comminuted bedrock alone is not soil in any real sense; the Antarctic continent, where not ice-covered, has a surface of comminuted bedrock, as does the Moon, but neither material can properly be termed soil.

Soils result from the weathering of rocks, and hence their composition might be expected to reflect the composition of the rocks from which they were formed. This is true only in a very broad sense, however. Environmental factors play an important part in soil formation. The same parent rock may give rise to very different soils under different conditions. Climate, topography, vegetation, biological activity, and time are all important factors in determining the nature of a soil. Climate is probably the most important of these, as can be demonstrated by contrasting the soils developed on the same rock type under tropical and temperate conditions. In general, the soil in the humid tropics will be different in texture and composition and much less fertile, as a result of the intense leaching brought about by high rainfall, high temperatures, and the almost complete removal of organic matter by microorganisms.

The complex of inorganic compounds, organic compounds, water, and air that makes up the soil is in a continual state of change. Water tends to dissolve and remove the relatively soluble elements such as calcium, magnesium, sodium, and potassium, and the comparatively insoluble elements—aluminum, iron, and silicon—are thereby relatively enriched in the soil. The enrichment of iron is frequently manifested by a red-brown or yellow-brown colour caused by an accumulation of iron oxides. The most reactive part of the soil is the complex of clay minerals and organic matter, which is largely responsible for its agronomic characteristics. True soil does not exist without the presence of colloidal and organic matter. The relative absence of soils in desert areas reflects the fact that chemical and physical weathering of rocks alone does not necessarily result in soil formation. Most soil processes are directly or indirectly biological in nature. Organisms and organic compounds produced by their vital activities or their decomposition are effective agents for dissolving and extracting many elements from the inorganic constituents of the soil, thereby making them available for plant growth.

Helium in natural gas

Although soils do differ in composition, the range of variation in the major elements is rather small. Minor and trace elements may show considerably greater variability, as is illustrated by Figure 4. The importance of certain trace elements in the soil for the healthy growth of plants, and through the plants, of the animals that graze on them, has become increasingly apparent in recent years. Most soils contain these trace elements in sufficient amounts, but when deficiencies are present, puzzling diseases appear, which in the past have rendered large areas of otherwise suitable land unavailable for farming. On a large area in the North Island of New Zealand, for example, although it grew satisfactory pasture, sheep and cattle failed to thrive and eventually died if not removed. As a result, much of this area was given over to afforestation. It was eventually discovered that cobalt, in the amount of a few parts per million, would completely eliminate the disease when applied in fertilizer or administered directly to the animals. The ultimate explanation is the need of animals (but not plants) for vitamin B_{12}, which contains an atom of cobalt in its structure.

From *Chemistry of the Soil* by Firman Bear. Copyright 1964 by Litton Educational Publishing,Inc.

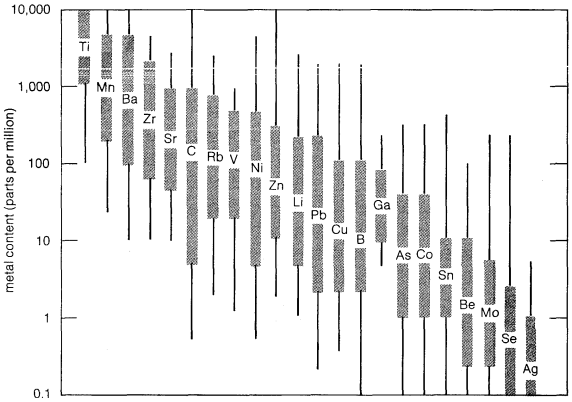

Figure 4: Range of the content of some minor elements in normal soils. Thin lines indicate ranges of more unusual values.

Occasionally, an excess of a specific element may have a deleterious effect on plant growth. Most obvious, of course, are the alkaline or saline soils of desert and coastal areas on which only an impoverished vegetation exists. Magnesium-rich soils are notably infertile; such soils develop on areas of ultrabasic igneous rocks consisting largely of olivine, $(Mg,Fe)_2SiO_4$, and the boundaries of these areas can frequently be readily mapped from aerial photographs by the marked change in vegetation. Sometimes plants take up available trace elements in amounts deleterious to animals grazing on them. A well-known example is *Astragalus racemosus* (locoweed), which in some areas of the western U.S. contains sufficient selenium to be poisonous to grazing animals.

The possible correlation between soil geochemistry and the geographical distribution of disease is thus a field of extreme significance which as yet has been insufficiently studied. The problem is a complex one, in large part because of the difficulty in isolating the numerous factors involved.

THE HYDROSPHERE

The hydrosphere is the discontinuous shell of water—fresh, salt, and solid—on the surface of the Earth. As such it comprises the oceans and the connecting seas and inlets, the lakes, rivers, and streams, the groundwater that feeds them, and the snow and ice cover of high altitudes and high latitudes. The mass of the ocean waters far outweighs the other parts of the hydrosphere. Goldschmidt estimated that there are 273 litres of water in all its forms for every square centimetre of the Earth's surface made up as follows:

	Litres	Kilograms	Total mass
Seawater	268.4	278.1	1.4×10^{18} tons
Freshwater	0.1	0.1	5.1×10^{14} tons
Continental ice	4.5	4.5	2.3×10^{16} tons

Seawater thus makes up over 98 percent of the total mass of the hydrosphere, and its composition (Table 3) essentially can be taken as giving the average composition of the hydrosphere.

Research during the past century has demonstrated that the composition of seawater is essentially uniform and that the relative proportions of the various ions are practically constant. In the open ocean the salinity (approximately the total weight of dissolved solids per kilogram) averages about 35 parts per thousand, but may rise to 40 parts per thousand in regions such as the Red Sea and the Persian Gulf, where rainfall and inflow are low and evaporation high. Sodium chloride is the dominant compound of the salts in solution and comprises about three-quarters of the whole; the remainder consists largely of chlorides and sulfates of magnesium, calcium, and potassium.

Minor and trace elements in soils

Though many data on minor and trace elements in seawater (Table 3) are available, the interpretation of these data is subject to some uncertainties. The concentrations of these elements are probably more variable than for the major elements and may depend to some degree on the sampling location. This is particularly true for the elements that are utilized by marine organisms. Phosphorus is a good example; it is markedly depleted in surface and near-surface waters by biological activity, but it enriches the deeper parts of the ocean through the dissolution of dead organisms. Silica is brought into the ocean in large amounts in solution in river water, but most of it is soon removed to become the skeletal material of diatoms, radiolaria, and sponges.

Seawater also contains dissolved gases in variable amounts. Seawater of normal salinity at 0° C (32° F) in equilibrium with the atmosphere will contain about eight millilitres per litre of dissolved oxygen and 14 millilitres per litre of dissolved nitrogen. Dissolved nitrogen is essentially an inert constituent, but dissolved oxygen plays a fundamental role in the growth and decay of organisms and so varies greatly in concentration from place to place. In stagnant regions that are rich in decaying organic matter the water may be completely depleted in free oxygen, and a considerable concentration of hydrogen sulfide may be present. Much of the Black Sea below a depth of a few hundred metres is in this condition.

Another dissolved gas of prime importance for biological activity is carbon dioxide. The conditions controlling its concentration are quite complex, however, because in solution it can be present as free carbon dioxide, as undissociated carbonic acid, as carbonate ions, and as bicarbonate ions. The concentration of these ions will also be affected by biological activity and by the precipitation or dissolution of calcium carbonate.

The circulation of water through the hydrosphere is controlled in large part by the reservoir effect of the oceans. Evaporation from the ocean surface is precipitated as rainfall. Of that falling on the land, some is directly reevaporated, some is absorbed into the reservoir of groundwater, and some flows off directly into rivers and streams. The total annual rainfall on the Earth is estimated to be 123×10^{18} grams, and the total annual runoff to the oceans 32×10^{18} grams.

Even the purest rainfall contains some material in solution, not only dissolved gases but also nonvolatile material. Rainfall near seacoasts always contains some sodium chloride and small amounts of other marine salts, the concentration of which falls off generally with distance from the ocean. Rainfall in industrial regions may of course contain a variety of pollutants; in many areas it is essentially a dilute sulfuric acid solution. Such material may also be carried far beyond the place of origin; acid rainfall in the Scandinavian countries probably originates in part from England and Germany.

Chemical composition of seawater

The runoff from the land contains additional material in solution, picked up during its circulation through the crustal rocks. River water averages about 120 parts per million dissolved solids, but the range is great, from about 10 parts per million up to several thousand parts per million. Commonly, the range is from 50 to 200 parts per million; contents greater than 200 parts per million are usually the result of human activities or of drainage from soils containing soluble salts, as in desert regions.

With an average content of 120 parts per million dissolved matter, the rivers of the world deliver 3.9×10^9 tons of material in solution to the sea each year. The average concentration of the important constituents (in parts per million) is: bicarbonate, 58.4; sulfate, 11.2; chloride, 7.8; nitrate, 1.0; calcium, 15.0; magnesium, 4.1; sodium, 6.3; potassium, 2.3; iron, 0.67; and silica, 13.1. Although these ten constituents account for most of the dissolved material, many other elements have been detected in river and lake waters. Comparatively little information is available for these elements, but the results of an extensive study of the large rivers of North America is summarized in Figure 5. The figures are in micrograms per litre—that is, in parts per thousand million.

From W.H. Durum and Joseph Haffty, *Geochimica et Cosmochimica, Acta*, vol. 27 (1963); Pergamon Press

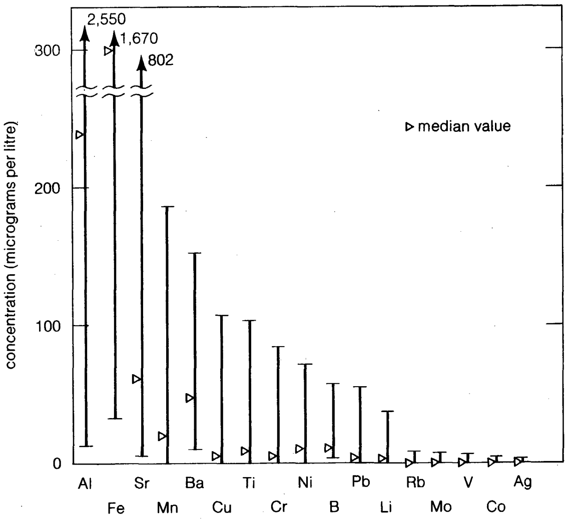

Figure 5: Concentrations of minor and trace elements in river waters of North America.

The 3.9×10^9 tons carried annually in solution to the oceans are but a small fraction of the total amount of material in solution in the oceans. Nevertheless, when integrated over the whole of geological time, more than 4×10^9 years, it greatly exceeds the present material in solution. Some of the material, especially sodium chloride, is of course cyclical, being circulated from the oceans to the land as aerosols and incorporated in marine sedimentary rocks and ultimately in large part being returned to the oceans in runoff.

Table 7: Geochemical Balance of Some Elements in Seawater

element	potential amount supplied to oceans (g/ton)	amount present in seawater (g/ton)	percentage in solution
Lithium	39	0.17	0.4
Boron	2	4.5	250
Fluorine	540	1.3	0.2
Sodium	16,980	10,800	64
Magnesium	12,540	1,290	10
Phosphorus	708	0.09	0.01
Sulfur	312	904	290
Chlorine	188	19,400	10,300
Potassium	15,540	392	2.5
Calcium	21,780	411	1.9
Arsenic	3	0.003	0.1
Bromine	0.97	67	6,900
Rubidium	186	0.12	0.06
Strontium	180	8.1	4.6
Iodine	0.18	0.06	33
Cesium	4	0.0003	0.008
Barium	150	0.02	0.01

Goldschmidt made an interesting calculation on the geochemical balance in seawater. From the amount and composition of sedimentary rocks he estimated that erosion during geological time had amounted to about 160 kilograms of igneous rock per square centimetre of the Earth's surface. Combining this figure with the amount of seawater per square centimetre, 273 kilograms, he derived a figure of 600 grams of igneous rock eroded per kilogram of seawater. Assuming this 600 grams had gone fully into solution (obviously a gross simplification but a limiting one), he drew up a balance sheet between the amounts of different elements potentially supplied to the oceans and the amounts actually present. Some of these figures are presented in Table 7. Despite the imperfections of the method, the results are certainly significant in a qualitative sense. Some elements—chlorine, bromine, boron, and sulfur—are present in seawater in amounts far in excess of those that can have been derived by erosion. The source of these "superabundant" elements has probably been volcanism and related magmatic activity. Halides, sulfates, and borates are deposited by volcanic gases and carried in solution in hot springs. The relative depletion of fluorine with respect to chlorine in seawater can be ascribed to the precipitation of highly insoluble fluorine-bearing compounds, mainly apatite (calcium fluophosphate). Sodium clearly remains in solution to a much greater extent than potassium; the latter element reacts with sedimentary materials to form insoluble potassium-bearing silicates such as illite and glauconite, which have no sodium-bearing analogs. Calcium is removed from solution much more effectively than strontium, evidently because it is utilized by organisms. Goldschmidt pointed out that many highly poisonous elements, such as arsenic and selenium, have been potentially supplied in dangerous amounts. Their concentration remains very low, however, presumably because of efficient processes of removal as insoluble compounds. Adsorption on colloidal particles of clay and iron oxides is a likely process.

Steady state of oceanic composition

The geological and geochemical evidence indicates that the ocean waters are, and have been for a long time, in a steady state of essentially unchanging composition. The addition of material by runoff from the land is adjusted by reactions within the ocean waters or between the ocean waters and sedimentary materials whereby the concentrations of the individual elements remain essentially constant. How far back in geological time this steady state has persisted remains something of an open question. The existence of most forms of marine life from the Cambrian to the present indicates a uniformity of marine conditions over the past 600,000,000 years; how far back into the Precambrian this uniformity extended is more difficult to elucidate. The earlier discussion of Precambrian iron formations suggested the possibility of very different atmospheric composition some 2,000,000,000 years ago, and the considerable interdependence of atmospheric and oceanic composition indicates that this might have resulted in marked geochemical differences in the ocean waters.

THE ATMOSPHERE

The atmosphere is the most homogeneous and thus the most easily studied of the geospheres. Its mass is readily determined from the product of the average height of the mercury barometer in centimetres, the density of mercury (13.6 grams per cubic centimetre), and the area of the Earth (5.1×10^{18} square centimetres). Recent calculations give 51.17×10^{20} grams for its total mass.

The composition is also relatively simple, although a considerable number of gases may be present in small amounts (Table 8). Almost 99 percent consists of oxygen and nitrogen, with argon making up most of the remainder. Carbon dioxide, essential for plant life, is present in an extremely small amount. Some gases not listed in Table 8 may be present as local or even regional pollutants—city dwellers are becoming increasingly aware of oxides of sulfur as atmospheric pollutants, and the scientific study of smog is largely concerned with reactions taking place between hydrocarbons, oxides of nitrogen, oxygen and ozone.

Table 8: Average Composition of the Atmosphere

gas	composition by volume (ppm)*	composition by weight (ppm)*	total mass ($\times 10^{20}$ g)
Nitrogen	780,900	755,100	38.648
Oxygen	209,500	231,500	11.841
Argon	9,300	12,800	0.655
Carbon dioxide	300	460	0.0233
Neon	18	12.5	0.000636
Helium	5.2	0.72	0.000037
Methane	1.5	0.94	0.000043
Krypton	1	2.9	0.000146
Nitrous oxide	0.5	0.8	0.000040
Hydrogen	0.5	0.035	0.000002
Ozone†	0.4	0.7	0.000035
Xenon	0.08	0.36	0.000018

*ppm = parts per million. †Variable, increases with height.

The atmosphere gradually thins out into the vacuum of outer space, and its upper limit can conveniently be placed at about 600 kilometres. An important zone in the stratosphere is known as the ozonosphere, a diffuse layer characterized by an increase in the concentration of ozone, O_3. This zone is highly important for life on Earth because it absorbs most of the ultraviolet radiation from the Sun; if this penetrated to the Earth's surface it would act as a potent sterilizer, fatal for most forms of life. It also helps to maintain a more uniform surface temperature by reducing the loss of heat by radiation to space—the so-called greenhouse effect.

The geochemical history of the atmosphere has been a complex one. Scientists agree that the present atmosphere is quite different from the original one. It is certainly quite different from those of the other planets. It is reasonable to conclude that this reflects, in part at least, the Earth as the abode of life. The Earth's atmosphere differs from those of its neighbours in the solar system probably in large part through the action of photosynthesis, a complex biological process which was probably preceded by a lengthy period of organic evolution.

The nature of the Earth's primitive atmosphere is still a subject of some speculation. Some scientists, reasoning by analogy with the larger planets such as Jupiter, have argued for an original atmosphere consisting largely of methane and ammonia. Others have considered that present-day volcanic gases may indicate the nature of the primitive atmosphere, in which case it contained carbon dioxide, possibly carbon monoxide, nitrogen, and water vapour. In either case, free oxygen was absent. If the evolution of the atmosphere is traced backward in time through the geological record, then extensive terrestrial photosynthesis is indicated by an abundance of land plants in Devonian times, about 400,000,000 years ago. Marine photosynthesis, however, is much older, since practically all the major groups of marine organisms were established by the beginning of the Cambrian period, some 570,000,000 years ago. As discussed earlier, the extensive Precambrian iron formations suggest an oxygen-free atmosphere which was terminated about 2,000,000,000 years ago. This evidence has been translated into estimates of oxygen content of the atmosphere of about 1 percent of the present level 2,000,000,000 years ago, about 10 percent of the present level at the beginning of the Cambrian Period, and essentially the present content by Devonian times.

Although it is not yet possible to know the quantitative composition of the primitive atmosphere, the geochemical processes that have operated to modify its composition during geological time can be evaluated. These processes can be summarized as a series of gains and losses. Additions to the atmosphere comprise: (1) gases released by igneous activity; (2) oxygen and hydrogen produced by the photochemical dissociation of water vapour; (3) oxygen produced by photosynthesis; (4) helium produced by the radioactive breakdown of uranium and thorium; and (5) argon produced by the radioactive breakdown of potassium. Atmospheric losses include: (1) oxygen removal by oxidation of ferrous to ferric iron, sulfur compounds to sulfates, hydrogen to water, and similar reactions; (2) carbon dioxide removed by the formation of coal, petroleum, and the death and burial of organisms; (3) carbon dioxide removed by the formation of calcium and magnesium carbonates; (4) nitrogen removed by the formation of oxides of nitrogen in the air and by the action of nitrifying bacteria in the soil; and (5) hydrogen and helium by escape from the Earth's gravitational field.

Photosynthesis has certainly been the most significant process in controlling atmospheric composition during much of geological time. Through this process carbon dioxide and water are converted to carbohydrate, with the accompanying release of oxygen. Much of this carbohydrate is consumed by animals and reconverted to carbon dioxide and water by respiration, and oxidative decay leads to the same result. Some, however, is incorporated into sediments; part may go to form exploitable deposits of coal and petroleum, but most of it remains as disseminated carbonaceous material; the average carbon content of sedimentary rocks is about 0.4 percent.

Removal of carbon dioxide

Quantitatively, more significant amounts of carbon dioxide have been removed from the atmosphere in the form of limestone and dolomite. Most of this removal has been effected by marine organisms, especially algae and corals, but direct inorganic precipitation may occur, especially in warm tropical waters. Judging from the vast deposits of limestone and dolomite throughout the sedimentary record, this process has operated with a remarkable degree of uniformity throughout geological time. Extensive limestone formations are possibly less common in older Precambrian rocks, indicating a slower beginning of carbonate precipitation. It is truly remarkable that so much carbonate rock has been deposited during geological time, with the carbonate being ultimately derived from an atmosphere which may never have contained a much higher concentration of carbon dioxide than is present today. It has been pointed out that reactions like the decomposition of calcium silicate—$CaSiO_3 + CO_2 = CaCO_3 + SiO_2$, in which $CaSiO_3$ is calcium silicate, CO_2 is carbon dioxide, $CaCO_3$ is calcium carbonate, and SiO_2 is silicon dioxide, which tends to go toward the right at ordinary temperatures—will act as buffering mechanisms to keep the carbon dioxide concentration of the atmosphere at a continuously low level.

If the carbon dioxide concentration has remained essentially constant, and yet this compound has been continuously extracted to form carbonates and organic compounds, then clearly a balancing source of "new" carbon dioxide is required. This evidently has been provided by volcanism and other igneous activity. The Earth is steadily being degassed, in the sense that gaseous compounds contained in the mantle are escaping to the surface. The presence of carbon dioxide in the mantle has been demonstrated by the presence of microscopic inclusions of liquid carbon dioxide in the minerals of the peridotite xenoliths (rocks contained within other rocks) brought up in some volcanoes. Along with carbon dioxide, much water and small amounts of other volatiles are being added continuously from sources in the mantle. Ultimately, the hydrosphere, as well as the atmosphere, is the product of the degassing of the Earth's interior.

Of the remaining atmospheric gases, argon presents some intriguing features. Argon is by far the most abundant of the inert gases on Earth, whereas in the universe as a whole it is much less abundant than either helium or neon. In addition, its isotopic composition is quite distinct, consisting almost entirely of argon-40, whereas in the Cosmos argon-36 is the most abundant isotope. The reason for these anomalies is that atmospheric argon is almost entirely radiogenic, the product of the decay of the potassium-40 isotope of potassium.

Similarly, the helium in the atmosphere is probably entirely the product of the radioactive decay of uranium and thorium. Actually, the atmosphere contains only about 10 percent of the total amount of helium generated from these sources during geological time. Some of this helium remains occluded in the rocks where it was formed, some has escaped from the upper atmosphere. Helium (and hydrogen), consisting of light atoms, can escape from the gravitational field of the Earth, whereas heavier gases cannot. A minor source of atmospheric oxygen throughout geological time is probably the photochemical decomposition of water vapour in the upper atmosphere, with the subsequent loss of the hydrogen to outer space.

Some oxygen has been removed from the atmosphere by oxidative reactions, of which the most significant has been the conversion of ferrous to ferric iron. In igneous rocks the average ferrous-to-ferric iron ratio (FeO/Fe_2O_3) is greater than unity, whereas in sedimentary rocks the proportion is reversed, ferric iron being dominant over ferrous iron. Other oxidative reactions are the conversion of manganous compounds to manganese dioxide and of hydrogen sulfide to free sulfur and sulfate. Nitrogen is almost inert geochemically, but a little is fixed as oxides of nitrogen by lightning, and somewhat more by the action of nitrifying bacteria in the soil. Most of this nitrogen is ultimately returned to the atmosphere by the decay of the organisms. Oxides of nitrogen formed in the atmosphere are removed in rain as nitrite and nitrate. Nitrogen does not accumulate in the soil, however, except perhaps under extremely arid conditions, as in the deserts of northern Chile, the locale of the unique nitrate deposits.

The geochemical cycle

The preceding discussion has shown that at the time of formation of the Earth the chemical elements already had been considerably fractionated: the universe consists almost entirely of hydrogen and helium, probably with less than 1 percent of the heavier elements. The Earth, on the other hand, consists almost entirely of the heavier elements. Helium is a very rare element on Earth, so rare in fact that it was first discovered as an unidentified line in the Sun's spectrum in 1868, some 30 years before it was detected on Earth. Hydrogen is moderately abundant on Earth, largely because it combines with oxygen to form water, whereas helium is an inert element.

Significance of inert gases

The rarity of helium and the other inert gases neon, krypton, and xenon on Earth is good evidence that the Earth formed by the accretion of small solid objects, or planetesimals. (Argon is a special case, since most of the Earth's argon has been formed within the planet by the radioactive decay of potassium.) These planetesimals had no atmosphere, and the atmosphere of the Earth has been derived by the outgassing of combined and occluded gases within these planetesimals. This process has operated throughout geological history and is probably still continuing; volcanic activity not only brings up solid material from the Earth's interior but also large amounts of gases, principally water vapour, carbon monoxide and dioxide, and nitrogen. The oxygen in the present atmosphere is almost entirely the product of photosynthesis, whereby carbon dioxide and water are converted to carbohydrate and free oxygen.

Direct information on the composition of the Earth's crust is available in the form of thousands of analyses of individual rocks, the average of which provides a reasonably precise estimate of the bulk composition. For the mantle and the core the information is indirect and thus much less precise. The origin of the Earth by the accretion of planetesimals is a well-founded hypothesis, however, and meteorites are probably examples of planetesimals that have survived from the preplanetary stage of the solar system. It thus seems likely that the Earth formed by the accretion of solid bodies with the average composition of stony meteorites. The accretion process, however, led to massive segregation of the elements. Much of the iron was reduced to the metallic state and sank to the centre to form the core, carrying with it the major part of the siderophile elements. Lithophile elements, those with a greater affinity for oxygen than iron, combined as oxide compounds, mostly silicates, and provided material for the mantle and crust. Chalcophile elements would tend to form sulfides; however, few sulfides are stable at the high temperatures of the Earth's interior, so the fate of the chalcophile elements during the early history of the Earth is somewhat uncertain.

This primary geochemical differentiation of the Earth can be interpreted in terms of the system iron–magnesium–silicon–oxygen–sulfur, because these five elements make up about 95 percent of the Earth. There was insufficient oxygen to combine with the major metallic elements iron, magnesium, and silicon; because magnesium and silicon have a greater affinity for oxygen than iron, these elements combined completely with oxygen, and the remaining oxygen combined with part of the iron, leaving the remainder as the metal iron and iron sulfide. As indicated above, the metal sank to form the core, carrying with it the major part of the siderophile elements. The iron sulfide phase probably incorporated much of the chalcophile elements; it does not seem to have formed a distinct shell within the Earth and probably remains primarily in disseminated form through the mantle and the core.

This primary geochemical differentiation was largely controlled by two independent factors, the geochemical affinity of the individual elements and the density of the principal phases. It is significant that the density of the individual elements is irrelevant in this context. Uranium and thorium, for example, are very heavy elements; nevertheless, they are concentrated in the crust, not in the core, because of their lithophile character (affinity for oxygen).

Separation of crust from mantle

The separation of crust from mantle has involved rather different geochemical processes than those of the segregation of the core. The core represents the physical separation of a high-density metallic liquid immiscible with the silicate material of the mantle and crust, whereas the separation of crust from mantle has resulted from more subtle geochemical processes. The mantle is made up very largely of the magnesium-iron silicates olivine and pyroxene (or their high-pressure equivalents). As discussed earlier, these minerals act as sorting mechanisms for other elements, accepting those of ionic size comparable to magnesium and iron and rejecting those much larger or smaller. The crust differs from the mantle in being enriched in those elements that do not readily enter the crystal structures of olivine and pyroxene. The common elements include the alkali metals (except lithium), aluminum, and calcium to some degree. These are combined in the crust in the form of the feldspar minerals, and one of the principal differences between crust and mantle is the dominance of feldspar in the former and its absence in the latter.

The differentiation of the crust from the mantle and core permits consideration of the outer part of the Earth as a distinct geochemical system. The distribution and migration of the elements within the crust (and in the hydrosphere and atmosphere) are the results of processes of magmatism, sedimentation, and metamorphism. The fate of an element during magmatic crystallization is primarily a function of its ionic size. If of appropriate size it enters the structure of one or other of the major minerals; otherwise, it tends to remain in the magmatic liquid until its concentration increases sufficiently for it to form specific minerals in which it is a major component. Volatile elements and compounds in the magma (principally water, carbon dioxide, nitrogen, and sulfur compounds) escape and are added to the atmosphere and hydrosphere.

Sedimentary processes lead to further geochemical differentiation. Liquid water is the medium in which these processes largely operate, and the solution chemistry of the individual elements is the key to their geochemical behaviour. The atmosphere and hydrosphere interact importantly with the lithosphere. Water and carbon dioxide are incorporated in sedimentary minerals; soluble ions, especially sodium, are added to the hydrosphere. Processes involving living organisms are intimately associated with sedimentation; indeed, some abundant and widespread sedimentary rocks, such as coal and limestone, are essentially biological in origin. These biological processes thus have had significant geochemical results. Photosynthesis also has been responsible for the present composition of the atmosphere.

Effects of metamorphism

Metamorphism tends in some degree to reverse the geochemical differentiation of the elements produced by igneous and sedimentary processes. In general, metamorphism promotes a more uniform distribution of the elements and tends to erase compositional differences within large rock masses. Unlimited metamorphism would result in a situation in which the whole lithosphere reached a uniform composition; such a trend is exemplified by the comparatively monotonous chemical and mineralogical composition of many extensive areas of metamorphic rocks.

This overall picture of the migration of the elements in the outer part of the Earth is the basis for the concept of the geochemical cycle (Figure 6). The geochemical cycle may be considered as beginning with the crystallization of a magma, which may produce a variety of igneous rocks and which adds volatile materials to the atmosphere and hydrosphere. Weathering decomposes the igneous rocks, and erosion eventually transports the decomposed rock to the oceans, partly as solid matter to form sedimentary rocks and partly as material in solution. Crustal movements may transport sedimentary and igneous rocks to deeper levels in the crust, where the combined effects of heat and pressure induce metamorphism. If the temperature rises above the melting point of some of the rock material, magma is regenerated, and the cycle is complete. Such a geochemical cycle seldom goes to completion; at some stage it may be indefinitely halted or its direction reversed. Nor is the cycle a closed one, either materially or energetically. The crust receives "primary" magma generated in the upper mantle, bringing with it additional material and energy in the form of heat. The surface of the Earth receives an increment of meteoritic matter from outer space, insignificant in amount but nevertheless detectable in deep-sea deposits, where the rate of sedimentation is very low.

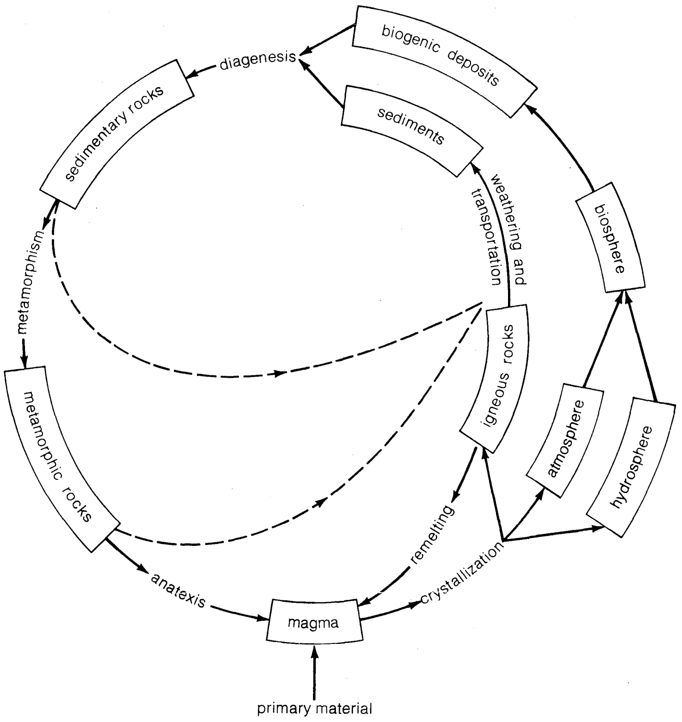

Figure 6: The geochemical cycle.

From B. Mason, *Principles of Geochemistry*, 3rd ed. (1966); John Wiley & Sons, Inc.

The geochemical cycle provides a useful conceptual framework for considering the course followed by an individual element in proceeding through the different stages. For a specific element, a complete understanding of its behaviour throughout the cycle is one of the major objectives of geochemical research. An element may tend to concentrate in a specific type of deposit at a particular stage in the cycle, or it may remain dispersed throughout the entire cycle. The geochemical cycles of a few elements have been elucidated in considerable detail, but for many of them knowledge is still fragmentary. (B.H.M./Ed.)

PERIODIC LAW AND TABLE

Dmitry I. Mendeleyev discovered in the mid-19th century that the chemical elements show a periodic recurrence of properties when they are arranged in a certain order, which is approximately the order of increasing atomic weight. The statement of this fact, which has been of inestimable value in the development of chemistry, is called the periodic law; a tabular arrangement of the elements that brings those with similar properties into juxtaposition is called the periodic table or periodic system of the elements.

It was recognized during the second decade of the 20th century that the order of elements in the periodic system is that of their atomic numbers, the integers which are equal to the positive electrical charges of the atomic nuclei expressed in electronic units; and in subsequent years great progress was made in explaining the periodic law in terms of the electronic structure of atoms and molecules. This clarification has increased the value of the law, which is used as much today as it was at the beginning of the 20th century, when it expressed the only known relationship among the elements.

History of the periodic law

The early years of the 19th century witnessed a rapid development in analytical chemistry—the art of distinguishing different chemical substances—and the consequent building up of a vast body of knowledge of the chemical and physical properties of both elements and compounds. This rapid expansion of chemical knowledge soon necessitated classification, for on the classification of chemical knowledge are based not only the systematized literature of chemistry but also the laboratory arts by which chemistry is passed on as a living science from one generation of chemists to another. Relationships were discerned more readily among the compounds than among the elements; it thus occurred that the classification of elements lagged many years behind that of compounds. In fact, no general agreement had been reached among chemists as to the classification of elements for nearly half a century after the systems of classification of compounds had become established in general use.

Triads of elements

J.W. Döbereiner in 1817 showed that the combining weight, meaning atomic weight, of strontium lies midway between those of calcium and barium; and some years later he showed that other such "triads" exist (chlorine, bromine, and iodine [halogens] and lithium, sodium, and potassium [alkali metals]). J.-B.-A. Dumas, L. Gmelin, E. Lenssen, Max von Pettenkofer, and J.P. Cooke expanded Döbereiner's suggestions between 1827 and 1858 by showing that similar relationships extended further than the triads of elements, fluorine being added to the halogens, and magnesium to the alkaline-earth metals; while oxygen, sulfur, selenium, and tellurium were classed as one family, and nitrogen, phosphorus, arsenic, antimony, and bismuth as another family of elements.

Attempts were made subsequently to show that the atomic weights of the elements could be expressed by an arithmetic function, and in 1862 A.-E.-B. de Chancourtois proposed a classification of the elements based on the new values of atomic weights given by Stanislao Cannizzaro's system of 1858. De Chancourtois plotted the atomic weights on the surface of a cylinder with a circumference of 16 units, corresponding to the approximate atomic weight of oxygen. The resulting helical curve brought closely related elements onto corresponding points above or below one another on the cylinder, and he suggested in consequence that "the properties of the elements are the properties of numbers," a remarkable prediction in the light of modern knowledge.

CLASSIFICATION OF THE ELEMENTS

Several years later, in 1864, J.A.R. Newlands proposed a system of classification of the elements in the order of increasing atomic weights, the elements being assigned ordinal numbers from unity upward and divided into seven groups having properties closely related to the first seven of the elements then known: hydrogen, lithium, beryllium, boron, carbon, nitrogen, and oxygen. This relationship was termed the law of octaves, by analogy with the seven intervals of the musical scale.

Then in 1869, as a result of an extensive correlation of the properties and the atomic weights of the elements, with special attention to valency (that is, the number of single bonds the element can form), Mendeleyev proposed the periodic law, by which "the elements arranged according to the magnitude of atomic weights show a periodic change of properties." Lothar Meyer had independently reached a similar conclusion, published after the appearance of Mendeleyev's paper.

The first periodic table. Mendeleyev's periodic table of 1869 contained 17 columns, with two nearly complete periods (sequences) of elements, from potassium to bromine and rubidium to iodine (see Figures 8 and 9), preceded by two partial periods of seven elements each (lithium to fluorine and sodium to chlorine), and followed by three incomplete periods. In an 1871 paper Mendeleyev presented a revision of the 17-group table, the principal improvement being the correct repositioning of 17 elements. He, as well as Lothar Meyer, also proposed a table with eight columns obtained by splitting each of the long periods into a period of seven, an eighth group containing the three central elements (such as iron, cobalt, nickel; Mendeleyev also included copper, instead of placing it in Group I), and a second period of seven. The first and second periods of seven were later distinguished by use of the letters "a" and "b" attached to the group symbols, which were the Roman numerals.

Addition of a new "zero" group

With the discovery of the noble gases helium, neon, argon, krypton, radon, and xenon by Lord Rayleigh (John William Strutt) and Sir William Ramsay in 1894 and the following years, Mendeleyev and others proposed that a new "zero" group to accommodate them be added to the periodic table. The "short-period" form of the periodic table, Figure 7, with Groups 0, I, II, . . . VIII, became popular, and remained in general use until about 1930.

Based upon an earlier (1882) model of T. Bayley, J. Thomsen in 1895 devised a new table. This was interpreted in terms of the electronic structure of atoms by Niels Bohr in 1922. In this table, Figure 8, there are periods of increasing length between the noble gases; the table thus contains a period of 2 elements, two of 8 elements, two of 18 elements, one of 32 elements, and an incomplete period. The elements in each period may be connected by tie lines with one or more elements in the following period. The principal disadvantage of this table is the large space required by the period of 32 elements and the difficulty of tracing a sequence of closely similar elements. A very satisfactory compromise, shown in Figure 9, is to compress the period of 32 elements into 18 spaces by omitting the 14 lanthanons (lanthanides) and the 14 actinons (actinides) and listing them in a special double row below the other periods.

Other versions of the periodic table. Alternate long forms of the periodic table have been proposed from time to time. One of the earliest of these, described by A. Werner in 1905, is notable because it divides each of the shorter periods into two parts, one at either end of the table over the elements in the longer periods that they most resemble. The multiple tie lines connecting the periods in the Bayley-type table are thereby dispensed with. This class of table, too, can be greatly simplified by removing the lanthanon and actinon elements to a separate area. By the mid-20th century this version of the table (Figure 10) had become the most commonly used.

PREDICTIVE VALUE OF THE PERIODIC LAW

Discovery of new elements. The great value of the periodic law was made evident by Mendeleyev's success in 1871 in finding that the properties of 17 elements could be correlated with those of other elements by moving the 17 to new positions from those indicated by their atomic weights. This change indicated that there were small errors in the previously accepted atomic weights of several of the elements and large errors for several others, for which wrong multiples of the combining weights had been used as atomic weights (the combining weight being that weight of an element that combines with a given weight of a standard). Mendeleyev was also able to predict the existence, and many of the properties, of the then undiscovered elements ekaboron, ekaaluminum, and

ekasilicon, now identified with the elements scandium, gallium, and germanium, respectively. Similarly, after the discovery of helium and argon, the periodic law permitted the prediction of the existence of neon, krypton, xenon, and radon. Moreover, Bohr pointed out that the missing element 72 would be expected, from its position in the periodic system, to be similar to zirconium in its properties rather than to the rare earths; this observation led G. de Hevesy and D. Coster in 1922 to examine zirconium ores and to discover the unknown element, which they named hafnium.

In spite of the corrections made by the redetermination of atomic weights, some of the elements in the Mendeleyev and Lothar Meyer periodic tables of 1871 were still required by their properties to be put in positions somewhat out of the order of atomic weights. Thus, in the pairs argon and potassium, cobalt and nickel, and tellurium and iodine, the first element has the greater atomic weight but the earlier position in the periodic system. The eventual solution to this difficulty was found only when the structure of the atom was better understood.

Significance of the atomic number

About 1910, Sir Ernest Rutherford's experiments on the scattering of alpha particles by the nuclei of heavy atoms led to the determination of the nuclear electrical charge. The ratio of the nuclear charge to that of the electron was noted to be roughly one-half the atomic weight. In 1911 A. van den Broek suggested that this quantity, the atomic number, might be identified with the ordinal number of the element in the periodic system (following the lead of Newlands, it had become customary to number the elements according to their position in the table). This suggestion was brilliantly confirmed in 1913 by H.G.J. Moseley's measurements of the wavelengths of the characteristic X-ray spectral lines of many elements, which showed that the wavelengths did indeed depend in a regular way upon the atomic numbers—identical with the ordinal numbers of the elements in the table. There is no longer any uncertainty about the position of any element in the ordered series of the periodic system. All of the elements from 1 to 107 are now known, and it is to be expected that new elements beyond 107 will be made by nuclear reactions.

Figure 9: Long-period form of periodic system of elements.

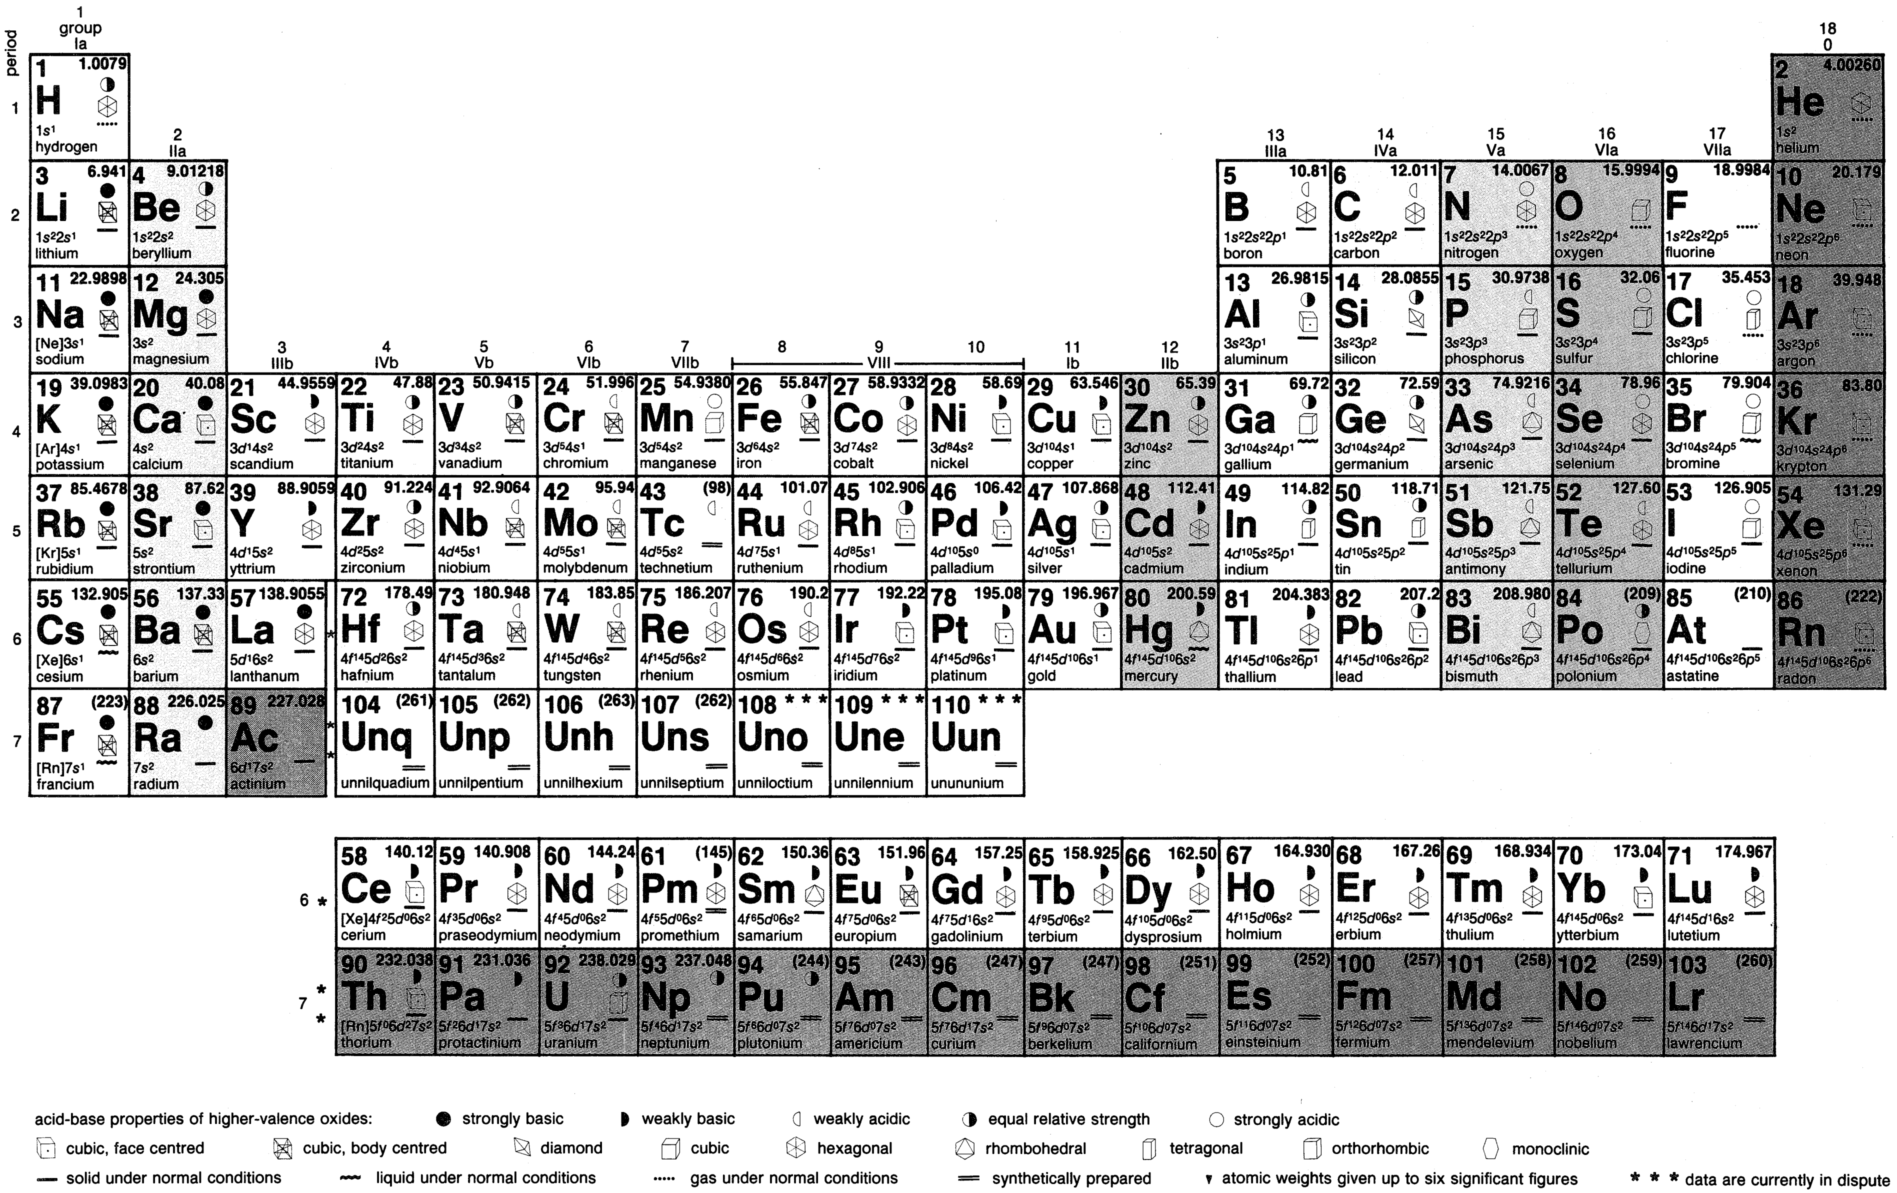

Figure 10: Modern version of the periodic table of the elements.

That the exact atomic weight of an element is of small significance for its position in the periodic system is shown by the existence of isotopes of every element, atoms with the same atomic number but different atomic weights. The chemical properties of the isotopes of an element are essentially the same, and all of the isotopes of an element occupy the same place in the periodic system in spite of their differences in atomic weight.

Elucidation of the periodic law. Detailed understanding of the periodic system has developed along with the quantum theory of spectra and the electronic structure of atoms, beginning with the work of Bohr in 1913. Important forward steps were the formulation of the general rules of the old quantum theory by W. Wilson and A. Sommerfeld in 1916, the discovery of the exclusion principle by W. Pauli in 1925 (see ATOMS), the discovery of the spin of the electron by G.E. Uhlenbeck and S. Goudsmit in 1925, and the development of quantum mechanics (see MECHANICS: *Quantum mechanics*) by W. Heisenberg and E. Schrödinger during the same year. The development of the electronic theory of valence and molecular structure (see MOLECULES), beginning with the postulate of the shared electron pair by G.N. Lewis in 1916, also played a very important part in explaining the periodic law (see MOLECULES and CHEMICAL REACTIONS).

The long form of the periodic table

PERIODS

The long-period form of the periodic system of the elements, presented here in two forms, Figures 9 and 10, contains all of the chemical elements that have been discovered or made; they are arranged, in the order of their atomic numbers, in seven horizontal periods, with the lanthanons (lanthanum, 57, to lutetium, 71) and the actinons (actinium, 89, to lawrencium, 103) indicated separately below (unless otherwise stated, Figure 9 will be used as reference). The periods are of varying lengths. First there is the hydrogen period, consisting of the two elements hydrogen, 1, and helium, 2. Then there are two periods of eight elements each: the first short period, from lithium, 3, to neon, 10; and the second short period, from sodium, 11, to argon, 18. There follow two periods of 18 elements each: the first long period, from potassium 19, to krypton, 36; and the second long period, from rubidium, 37, to xenon, 54. The very long period of 32 elements, from cesium, 55, to radon, 86, is condensed into 18 columns by the omission of the lanthanons (which are indicated separately below), permitting the remaining 18 elements, which are closely similar in their properties to corresponding elements of the first and second long periods, to be placed directly below these elements. The last period is incomplete. The properties of these elements indicate that this period is a second very long period of 32 elements, which would be completed at element 118.

GROUPS

The six noble gases, helium, neon, argon, krypton, xenon, and radon, occur at the ends of the six completed periods and constitute the 0 group of the periodic system. (It is customary to refer to horizontal series of elements in the table as periods and vertical series as groups.) The seven elements lithium to fluorine and the seven corresponding elements sodium to chlorine are placed, in Figure 9, in the seven groups, I, II, III, IV, V, VI, and VII, respectively. The 17 elements of the fourth period, from potassium, 19, to bromine, 35, are distinct in their properties and might well be considered to constitute 17 subgroups of the periodic system. Largely for historical reasons (the use of the short-period form of the periodic system, Figure 7), however, it is customary to describe them as constituting 15 subgroups, the three consecutive elements iron, cobalt, and nickel and their congeners in the succeeding periods being placed in a single group, VIII. The elements potassium, 19, to manganese, 25, are assigned to subgroups Ia, IIa, IIIa, IVa, Va, VIa, and VIIa, respectively; and the elements copper, 29, to bromine, 35, are assigned to subgroups Ib, IIb, IIIb, IVb, Vb, VIb, and VIIb. (In some modern versions of the periodic system, the members of subgroups a and b in Groups III and above are the reverse of the arrangement shown here. There is no one standard form of the system.)

Subgroups

The first group, the alkali metals, thereby includes, in addition to lithium and sodium, the metals from potassium down the table to francium, but not the much less similar metals of subgroup Ib (copper, etc.). Also the second group, the alkaline-earth metals, is considered to include beryllium, magnesium, calcium, strontium, barium, and radium but not the elements of subgroup IIb. The properties of the elements do not indicate unambiguously whether the boron group might be considered better to include the subgroup IIIa or the subgroup IIIb, although the former is often so included. The other four groups are as follows: the carbon group, IV, consists of carbon, silicon, germanium, tin, and lead; the nitrogen group, V, includes nitrogen, phosphorus, arsenic, antimony, and bismuth; the oxygen group, VI, includes oxygen, sulfur, selenium, tellurium, and polonium; and the halogen group, VII, includes fluorine, chlorine, bromine, iodine, and astatine.

Although hydrogen is included in Group I in some versions of the table, it is not closely similar to either the alkali metals or the halogens in its chemical properties. It is, however, assigned the oxidation number +1 in compounds such as hydrogen fluoride, HF, and −1 in compounds such as lithium hydride, LiH; and it may hence be considered as being similar to a Group Ia element and to a Group VII element, respectively, in compounds of these two types, taking the place first of Li and then of F in lithium fluoride, LiF. Hydrogen is, in fact, the most individualistic of the elements: no other element resembles it in the way that sodium resembles lithium, chlorine resembles fluorine, and neon resembles helium. It is a unique element, the only element that cannot conveniently be considered a member of a group.

A number of the elements of each long period are called the transition metals. These are usually taken to be scandium, 21, to zinc, 30 (the iron-group transition metals); yttrium, 39, to cadmium, 48 (the palladium-group transition metals); and hafnium, 72, to mercury, 80 (the platinum-group transition metals). By this definition, the transition metals include Groups IIIa to VIIa, VIII, and Ib and IIb (Figure 9) in the long periods.

Periodic properties

The periodicity in properties of the elements arranged in order of atomic number is strikingly shown by the consideration of the physical state of the elementary substances and such related properties as the melting point, density, and hardness. The elements of Group 0 are gases that are difficult to condense. The alkali metals, in Group I, are soft, metallic solids with low melting points. The alkaline-earth metals, in Group II, are harder and have higher melting points than the adjacent alkali metals. The hardness and melting point continue to increase through Groups III and IV and then decrease through Groups V, VI, and VII. The elements of the long periods show a gradual increase in hardness and melting point from the beginning alkali metals to near the centre of the period and then at Group VIb an irregular decrease to the halogens and noble gases.

The valence of the elements (that is, the number of bonds formed with a standard element) is closely correlated with position in the periodic table, the elements in the main groups having maximum positive valence, or oxidation number, equal to the group number, and maximum negative valence equal to the difference between eight and the group number.

The general chemical properties described as metallic or base forming, metalloid or amphoteric, and nonmetallic, or acid forming, are correlated with the periodic table in a simple way: the most metallic elements are to the left and to the bottom of the periodic table, and the most nonmetallic elements are to the right and to the top (ignoring the noble gases). The metalloids are adjacent to a diagonal line from boron to polonium. A closely related property is electronegativity, the tendency of atoms to retain their electrons and to attract additional electrons. The degree of electronegativity of an element is shown by ionization potential, electron affinity, oxidation-reduction potential, the energy of formation of chemical bonds, and other properties. It is shown to depend upon the element's position in the periodic table in the same way that nonmetallic character does, fluorine being the most electronegative element and cesium (or francium) the least electronegative (most electropositive) element.

Atomic sizes

The sizes of atoms of elements vary regularly throughout the periodic system. Thus, the effective bonding radius (or one-half the distance between adjacent atoms) in the elementary substances in their crystalline or molecular forms decreases through the first short period from 1.52 Å for lithium to 0.73 Å for fluorine; at the beginning of the second period, the bonding radius rises abruptly to 1.86 Å for sodium and gradually decreases to 0.99 Å for chlorine. The behaviour through the long periods is more complex: the bonding radius decreases gradually from 2.31 Å for potassium to a minimum of 1.25 Å for cobalt and nickel, then rises slightly, and finally falls to 1.14 Å for bromine. The sizes of atoms are of importance in the determination of coordination number (that is, the number of groups attached to the central atom in a compound) and hence in the composition of compounds. The increase in atomic size from the upper right corner of the periodic table to the lower left corner is reflected in the formulas of the oxygen acids of the elements in their highest states of oxidation (see Table 9). The smallest atoms group only three oxygen atoms about themselves; the next larger atoms, which coordinate a tetrahedron of four oxygen atoms, are in a diagonal belt; and the still larger atoms, which form octahedral oxygen complexes (stannic acid, antimonic acid, telluric acid, paraperiodic acid), lie below and to the left of this belt. Only the chemical and physical properties of the elements are determined by the extranuclear electronic structure; these properties show the periodicity described in the periodic law. The properties of the atomic nuclei themselves, such as the magnitude of the packing fraction and the power of entering into nuclear reactions, are, although dependent upon the atomic number, not dependent in the same periodic way.

Table 9: Formulas of Oxygen Acids of Elements in Their Highest Oxidation State

$H_2Be(OH)_4$	H_3BO_3	H_2CO_3	HNO_3		
	$HAl(OH)_4$	H_4SiO_4	H_3PO_4	H_2SO_4	$HClO_4$
		H_4GeO_4	H_3AsO_4	H_2SeO_4	
		$H_2Sn(OH)_6$	$HSb(OH)_6$	H_6TeO_6 and H_2TeO_4	HIO_4 and H_5IO_6

The basis of the periodic system

ELECTRONIC STRUCTURE

The noble gases—helium, neon, argon, krypton, xenon, and radon—have the striking chemical property of forming few chemical compounds. This property would depend upon their possessing especially stable electronic structures (that is, structures so firmly knit that they would not yield to accommodate ordinary chemical bonds). During the development of modern atomic physics and the theory of quantum mechanics, a precise and detailed understanding was obtained of the electronic structure of the noble gases and other atoms that explains the periodic law in a thoroughly satisfactory manner.

Quantum numbers

The Pauli exclusion principle states that no more than two electrons can occupy the same orbit—or, in quantum-mechanical language, orbital—in an atom and that two electrons in the same orbital must be paired (that is, must have their spins opposed). The orbitals in an atom may be described by a principal quantum number, n, which may assume the values 1, 2, 3, . . . , and by an azimuthal quantum number, l, which may assume the values 0, 1, 2, . . . , $n-1$. There are $2l+1$ distinct orbitals for each set of values of n and l. The most stable orbitals, which bring the electron closest to the nucleus, are those with the smallest values of n and l. The electrons that occupy the orbital with $n=1$ (and $l=0$) are said to be in the *K* shell of electrons; the *L*, *M*, *N*, . . . shells correspond respectively to $n=2$, 3, 4, ... Each shell except the *K* shell is divided into subshells corresponding to the values 0, 1, 2, 3, . . . of the orbital quantum number l; these subshells are called the *s*, *p*, *d*, *f*, . . . subshells, and they can accommodate a maximum of 2, 6, 10, 14, . . . electrons. (There is no special significance to the letter designations of the quantum numbers or of the shells and subshells.)

The approximate order of stability of the successive subshells in an atom is indicated in the chart below. The number of electrons in the atoms of the elements increases with increasing atomic number, and the added electrons go, of necessity, into successively less stable shells. The most stable shell, the *K* shell, is completed with helium, which has two electrons. The *L* shell is then completely filled at neon, with atomic number 10. The atoms of the heavier noble gases do not, however, have a completed outer shell but instead have *s* and *p* subshells only. The outer shell of eight electrons is called traditionally an octet. The *d* subshells and *f* subshells subsequently are also filled with electrons after the initially less stable orbitals are occupied, an inversion of stability having occurred with increasing atomic number.

The electron occupancy of the shells in the noble gas atoms is as follows:

Electrons in	*K*	*L*	*M*	*N*	*O*	*P*	*Q*	shell
He 2:	2							
Ne 10:	2	8						
Ar 18:	2	8	8					
Kr 36:	2	8	18	8				
Xe 54:	2	8	18	18	8			
Rn 86:	2	8	18	32	18	8		
118:	2	8	18	32	32	18	8	

The numbers 2, 8, 18, and 32 correspond to filling the *s*; *s* and *p*; *s*, *p*, and *d*; and *s*, *p*, *d*, and *f* subshells, respectively.

Periods and electron shells

The first period of the periodic table is complete at helium, when the *K* shell is filled with two electrons. The first and second short periods represent the filling of the 2*s* and 2*p* subshells (completing the *L* shell at neon) and the 3*s* and 3*p* subshells (at argon), leaving the *M* shell incomplete. The first long period begins with the introduction of electrons into the 4*s* orbital. Then, at scandium, the five 3*d* orbitals of the inner *M* shell begin to be occupied. It is the successive occupancy of these five 3*d* orbitals by their complement of ten electrons that characterizes the ten elements of the iron-group transition series. At krypton the *M* shell is complete and there is an octet in the *N* shell. The second long period, of 18 elements, similarly represents the completion of an outer octet and the next inner subshell of ten 4*d* electrons.

The very long period of 32 elements results from the completion of the 4*f* subshell of 14 electrons, the 5*d* subshell of 10 electrons, and the 6*s*, 6*p* octet. The filling of the 4*f* orbitals corresponds to the sequence of 14 lanthanons, and that of the 5*d* orbitals to the 10 platinum-group transition metals.

The next period, which is incomplete, involves the 5*f* subshell of 14 electrons, the 6*d* subshell of 10 electrons, and the 7*s*, 7*p* octet. The filling of the 5*f* orbitals corresponds to the actinons, the elements beginning with thorium, atomic number 90.

The successive periods of the system hence correspond to the introduction of electrons into the following orbitals:

The very short period, H, He.	2 elements. 1*s*.
The first short period, Li to Ne.	8 elements. 2*s*, 2*p*.
The second short period, Na to Ar.	8 elements. 3*s*, 3*p*.
The first long period, K to Kr.	18 elements. 3*d*, 4*s*, 4*p*.
The second long period, Rb to Xe.	18 elements. 4*d*, 5*s*, 5*p*.
The very long period, Cs to Rn.	32 elements. 4*f*, 5*d*, 6*s*, 6*p*.
The incomplete period, Fr to 118.	32 elements. 5*f*, 6*d*, 7*s*, 7*p*.

There are advantages to replacing the *K*, *L*, *M*, . . . shells by a different grouping of the subshells, in which those with nearly the same energy are grouped together, in close correlation with the periodic system. The new set of shells is the following:

The helium shell.	2 electrons. 1*s*.
The neon shell.	8 electrons. 2*s*, 2*p*.
The argon shell.	8 electrons. 3*s*, 3*p*.
The krypton shell.	18 electrons. 4*s*, 4*p*, 3*d*.
The xenon shell.	18 electrons. 5*s*, 5*p*, 4*d*.
The radon shell.	32 electrons. 6*s*, 6*p*, 5*d*, 4*f*.
The eka-radon shell.	32 electrons. 7*s*, 7*p*, 6*d*, 5*f*.

PERIODICITY IN PROPERTIES OF THE ELEMENTS

Properties and electronic structure

The periodicity of properties of the elements is caused by the periodicity in electronic structure. The noble gases are chemically unreactive, or nearly so, because their electronic structures are stable—their atoms hold their quota of electrons strongly, have no affinity for more electrons, and have little tendency to share electrons with other atoms. An element close to a noble gas in the periodic system, on the other hand, is reactive chemically because of the possibility of assuming the stable electronic configuration of the noble gas, by losing one or more electrons to another atom, by gaining one or more electrons from another atom, or by sharing electrons. The alkali metals, in Group I, can assume the noble-gas configuration by losing one electron, which is loosely held in the outermost (valence) shell, to another element with greater electron affinity, thus producing the stable singly charged positive ions. Similarly the alkaline-earth metals can form doubly charged positive ions with the noble-gas electronic configuration by losing the two loosely held electrons of the valence shell; the positive ionic valences of the elements of the first groups are hence equal to the group numbers. The elements just preceding the noble gases can form negative ions with the noble-gas configuration by gaining electrons; the negative ionic valences of these elements are equal to the difference between eight and their group numbers. The covalence (or number of shared electron pairs) of an atom is determined by its electron number and the stable orbitals available to it. An atom such as fluorine, with seven electrons in its outer shell, can combine with a similar atom by sharing a pair of electrons with it; each atom thus achieves the noble-gas configuration by having three unshared pairs and one shared electron pair in its valence shell.

The properties of elements in the same group of the periodic system are, although similar, not identical. The trend in properties from the lighter to the heavier elements may be attributed to changes in the strength of binding of the outer electrons and especially to the increasing size of the atoms. (L.C.P.)

Other chemical and physical classifications

Certain methods of classifying elements on the basis of chemical properties are not strictly related to the groups in which the elements appear. Such classification schemes illustrate the fact that useful horizontal as well as vertical relationships exist in the periodic table. Thus, the transition elements, either as a whole or as three horizontal series, are often considered together when chemical properties are discussed. The transition elements in each horizontal series exhibit much less variation in atomic size than do the elements in other parts of the same periods, leading to a similarity in chemical and physical properties. The lanthanide and actinide elements exhibit an even greater similarity for the same reason. The metallic elements in Groups Ia and IIa are often classed together because they are markedly more reactive than the other metallic elements. At the other extreme, elements of the platinum group—including ruthenium, rhodium, palladium, osmium, iridium, and platinum—are chemically inert, as are silver and gold; these elements are collectively designated the noble metals because they do not readily enter into combination with other elements.

Solid, liquid, and gaseous elements

Of all the 107 known elements, 11 are gaseous, 2 are liquid, and the remainder are solids under ordinary conditions. Except for hydrogen and mercury, the gaseous and liquid elements occur in the right-hand part of the periodic table, the region associated with the nonmetallic elements.

The physical characteristics of the elements provide convenient means of identification. The melting points of the various elements range from −272° C (for helium) to greater than 3,500° C (for carbon in the form of diamond). Properties such as boiling points, electrical conductivity, and thermal conductivity also can be used for identification because they are unique for each element. Perhaps the single most useful characteristic for identifying an element is its pattern of light absorption, or emission, which is called a spectrum. An element exhibits its own characteristic spectrum whether it exists in the free state, in a mixture, or in chemical combination with other elements. Since the intensity of the spectrum is dependent upon the amount of the element contained in the sample, the spectrum also can be used as a means for quantitative analysis of the elements. There are several chemical methods for estimating the percentage of an element present in a sample; these, however, require a detailed knowledge of the chemistry of the element in question (see ANALYSIS AND MEASUREMENT).

Man-made elements

All naturally occurring elements with atomic numbers greater than 84 are radioactive; these constitute the three families of radioactive elements (*i.e.,* the uranium, thorium, and actinide series), the elements of which are converted from one to another by radioactive processes. In addition, several naturally occurring isotopes of the lighter elements are radioactive. The atomic nuclei of all radioactive elements are unstable and emit highly energetic particles. In the process, the number of protons in the nucleus changes, and the atom is transformed into one of a different element. The half-life of a radioactive isotope is the time required for half of any amount of the isotope to disintegrate by radioactive decay. The common modes of decay of radioactive isotopes are loss of beta or alpha particles or the capture of an electron. The loss of a beta particle, or electron, from the nucleus increases the atomic number by one unit; the loss of an alpha particle, or helium nucleus (two protons and two neutrons), decreases the atomic number by two units; and the process of electron capture, in which an electron from an inner shell is drawn into the nucleus, corresponds to a decrease of atomic number by one unit. Eleven radioactive synthetic, or man-made, elements (see below *Transuranium elements*) have not as yet been found in nature and the presence of two nontransuranium elements has not been verified absolutely. Although the remaining elements generally are not considered to be radioactive, some do have radioactive isotopes that exist naturally in very small concentrations, and more than 1,000 radioactive isotopes of these elements have been prepared in the laboratory. (J.J.L./Ed.)

THE ELEMENT GROUPS

Hydrogen, the introductory element to the entire periodic classification, has unusual properties. In some of its reactions hydrogen resembles the alkali metals, but in others it appears closely akin to the halogens. It is the only element that cannot be considered a distinct member of any particular group and is therefore often, as here, treated by itself. The balance of the section treats the main groups of the periodic table, the transition elements, and the related inner transition series—the lanthanides and the actinides. The transuranium elements beyond those usually included among the actinides, the so-called transactinides, are also discussed in brief and the possible existence of superheavy elements (*i.e.,* elements with atomic numbers of 110 or higher) is considered. (Ed.)

Hydrogen

Although hydrogen is the most abundant element in the Galaxy (ten times as abundant as helium, the next most widely occurring element), it makes up only about 0.14 percent of the Earth's crust by weight. It occurs, however, in vast quantities as part of the water in oceans, ice packs, rivers, lakes, and the atmosphere. As part of innumerable carbon compounds, hydrogen is present in all animal and vegetable tissue and in petroleum. Even though it is often said that there are more known compounds of carbon than of any other element, the fact is that since hydrogen is contained in almost all carbon compounds and also forms a multitude of compounds with all other elements (except some of the noble gases), it is possible that hydrogen compounds are more numerous. Hydrogen is an odourless, tasteless, colourless gas; the lightest and simplest chemical element. A hydrogen atom, represented by the symbol H, has, for its nucleus, a single proton (*i.e.,* a particle of matter with a positive charge equal to the opposite, negative charge of an electron) surrounded by one orbiting electron. Under ordinary conditions, hydrogen gas is a loose aggregation of hydrogen molecules, each consisting of a pair of atoms, a diatomic molecule, H_2. The earliest known important chemical property of hydrogen is that it burns with oxygen to form water, H_2O; indeed, the name hydrogen is derived from Greek words meaning "maker of water."

Elementary hydrogen finds its principal industrial application in the manufacture of ammonia (a compound of hydrogen and nitrogen, NH_3) and in the hydrogenation of carbon monoxide and organic compounds.

Hydrogen has three known isotopes. The mass numbers of hydrogen's isotopes are 1, 2, and 3, the most abundant being the mass 1 isotope generally called hydrogen (symbol H, or ^1H) but also known as protium. The mass 2 isotope, which has a nucleus of one proton and one neutron and has been named deuterium, or heavy hydrogen (symbol D, or ^2H), constitutes 0.0156 percent of the ordinary mixture of hydrogen. Tritium (symbol T, or ^3H), with one proton and two neutrons in each nucleus, is the mass 3 isotope and constitutes about 10^{-15} to 10^{-16} percent of hydrogen. The practice of giving distinct names to the hydrogen isotopes is justified by the fact that there are significant differences in their properties.

Early experimentation with hydrogen

Paracelsus, physician and alchemist, in the 16th century unknowingly experimented with hydrogen when he found that an inflammable gas was evolved when a metal was dissolved in acid. The gas, however, was confused with other inflammable gases, such as hydrocarbons and carbon monoxide. In 1766 Henry Cavendish, English chemist and physicist, showed that hydrogen, then called inflammable air, phlogiston, or the inflammable principle, was distinct from other combustible gases because of its density and the amount of it that evolved from a given amount of acid and metal. In 1781 Cavendish confirmed previous observations that water was formed when hydrogen was burned, and Antoine-Laurent Lavoisier, the father of modern chemistry, coined the French word *hydrogène* from which the English form is derived. In 1929 Karl Friedrich Bonhoeffer, a German physical chemist, and Paul Harteck, an Austrian chemist, on the basis of earlier theoretical work, showed that ordinary hydrogen is a mixture of two kinds of molecules, *ortho*-hydrogen and *para*-hydrogen. Because of the simple structure of hydrogen, its properties can be theoretically calculated relatively easily. Hence hydrogen is often used as a theoretical model for more complex atoms, and the results are applied qualitatively to other atoms.

Table 10: Some Properties of Normal Hydrogen and Deuterium

	normal hydrogen	deuterium
Atomic hydrogen		
Atomic number	1	1
Atomic weight	1.0080	2.0141
Ionization potential	13.595 eV	13.600 eV
Electron affinity	0.754 eV	—
Nuclear spin	½	1
Nuclear magnetic moment (nuclear magnetons)	2.7927	0.8574
Nuclear quadrupole moment	0	2.77×10^{-27} cm^2
Electronegativity (Pauling)	2.1	~2.1
Molecular hydrogen		
Bond distance	0.7416 Å	0.7416 Å
Dissociation energy (25° C)	104.19 kcal/mole	105.97 kcal/mole
Ionization potential	15.427 eV	15.457 eV
Density of solid	0.08671 g/cm^3	0.1967 g/cm^3
Melting point	−259.20° C	−254.43° C
Heat of fusion	28 cal/mole	47 cal/mole
Density of liquid	0.07099 (−252.78°)	0.1630 (−249.75°)
Boiling point	−252.77° C	−249.49° C
Heat of vaporization	216 cal/mole	293 cal/mole
Critical temperature	−240.0° C	−234.8° C
Critical pressure	13.0 atm	16.4 atm
Critical density	0.0310 g/cm^3	0.0668 g/cm^3
Heat of combustion to H_2O(g)	−57.796 kcal/mole	−59.564 kcal/mole

PHYSICAL AND CHEMICAL PROPERTIES

Table 10 lists the important properties of molecular hydrogen, H_2. The extremely low melting and boiling points result from weak forces of attraction between the molecules. The existence of these weak intermolecular forces is also revealed by the fact that, when hydrogen gas expands from high to low pressure at room temperature, its temperature rises, whereas the temperature of most other gases falls. According to thermodynamic principles, this implies that repulsive forces exceed attractive forces between hydrogen molecules at room temperature, otherwise the expansion would cool hydrogen. In fact, at −68.6° C attractive forces predominate, and hydrogen, therefore, cools upon being allowed to expand below that temperature. The cooling effect becomes so pronounced at temperatures below that of liquid nitrogen (−196° C) that the effect is utilized to achieve the liquefaction temperature of hydrogen gas itself.

Hydrogen is transparent to visible light, to infrared light, and to ultraviolet light to wavelengths below 1800 Å. Because its molecular weight is lower than that of any other gas, its molecules have a velocity higher than those of any other gas at a given temperature and it diffuses faster than any other gas. Consequently, kinetic energy is distributed faster through hydrogen than through any other gas; it has, for example, the greatest heat conductivity.

The hydrogen molecule

A molecule of hydrogen is the simplest possible molecule. It consists of two protons and two electrons held together by electrostatic forces. Like atomic hydrogen, the assemblage can exist in a number of energy levels.

Ortho-hydrogen and para-hydrogen. Two types of molecular hydrogen (*ortho* and *para*) are known. These differ in the magnetic interactions of the protons due to the spinning motions of the protons. In *ortho*-hydrogen, the spins of both protons are aligned in the same direction—that is, they are parallel. In *para*-hydrogen, the spins are aligned in opposite directions and are therefore antiparallel. The relationship of spin alignments determines the magnetic properties of the atoms. Normally, transformations of one type into the other (*i.e.,* conversions between *ortho* and *para* molecules) do not occur and *ortho*-hydrogen and *para*-hydrogen can be regarded as two distinct modifications of hydrogen. The two forms may, however, interconvert under certain conditions. Equilibrium between the two forms can be established in several ways. One of these is by the introduction of catalysts (such as activated charcoal or various paramagnetic substances); another method is to apply an electrical discharge to the gas or to heat it to a high temperature.

The concentration of *para*-hydrogen in a mixture that has achieved equilibrium between the two forms depends on the temperature as shown by the following figures:

−253.1° C	99.82%	−153.1° C	32.87%
−223.1° C	76.89%	0° C	25.13%
−193.1° C	48.39%	200° C	25.00%

Isolation of *para*-hydrogen

Essentially pure *para*-hydrogen can be produced by bringing the mixture into contact with charcoal at the temperature of liquid hydrogen; this converts all the *ortho* into *para*. The *ortho*-hydrogen, on the other hand, cannot be prepared directly from the mixture because the concentration of *para*-hydrogen is never less than 25 percent.

The two forms of hydrogen have slightly different physical properties. The melting point of *para*-hydrogen is 0.10° lower than that of a 3:1 mixture of *ortho*-hydrogen and *para*-hydrogen. At −252.77° C the pressure exerted by the vapour over liquid *para*-hydrogen is 1.035 atmospheres (one atmosphere is the pressure of the atmosphere at sea level under standard conditions, equal to about 14.69 pounds per square inch), compared with 1.000 atmosphere for the vapour pressure of the 3:1 *ortho–para* mixture. As a result of the different vapour pressures of *para*-hydrogen and *ortho*-hydrogen, these forms of hydrogen can be separated by low-temperature gas chromatography, an analytical process that separates different atomic and molecular species on the basis of their differing volatilities.

Reactivity of hydrogen. One molecule of hydrogen dissociates into two atoms ($H_2 \rightarrow 2H$) when an energy equal to or greater than the dissociation energy (*i.e.,* the amount of energy required to break the bond that holds together the atoms in the molecule) is supplied. The dissociation energy of molecular hydrogen is 104,000 calories per mole—written 104 kcal/mole (mole: the molecular weight expressed in grams, which is two grams in the case of hydrogen). Sufficient energy is obtained, for example, when the gas is brought into contact with a white-hot tungsten filament or when an electric discharge is established in the gas. If atomic hydrogen is generated in a system at low pressure, the atoms will have a significant lifetime—*e.g.,* 0.3 second at a pressure of 0.5 millimetre of mercury. Atomic hydrogen is very reactive. It combines with most elements to form hydrides (*e.g.,* sodium hydride, NaH), and it reduces metallic oxides, a reaction that produces the metal in its elemental state. The surfaces of metals that do not combine with hydrogen to form stable hydrides (*e.g.,* platinum) catalyze the recombination of hydrogen atoms to form hydrogen molecules and are thereby heated to incandescence by the energy that this reaction releases.

Molecular hydrogen can react with many elements and compounds, but at room temperature the reaction rates are usually so low as to be negligible. This apparent inertness is in part related to the very high dissociation energy of the molecule. At elevated temperatures, however, the reaction rates are high.

Explosive mixtures

Sparks or certain radiations can cause a mixture of hydrogen and chlorine to react explosively to yield hydrogen chloride, as represented by the equation $H_2 + Cl_2 \rightarrow 2HCl$. Mixtures of hydrogen and oxygen react at a measurable rate only above 300° C, according to the equation $2H_2 + O_2 \rightarrow 2H_2O$. Such mixtures containing 4 to 94 percent hydrogen ignite when heated to 550°–600° C or when brought into contact with a catalyst, spark, or flame. The explosion of a 2:1 mixture of hydrogen and oxygen is especially violent. Almost all metals and nonmetals react with hydrogen at high temperatures. At elevated temperatures and pressures hydrogen reduces the oxides of most metals and many metallic salts to the metals. For example, hydrogen gas and ferrous oxide react, yielding metallic iron and water, $H_2 + FeO \rightarrow Fe + H_2O$; hydrogen gas reduces palladium chloride to form palladium metal and hydrogen chloride, $H_2 + PdCl_2 \rightarrow Pd + 2HCl$.

Hydrogen is absorbed at high temperatures by many transition metals (scandium, 21, through copper, 29; yttrium, 39, through silver, 47; hafnium, 72, through gold, 79); and metals of the actinide (actinium, 89, through lawrencium, 103) and lanthanide series (lanthanum, 57, through lutetium, 71) to form hard, alloy-like hydrides. These are often called interstitial hydrides because, in many cases, the metallic crystal lattice merely expands to accommodate the dissolved hydrogen without any other change.

Hydrogen bond. Some covalently bonded hydrides have a hydrogen atom bound simultaneously to two separate electronegative atoms, which are then said to be hydrogen bonded. The strongest hydrogen bonds exist between the small, highly electronegative atoms of fluorine (F), oxygen, and nitrogen. In the bifluoride ion, HF_2^-, the hydrogen atom links two fluorine atoms. In the crystal structure of ice, each oxygen atom is surrounded by four other oxygen atoms, with hydrogen atoms between them. Some of the hydrogen bonds are broken when ice melts, and the structure collapses with an increase in density. Hydrogen bonding is important in biology because of its major role in determining the configurations of molecules. The helical (spiral) configurations of certain enormous molecular chains, as in proteins, are held together by hydrogen bonds. Extensive hydrogen bonding in the liquid state explains why hydrogen fluoride (HF), water (H_2O), and ammonia (NH_3) have boiling points much higher than those of their heavier analogues, hydrogen chloride (HCl), hydrogen sulfide (H_2S), and phosphine (PH_3). At the higher boiling temperatures, thermal energy is available to break up the hydrogen bonds and to permit vaporization.

Oxidation potential

The hydrogen in a strong acid, such as hydrochloric (HCl) or nitric (HNO_3), behaves quite differently. When these acids dissolve in water, hydrogen in the form of a proton, H^+, separates completely from the negatively charged ion, the anion (Cl^- or NO_3^-), and interacts with the water molecules. The proton is strongly attached to one water molecule (hydrated) to form the oxonium ion (H_3O^+), which in turn is hydrogen-bonded to other water molecules, forming species with formulas such as $H(H_2O)_n^+$ (the subscript n indicates the number of H_2O molecules involved). The oxidation of hydrogen (oxidation is the chemical change in which an atom loses one or more electrons) can be represented as the half reaction: $\frac{1}{2}H_2 \rightarrow H^+ + e^-$. The energy needed to bring about this reaction can be expressed as an oxidation potential. The oxidation potential for hydrogen is taken by convention to be zero, and all metals with positive oxidation potentials—*i.e.,* metals that are more easily oxidized (*e.g.,* zinc; $Zn \rightarrow Zn^{2+} + 2e^-$, 0.763 volt)—can, in principle, displace hydrogen from a strong acid solution: $Zn + 2H^+ \rightarrow Zn^{2+} + H_2$. Metals with negative oxidation potentials (*e.g.,* silver; $Ag \rightarrow Ag^+ + e^-$, −0.7995 volt) are inert toward the aqueous hydrogen ion.

ISOTOPES OF HYDROGEN

Discovery of deuterium, ^2H, or D

By means of the mass spectrograph he had invented, Francis William Aston in 1927 observed that the line for hydrogen corresponded to an atomic weight on the chemical scale of 1.00756. This value differed by more than the probable experimental error from the value based on the combining weights of hydrogen compounds, 1.00777. Other workers showed that the discrepancy could be removed by postulating the existence of a hydrogen isotope of mass 2 in the proportion of one atom of ^2H to 4,500 atoms of ^1H. The problem interested the U.S. chemist Harold C. Urey, who from theoretical principles predicted a difference in the vapour pressures of hydrogen (H_2) and hydrogen deuteride (HD) and thus the possibility of separating these substances by distillation of liquid hydrogen. In 1931 Urey and two collaborators detected deuterium by its atomic spectrum in the residue of a distillation of liquid hydrogen. Deuterium was first prepared in pure form by the electrolytic method of concentration: when a water solution of an electrolyte, such as sodium hydroxide, is electrolyzed, the hydrogen formed at the cathode contains a smaller fraction of deuterium than the water, and thus deuterium is concentrated in the residue. Almost pure deuterium oxide (D_2O, heavy water) is obtained when the solution is reduced to 0.00001 of its original volume. Deuterium can be concentrated also by the fractional distillation of water and by various chemical exchange reactions such as the following (g and l indicate gaseous and liquid states, respectively): $H_2O(g) + HD(g) \rightleftharpoons HDO(g) + H_2(g)$; $HDO(g) + H_2S(g) \rightleftharpoons HDS(g) + H_2O(g)$; $NH_3(l) + HD(g) \rightleftharpoons NH_2D(l) + H_2(g)$.

Creation of tritium, ^3H, or T

Tritium was first prepared in 1935 by bombarding deuterium (in the form of deuterophosphoric acid) with high-energy deuterons (deuterium nuclei):

$$^2D + {}^2D \longrightarrow {}^1H + {}^3T.$$

Tritium is present in minute concentrations in natural water. It is formed continuously in the upper atmosphere by cosmic-ray-induced nuclear reactions. Cosmic rays, consisting mainly of high-energy protons, react with nitrogen atoms to form neutrons, which in turn react with more nitrogen atoms to form tritium:

$$^{14}N + {}^1H \longrightarrow {}^{14}O + {}^1n \qquad {}^{14}N + {}^1n \longrightarrow {}^{12}C + {}^3T.$$

This naturally formed tritium ends up in the form of water and reaches the surface of the Earth in rain. Tritium is radioactive; it has a half-life of 12.5 years, decaying to a very soft (low energy) negative beta particle (electron; the positive beta particle is called a positron) and a helium-3 nucleus. When a sample of water is stored, it gradually loses its tritium because of radioactive decay. Thus by analyzing water for its tritium content, it is possible to elucidate details of water circulation among oceans, the atmosphere, rivers, and lakes. Tritium is made artificially in nuclear reactors by the reaction of thermal neutrons with lithium:

$$^6Li + {}^1n \longrightarrow {}^3T + {}^4He.$$

Corresponding compounds of the hydrogen isotopes differ slightly in their physical properties. This difference is shown by the properties of the waters, listed in Table 11, and of the elements, listed in Table 10. The same is true of their chemical properties, both thermodynamic and kinetic. Both deuterium and tritium are useful as isotopic tracers for the investigation of chemical structures and of reaction mechanisms. Generally the value of a tracer arises from the fact that, although its difference in mass or its radioactivity permits its detection, it is essentially active in the same way that the ordinary atoms of the element are. For most elements, a change of one or of a few mass units is such a small percentage of the total mass that the chemical differences between isotopes are negligible. For hydrogen, however, chemical reactions involving the different isotopes proceed at measurably different rates. These kinetic-isotope effects can be utilized in detailed studies of reaction mechanisms. The rates of reactions of compounds containing deuterium or tritium are usually less than those of the corresponding compounds of ordinary hydrogen.

Table 11: Physical Properties of the Waters

	H_2O	D_2O	T_2O
Density at 25° C in g/ml	0.99707	1.10451	—
Melting point, °C	0	3.81	4.49
Boiling point, °C	100	101.41	—
Temperature of maximum density, °C	3.98	11.21	13.4
Maximum density in g/ml	1.00000	1.10589	1.21502

The replacement of hydrogen by deuterium in biological systems can markedly alter the delicately balanced processes. It has been established that neither plants nor animals continue to live and thrive in water containing deuterium oxide in high concentrations.

Energy from deuterium and tritium

Deuterium and tritium are of interest in connection with thermonuclear (fusion) reactions. The explosion of a hydrogen bomb involves the collision and fusion of light nuclei, including deuterium and tritium. Should a method be found for controlling such fusion processes, as was done with the fission process of the earlier atomic bomb, the raw material for a practically unlimited supply of energy would be available in the deuterium content of water.

Deuterium oxide is useful in nuclear reactors as a moderator to slow down but not appreciably capture neutrons. It has the advantage of being a liquid that absorbs neutrons only slightly.

PRODUCTION AND APPLICATIONS OF HYDROGEN

The most important industrial method for the production of hydrogen is the catalytic steam–hydrocarbon process, in which gaseous or vaporized hydrocarbons are treated with steam at high pressure over a nickel catalyst at 650°–950° C to produce carbon oxides and hydrogen: $C_nH_{2n+2} + nH_2O \rightarrow nCO + (2n + 1)H_2$; $C_nH_{2n+2} + 2nH_2O \rightarrow nCO_2 + (3n + 1)H_2$. The primary reaction products are processed further in various ways, depending on the desired application of the hydrogen.

Another important process for hydrogen production is the noncatalytic partial oxidation of hydrocarbons under elevated pressures: $C_nH_{2n+2} + (n/2)O_2 \rightarrow nCO + (n + 1)H_2$. This process requires a feed system for delivering precise rates of fuel and oxygen, burners of special design to give rapid mixing of the reactants, a refractory-lined reactor, and a cooling system to recover heat from the effluent gases. The latter process is exothermic (heat producing), in contrast to the endothermic (heat absorbing) steam–hydrocarbon process.

In a third process, called the pressure catalytic partial oxidation method, the two preceding processes are combined to maintain the required reaction temperature without external heating of the catalyst bed. Superheated steam and hydrocarbons are mixed, preheated, and blended with heated oxygen in a diffuser at the top of the catalytic reactor. The oxygen reacts with the hydrocarbons in a space above the catalyst. The reactants then pass through a bed of nickel catalyst in which the steam–hydrocarbon reactions proceed almost to equilibrium.

Before 1940 most of the world production of hydrogen was made by processes based on coal or coke, the principal one being a water–gas reaction between steam and red-hot coke: $H_2O + C \rightarrow CO + H_2$. By 1970, however, relatively little hydrogen was being produced by such processes. For many years relatively small amounts of hydrogen had been produced by the electrolysis of aqueous solutions of salt or sodium hydroxide, the electrode reaction being $H_2O + e^- \rightarrow \frac{1}{2}H_2 + OH^-$. The reaction between sulfuric or hydrochloric acid and an active metal like zinc is utilized to liberate hydrogen in the laboratory, but such hydrogen usually contains trace quantities of volatile hydrides, such as arsine (AsH_3) and phosphine (PH_3), produced by impurities in the metal. These volatile impurities may be removed by bubbling the mixture of gases through a solution of a strong oxidizing agent, such as potassium permanganate.

A commercial method was developed for separating hydrogen from carbon monoxide synthesis gas by diffusion. The gas flows under pressure through bundles of tiny hollow polyester fibres through whose walls the hydrogen passes.

Use in ammonia manufacture

The largest single use of hydrogen in the world is in ammonia manufacture, which consumes about two-thirds of the world's hydrogen production. Ammonia is manufactured by the so-called Haber process, in which hydrogen and nitrogen react in the presence of a catalyst at pressures around 1,000 atmospheres and temperatures around 500° C: $N_2 + 3H_2 \rightarrow 2NH_3$. Large amounts of hydrogen are used in the preparation of methanol by the reaction $CO + 2H_2 \rightarrow CH_3OH$. This process is carried out in the presence of certain mixed catalysts containing zinc oxide and chromium oxide at temperatures between 300° and 375° C and at pressures between 275 and 350 atmospheres.

Another major application of hydrogen is in the catalytic hydrogenation of organic compounds. Unsaturated vegetable and animal oils and fats are hydrogenated to make margarine and vegetable shortening. Hydrogen is used to reduce aldehydes, fatty acids, and esters to the corresponding alcohols. Aromatic compounds can be reduced to the corresponding saturated compounds, as in the conversion of benzene to cyclohexane and of phenol to cyclohexanol. Nitro compounds can be reduced easily to amines.

Use as rocket fuel

Hydrogen has been used as a primary rocket fuel for combustion with oxygen or fluorine and is favoured as a propellant for nuclear-powered rockets and space vehicles. Another increasing use of hydrogen is in the direct reduction of iron ores to metallic iron and in the reduction of the oxides of tungsten and molybdenum to the metals. A hydrogen (reducing) atmosphere is employed in the pouring of special castings, in the manufacture of magnesium, in the annealing of metals, and for the cooling of large electric motors. Hydrogen was once used for inflating lighter-than-air vessels, such as dirigibles and balloons, but now helium is generally used because it is nonflammable. The barrage balloons used in England during World War II, however, were filled with hydrogen. Liquid hydrogen is used in the laboratory to produce low temperatures.

ANALYSIS

When atoms are excited, as in an electric discharge, they radiate light at discrete wavelengths that appear as lines in the spectrum. Inasmuch as the wavelengths of atomic spectral lines are characteristic of the element, the atomic spectrum may be used for identifying the element. The simplest of all such spectra is that of hydrogen. Johann Jakob Balmer, a Swiss mathematician and secondary school teacher, in 1885 discovered an equation for representing the wavelengths of hydrogen spectral lines, of which nine had been observed in the laboratory and of which five more were photographed in the spectrum of the star Sirius. The wavelengths, lambda (λ), in angstroms, were represented by the formula: $\lambda = 3645.6\ [m^2/(m^2 - 4)]$, m taking the successive values 3, 4, 5, etc. It was not until 1913 that a theoretical basis for this empirical relation was given by the Danish physicist Niels Bohr in his theory of atomic radiation.

The spinning motion of the proton gives it magnetic properties and causes it to precess in an applied magnetic field, much as a spinning top precesses in a gravitational field. The frequency at which a particular proton precesses is determined by its local electrical environment and by the strength of the applied magnetic field. When hydrogen compounds are irradiated with electromagnetic waves of a particular frequency, the phenomenon of resonance absorption occurs at magnetic field strengths that are different for each structurally (magnetically) distinguishable proton in the compound. Thus, proton magnetic resonance makes it possible to distinguish the structural types of hydrogen atoms present; furthermore, the absorption peak intensities are proportional to the number of hydrogen atoms of each kind. The absorption peaks are often split, however, because of the magnetic interaction of the proton magnetic moments among themselves. Proton-magnetic-resonance measurements provide data for the investigation of chemical structure.

One method for determining the total hydrogen content of a substance is to oxidize the substance completely in a stream of pure oxygen, which reacts with the hydrogen to produce water vapour. The resulting vapours are passed through a powerful dehydrating agent, such as magnesium perchlorate, which absorbs the water. From the increase in weight of the absorption tube containing the desiccant, the amount of hydrogen oxidized can be calculated. Gaseous hydrogen or hydrogen compounds may be oxidized by passing them over hot copper oxide, and the resulting water can then be collected and weighed and the amount of hydrogen calculated; to measure the hydrogen gas itself, the water vapour from the oxidation may be reduced to hydrogen gas by passing it over hot uranium metal—the hydrogen then being measured in a simple device called a gas buret.

Strongly acidic hydrogen atoms (as in compounds such as HCl, HNO_3, H_2SO_4, etc.) can be determined in solution by adding measured amounts of a strong base, such as sodium hydroxide, NaOH, until the acid is neutralized, using an indicator to determine the end point. The net reaction is $H^+ + OH^- \rightarrow H_2O$. Weakly acidic hydrogen atoms (such as that attached to the oxygen in ethanol, C_2H_5OH, and those attached to the nitrogen in acetamide, CH_3CONH_2) can be converted to methane (measured in a gas buret) by reaction with the methyl Grignard reagent, CH_3MgI. Hydridic hydrogen atoms (as in $NaBH_4$, LiH, etc.) can be converted to molecular hydrogen (measured in a gas buret) by reaction with an aqueous acid.

(W.L.J./Ed.)

Alkali metals

The alkali metals are the elements in Group Ia of the periodic table of the elements (see Figure 10). In order of increasing atomic number they are lithium (Li), sodium (Na), potassium (K), rubidium (Rb), cesium (Cs), and francium (Fr). Sodium and potassium are the sixth and seventh most abundant of the elements, comprising respectively 2.6 and 2.4 percent of the Earth's crust. The other alkali metals are considerably more rare, with rubidium, lithium, and cesium respectively forming 0.03, 0.007, and 0.0007 percent of the Earth's crust. Francium, a natural radioactive isotope, is very rare and was not discovered until 1939. Because of their high reactivity, the alkali metals are never found as free metals in their natural state. They generally are found combined with other elements in the form of simple or complex compounds. The simpler compounds of the alkali metals are soluble in water and therefore are easily extracted and subjected to chemical operations for purposes of separation and purification. Minerals belonging to this class, such as halite (sodium chloride, NaCl), sylvite (potassium chloride, KCl), and carnallite (a potassium-magnesium chloride, $KCl \cdot MgCl_2 \cdot 6H_2O$), although somewhat rare, are the most important commercial sources of the alkali metals; the more complex, water-soluble minerals are far more abundant in the Earth's crust.

The alkali metals have all of the physical properties generally associated with metals, including silver-like lustre, high ductility, and excellent conductivity of electricity and heat. Lithium is the lightest metallic element. The alkali metals are low melting, ranging from a high of 179° C for lithium to a low of 28.5° C for cesium. Alloys of alkali metals exist that melt as low as −78° C.

High reactivity

The alkali metals are extremely reactive and combine readily with most of the substances found in the atmosphere. (Only lithium, however, reacts with nitrogen.) The alkali metals all react vigorously, and often violently, with water, releasing hydrogen and forming strong caustic solutions. Most common nonmetallic substances such as the halogens, halogen acids, sulfur, and phosphorus react with the alkali metals. The alkali metals themselves react with many organic compounds, particularly those containing an active hydrogen atom (that is, one that can be replaced readily).

Sodium is by far the most important alkali metal in terms of industrial use. It is employed in the reduction of organic compounds, in the preparation of sodium peroxide and sodium cyanide, and in the manufacture of tetraethyl lead. As a free metal, it is used as a heat transfer fluid in nuclear reactors. Its compounds, of the widest industrial importance and manufactured in hundreds of thousands of tons annually, include common salt (NaCl), baking soda ($NaHCO_3$), soda ash (Na_2CO_3), and caustic soda (NaOH). Potassium has considerably less use than sodium as a free metal. Potassium salts, however, are consumed in considerable tonnages in the manufacture of fertilizers. Lithium metal is used in certain light-metal alloys, and it is employed as a reactant in organic syntheses. Lithium also has potential use as a battery anode in electrically propelled automobiles. Rubidium and cesium and their compounds have but limited use.

HISTORY

Saltpetre

Alkali metal salts were known to the ancients. The Old Testament refers to a salt called *neter* (sodium carbonate), which was extracted from the ash of vegetable matter. Saltpetre (potassium nitrate) was used in gunpowder, which was introduced into Europe in about the 12th century. Saltpetre was also one of the chief ingredients of the incendiary mixture called Greek fire.

In October 1807 the English chemist Sir Humphry Davy isolated potassium and then sodium, the discoveries coming only a few days apart. The term sodium is derived from the Italian *soda*, a term applied in the Middle Ages to all alkalies; potassium comes from the French *potasse*, a name used for the residue left in the evaporation of aqueous solutions derived from wood ashes.

Lithium was discovered by the Swedish chemist J.A. Arfvedson in 1817 while analyzing the mineral petalite. The name lithium is derived from *lithos*, the Greek word for stony. The element was not isolated in pure form until Davy produced a minute quantity by the electrolysis of lithium chloride.

While the German chemists Robert Bunsen and Gustav Kirchhoff were investigating the mineral waters in the Palatinate in 1860, they obtained a filtrate that was characterized by two lines in the blue region of its spectrum (the light emitted when the sample was inserted into a flame). They suggested the presence of a new alkali element and called it cesium, derived from the Latin *caesius*, used to designate the blue of the sky. The same researchers, on extracting the alkalies from the mineral lepidolite, separated another solution, which yielded two spectral lines of violet colour. They proposed the name rubidium for the element in this solution from the Latin *rubidus*, which was used for the darkest red colour. Francium was not discovered until 1939 by Marguerite Perey of the Curie Institute in Paris.

Electrolytic production

In the 19th century the only use for the alkali metals was the employment of sodium as a reagent in the manufacture of aluminum. When the electrolytic process for aluminum purification was established, it appeared that large-scale use of sodium would cease. Subsequent improvements in the electrolytic production of sodium, however, reduced the cost of this element to such an extent that it could be employed economically in processes such as the preparation of sodium peroxide. The chief improvement in the electrolytic process was the introduction of continuous electrolysis of sodium hydroxide, a technique called the

Castner process. The Castner process was used until the evolution of the Downs-cell process in 1926. This process, in which a molten sodium chloride–calcium chloride mixture is electrolyzed, has largely supplanted the older process in the production of sodium.

GENERAL PROPERTIES OF THE GROUP

Physical properties. Metals are ordinarily characterized by their high thermal and electrical conductivity and by their lustre, ductility, and malleability. The alkali metals as a class exhibit these properties to a high degree. Chemically, each of the alkali metals has a valence of one (*i.e.,* one atom of an alkali metal combines with one atom of another univalent element, such as fluorine); this property is a consequence of their having only a single electron in the outermost shell of their atoms. In passing from lithium to francium, this single electron tends to be less strongly held. Generally, the energy necessary to remove the outermost electron from the atoms of an element, the ionization energy, decreases in the periodic table toward the left and downward in each vertical file, with the result that the most easily ionizable element in the entire table is francium, followed closely by cesium. The alkali metals, which make up the extreme left-hand file, have ionization energies ranging from 124.3 kilocalories per mole (Li) to 89.7 kcal/mole (Cs) (omitting the rare radioactive element francium). The alkaline-earth metals, the next group to the right, have higher ionization energies, ranging from 214.9 (beryllium) to 120.1 kcal/mole (barium).

Electronegativities

The electronegativity scale of the elements compares the ability of the atoms of the various elements to attract electrons to themselves. In the periodic table the electronegativities range from 0.7 for cesium, the least electronegative of the elements, to 4.0 for fluorine, the most electronegative. Metals are ordinarily considered to be those elements having values less than 2.0 on the electronegativity scale. As a group the alkali metals are the least electronegative of the elements, ranging from 0.7 to 1.0 on the scale, while the alkaline earths, the next group on the table, have electronegativities ranging from about 0.9 to 1.5.

The relatively simple electronic structure of the atoms of the alkali metals (a single electron in the outermost shell of each) results in a considerable degree of regularity and predictability in their physical and chemical properties. Bonds of the alkali metals with all nonmetals are essentially ionic (resulting from mutually attractive forces existing between positive and negative electrical charges). The physical properties vary in a regular pattern and, to a considerable extent, can be attributed to the effects of the mobile outermost electron.

Table 12 summarizes the important physical and thermodynamic properties of the alkali metals. Generally, the mobile electrons in metals are responsible for their high thermal and electrical conductivity and their high heat capacity; this is especially true of the alkali metals. These metals are all characterized by a body-centred cubic crystallographic arrangement (a standard pattern of atoms in their crystals), with eight nearest neighbours to each atom.

The closest distance between atoms, a characteristic property of crystals, increases with increasing atomic weight of the alkali metal atoms. As a group, the alkali metals have a looser crystallographic arrangement than any of the other metallic crystals, and cesium, because of its greater atomic weight, has an interatomic distance that is greater than that of any other metal.

Vapour-pressure data for the alkali metals and for two alloys formed between elements of the group are given in Figure 11, which shows that the vapour pressures increase in regular fashion with increasing atomic weight.

Melting points and boiling points

The melting points of the alkali metals as a group are lower than those of any other nongaseous group of the periodic table, ranging between 179° C for lithium and 28.5° C for cesium. Only mercury among the metallic elements has a lower melting point than cesium. The low melting points of the alkali metals are a direct result of the large interatomic distances in their crystals and the weak bond energies associated with such loose arrays. These same factors are responsible for the low densities, low heats of fusion, and small changes in volume upon fusion of the metals. Lithium, sodium, and potassium are less dense than water.

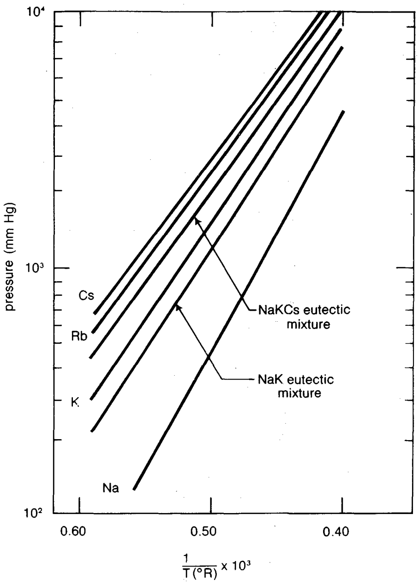

Figure 11: Vapour pressure in millimetres of mercury (mm Hg) plotted against the inverse of absolute temperature on the Rankine scale (T [°R]), for the alkali metals sodium (Na), potassium (K), rubidium (Rb), and cesium (Cs). As the atomic weight increases toward cesium the vapour pressure is higher at any temperature chosen. Alloys of metals that have single melting points, called eutectic mixtures, follow the same rule.

From J. Mansteller, F. Tepper, and S. Rodgers, *Alkali Metal Handling and Systems Operating Techniques* (1967); Gordon & Breach

Cesium is the most volatile of the alkali metals, with a boiling point of 671° C. The boiling points of the alkali metals increase in regular fashion as the atomic numbers decrease, the highest, 1,317° C, being that of lithium.

Chemical properties. Since the alkali metals are the most electropositive (the least electronegative) of elements, they react with a great variety of nonmetals.

Reactions with oxygen. All of the alkali metals react with oxygen—lithium and sodium to form monoxides and the heavier alkali metals to form superoxides. The rate of reaction with oxygen, or with air, depends upon whether the metals are in the solid or liquid state, as well as upon the degree of mixing of the metals with the oxygen, or air. In the liquid state alkali metals can be ignited in air with ease, generating copious quantities of heat and a dense choking smoke of the oxide.

In its chemical reactivity lithium more closely resembles Group IIa of the periodic table than it does the other metals of its own group. It is less reactive than the other alkali metals with water, oxygen, and halogens and more reactive with nitrogen, carbon, and hydrogen.

The free energy of formation (a measure of stability) of the alkali metal oxides at 25° C varies widely from a high of −133 kilocalories per mole for lithium oxide to −63 kilocalories per mole for cesium oxide. The close approach of the small lithium ion to the oxygen atom results in the unusually high free energy of formation of the oxide. Normal oxide formed on combustion of lithium is the simple oxide (Li_2O); it also is possible to make the peroxide (Li_2O_2) by passing oxygen through a liquid-ammonia solution of lithium metal. Sodium peroxide (Na_2O_2) can be similarly made, although the commercial method is by oxidation of sodium monoxide (Na_2O) with oxygen. Sodium superoxide (NaO_2) can be prepared with high oxygen pressures, whereas the superoxides of rubidium, potassium, and cesium can be prepared directly by combustion in air. By contrast, no superoxides have been isolated in pure form in the case of the alkaline-earth metals, although the heavier members of that group can be oxidized to the peroxide state. The ozonides of potassium, rubidium, and cesium, which are less stable than the lower

*Body-centred cubic.

oxides, can be prepared by the reaction of the superoxides with ozone.

Reactions with water. The alkali metals all react violently with water. The rate of the reaction depends on the degree of metal surface presented to the liquid. With small metal droplets or thin films of alkali metal, the reaction can be explosive. The rate of the reaction of water with the alkali metals increases with increasing atomic weight of the metal. With the heavier alkali metals the hydroxides are highly soluble; thus they are removed readily from the reacting surface, and the reaction can proceed with unabated vigour. The reaction involves equimolar mixtures (that is, equal numbers of atoms or molecules) of the alkali metal and water to form a mole (an amount equal to that of the reactants) of alkali metal hydroxide and half a mole of hydrogen gas. These reactions are highly exothermic (give off heat), and the hydrogen that is generated can react with oxygen to further increase the heat that is generated.

Reactions with nonmetals. Of the alkali metals, only lithium reacts with nitrogen, and it forms a nitride (Li_3N). In this respect it is more similar to the alkaline-earth metals than to the Group Ia metals. Lithium also forms a relatively stable hydride, whereas the other alkali metals form hydrides that can be more readily dissociated. Lithium forms a carbide (Li_2C_2) similar to that of calcium. The other alkali metals do not form stable carbides, although they do react with the graphite form of carbon to give intercalation compounds (substances in which the metal atoms are inserted between layers of carbon atoms in the graphite structure).

The alkali metals can be burned in atmospheres of the various halogens to form the corresponding halides. The reactions are highly exothermic, producing up to 235 kcal/mole for lithium fluoride. The alkali metals react with nonmetals in Groups Va and VIa of the periodic table. Sulfides can be formed by the direct reaction of the alkali metals with elemental sulfur, furnishing a variety of sulfides. Phosphorus combines with the alkali metals to form phosphides with the general formula M_3P.

Formation of alloys. The characteristics of alloy behaviour in alkali metals can be evaluated in terms of the similarity of the elements participating in the alloy. Elements with similar atomic volumes form solid solutions (that is, mix completely in all proportions); some dissimilarity in atomic volumes results in eutectic-type systems (solutions formed over limited concentration ranges); and further dissimilarity results in totally immiscible systems.

The elements potassium, rubidium, and cesium, which have rather similar atomic volumes and ionization energies, form complete solid solutions and mixed crystals. Sodium, which is a significantly smaller atom than potassium and has a higher ionization energy, tends to form eutectic systems with potassium, rubidium, and cesium. Even greater dissimilarity exists in the atomic volumes of sodium and lithium, resulting in insolubilities of the liquid phases. The consolute temperature (the temperature at which the two liquids become completely miscible) increases on going from the lithium–sodium alloy system to the lithium–cesium system. Lithium and cesium can coexist as two separate liquid phases at temperatures up to at least 1,100° C.

Eutectics

There is only one example of solid miscibility in alkali–alkaline-earth-metal binaries—the lithium–magnesium system, in which the two elements are very similar. Sodium forms compounds only with barium in the alkaline-earth-metal series. The heavier alkali metals all tend to form immiscible liquid phases with the alkaline earths.

Several of the elements of the Group IIb of the periodic table (zinc, cadmium, and mercury) react with the alkali metals to form compounds. Mercury forms at least six compounds, commonly termed amalgams, with each of the five alkali metals; and, with the exception of the amalgam with lithium, the highest melting point compound in each series has the formula MHg_2. Lithium and sodium also form compounds with cadmium and zinc.

INDIVIDUAL ALKALI METALS

Lithium. *Occurrence and production.* Lithium occurs as salts in mineral springs, and its concentration in seawater is 0.1 parts per million. Crude phosphate, containing 20 percent lithia, or lithium oxide (Li_2O), is recovered from brines at Searles Lake, California. Lithium is found in pegmatite ores, such as spodumene ($LiAlSi_2O_6$) and lepidolite (of varying structure), or in amblygonite ($LiAlFPO_4$) ores, with Li_2O contents ranging between 4 and 8.5 percent.

Method of manufacture

Lithium is manufactured by the electrolysis of a fused mixture of lithium and potassium chlorides. The lithium chloride consumed in the electrolysis may be obtained from lithium-containing silicate minerals by a number of different processes. Spodumene, for example, is calcined (heated), treated with sulfuric acid, and then neutralized with calcium carbonate to form lithium sulfate solution. Soda ash (sodium carbonate) is added to produce lithium carbonate, the basic material from which other lithium compounds are derived. Lithium chloride may be volatilized from aluminosilicate materials by heating with carbon in a stream of chlorine. Lithium chloride also may be prepared in high yield by passing hydrogen chloride over lepidolite ore at 935° C.

The addition of potassium chloride to lithium chloride allows electrolysis to occur at 400°–420° C. Since the voltage at which decomposition of lithium chloride takes place is lower than that of potassium chloride, lithium is deposited in purities greater than 97 percent. Graphite anodes are used in the electrolytic production of lithium, while the cathodes are made of steel. The pure lithium formed at the cathode coalesces at the surface of the electrolyte to form a molten pool, which is protected from reaction with air by a thin film of the electrolyte. The lithium is ladled from the cell and cast by pouring it into a mold at a temperature only slightly above the melting point, leaving the solidified electrolyte behind. The solidified lithium is then remelted, and materials insoluble in the melt either float to the surface or sink to the bottom of the melt pot. The remelting step reduces the potassium content to less than 100 parts per million (ppm).

Many lithium alloys are produced directly by the electrolysis of molten salts, containing lithium chloride in the presence of a second chloride, or by the use of cathode materials that interact with the deposited lithium, introducing other elements into the melt.

Significant uses. The isotope lithium-6, the less common of the two chief isotopes, yields tritium gas when bombarded with neutrons. Tritium so produced is employed in the manufacture of hydrogen bombs, among other uses. The principal industrial applications for lithium are in metallurgy, where the active element is used as a scavenger (remover of impurities) in the refining of such metals as iron, nickel, copper, and zinc, and their alloys. A large variety of nonmetallic elements are scavenged by lithium, including oxygen, hydrogen, nitrogen, carbon, sulfur, and the halogens. Lithium is utilized to a considerable extent in organic synthesis. Organolithium compounds act somewhat like organomagnesium compounds and undergo reactions similar to the Grignard reaction, a standard synthetic procedure in organic chemistry. Lithium compounds also serve as catalysts in synthetic rubber manufacture.

Lithium has potential value as a heat-transfer fluid for high power-density nuclear reactors. The lithium-7 isotope, the more common stable isotope, has a low nuclear cross section (that is, absorbs neutrons very poorly) and is an ideal primary coolant for nuclear reactors in which coolant temperatures above about 800° C are required.

Lightweight lithium–magnesium alloys have structural applications in the aerospace and other industries. Metallic lithium is used in the preparation of compounds such as lithium hydride.

Chemical properties. In many of its properties lithium exhibits the same characteristics as do the more common alkali metals sodium and potassium; thus, the metal is highly reactive and forms strong hydroxide solutions. In many respects lithium also shows similarities to the elements of the alkaline-earth group, especially magnesium, which has similar atomic and ionic radii. This similarity is seen in oxidation properties, the monoxide being normally formed in each case.

Nuclear properties. Lithium, which exhibits no natural radioactivity, has two isotopes of mass number 6 and 7 respectively. The ^{7}Li : ^{6}Li ratio is between 12 and 13. The isotopes ^{8}Li (half-life 0.855 sec) and ^{9}Li (half-life 0.17 sec) have been produced by nuclear bombardment. The ^{7}Li isotope has a low nuclear cross section (0.003 barn) permitting consideration of the substance as a coolant for nuclear reactors in such mobile systems as satellites and spacecraft.

Biological properties. The widespread occurrence of lithium in plants results in a wide, although low-level, distribution of lithium in animals. Lithium salts have complex effects when absorbed into the body. They are not highly toxic, although they can affect body processes dependent upon salt balance. Lithium poisoning can occur, particularly with patients on low sodium diets. Lithium salts that are ingested are absorbed and are rapidly excreted in the urine.

The most abundant of the alkali metals

Sodium. *Occurrence and production.* Sodium is the most abundant of the alkali metals. Sodium chloride (table salt) is the most common compound of sodium, but many others also are known. Sodium is an important constituent of a number of silicate materials, such as feldspars and micas. There are huge deposits of rock salt in various parts of the world, and sodium nitrate deposits exist in Chile and Peru. The sodium content of the sea is approximately 1.05 percent, corresponding to a concentration of approximately 3 percent of sodium halides. Sodium has been identified in both the atomic and ionic forms in the spectra of stars and the interstellar medium. Analysis of meteorites indicates that the silicate material present has an average content of approximately 4.6 atoms of sodium for every hundred atoms of silicon.

Sodium is the alkali metal of most commercial importance by far. Most processes for the production of sodium involve the electrolysis of sodium chloride. The element is used chiefly to produce tetraethyl lead, which increases the antiknock rating of gasoline.

The principal sodium compounds of commerce are the chloride, carbonate, and sulfate. Large quantities of sodium chloride are, for example, employed in the production of other heavy (industrial) chemicals.

Significant uses. Two of the earliest uses of sodium were in the manufacture of sodium cyanide and sodium peroxide, both uses that continue in importance. A present major use for sodium is in the manufacture of tetraethyl lead by means of the reaction of lead–sodium alloy with ethyl chloride. Substantial amounts of sodium are also used in the manufacture of sodium alkyl sulfates for the synthetic-detergent industry, in which the sodium alkyl sulfates are employed as the principal ingredient.

Sodium also is used as a starting material in the manufacture of sodium hydride. In addition, sodium is employed in the production of dyes and dye intermediates, in the synthesis of perfumes, and in a wide variety of organic reductions. It is used in the purification of hydrocarbons and in the polymerization of unsaturated hydrocarbons. In many organic applications, sodium is used in the form of dispersions in hydrocarbon liquid media.

Heat-transfer uses of sodium

Sodium is an excellent heat-transfer fluid, and because of this property, it has potentially large-scale uses. Fast-breeder nuclear reactors, cooled by sodium, may generate a portion of the world's electrical power by the year 2000. Sodium forms an alloy with potassium (NaK) which melts at −10° C. At one time NaK was considered for use as the heat-transfer fluid in submarine reactor systems. Later, sodium was investigated as the secondary coolant system in a high power-density reactor system for space use. The alloy also is used for cooling crucibles in consumable arc-melting processes for preparing titanium.

Because of the excellent electrical conductivity of sodium, the substance has been considered as a substitute for copper in electrical conductors. It is used extensively in metallurgy as a deoxidant and as a reducing agent for the preparation of calcium, zirconium, titanium, and other transition metals. Commercial production of titanium involves reduction of titanium tetrachloride with sodium.

Chemical properties. Generally, elemental sodium is more reactive than lithium, and in aqueous solution it reacts to form a stronger base than LiOH. Its chemistry is well explored.

Reaction with oxygen

Sodium is ordinarily quite reactive with air, and the reactivity is a function of the relative humidity, or water-vapour content, of the air. The corrosion of solid sodium by oxygen also is accelerated by the presence of small amounts of impurities in the sodium. In ordinary air, sodium metal reacts to form a sodium hydroxide film, which can rapidly absorb carbon dioxide from the air, forming sodium bicarbonate. Sodium does not react with nitrogen. It is significantly more reactive in air as a liquid than as a solid, and the liquid can ignite at about 125°

C. In a comparatively dry atmosphere, sodium burns quietly, giving off a dense, white, caustic smoke, which can cause choking and coughing. The temperature of burning sodium increases rapidly to more than 800° C, and under these conditions the fire is extremely difficult to extinguish.

Sodium monoxide (Na_2O) is ordinarily formed upon oxidation of sodium in dry air. The superoxide (NaO_2) can be prepared by heating metallic sodium to 300° C in an autoclave (heated pressure vessel) containing oxygen at high pressure. Another route to the superoxide is oxidation of sodium peroxide treated to have a large surface area.

Sodium that is heavily contaminated with the monoxide may be readily purified by filtration since the solubility of the oxide in molten sodium is low. This low solubility is utilized to a considerable extent in continuous purification processes of the sodium in large liquid-metal reactor systems. A second technique for removing the oxide, called cold trapping, involves running the molten sodium through a cooled, packed bed of material, upon which the oxide can precipitate. Filtration and cold trapping also are effective in removal of gross quantities of carbonate, hydroxide, and hydride.

Reaction with water and hydrogen

The reaction with water of liquid sodium having a high surface area can be explosive. The sodium–water reaction is highly exothermic (that is, heat is given off):

$$Na + H_2O \longrightarrow NaOH + {}^1/_2\,H_2 + 33.67 \text{ kilocalories per mole at } 25^\circ \text{ C.}$$

Tests have indicated, however, that sodium and water cannot be mixed fast enough to produce the shock waves characteristic of high explosives. The explosive hazards of the reaction are associated primarily with the hydrogen gas that is formed.

Pure sodium begins to absorb hydrogen appreciably at about 100° C, the rate of absorption increasing with the temperature. Pure sodium hydride can be formed at temperatures above 350° C by exposing sodium to hydrogen gas at a high flow rate. The dissociation of sodium hydride is considerably greater than that of lithium hydride but slightly less than that of potassium hydride.

Reactions with nonmetals

Generally, alkali metals react with halogen gases, the degree of reactivity decreasing with increasing atomic weight of the halogen. Sodium is no exception to this statement. Under certain conditions of reaction, sodium and halogen vapours react to produce light (chemiluminescence). Halogen acids, such as hydrochloric acid, react vigorously with sodium, yielding the sodium halides. The reactions are highly exothermic, with heats of reaction (energy given off) of −71.8 and −76.2 kilocalories respectively for the reactions with hydrofluoric and hydrochloric acids. Sodium is attacked by other strong mineral acids to form the corresponding salts. It reacts with the fumes of nitric acid at 15° C to form sodium nitrate and with acetic and sulfuric acids to form sodium acetate and sodium sulfate. With molten sulfur it reacts violently to produce polysulfides; under more controlled conditions it reacts with organic solutions of sulfur. Liquid selenium and tellurium both react vigorously with solid sodium to form selenides and tellurides.

Sodium shows relatively little reactivity with carbon, although the existence of lamellar (layer-like) materials prepared from graphite with the formula NaC_{64} has been reported. At 625° C carbon monoxide reacts with sodium to form sodium carbide and sodium carbonate.

With the exception of the oxides of the Group IVb metals (titanium, zirconium, and hafnium), the oxides of the transition metals are all reduced to the respective metals with elemental sodium. Sodium also reacts with a large number of metallic halides, displacing the metal from the salt and forming a sodium halide in the process. This reaction is used in the preparation of several of the transition metals themselves, including titanium and tantalum.

Reactions in liquid ammonia

Sodium dissolves in liquid ammonia to give intense blue solutions, and at ordinary temperatures a slow reaction occurs in such solutions, resulting in the formation of sodamide, $NaNH_2$, and hydrogen. Conversion of alkali metals to their amides takes several days in the case of lithium and sodium, but for the heavier alkali metals conversion occurs in a half-hour or less—and with cesium it takes only 15 minutes. The reaction of sodium and liquid ammonia can be catalyzed by the addition of any of a number of metal and metal oxide catalysts.

Liquid ammonia often is used as a solvent for sodium, allowing a number of reactions to occur at ordinary temperatures that would otherwise need heat. Sodium superoxide (NaO_2), for example, can be formed by passing oxygen through ammonia solutions of sodium at −77° C. Ammonia also serves as a solvent for reactions of sodium with arsenic, tellurium, antimony, bismuth, and a number of other low-melting metals.

Organic reactions

The organic reactions of sodium have been studied to a greater extent than those of any of the other alkali metals. Sodium reacts with anhydrous alcohols to form the respective alcoholates. The reaction is most vigorous with methanol and decreases with increasing molecular weight of the alcohol. Sodium methoxide is produced on an industrial scale by reaction of sodium with excess methanol. Organic acids react with sodium to form sodium salts.

The high free energy of formation of sodium halides permits the dehalogenation of a large number of organic halides, the formation of the sodium halide being energetically favoured. The so-called Wurtz reaction—based on this principle—is used in organic synthesis to a considerable extent:

$$2RCl + 2Na \rightarrow R\text{–}R + 2NaCl.$$

By this reaction, octane can be made from bromobutane and sodium. Organosodium compounds include a number in which the sodium atom is bonded directly to a carbon atom; an example is methylsodium, $Na\text{–}CH_3$. Such compounds can be prepared by the action of sodium on mercury dialkyls or diaryls, as in the following equation:

$$Hg(CH_3)_2 + 2Na \rightarrow 2NaCH_3 + Hg.$$

Sodium reacts violently with a number of halogenated hydrocarbons. A violent explosion occurs when a mixture of carbon tetrachloride and sodium is subjected to shock, and even when the sodium is diluted to a considerable extent—as in sodium amalgam—a brisk reaction with carbon tetrachloride occurs.

Alloys

Sodium is completely miscible with the alkali metals below it in the periodic table (potassium, rubidium, and cesium). A eutectic (that is, an alloy that melts lower than its components) melting at −10° C is formed in the sodium–potassium system and is known commercially as NaK. Its composition is approximately 78 percent potassium, and it is used as a heat-transfer fluid and as an organic reactant. The eutectics formed in the sodium–rubidium and sodium–cesium binary systems melt respectively at −4.5° and −30° C. Sodium is the minor component with potassium and cesium of the ternary alloy NaKCs, melting at −78° C. This fluid is the lowest melting liquid alloy yet isolated.

Sodium also forms alloys with the alkaline-earth metals. Beryllium is soluble in sodium only to the extent of a few atomic percent at approximately 800° C. Liquid sodium and magnesium are only partially miscible. The degree of solubility in sodium of the alkaline-earth metals increases with increasing atomic weight, with the result that the solubility of calcium is 10 percent by weight at 700° C. In the sodium–strontium system, there is a considerable degree of miscibility. Sodium forms a number of compounds with barium, and several eutectics exist in the system.

The precious metals, silver, gold, platinum, palladium, and iridium, and the white metals, such as lead, tin, bismuth, and antimony, alloy to an appreciable extent with liquid sodium. Cadmium and mercury also react with sodium, and a number of compounds exist in both binary systems. Seven sodium–mercury compounds, or amalgams, exist, with Hg_2Na having the highest melting point (354° C). Sodium amalgams are used chiefly for carrying out reactions in situations in which pure elemental sodium would be violently reactive and difficult to control. The solubility of transition metals in alkali metals is generally very low, often in the one to ten parts per million range even at temperatures in excess of 500° C.

The sodium compounds of major commercial importance are the chloride, hydroxide, carbonate, sulfate, and, to a lesser extent, the peroxide, sulfide, and halides other than the chloride.

Nuclear properties. In its nuclear properties, sodium is a simple element, with but one natural isotope, ^{23}Na, exhibiting no natural radioactivity. Several isotopes have been prepared by nuclear reactions, with the ^{22}Na isotope having the longest half-life—2.6 years. The ^{24}Na isotope (half-life 15 hours) is produced by irradiation in a nuclear reactor. Because of this reaction a sodium-cooled reactor must have a second heat-transfer loop so that radioactive sodium does not come in contact with the environment.

Biological properties. Sodium salts, particularly sodium chloride, are found almost everywhere in biological material. Sodium is an essential element for life, as is potassium, and the two elements maintain a definite balance within the cell structure. Most of the biological effects of sodium salts are the result of the cation (sodium ion), with the anion (negative ion) apparently not playing a dominant role.

The presence of salinity in soils is often detrimental to plant growth. Sodium ions replace calcium and other ions in clay complexes, transforming the clay to a sticky mass; water percolation is then drastically reduced, and the basicity of the soil rises markedly.

Sodium as a dietary requirement

The tolerance of fish to changes in salinity is often quite remarkable. Many marine bacteria and diatoms are able to tolerate salt concentrations as great as 25 percent. The minimum sodium requirement for mammals appears to be 0.05 percent of the diet, corresponding in a normal man to a requirement of one to two grams of salt per day, resulting in an average sodium content of body tissues of 0.24 percent. There is a wide variation of sodium content in the different tissues, with whole blood containing approximately 0.62 percent sodium chloride, whereas skin has a sodium content of less than 0.1 percent. There is a relationship between salt content and water balance of the body, a low intake of salt causing loss of water. Considerable quantities of sodium are lost through the skin by sweating, and considerable quantities can be excreted in the urine.

Potassium. *Occurrence and production.* Igneous rocks, shale, and sediment are minerals containing much of the potassium that is found in nature. The potassium content of the Dead Sea is estimated at approximately 1.7 percent potassium chloride, and many other salty bodies of water are rich in potassium. The waste liquors from certain salt works may contain up to 40 grams per litre of potassium chloride and are used as a source of potassium. The salt deposits in Stassfurt, Germany, which are rich in potassium sulfate and chloride, are one of the most important sources of potassium in the world. Potassium also is found in nature as the nitrate.

Extraction and purification of potassium salts

The techniques used for extracting potassium salts depend to a considerable extent on the nature of the ore body and the character of the foreign salts mixed with the potassium salt. The Stassfurt salt deposit contains large deposits of carnallite, $MgCl_2 \cdot KCl \cdot 6H_2O$. These deposits became so important with respect to potash (potassium hydroxide) production that Germany had a virtual monopoly on production of that substance up to the time of World War I. The other chief sources of potash are in France, Austria, Spain, India, and Chile. Seawater, brines, many lake deposits, and the ashes of vegetation also are used as sources of potash.

Potassium chloride can be separated from carnallite ore by preferential precipitation of potassium chloride during evaporation of the mother liquor. In the Searles Basin, California, deposit, brine is evaporated in vacuum pans, and the sodium chloride and sulfate are deposited. The resulting liquor is boiled to a point where potassium chloride is separated, producing a crude potash deposit containing about 66 percent potassium chloride.

Production of potassium

Potassium is produced by sodium reduction of molten potassium chloride at 870° C. Molten KCl is continuously fed into a packed distillation column, while sodium vapour is passed up through the column. By condensation of the volatile potassium at the top of the distillation tower, the reaction

$$Na + KCl \rightarrow K + NaCl$$

is forced to the right. Efforts to devise a scheme for the electrolytic production of potassium have been unsuccessful because there are few salt additives that can reduce the melting point of potassium chloride to temperatures where electrolysis is efficient.

Significant uses. Most of the potassium produced is converted to the superoxide directly by combustion in dry air. The superoxide is used as a source of oxygen in respiratory equipment, since it generates oxygen and also absorbs carbon dioxide.

Sodium–potassium alloy (NaK) is used only to a limited extent as a heat-transfer coolant, although it has significant potential for this purpose. It is presently being evaluated for use in crucible cooling in titanium arc melting. The alloy also is used as an organic catalyst.

Chemical properties. The chemical properties of potassium are similar to those of sodium, although the former is considerably more reactive. Potassium differs from sodium in a number of respects. Whereas sodium is essentially unreactive with graphite, potassium, rubidium, and cesium react to form a series of interlamellar compounds, the richest in metal having the formula MC_8. Compounds are formed with carbon–alkali metal atomic ratios of 8, 16, 24, 36, 48, and 60 : 1. The graphite lattice is expanded during penetration of the alkali metal between the layers. Potassium reacts with carbon monoxide at temperatures as low as 60° C to form an explosive carbonyl ($K_6C_6O_6$), a derivative of hexahydroxybenzene. Sodium is essentially nonreactive with carbon monoxide.

Liquid potassium and NaK both are more reactive than liquid sodium with air and oxygen. Potassium superoxide (KO_2) is the preferred oxide, whereas sodium forms the monoxide (Na_2O). Oxidation of NaK produces Na_2O preferentially. The superoxide of potassium is a yellow solid consisting of $K^+$and O_2^-ions. It also can be formed by oxidation of potassium amalgam with dry air or oxygen.

Potassium reacts violently with water to produce one-half mole of hydrogen per mole of potassium and water and generating approximately 47 kcal/gram-atom of heat. It can be stored under nitrogen gas with no reaction. It reacts with hydrogen at approximately 350° C to form the hydride.

Reactions with halogens

Potassium is highly reactive with halogens and detonates when it contacts liquid bromine. Violent explosions also have been observed when mixtures of potassium and halogen acids are subject to shock. Explosions also have occurred when potassium is being mixed with a number of metal halide salts or with organic-halogen compounds.

At elevated temperatures, potassium reduces carbon dioxide to carbon monoxide and carbon. Solid carbon dioxide and potassium react explosively when subjected to shock. Oxidation of potassium amalgam with carbon dioxide results in the formation of potassium oxalate. Potassium is not reactive with benzene, although heavier alkali metals such as cesium add across the double bonds between carbon atoms in the benzene molecules, giving organometallic products.

In addition to the alloys of potassium with lithium and sodium (see above), alloys with other alkali metals are known. Complete miscibility exists in the potassium–rubidium and potassium–cesium binary systems. The latter system forms an alloy melting at approximately −38° C. Modification of the system by the addition of sodium results in a ternary eutectic melting at approximately −78° C. The composition of this alloy is 3 percent sodium, 24 percent potassium, and 73 percent cesium. Potassium is essentially immiscible with all of the alkaline-earth metals, as well as with zinc, aluminum, and cadmium.

Nuclear properties. The two stable isotopes of potassium are ^{39}K and ^{41}K, which together comprise 99.99 percent of the element as it occurs in nature, about 13.5 times as much of the former isotope normally being present. The natural radioactivity of potassium is due to beta radiation from the ^{40}K isotope (10^9 years half-life), which is present in the element in nature to the extent of about 0.01 percent. The disintegration of ^{40}K is used in geological age calculations.

Biological properties. Potassium is an essential ingredient in all forms of life. Each organism has a closely maintained potassium level and a relatively fixed potassium–sodium ratio. Potassium is the primary inorganic cation within the living cell, and sodium is the most abundant cation in extracellular fluids. Potassium is an essential ingredient of fertilizers. The potassium content of plants varies considerably, but it is ordinarily in the range of 0.5 to 2 percent. In man, the ratio of potassium between the cell and plasma is approximately 27 : 1. The potassium content of muscle tissue is approximately 0.3 percent, whereas that of blood serum is about 0.01 to 0.02 percent. The dietary requirement for normal growth is approximately 3.3 grams of potassium per day, but the ingestion of more than 20 grams of potassium results in distinct physiological effects. Excess potassium is excreted in the urine, and a significant quantity may be lost during sweating.

Rubidium and cesium. Because rubidium and cesium are very similar in their physical and chemical properties, they are conveniently discussed together.

Occurrence and production. Rubidium and cesium often occur together in nature. Rubidium, however, is more widely scattered and seldom forms a natural mineral; it is found only as an impurity in other minerals, ranging in content up to 5 percent in such minerals as lepidolite and pollucite. Brine samples have been analyzed that contain up to six parts per million of rubidium.

The Earth's crust is estimated to contain only 7 ppm of cesium, whereas it contains 310 ppm of rubidium. Pollucite ($Cs_4Al_4Si_9O_{26} \cdot H_2O$), however, is a cesium-rich mineral resembling quartz. It contains 40.1 percent cesium on a pure basis, and impure samples are ordinarily separated by hand-sorting methods to greater than 25 percent cesium. Large pollucite deposits have been found in Rhodesia and in the lithium-bearing pegmatites at Bernic Lake, Manitoba. Cesium also occurs in a rare mineral called rhodizite, and it is found in low concentrations in lepidolite and in salt brines and saline deposits.

Source of rubidium

The principal commercial source of rubidium is accumulated stocks of a mixed carbonate produced as a by-product in the extraction of lithium salts from lepidolite. Primarily a potassium carbonate, the by-product also contains approximately 23 percent rubidium and 3 percent cesium carbonates. The primary difficulty associated with the production of either pure rubidium or pure cesium is that these two elements are always found together in nature and also are mixed with other alkali metals; because these elements are very similar chemically, their separation presents numerous problems. Before development of procedures based on thermochemical reduction and fractional distillation, the elements were purified in the salt form through laborious crystallization techniques. Once pure salts have been prepared by precipitation methods, it is a relatively simple task to convert them to the free metal. This end is ordinarily accomplished by calcium reduction in a high-temperature vacuum system in which the highly volatile alkali metal is distilled from the reaction mixture.

Direct reduction of the mixed carbonates from lepidolite purification, followed by fractional distillation, is perhaps the most important of the commercial methods for producing rubidium. The mixed carbonate is treated with excess sodium at approximately 650° C, and much of the rubidium and cesium passes into the metal phase. The resulting crude alloy is vacuum distilled to form a second alloy considerably richer in rubidium and cesium. This product is then refined by fractional distillation in a tower to produce elemental rubidium more than 99.5 percent pure.

The direct thermochemical reduction of pollucite ore with sodium metal is the primary commercial source of cesium metal. Use of this process may lead to significant decreases in cesium prices if the market for cesium increases. In the process ground pollucite ore is treated with elemental sodium at approximately 650° C to form a sodium–cesium alloy containing some rubidium impurity. Fractional distillation of this alloy in a distillation tower at approximately 700° C produces 99.9 percent pure cesium metal.

Significant uses. Rubidium metal has few commercial uses, and it is of very minor economic significance. The high prices and uncertain and limited supply of the metal discourage the development of any uses. Only a few commercial uses have been developed for the metal itself, although the salts are of slightly greater economic significance because of their use in photocells and radio vacuum tubes. Cesium metal also is produced in rather limited amounts because of its relatively high cost. Cesium has been evaluated for power systems for space applications and as a potential rocket fuel for interplanetary travel. Because the cesium atom can be ionized thermally and the positively charged ions accelerated to great speeds, cesium systems can provide specific impulses for rocket propulsion that are extraordinarily high. Cesium also has application in thermionic converters that generate electricity directly within nuclear reactors. Another potentially large application of cesium metal is in the production of low-melting NaKCs eutectic alloy. Cesium salts are used in moderate quantities in the manufacture of photomultiplier tubes, infrared lamps, scintillation counters, and spectrophotometers.

Space applications of cesium

Chemical properties. Rubidium and cesium are difficult to handle because they react spontaneously in air. If the surface area of a sample of the metal is large, it can burn to form superoxides. Rubidium superoxide (RbO_2) is a yellow powder; cesium superoxide has a more reddish cast. Peroxides of both metals (Cs_2O_2 and Rb_2O_2) can be formed by oxidation of the metal with the required amount of oxygen. Rubidium forms two other oxides (Rb_2O and Rb_2O_3), but the reactions of cesium with oxygen are much more complex.

Rubidium and cesium are miscible in all proportions and have complete solid solubility; a melting-point minimum of +9° C is reached. Both rubidium and cesium form a number of mercury amalgams. Because of the increased specific volumes of rubidium and cesium, as compared to the lighter alkali metals, there is less tendency for them to form alloy systems with other metals.

Nuclear properties. Two rubidium isotopes are found in nature. The stable rubidium-85 makes up 72 percent of the mixture. Radioactive rubidium-87 makes up 28 percent; it emits beta rays with a half-life of about 6×10^{11} years. Cesium has only one naturally occurring isotope, with a mass number of 133. A number of cesium isotopes with short half-lives have been produced artificially by nuclear reactions.

Francium. The existence of francium was predicted by Mendeleyev in his periodic classification of the elements. In 1939 the French chemist Marguerite Perey discovered the radioactive element, which has beta activity and a half-life of 22 minutes (^{223}Fr). Nineteen other isotopes of francium also have been reported. It has been calculated that the total quantity of francium in the Earth's crust is only 24.5 grams. Information on biological and chemical aspects of the element is virtually nonexistent.

ANALYTICAL CHEMISTRY OF THE ALKALI METALS

Chemical separation of lithium can be effected by the use of the organic nitrogen-containing compound picrolonic acid, which precipitates the heavier alkali metals from chloride solutions, leaving lithium behind. Lithium can be detected with a number of azo dyes that give highly sensitive colour reactions with lithium ions in alkaline solution. A modification of the uranyl acetate test (the precipitation of an insoluble sodium salt with uranyl acetate) is used as a standard test for the presence of sodium. The use of a cobaltinitrite solution permits separation of potassium from sodium by precipitation of the insoluble potassium salt. There are essentially no satisfactory analytical methods for rubidium and cesium based on the use of reagents in solution; these elements are commonly determined spectroscopically—that is, by measurements of their flame spectra or light-emission patterns.

Instrumental analysis

Ordinary methods of chemical analysis generally require extensive preliminary separation. With the alkali metals this process frequently can be avoided by the use of flame tests, which are quickly and easily applied and able to detect small amounts of the alkali metals in the presence of other elements. When salt solutions of the alkali metals are atomized in the coal gas burner of a simple flame photometer, which measures emitted light and must be provided with a suitable interference filter (to remove unwanted emissions), the metals can be determined generally in the parts-per-million range. Determination of one alkali metal in the presence of another, however, can result in interference, which can be reduced using specially prepared standard solutions containing known amounts of the interfering metals for comparative purposes.

Emission spectrographic analysis (measuring light emitted at particular wavelengths, a more precise method than by a photometer) is a useful method for analyzing trace quantities of one alkali metal in another and is also very helpful for analyzing metallic impurities. Colorimetric methods, which compare colours produced in solution, are often used for the analysis of metallic impurities.

The analysis of the alkali-metal samples for the presence of nonmetallic elements, such as oxygen, carbon, hydrogen, and nitrogen, requires specialized techniques. The oxygen content of sodium and potassium samples can be determined by extraction of the free alkali metal with mercury, leaving behind mercury-insoluble oxides and carbonates, which can subsequently be analyzed using solution methods. The oxygen content of rubidium and cesium can be accurately determined by precise measurement of the freezing point of these two elements.

The carbon content of alkali metals can be analyzed by oxidation of the alkali metal in pure oxygen, followed by infrared measurement of the carbon dioxide generated during combustion. For the analysis of nitride in lithium, the nitride commonly is converted to ammonia, and the ammonia is measured by colorimetric analysis.

The sampling of alkali metals to obtain representative examples for the analysis of nonmetallic elements is a difficult art. Such sampling ordinarily is carried out by melting the whole batch of alkali metal and extracting a sample by dipping a bucket into the melt, withdrawing it, and analyzing the contents of the bucket. (F.T./Ed.)

Alkaline-earth metals

The term alkaline-earth metals is the generic name for the chemical elements beryllium (Be), magnesium (Mg), calcium (Ca), strontium (Sr), barium (Ba), and radium (Ra), which are the members of group IIa of the periodic table (see Figure 10) of the elements. Prior to the 19th century, substances that were nonmetallic, insoluble in water, and unchanged by fire were known as earths. Those earths, like lime, that resembled the alkalies (soda ash and potash) were designated alkaline earths. Alkaline earths were thus distinguished from the alkalies and from other earths, such as alumina and the rare earths. By the first decade of the 19th century it became clear that the earths, formerly considered to be elements, were in fact oxides, compounds of a metal and oxygen. The metals whose oxides make up the alkaline earths then came to be known as the alkaline-earth metals and have been classified in group II of the periodic table ever since Mendeleyev proposed his first table in 1869.

Chemical and physical properties

The alkaline-earth metals are extremely electropositive; that is, like the alkali metals of group Ia, their atoms easily lose electrons to become positive ions (cations). Most of their typical compounds are therefore ionic: salts in which the metal occurs as uniformly divalent cations, M^{2+}, where M represents any group IIa atom. The salts are colourless unless they include a coloured anion (negative ion). Typical alkaline-earth compounds, calcium chloride ($CaCl_2$) and calcium oxide (CaO), may be contrasted with the compounds of the uniformly monovalent alkali metals, sodium chloride (NaCl) and sodium monoxide (Na_2O). The oxides of the alkaline-earth metals are basic (*i.e.,* alkaline, in contrast to acidic). A fairly steady increase in electropositive character is observed in passing from beryllium, the lightest member of the group, to radium, the heaviest; as a result of this trend, beryllium oxide is only weakly basic and even shows acidic properties, whereas barium and radium oxide are strongly basic. The metals themselves are highly reactive reducing agents; that is, they readily give up electrons to other substances that are, in the process, reduced.

All the metals and their compounds find commercial application to some degree, especially magnesium alloys and a variety of calcium compounds. Magnesium and calcium, particularly the latter, are abundant in nature and play significant roles in geological and biological processes. Radium is a rare element; all its isotopes are radioactive.

HISTORY

The earliest known alkaline earth was lime (Latin *calx*), which is now known to be calcium oxide; it was used in ancient times in the composition of mortar. Magnesia, (the name derives probably from the ancient district of Magnesia in Asia Minor), the oxide of magnesium, was shown to be an alkaline earth different from lime by the Scottish chemist Joseph Black in 1755; he observed that magnesia gave rise to a soluble sulfate, whereas that derived from lime was known to be insoluble. In 1774 Carl Wilhelm Scheele, the Swedish chemist who discovered oxygen, found that the mineral called heavy spar or *barys* (Greek, heavy) contained a new earth, which became known as baryta (barium oxide). A further earth, strontia (strontium oxide), was identified by Adair Crawford, a London physician and chemist, in 1790 on examining a mineral (strontium carbonate) found in a lead mine at Strontian in Argyllshire, Scotland. Beryllia (beryllium oxide) was extracted from the mineral beryl and recognized as an earth by the French analytical chemist Louis-Nicolas Vauquelin in 1797. Though at first confused with alumina (aluminum oxide) because both dissolve in alkali, beryllia was shown to be distinct; unlike alumina, it reprecipitated when the alkaline solution was boiled for some time. Beryllia was originally called *glucina* (Greek *glykys,* sweet) because of its sweet taste. (This etymological root is retained in France, where the element beryllium is also known as glucinium.)

Magnesium, calcium, strontium, and barium, elements derived from alkaline earths, were isolated as impure metals by Sir Humphry Davy in 1808 by means of the electrolytic method he had previously used for the isolation of the alkali metals potassium and sodium. The alkaline-earth metals were later produced by reduction of their salts with free alkali metals, and it was in this way (the action of potassium on beryllium chloride) that beryllium was first isolated by the German chemist Friedrich Wöhler in 1828. Radium was discovered in 1898 by means of its radioactivity by Pierre and Marie Curie, who separated it with great difficulty from barium.

Discovery of alkaline-earth metals

PHYSICAL AND CHEMICAL BEHAVIOUR

The alkaline-earth elements are highly metallic and are good conductors of electricity. They have a gray-white lustre when freshly cut but tarnish readily in air, particularly the heavier members of the group. Beryllium is sufficiently hard to scratch glass, but barium is only slightly harder than lead. The melting points and boiling points of the group are higher than those of the corresponding alkali metals; they vary in an irregular fashion, magnesium having the lowest (mp 650° C and bp 1,105° C) and beryllium the highest (mp 1,283° and bp about 2,500°). The elements crystallize in one or more of the three regular close-packed metallic crystal froms. Chemically, they are all strong reducing agents. The free metals are soluble in liquid ammonia—the dark-blue solutions of calcium, strontium, and barium arousing considerable interest because they are thought to contain metal ions and the most unusual species, solvated electrons, or electrons resulting from the interaction of the metal and the solvent. Highly concentrated solutions of these elements have a metallic, copper-like appearance, and further evaporation yields residues containing ammonia, which correspond to the general formula $M(NH_3)_6$. The solutions are strong reducing agents and are useful in a number of chemical processes.

The atoms of the alkaline-earth elements all have similar electronic structures, consisting of a pair of electrons (designated *s* electrons) in an outermost orbital, within which is a stable electronic configuration corresponding to that of a noble gas. The noble gas elements—helium (He), neon (Ne), argon (Ar), krypton (Kr), xenon (Xe), and radon

Table 13: Some Properties of the Alkaline-Earth Metals

	beryllium	magnesium	calcium	strontium	barium	radium
Atomic number	4	12	20	38	56	88
Atomic weight (stablest isotope)	9.0122	24.312	40.08	87.62	137.34	(226)

*HCP = hexagonal close packed, FCC = face-centred cubic (cubic close packed), BCC = body-centred cubic.

Electronic configuration

(Rn)—have generally complete electron shells. Strontium has the configuration $1s^2 2s^2 2p^6 3s^2\ 3p^6 3d^{10} 4s^2 4p^6 5s^2$, which may be written as (krypton core) $5s^2$, or simply (Kr) $5s^2$. Similarly, Be may be designated as (He) $2s^2$, Mg as (Ne) $3s^2$, Ca as (Ar) $4s^2$, Ba as (Xe) $6s^2$, and Ra as (Rn) $7s^2$. The prominent lines in the atomic spectra of the elements, obtained when the elements are heated under certain conditions, arise from states of the atom in which one of the two *s* electrons has been promoted to a higher energy orbital. The *s* electrons are relatively easily ionized (removed from the atom), and this ionization is the characteristic feature of alkaline-earth chemistry. The ionization potential (the energy required to strip an electron from the atom) falls continuously in the series from beryllium (9.32 electron volts [eV]) to barium (5.21 eV); radium, the heaviest in the group, has a slightly higher ionization potential (5.28 eV). The small irregularities observed in the otherwise smooth change as one proceeds down the group as it appears in the periodic table are explained by the uneven filling of electron shells in the successive rows of the table. The *s* electrons may also be promoted to *p* orbitals of the same principal quantum number (within the same shell) by energies similar to those required to form chemical bonds; the atoms are, therefore, able to form stable covalently bonded structures, unlike helium, which has the otherwise analogous electronic configuration of $1s^2$.

Zinc, cadmium, and mercury, the group IIb elements, are often compared with the alkaline-earth elements calcium, strontium, and barium. Cadmium, for example, has the electronic configuration (Kr) $4d^{10}5s^2$, with the ten $4d$ electrons taking virtually no part in chemical bonding. The $5s^2$ electrons, however, are much less readily ionized in cadmium than they are in strontium, for the $4d$ electrons act as an ineffective shield for the corresponding increased charge on the cadmium nucleus. The chemistry of the IIb metals, therefore, is markedly less ionic than the chemistry of the alkaline-earth metals.

Ionic character. The chemistry of the alkaline-earth metals, like that of the alkali metals, is for the most part reasonably interpreted in terms of an ionic model for the compounds formed. This model is less satisfactory for the chemistry of beryllium and magnesium than for the heavier alkaline-earth metals. In fact, most beryllium compounds are molecular (covalent) rather than ionic. Although there is some evidence for the transient existence of singly charged alkaline-earth ions, in most cases the chemistry of these elements is dominated by the formation and properties of the doubly charged M^{2+} ions, in which the outermost *s* electrons have been stripped from the metal atom. The resulting ion is stabilized by electrostatic interaction with a solvent, like water, which has a high dielectric constant and a great ability to absorb electrical charge, or by combination with ions of opposite charge in an ionic lattice such as is found in salts. The extra energy required to remove the second *s* electron (the second ionization potential being approximately twice the first) is more than compensated for by the extra binding energy present in the doubly charged ion. The removal of a third electron from an alkaline-earth atom, however, would require an expenditure of energy greater than could be recouped from any chemical environment. As a result, therefore, the alkaline-earth metals show a constant valence of +2 in their compounds.

Ionic sizes

The sizes of the ions of the alkaline-earth elements increase steadily from Be^{2+}, which has a radius of 0.31Å or 31×10^{-10} cm, to Ra^{2+} with a radius of 1.40Å. The ionic radius of the europium ion Eu^{2+} (1.12Å) is very close to that of strontium Sr^{2+} (1.13Å); this means that Eu^{2+} ions can sometimes be used as a "probe" for the alkaline-earth metals, substituting for strontium ions in situations where advantage can be taken of the spectroscopic and magnetic properties that make Eu^{2+} readily identifiable. The ionic radius of the cadmium ion Cd^{2+} (0.97Å) is very similar to that of calcium Ca^{2+} (0.99Å). A quantitative comparison of cadmium and calcium chemistry, therefore, clearly shows up the less ionic character of cadmium chemistry without complications due to differences in ionic size. A related comparison may be made between mercury and strontium, because of the similar ionic radii of Hg^{2+} (1.10Å) and Sr^{2+} (1.13Å).

The chemistry of radium is less well investigated than that of the other alkaline-earth metals. As expected, however, it is in general an extrapolation of the chemistry of calcium, strontium, and, especially, barium.

The group IIa ions are readily hydrated, with the strength of bonding to the water molecules increasing with decreasing ionic radius. Although the number of water molecules directly attached to the metal ion may be greater with the larger ions for purely steric (geometrical) reasons, the total number of water molecules associated with the metal ion nevertheless increases inversely with the size of the ion itself (as shown by migration experiments conducted in aqueous solution). Large anions, such as sulfate, tend to form weak ion-pair complexes more readily with the larger metal ions of the family, but weak-acid anions, such as acetate, tend to form stronger complexes with the smaller metal ions, particularly those of magnesium and beryllium. That many of these complexes are molecular rather than ionic is shown by their ready extraction from aqueous solution (which preferentially dissolves ionic substances) into organic solvents (which dissolve molecular ones).

INDIVIDUAL ALKALINE-EARTH METALS

Beryllium. Beryllium is widely distributed in the Earth's crust, of which it composes about 0.001 percent; its cosmic abundance is 20 on the scale in which silicon, the standard, is one million. Although there are about 30 recognized minerals containing beryllium, only three—beryl ($3\,BeO \cdot Al_2O_3 \cdot 6SiO_2$), phenacite ($2\,BeO \cdot SiO_2$), and chrysoberyl ($BeO \cdot Al_2O_3$)—are of any significance, and only the first is of industrial importance. The precious forms of beryl, emerald and aquamarine, have a composition closely approaching that given above, but industrial ores contain less beryllium; most beryl is obtained as a by-product of other mining operations, the larger crystals being picked out by hand.

Exploration for beryllium has been considerably facilitated by the development of the berylometer, a portable device that detects very small quantities of beryllium in almost any mixture. The device depends on the bombardment of the sample with gamma rays from the radioactive isotope antimony-24. The gamma rays interact specifically with beryllium atoms to give neutrons that can be counted electronically.

The extraction of beryllium is complicated by the fact that beryllium oxide is found only as a minor constituent, tightly bound to alumina and silica. Treatment with acids, roasting with complex fluorides, and liquid–liquid extraction have all been employed to concentrate beryllium oxide. The oxide is converted to fluoride via ammonium beryllium fluoride and then heated with magnesium to form elemental beryllium. The element is purified by vacuum melting.

Uses of beryllium

Metallic beryllium is grayish, and its chemical properties somewhat resemble those of aluminum. Though resistant to air oxidation under normal conditions, it is readily attacked by acids and alkalies. The applications of beryllium depend upon its unusual combination of physical properties. A very light metal, it has a high mechanical strength and a high melting point. Because of its low atomic weight it has a high transparency to X-rays (17 times greater than aluminum), which makes it ideal as a material for windows of X-ray tubes. Its ability to slow down fast neutrons has found considerable application in atomic piles. Beryllium has been developed as a structural material for specific applications particularly within the aerospace industry.

Beryllium is used in a number of commmercial neutron sources. The alpha particles released by radioactive decay of radium atoms react with atoms of beryllium to give, among the products, neutrons with a wide range of energies—up to about 5×10^6 eV. If radium is encapsulated, however, so that none of the alpha particles reach beryllium, neutrons of energy less than 600,000 eV are produced by the more penetrating gamma radiation from the decay products of radium.

Magnesium. Magnesium, comprising about 2.5 percent of the Earth's crust, is the eighth most abundant element and, after aluminum and iron, the third most plentiful structural metal; its cosmic abundance is estimated as 9.1×10^5 atoms (Si = 10^6 atoms). It occurs as carbonates (magnesite, $MgCO_3$, and dolomite, $CaCO_3 \cdot MgCO_3$) and in many common silicates, including asbestos, talc, and olivine. It also is found as the hydroxide (brucite), chloride (carnallite, $KCl \cdot MgCl_2 \cdot 6H_2O$), and sulfate (kieserite).

Magnesium is commercially produced chiefly by the electrolysis of molten magnesium chloride and by the thermal reduction of magnesium oxide with ferrosilicon (see INDUSTRIES, EXTRACTION AND PROCESSING: *Magnesium production*).

It is the lightest metal that can be commonly used for structural purposes (its density is 65 percent that of aluminum and 22 percent that of iron), a property widely exploited. Its thermal and electrical conductivity and its melting point are very similar to those of aluminum. Whereas aluminum is attacked by alkalies but is resistant to most acids, magnesium is resistant to most alkalies but is readily attacked by most acids (chromic and hydrofluoric acids are important exceptions). At normal temperatures it is stable in air and water due to the formation of a thin protective skin of oxide (but burns rapidly when heated in air), and it is attacked by steam. Magnesium is a powerful reducing agent and is used to produce other metals from their compounds (*e.g.,* titanium, zirconium, and hafnium). It reacts directly with many elements; with organic halides in ether solution it forms Grignard reagents. Because of its ready combustibility, magnesium finds application in explosive and pyrotechnic devices.

Uses of magnesium

Magnesium is mainly used in the form of alloys, which usually contain 10 percent or less of other elements, generally added to increase the strength of the metal. The most important alloys are those of aluminum and zinc. Casting, rolling, extruding, and forging techniques are all employed with the alloys, and further fabrication of the resulting sheet, plate, or extrusion is carried out by normal forming, joining, and machining operations. Magnesium is the easiest structural metal to machine and has often been used when a large number of machining operations are required.

Magnesium is essential to all living systems. The photosynthetic function of plants depends upon the action of chlorophyll pigments, which contain magnesium at the centre of a complex, nitrogen-containing ring system (porphyrin). These magnesium compounds enable the energy of light to be used to convert carbon dioxide and water to carbohydrates and oxygen and thus directly or indirectly provide the key to nearly all living processes. Magnesium also takes part in a number of enzyme reactions, which control energy transfer in living cells.

Natural sources of calcium

Calcium. Calcium is the fifth most abundant element in the Earth's crust, to which it contributes an estimated 3.64 percent; its cosmic abundance is estimated at 4.9×10^4 atoms (Si = 10^6 atoms). One of the most widely distributed elements, it occurs as carbonate (chalk, limestone, marble, calcite), sulfate (anhydrite, gypsum), fluoride (fluorite or fluorspar), and phosphate (apatite). It is also found in a large number of silicates and aluminosilicates, in salt deposits, and in natural waters, including the sea. Calcium carbonate deposits dissolve in water that contains carbon dioxide to form calcium bicarbonate, $Ca(HCO_3)_2$. This process often results in the formation of caves, and may reverse to deposit limestone as stalactites and stalagmites. Calcium is essential to plant and animal life. Many living organisms concentrate calcium in their shells or skeletons, and indeed in higher animals calcium is the most abundant inorganic element. Many important carbonate and phosphate deposits owe their origin to living organisms.

The metal is produced by thermal reduction of lime with aluminum under high vacuum and by electrolysis of fused calcium chloride (see INDUSTRIES, EXTRACTION AND PROCESSING: *Production of other important industrial metals.*) It reacts with water and, on heating, with oxygen, nitrogen, hydrogen, halogens, boron, sulfur, carbon, and phosphorus; its commercial applications depend largely on these reactions. Although it compares favourably with sodium as a reducing agent, calcium is more expensive and less reactive. In many deoxidizing, reducing, degasifying, and alloying applications, however, calcium often is preferred because of its lower volatility. Small percentages of calcium are used in many alloys for special purposes.

The sulfate (as uncalcined gypsum) is employed as a soil corrector. Calcined gypsum is used in making tile, wallboard, lath, and various plasters. Plaster of Paris, the hemihydrate, $CaSO_4 \cdot \frac{1}{2} H_2O$, is produced by partial calcination at about 120° C; mixed with water, it forms a plastic mass that hydrates to a hard white plaster.

The dihydrogen sulfite, $Ca(HSO_3)_2$, is made by the action of sulfur dioxide on a slurry of $Ca(OH)_2$. Its aqueous solution under pressure dissolves the lignin in wood to leave cellulose fibres and thus finds considerable application in the paper industry.

The phosphates are the principal minerals for the production of phosphate fertilizers and for a whole range of phosphorus compounds. The rock is usually treated with sulfuric acid to form $Ca(H_2PO_4)_2$, which may be applied directly to the land. The fluoride, CaF_2, is important to the production of hydrofluoric acid, which is made from CaF_2 by the action of sulfuric acid.

Strontium. Strontium comprises about 0.025 percent of the Earth's crust; its cosmic abundance is estimated as 18.9 atoms ($Si = 10^6$ atoms). Although it is widely distributed with calcium, there are only two principal ores of strontium alone, celestite ($SrSO_4$) and strontianite ($SrCO_3$). Metallic strontium may be obtained by the electrolysis of strontium chloride or by reduction of the oxide with aluminum, but there is little commercial demand for the metal because calcium and barium are more readily obtainable and fulfill the functions for which strontium might be used.

The chemistry of strontium is quite similar to that of calcium. The biological properties of strontium are also very close to those of calcium and distinct from those of barium, whose soluble compounds, for example, are poisonous.

Hazards of strontium-90

The artificial isotopes strontium-89 (52-day half-life) and more especially strontium-90 (28-year half-life), found in radioactive fallout, are extremely hazardous. They become deposited in bones, where they replace calcium; their radiation then damages bone marrow, impairs the process of forming new blood cells, and may induce cancer.

Barium. Barium occurs to the extent of about 0.05 percent in the Earth's crust; its cosmic abundance is estimated as 3.7 atoms ($Si = 10^6$ atoms). Two minerals are common: the more important sulfate ($BaSO_4$, barite, barytes or heavy spar), used principally in oil-drilling "mud," and the carbonate ($BaCO_3$, witherite). The metal may be produced by electrolysis of barium chloride, but the most effective method is the reduction of the oxide by heating with aluminum or silicon in a high vacuum. Only a few tons of the metal are produced each year. It is used chiefly as a "getter" in vacuum tubes, where it removes the last traces of various gases.

Radium. About 16 isotopes of radium, all radioactive, are known; their half-lives, except for radium-226 (1,600 years) and radium-228 (5.8 years), are less than a few weeks. The long-lived radium-226 is found in nature as a result of its continuous formation from uranium-238 decay. Radium thus occurs in all uranium ores, but it is more widely distributed because it forms water-soluble compounds; the Earth's surface contains an estimated 1.8×10^{13} grams of radium.

The discovery of radium

The story of the discovery and isolation of radium by Pierre and Marie Curie (1898) is well known. The Curies observed that the major part of the radioactivity of pitchblende was caused by a previously unknown substance that could be concentrated with barium and then separated from it by laborious fractional crystallization. The separation was followed by the increase in intensity of new lines in the ultraviolet spectrum and by a steady increase in the apparent atomic weight of the material until a value of 225.18 was obtained, remarkably close to the accepted value of 226.03.

In modern technology, radium is separated from barium by fractional crystallization of the bromides, followed by purification by ion-exchange techniques for removal of the last 10 percent of the barium. Radium metal may be prepared by electrolytic reduction of its salts.

Radioactivity. The chemistry of radium is what would be expected of the heaviest of the alkaline earths, but the intense radioactivity is its most characteristic property. One gram of radium-226 undergoes 3.7×10^{10} disintegrations per second, producing energy equivalent to 6.8×10^{-3} calories, sufficient to raise the temperature of a well-insulated sample at the rate of 1° C every 10 seconds. The practical energy release is even greater than this, due to the production of a large number of short-lived radioactive decay products. The alpha particles emitted by radium may be used to initiate nuclear reactions; a mixture of beryllium (see above *Beryllium*) and radium is used as a neutron source. Radium mixed with a phosphor that could be excited by the alpha particles was widely used in the manufacture of luminous paints for watch and instrument dials until the early 1950s, but less hazardous alpha emitters have largely replaced it. Although radium-226 is not a very intense gamma emitter, its decay products are; thus radium has been used in medicine as a source of gamma rays for the irradiation of tumours. One of the products of radium decay is radon, the heaviest noble gas; this decay process is the chief source of that element.

Radium tends to concentrate in bone where alpha radiation interferes with red corpuscle production and can lead to bone cancer. The hazards of radium were disastrously emphasized by the deaths of a number of women who had been employed painting luminous dials during World War I and who had ingested considerable amounts of radium through the habit of licking the points of their brushes. The detection of exhaled radon provides a very sensitive test for radium absorption. (C.S.G.P./Ed.)

Zinc group elements

The zinc group elements consist of zinc (Zn), cadmium (Cd), and mercury (Hg), forming Group IIb of the periodic table of the elements (see Figure 10). They have properties in common, but they also differ in significant respects. All three are metals with a silvery-white appearance and relatively low melting points and boiling points; mercury is the only common metal that is liquid at room temperature, and its boiling point is lower than that of any other metal. The three are found in different proportions in the Earth's crust: it has been estimated that zinc is present to the extent of 80 parts per million (compared with 70 for copper and 16 for lead). The estimate for cadmium is only 0.15; commercially, it is always found associated with zinc or zinc–lead ores and is produced only as a by-product of zinc and lead smelting. The proportion of mercury in the Earth's crust is estimated at 0.08 parts per million. All important mercury deposits consist of mercuric sulfide, known as the mineral cinnabar.

Occurence in the Earth's crust

HISTORY

Zinc. Metallic zinc appeared much later in history than the other common metals. Copper, lead, tin, and iron can be obtained as the molten metals by heating their oxide ores with charcoal (carbon), a process called reduction, in shaft furnaces, which were developed quite early in history. Zinc oxide, however, cannot be reduced by carbon until temperatures are reached well above the relatively low boiling point of the metal (907° C). Thus, the furnaces developed to smelt the other metals could not produce zinc. Small quantities of metallic zinc can sometimes be found in the flues of lead blast furnaces. There is some evidence that the Greeks knew of the existence of zinc and called it *pseudargyras,* or "false silver," but they had no method of producing it in quantity. The Romans as early as 200 BC produced considerable quantities of brass, an alloy of zinc and copper, by heating in crucibles a mixture of zinc oxide and charcoal covered with lumps of metallic copper. The zinc oxide was reduced in the lower part of the crucible. Zinc vapour was formed and dissolved in the copper to form brass. At the end of the process the temperature was raised to melt the brass for casting into ingots. The realization that to make zinc it was necessary to produce the metal as a vapour and then condense it seems first to have been reached in India in the 14th century. In the West this principle was first applied in

Roman brass-making

England in 1743. At the end of the 18th century in Belgium and Poland improvements were made in the furnace, and the process remained unchanged until an electrolytic process was developed in 1917. At the end of the 1920s a radical advance was made in the United States by developing a continuous retort process, and during the 1930s an electrothermic process was designed for producing zinc continuously. A development of the 1960s was the zinc-lead blast furnace, in which rapid quenching of the gases is a key principle. Zinc production processes are treated in detail in INDUSTRIES, EXTRACTION AND PROCESSING: *Zinc production.*

Cadmium. Cadmium is a comparatively recent discovery, having been first found and described in 1817. Cadmium is present in small quantities in most zinc and lead ores, and it is produced entirely as an ancillary operation to zinc and lead smelting. The chief zinc ore, zinc blende, or sphalerite, consists mainly of zinc sulfide, containing from 0.1 to 0.3 percent cadmium. All methods of zinc production begin with the conversion of the sulfide into zinc oxide by roasting: the cadmium becomes concentrated in the fumes, which are treated in various steps until a product is obtained containing over 99.9 percent cadmium. Some lead ores also contain small quantities of cadmium, and if it is present in sufficient quantity it is recovered by a cycle of operations similar to that used by zinc smelters. Zinc producers who use the electrolytic process recover cadmium in a somewhat different way, but again the principle is the same, beginning with the roasting of zinc sulfide, followed by the treatment of the flue dusts.

Mercury. Mercury was known in Egypt and also probably in the East as early as 1500 BC. The name mercury originated in 6th-century alchemy, in which the symbol of the planet was used to represent the metal; the chemical symbol Hg derives from the Latin *hydrargyrum,* "liquid silver." Although its toxicity was recognized at an early date, its main application was for medical purposes.

Principal source of mercury

The chief commercial source of mercury is cinnabar, or mercury sulfide, which is mined in shaft or open-pit operations and refined by flotation. Over half the world supply of mercury comes from Spain and Italy. Most of the methods of extraction of mercury rely on the volatility of the metal and the fact that cinnabar is readily decomposed by air or by lime to yield the free metal. Because of the toxicity of mercury and the threat of rigid pollution control, attention is being directed toward safer methods of extracting mercury. These generally rely on the fact that cinnabar is readily soluble in solutions of sodium hypochlorite or sulfide, from which the mercury can be recovered by precipitation with zinc or aluminum or by electrolysis.

COMPARATIVE PROPERTIES OF THE GROUP

The electronic structure of the zinc group elements is shown in Table 14, and some of their properties are listed in Table 15.

Table 14: The Electron Structure of Zinc Group Elements

symbol	atomic number	shells					
		K	*L*	*M*	*N*	*O*	*P*
Zn	30	2	8	18	2		
Cd	48	2	8	18	18	2	
Hg	80	2	8	18	32	18	2

Chemical reactivity. All three elements can lose the two electrons in the outermost shell to form divalent (with two charges) positive ions, thereby exposing the next innermost shell with a stable configuration in each case of 18 electrons. Ordinary chemical reactions cannot supply enough energy to remove more than two electrons and thus increase the valency above 2, though any number of electrons can be removed under conditions that can provide the necessary energy, such as intense heat or powerful electric or magnetic fields. All three elements tend to use the two outer electrons for covalent bonding; this tendency is most marked in the case of mercury, less so in that of zinc, and least with cadmium.

Zinc is divalent only. It can give up two electrons to form an electrovalent compound; *e.g.,* zinc carbonate $ZnCO_3$. It may also share those electrons, as in zinc chloride, $ZnCl_2$, a compound in which the bonds are partly ionic and partly covalent. Mercury also forms covalent bonds in mercury(II) chloride, $HgCl_2$.

Cadmium compounds are mainly ionic, but cadmium also forms complex ions with ligands (atoms, ions, or molecules that donate electrons to a central metal ion); *e.g.,* the complex ion with ammonia NH_3, having the formula $[Cd(NH_3)_4]^{2+}$, or with the cyanide ion, formula

$[Cd(CN)_4]^{2-}$. Differing from zinc and mercury, cadmium can form the complex ions represented by the formulas $(CdCl_3)^-$ and $(CdCl_4)^{2-}$ in solution.

Mercury forms the mercury(II) ion Hg^{2+} and the mercury(I) ion $(Hg_2)^{2+}$. In the latter, two electrons are shared in a covalent bond between the two metal atoms. The mercury(I) ion shows little tendency to form complexes, whereas the mercury(II) ion does form them. In contrast to mercury(II) compounds, which are usually covalent, all the common mercury(I) salts are ionic, and the soluble compounds—*e.g.,* mercury(I) nitrate, $Hg_2(NO_3)_2$—show normal properties of ionic compounds, such as ease of dissociation or breakup into separate ions.

Jnique jualities of nercury

Mercury is exceptional in that, unlike zinc or cadmium, it does not react easily with oxygen on heating, and mercury(II) oxide does not show the acid property of forming salts (mercurates), whereas zinc oxide does this readily. Mercury is again anomalous in that it does not produce hydrogen, as do zinc and cadmium, upon treatment with dilute acids. With fairly concentrated nitric acid, zinc and cadmium evolve oxides of nitrogen and form zinc or cadmium nitrates; mercury gives both mercury(II) nitrate, $Hg(NO_3)_2$, and mercury(I) nitrate, $Hg_2(NO_3)_2$. A further characteristic of mercury that is uncommon among metals is its readiness to form stable compounds containing a mercury–carbon bond or a mercury–nitrogen bond. As a result, mercury forms a wide variety of organic compounds (compounds that always contain carbon, usually also hydrogen, and often one or more of the elements oxygen, nitrogen, sulfur). On the whole, therefore, the zinc group elements do not show a smooth gradation of properties, mainly because of the number of anomalous properties of mercury, which in many respects shows a greater similarity to silver than to zinc and cadmium.

Analysis. The classical chemical methods of analysis are now rarely employed except for standardization. When this is required, the methods most commonly employed are the titration of zinc (*i.e.,* addition of a measured volume of a standardized solution of ferrocyanide ion until the exact amount necessary for complete reaction has been added), the conversion of cadmium to cadmium sulfide, which is isolated and weighed, and the colorimetric estimation of mercury (comparison of the intensity of the colour produced by reaction with the substance dithizone with that produced by the same treatment of known amounts of mercury). In daily practice, colorimetry and polarography (a method based on the response of electric current to a steadily increasing electromotive force applied to a solution) are widely used but are being rapidly replaced by other techniques of greater rapidity, simplicity, or accuracy. These modern procedures include atomic absorption spectroscopy (based on the absorption of light of certain wavelengths by atoms present in a flame) and X-ray fluorescence (based on the emission of radiation of characteristic wavelengths when X-rays impinge on a sample).

Toxicity of the elements. The toxicity of the metals increases sharply in the order zinc, cadmium, mercury. The toxicity of zinc is low. In drinking water zinc can be detected by taste only when it reaches a concentration of 15 parts per million (ppm); water containing 40 parts per million zinc has a definite metallic taste. Vomiting is induced when the zinc content exceeds 800 parts per million. Cases of fatal poisoning have resulted through the ingestion of zinc chloride or sulfide, but these are rare. Both zinc and zinc salts are well tolerated by the human skin. Excessive inhalation of zinc compounds can cause such toxic manifestations as fever, excessive salivation, and a cough that may cause vomiting; but the effects are not permanent.

Compared with those of zinc, the toxic hazards of cadmium are quite high. It is soluble in the organic acids found in food and forms salts that are converted into cadmium chloride by the gastric juices. Even small quantities can cause poisoning, with the symptoms of increased salivation, persistent vomiting, abdominal pain, and diarrhea. Fatal cases have been reported. Cadmium has its most serious effect as a respiratory poison: a number of fatalities have resulted from breathing the fumes or dusts that arise when cadmium is heated. Symptoms are difficult or laboured breathing, a severe cough, and violent gastrointestinal disturbance.

Mercury and its compounds are highly toxic. They can be handled safely, but stringent precautions must be taken to prevent absorption by inhalation, by ingestion, and through the skin. The main result of acute poisoning is damage to kidneys.

Mercury poisoning

Numerous cases of poisoning through the industrial use of inorganic mercury compounds have been known. In the 19th century the use of mercuric nitrate in the hat industry to carrot, or lay, the felt caused tremors and a physical disturbance that gave rise to the phrase "as mad as a hatter" and consequently was banned. Organic compounds of mercury, most notably the compounds of the aryl and alkyl families, were once widely used, primarily as fungicides in seeds, paint, and paper. The toxicity of such compounds is different. The behaviour of aryl salts—as for example phenylmercuric acetate—in the body is similar to that of inorganic compounds. Both groups if ingested cause vomiting, colic, and diarrhea, and both are skin irritants. No fatal case of aryl salt poisoning has been reported; however, exposure to alkyl salts has caused a number of deaths. The main target seems to be the central nervous system, and alkyl salts are capable of penetrating brain cells. They are only slowly excreted. Concern has been expressed at an apparent buildup of mercury in tuna, swordfish, and salmon, and many countries have set limits on the amounts allowable in edible fish. The use of mercurial fungicides and pesticides and the discharge of mercury-containing industrial wastes were prohibited in the United States in the early 1970s because they were found to cause such contamination.

IMPORTANT APPLICATIONS

Zinc alloys

Zinc. Zinc, cadmium, and mercury are all of considerable commercial importance. The main application of zinc is as a coating for the protection of steel against corrosion. Zinc itself forms an impervious coating of its oxide on exposure to the atmosphere, and, hence, the metal is more resistant to ordinary atmospheres than iron, and it corrodes at a much lower rate. In addition, because zinc tends to oxidize in preference to iron, some protection is afforded the steel surface even if some of it is exposed through cracks. The zinc coating is formed either by alloying or, to a lesser extent, by electroplating. In the alloying or galvanizing process the steel parts, after suitable cleaning, are dipped in a bath of molten zinc. Some alloying occurs at the interface (surface between the two metals), and the zinc coating adheres tenaciously to the steel. In a continuous galvanizing process developed in the 1930s and '40s, which is displacing the batch dipping process for sheet production, steel strip is passed continuously through a cleaning treatment to remove scale and then through a bath of molten zinc. The zinc coating so formed is firmly adherent and can withstand considerable deformation (change of form). In the rolled state, considerable quantities of zinc are used for roofing, particularly in Europe; small additions of copper and titanium improve creep resistance; *i.e.,* resistance to gradual deformation. Alloyed with copper to form brass, zinc has been widely used since Roman times. Another important series of alloys are those formed by the addition of 4 to 5 percent aluminum to zinc; these have a relatively low melting point but possess good mechanical properties and can be cast under pressure in steel dies.

Cadmium. Cadmium is physically similar to zinc but is more dense and soft, takes a high polish, and is resistant to alkalies. Its main application is as an electrodeposited coating. The plated cadmium has a smaller grain size than electro-zinc coatings, and deposits tend to be more uniform and smooth. Consequently, good protection is afforded by thin coatings of cadmium, and thus, in spite of its high price, it is frequently used for the protection of precision parts. Its resistance to marine atmospheres is also superior to that of zinc. An important application of cadmium is its use with either nickel or silver and a caustic potash electrolyte in electrical storage batteries for uses in which lower weight, longer life, and stability upon storage in discharged condition are desirable as in aircraft. The use of cadmium in nuclear reactors depends on its property of absorbing neutrons. Small quantities of cadmium are added to a number of metals to strengthen them; 1 percent added to copper increases its strength and hardness with only a small reduction in electrical conductivity; alloyed with zinc, cadmium forms solders with good shear strength. The use for cadmium compounds in pigments was mentioned earlier.

Mercury. As has been noted, mercury is the only common metal that is liquid at room temperatures; it freezes at −39° C and boils at 357° C. It is a dense, mobile liquid having a lustrous, silvery-white colour. Because it expands rapidly and uniformly as the temperature increases and does not wet glass, it is specially suitable for thermometers. Because it is not attacked by dry air, oxygen, or carbon dioxide at ordinary temperatures and because it has good electrical conductivity, it is widely used in a variety of electrical measuring and control equipment. Lamps containing mercury vapour in a fused silica tube or bulb are used as a source of ultraviolet radiation.

Amalgams of mercury

The capacity of mercury to form amalgams, or liquid alloys, with solid metals is of interest. Gold and silver dissolve readily in mercury, and in the past this property was used in the extraction of these metals from their ores. Copper, tin, and zinc also form amalgams of some importance. An amalgam with silver is used as a filling in dentistry. The use of mercury in the manufacture of chlorine and caustic soda (sodium hydroxide) by electrolysis of brine depends upon the fact that mercury employed as the negative pole, or cathode, dissolves the sodium liberated to form a liquid amalgam. An interesting application, though not of great commercial significance, is the use of mercury vapour instead of steam in some electrical generating plants, the higher boiling point of mercury providing greater efficiency in the heat cycle. (S.W.K.M./Ed.)

Boron group elements

The five elements comprising the so-called boron group are: boron (B), aluminum (Al), gallium (Ga), indium (In), and thallium (Tl). Constituting Group IIIa of the periodic table (see Figure 10), they are characterized as a group by having three electrons in the outermost parts of their atomic structure. Boron, the lightest of these elements, is a nonmetal but the other members of the group are silvery-white metals.

None of these elements was known in a pure state before modern chemistry isolated them. Very soon after a method had been found to produce it in commercial quantities, aluminum revolutionized industry. The other members of the group, including boron, still have little commercial value. Some of the compounds of boron and aluminum, however, are indispensable in modern technology and have been widely used in many parts of the world throughout recorded history.

HISTORY

Isolation of aluminum metal

Historical importance of gallium

The use of a boron compound known as borax (sodium tetraborate, $Na_2B_4O_7 \cdot 10H_2O$) can be traced back to the ancient Egyptians, who used it as a metallurgical flux (a substance that aids the heat joining or soldering of metals), in medicine, and in mummification. During the 13th century, Marco Polo introduced borax into Europe but not until the mid-19th century, when vast deposits of borates were discovered in the Mojave Desert, did borax become relatively common. The ancient Egyptians, Greeks, and Romans used a compound of aluminum known as alum (the compound potassium aluminum sulfate) in dyeing as a mordant; *i.e.,* a substance that fixes dye molecules to the fabric. Lapis lazuli, a rare, dark blue mineral (the compound sodium aluminum silicate containing sulfur), has been widely used as a semiprecious stone throughout history. The metal aluminum was first isolated early in the 19th century but it was not until a modern electrolytic process based on the use of bauxite was developed that commercial production of aluminum became economically feasible. The other elements of the boron group were first detected spectroscopically (*i.e.,* by analysis of the light emitted by or passed through substances containing the element) in the late 19th century. The existence and properties of gallium were predicted by a Russian chemist, Dmitry Ivanovich Mendeleyev, on the basis of the periodic table of the elements that he had developed; the ultimate

discovery of gallium and the accuracy of his description of the properties of the then unknown element convinced scientists of the theoretical soundness of the table. Gallium is one of two metals (the other is cesium) whose melting points are low enough for them to turn to liquid when held in the hand.

GENERAL PROPERTIES OF THE GROUP

Table 16 gives a list of the electronic configurations and several ionization energies of the boron group elements. Every element in the boron group has three electrons in its outermost shell, and for each element there is a sharp jump in the amount of energy required to remove the fourth electron, reflecting the fact that this electron must be removed from an inner shell. Consequently the elements of the group will have maximum oxidation numbers of three, corresponding to loss of the first three electrons, and will form ions with three positive charges.

The apparently erratic way in which ionization energies vary among the elements of the group is due to the presence of the filled inner *d* orbitals in gallium, indium, and thallium, and the *f* orbital in thallium, which do not shield the outermost electrons from the pull of the nuclear charge as efficiently as do the inner *s* and *p* electrons. In Groups Ia and IIa, in contrast to the boron group, outer shell (always referred to as n) electrons are shielded in every case by a constant inner set of electrons, in the (n-1)s^2(n-1)p^6 orbitals, and the ionization energies of these Group-Ia and Group-IIa elements decrease smoothly down the group. The ionization energies of Ga, In, and Tl are thus higher than expected from their Group II counterparts because their outer electrons, being poorly shielded by the inner *d* and *f* electrons, are more strongly bound to the nucleus. This shielding effect also makes the atoms of gallium, indium, and thallium smaller than the atoms of their Group Ia and IIa neighbours by causing the outer electrons to be pulled closer toward the nucleus.

The M^{3+} state for Ga, In, and Tl will be energetically less favourable than Al^{3+} because the high ionization energies of these three elements cannot always be balanced by the crystal energies of possible reaction products. For example, of the simple, anhydrous compounds of trivalent thallium only the trifluoride, TlF_3, is ionic. For the group as a whole, therefore, the M^{3+} ionic state is the exception rather than the rule. More commonly the elements of the group form covalent bonds and achieve an oxidation state of three by promoting one electron from the *s* orbital in the outer shell (designated n*s* orbital) to an n*p* orbital, the shift permitting the formation of hybrid, or combination, orbitals (of the variety designated as sp^2). Increasingly down the group there is a tendency toward the formation of M^+ ions and at thallium the monovalent state is the more stable one. The basicity (a property of metals) of the elements also increases in proceeding down the group as shown by the oxides they form: boric oxide (formula B_2O_3) is acidic, the next three oxides, of aluminum, gallium, and indium (formulas Al_2O_3, Ga_2O_3, and In_2O_3) are either acidic or basic depending on the environment (a property called amphoterism), and thallic oxide (Tl_2O_3) is wholly basic.

The ionization energies listed in Table 16 suggest that the formation of salts of the M^{2+} ions might be feasible. At first glance, such appears to be the case, since gallium compounds with the formula GaX_2 (X representing chlorine, bromine, or iodine) can be made, and similar cases occur with the other metals of this group. Such compounds, however, are generally found to be of mixed valency—that is, they contain metal atoms in both the one and the three oxidation states, a condition symbolized as $M^+(M^{III}X_4)^-$. The nearest approach to M^{2+} derivatives occurs in gallium sulfide, selenide, and telluride, which are made by heating gallium with stoichiometric amounts of sulfur, selenium, and tellurium, respectively. Studies of the structure of these compounds by X-ray methods show that they contain $(Ga\text{-}Ga)^{4+}$ units arranged in a layer-like lattice; the coupling of the gallium atoms in such a manner pairs the electrons available for the bonds and thereby explains the diamagnetism of the compounds (diamagnetism is a property associated with paired electrons).

The large amount of energy required to remove three electrons from a boron atom makes the formation of salts containing the bare B^{3+} cation impossible; even water of hydration associated with such ions would be too highly deformed to be stable and hence the aquated ion $B^{3+}{}_{(aq)}$ is unknown. Much less energy is required to promote electrons from 2*s* orbitals into 2*p* orbitals in boron atoms with the result that boron compounds are always covalent. The boron orbitals are hybridized to either the sp^2 (when boron forms bonds with three other atoms) or the sp^3 (when boron forms bonds with four atoms) configuration (see MOLECULES).

Nuclear resonance studies

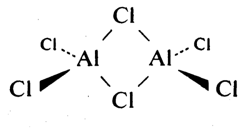
Although simple M^{3+} cations are uncommon in anhydrous compounds of the boron group elements, the hydrated (combined with water) trivalent ions of aluminum, gallium, indium, and thallium are well known in water solution. Nuclear magnetic resonance studies reveal that there are six water molecules held strongly by these positive ions in solution, and their salts often can be crystallized from solution combined with six water molecules. The high charge on the central cation of such hydrates induces the ionization of protons, or hydrogen nuclei, on the coordinated water molecules and thereby leads to the formation of basic salts. This reaction is represented in the following equations:

$$M(H_2O)_n^{3+} \rightleftharpoons (HO)M(H_2O)_{n-1}^{2+} + H_{aq}^+$$
$$\rightleftharpoons (HO)_2M(H_2O)_{n-2}^{+} + 2H_{aq}^+ \rightleftharpoons M(OH)_3 + 3H_{(aq)}^+$$

in which, as before, M represents an ion of one of the boron group elements; *n* is the number of water molecules joined to it; (HO)M represents a hydroxide group joined to the metal ion; and $H(aq)^+$ is a hydrated hydrogen ion. In these and other equations the arrows pointing in two directions indicate that the chemical reactions can proceed both ways depending on the reaction conditions. When acid is added to such aqueous solutions it depresses the hydrolytic processes by reversing the above reactions. At high acid concentrations, however, complex anions (negative ions) are sometimes formed, especially with the aqueous hydrogen halides. The following equation illustrates this: $Ga(aq)^{3+} + HX\ (conc.) \rightarrow GaX_4^-$, X being chlorine, bromine, or iodine. Intermediate complex ions, MX^{2+} and MX_2^+ can be detected in several cases.

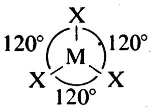
Conductivity of solid aluminum trichloride

The electrical conductivity of solid aluminum trichloride (formula $AlCl_3$), in which each aluminum ion has three positive charges, increases rapidly as the temperature is elevated toward the melting point, at which the conductivity suddenly falls to zero. This phenomenon occurs because the aluminum and chloride ions form an ionic lattice that partially conducts electricity; but upon melting, the compound changes to the electrically nonconducting, covalent state. The explanation is that the distribution of energy in the liquid state is insufficient to compensate for the ionization energy required to separate the Al^{3+} and Cl^- ions and these then acquire covalent bonds. The liquid consists of double or dimeric molecules with the formula Al_2Cl_6, which may be represented in the following manner that shows a molecule with the position of its atoms in three dimensions; the solid lines are in the plane of the paper, the dotted lines are behind the paper, and the shaded lines indicate that they extend toward the viewer:

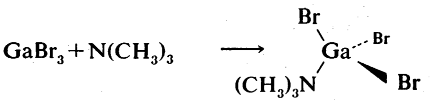


The delicate energy balance between ionic and covalent bonding for aluminum in the trivalent state can be appreciated when it is realized that whereas solid aluminum trifluoride, formula AlF_3, is ionic like the chloride, aluminum tribromide forms molecular crystals containing dimers, with the formula Al_2Br_6.

In contrast with the dimers, the single, or monomeric, trihalides of the boron group elements have trigonal planar structures. If M is the metal and X is any halogen, the arrangement of the atoms can be sketched as follows:

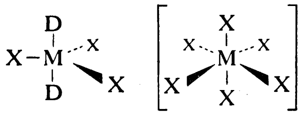


The trihalides of boron have this configuration in all phases whereas the trihalides of Al, Ga, In, and Tl become monomeric only on being heated in the gas phase. In MX_3 molecules, the central atom M has added three electrons to its own making only six electrons in the outer shell, although eight are required to achieve the desired inert-gas configuration. These halides, therefore, readily accept two more electrons from many donor molecules (*e.g.*, ethers, alcohols, amines, and phosphines) that carry unshared pairs of electrons. A typical case, the reaction of gallium tribromide with trimethylamine, is represented in the following equation:



The central gallium atom is coordinated or bonded to three bromine atoms and one nitrogen atom. The electron donor also can be a halide ion, in which case the tetrahedral complex anion, MX_4^- results.

A few compounds are known in which aluminum, gallium, indium, and thallium are coordinated to five or six atoms. These compounds have structures of the following types, M again representing any boron group element, D any donor molecule, and X any halogen (again, the solid lines are bonds in the plane of the paper, the atoms so bonded lying in that plane; the dotted lines lead behind the paper; the shaded lines reach toward the viewer):



In such compounds it is possible, but by no means certain, that the central element makes use of its vacant n*d* orbitals (see above) to increase its valency by way of sp^3d (five-coordination) or sp^3d^2 (six-coordination) hybridization. If the concept of the participation of *d* orbitals in the bonding of these compounds is valid, it would account for the fact that boron, which has no available *d* orbitals, does not form five- and six-coordinate compounds. In many cases, however, spatial requirements also would rule out the possibility of boron increasing its covalency above four because the boron atom is so small no more than four atoms can be arranged around it.

In the gas phase at high temperature all the boron group elements form diatomic halides MX, either by dissociation of the trihalides or, more commonly, by reduction of the trihalides with the free element as in the following equations for two such reactions:

$$\underset{\text{boron}}{2B} + \underset{\text{boron trifluoride}}{BF_3} \xrightarrow{2{,}000°} \underset{\text{boron monofluoride}}{3BF}$$

$$\underset{\text{aluminum}}{2Al} + \underset{\text{aluminum trichloride}}{AlCl_3} \xrightarrow{800°-1{,}000°} \underset{\text{aluminum monochloride}}{3AlCl}.$$

Most of these monohalides, especially those of boron, aluminum, and gallium, are unstable in the solid state under normal conditions; they exist only at high temperatures as gases; all are covalently bonded, except thallium fluoride, which exists as the ion pair, Tl^+F^-.

Thallium is the only element that forms a stable ion having an $(n\text{-}1)d^{10}ns^2$ outer electronic configuration. There is, therefore, no ion to which direct comparisons with the thallium(I) ion, Tl^+, might be made.

INDIVIDUAL BORON GROUP ELEMENTS

Boron. The first three ionization energies of boron, atomic number 5, are much too high to allow the formation of compounds containing the B^{3+} ion; in all its compounds boron is covalently bonded. One of boron's 2*s* electrons is promoted to a 2*p* orbital, giving the outer electron configuration $2s^12p^2$; the *s* and *p* orbitals can then be mixed to give sp^2 and sp^3 hybrids, which allow boron to be three- and four-coordinated, respectively. The three-coordinate derivatives (*e.g.*, halides, alkyls, aryls) are planar molecules that readily form donor-acceptor complexes (called adducts) with compounds containing lone pairs of electrons; in these adducts the boron atom is four coordinated, the four groups being tetrahedrally disposed around it.

Biological importance

Boron is an essential trace element for the healthy growth of many plants, and typical effects of long-term boron deficiency are stunted, misshapen growth and, in root crops, heart rot and dry rot; the deficiency can be alleviated by the application of soluble borates to the soil. Gigantism of several species of plants growing in soil naturally abundant in boron has been reported. It is not yet clear what the precise role of boron in plant life is, but most researchers agree that the element is in some way essential for the normal growth and functioning of apical meristems, the growing tips of plant shoots.

Boron is unique in its group in that it forms a rather large number of compounds with hydrogen, or hydrides, called boranes, many of which have most unusual, three-dimensional structures; it also forms a series of halides with the general formula B_nX_n. These molecules are interesting because they contain closed cages of boron atoms. Examples are the boron chlorides whose formulas are B_4Cl_4, B_8Cl_8, and B_9Cl_9. Unfortunately these interesting halides, most of which are highly coloured in sharp contrast to the more typical boron derivatives, are exceedingly difficult to prepare and to handle. The substance, formula B_4Cl_4, for example, can be prepared only in milligram quantities, and complex electrical-discharge techniques are needed for its production; furthermore, it ignites spontaneously in air and is rapidly decomposed both by water and even by the grease used to lubricate the vacuum equipment employed in its preparation. Closed cages containing 12 boron atoms arranged in the form of an icosahedron (see Figure 12) also occur in the various crystalline forms of elemental boron.

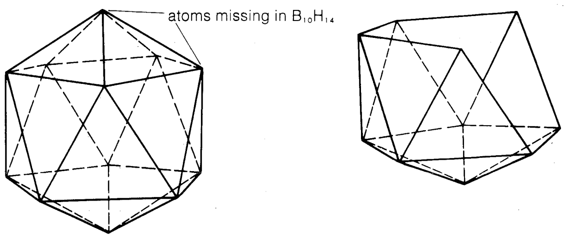


Figure 12: (Left) Icosahedron, basic unit of crystalline boron. (Right) $B_{10}H_{14}$ skeleton (see text).

Boron reacts with all halogen elements to give monomeric, highly reactive trihalides, which readily form complexes with amines, phosphines, ethers, and halide ions. Examples of complex formation between boron trichloride and trimethylamine, as well as between boron trifluoride and fluoride ion, are shown in the following equations:

$$BCl_3 + N(CH_3)_3 \longrightarrow (CH_3)_3N \cdot BCl_3$$

$$BF_3 + F^- \longrightarrow BF_4^-$$

in which the heavy dot indicates that a bond is formed between the nitrogen and boron atoms. When boron trichloride is passed at low pressure through devices delivering an electric discharge, diboron tetrachloride, the formula written as $Cl_2B\text{–}BCl_2$, and tetraboron tetrachloride, formula B_4Cl_4, are formed. Diboron tetrachloride decomposes at room temperatures to give a series of monochlorides having the general formula $(BCl)_n$, in which *n* may be 8, 9, 10, or 11; the compounds with formulas B_8Cl_8 and B_9Cl_9 are known to contain closed cages of boron atoms.

Nuclear properties of boron

Boron exists in nature as two isotopes, one of atomic mass 10 (18.8 percent) and one of atomic mass 11 (81.2 percent). Both nuclei possess nuclear spin (rotation of the atomic nuclei); that of boron-10 has a value of 3 and that of boron-11, 3/2, the values being dictated by quantum factors. These isotopes are, therefore, of use in nuclear magnetic resonance spectroscopy; and spectrometers specially adapted to detecting the boron-11 nucleus are available commercially. The boron-10 and boron-11 nuclei also cause splitting in the resonances (that is, the appearance of new bands in the resonance spectra) of other nuclei (*e.g.*, those of hydrogen atoms bonded to boron). The boron-10 isotope is unique in that it possesses an extremely large capture cross section for thermal neutrons (*i.e.*, it readily absorbs neutrons of low energy). The capture of a neutron by a nucleus of this isotope results in the expulsion of an alpha particle (nucleus of a helium atom, symbolized α):

$$^{10}\mathrm{B} + {}^{1}n \longrightarrow {}^{7}\mathrm{Li} + {}^{4}a.$$

Since the high-energy alpha particle does not travel far in normal matter, boron may be used in the fabrication of neutron shields (materials not penetrable by neutrons). In the Geiger counter, alpha particles trigger a response, whereas neutrons do not; hence if the gas chamber of a Geiger counter is filled with a gaseous boron derivative (*e.g.*, boron trifluoride), the counter will record each alpha particle produced when a neutron that passes into the chamber is captured by a boron-10 nucleus. In this way, the Geiger counter is converted into a device for detecting neutrons, which normally do not affect it. The affinity of boron-10 for neutrons also forms the basis of a technique for treating patients suffering from brain tumours. For a short time after certain boron compounds are injected into a patient with a brain tumour, the compounds collect preferentially in the tumour; irradiation of the tumour area with thermal neutrons, which cause relatively little general injury to tissue, results in the release of a tissue-damaging alpha particle in the tumour each time a boron-10 nucleus captures a neutron. In this way destruction can be limited preferentially to the tumour, leaving the normal brain tissue less affected.

The presence of boron compounds can be detected qualitatively by the green coloration they impart to the flame of an ordinary laboratory, or bunsen, burner. Quantitatively, boron is most easily analyzed by converting the material to be analyzed into boric acid by treatment with acid; the excess mineral acid is then neutralized and the much weaker boric acid is titrated (neutralized on a volume-volume basis) in the presence of a sugar, such as mannitol, to make the acid detectable.

Aluminum. In aluminum, atomic number 13, the configuration of the three outer electrons is such that in a few compounds (*e.g.*, crystalline aluminum fluoride [AlF_3] and aluminum chloride [$AlCl_3$]) the bare ion, Al^{3+}, formed by loss of these electrons, is known to occur. The energy required to form the Al^{3+} ion, however, is very high; and, in the majority of cases, it is energetically more favourable for the aluminum atom to form covalent compounds by way of sp^2 hybridization, as boron does. The Al^{3+} ion can be stabilized by hydration, and the octahedral ion $Al(H_2O)_6{}^{3+}$ occurs both in aqueous solution and in several salts. The alums, double salts of formula $M^{I}Al(SO_4)_2 \cdot 12H_2O$, also contain this ion; the univalent ion M can be sodium, potassium, rubidium, cesium, ammonium, or thallium, and the aluminum may be replaced by a variety of other M^{3+} ions; *e.g.*, gallium, indium, titanium, vanadium, chromium, manganese, iron, or cobalt. The name aluminum (British usage is aluminium) is derived from the Latin word *alumen* used to describe potassium alum, formula $KAl(SO_4)_2 \cdot 12H_2O$.

Aluminum can be detected in concentrations as low as one part per million using emission spectroscopy. Aluminum can be quantitatively analyzed as the oxide (formula Al_2O_3) or as a derivative of the organic nitrogen compound 8-hydroxyquinoline. The derivative has the molecular formula $Al(C_9H_6ON)_3$.

Gallium. Gallium, atomic number 31, is comparable to aluminum in its chemical properties. It does not dissolve in nitric acid because a protective film of gallium oxide is formed over the surface by the action of the acid, but the metal does dissolve in other acids to give gallium salts and it dissolves in alkalies, with evolution of hydrogen, to give gallates (compounds in which gallium appears in the anion). Of the halides, only gallium trifluoride is ionic; the others have molecular lattices containing dimeric molecules, with formula Ga_2X_6. Unlike aluminum, however, gallium forms several derivatives that contain gallium(I) oxidation state; for example, the oxide, formula Ga_2O. The sulfide (GaS), selenide (GaSe), and telluride (GaTe), made directly by combination of the elements at high temperature, are diamagnetic and contain gallium—gallium units with four positive charges $(Ga—Ga)^{4+}$, in a layer lattice. The metal gallium is stable in dry air. On burning in air or oxygen it forms the white oxide, formula Ga_2O_3. This oxide can be reduced to the metal when heated strongly in hydrogen, and with gallium metal at 700° C it gives the lower oxide Ga_2O. The hydroxide, formula $Ga(OH)_3$, is amphoteric; *i.e.*, it reacts either as an acid or a base depending on the circumstance; it is precipitated from solutions of gallium salts by alkali hydroxides.

Indium. Indium, atomic number 49, is an amphoteric element; it dissolves in acids to give indium salts and it also dissolves in concentrated alkalies to give indates. All anhydrous indium(III) derivatives, except indium trifluoride, formula InF_3, are covalent. There is a marked tendency for two of the outer electrons of the indium atom (the outer $5s^2$ electrons) not to be used in bonding; this circumstance results in univalent indium compounds.

Indium burns to the yellow oxide, formula In_2O_3, when heated in air or oxygen; a better method of preparation for the oxide is to heat the hydroxide, nitrate, or sulfate. This oxide is easily reduced to the metal, and on strong heating it loses oxygen to give the monoxide In^{I}_2O. Indium hydroxide dissolves in both acids and alkalies.

Monovalent thallium

Thallium. Thallium, atomic number 81, is typical of the Group IIIa elements in having an s^2p^1 outer electron configuration. Promoting an electron from an s to a p orbital allows the element to be three or four covalent. With thallium, however, the energy required for $s \rightarrow p$ promotion is high relative to the Tl–X covalent bond energy which is regained on formation of TlX_3; hence, a trivalent derivative is not a very energetically favoured reaction product. Thallium normally forms the more stable thallium (I), or thallous, salts containing the ion Tl^+ (in which the $6s^2$ electrons remain unused); it is the only element to form a stable univalent cation with the outer electron configuration $(n\text{-}1)d^{10}ns^2$, which is, unusually enough, not an inert gas configuration. In its oxidation state three, indicated as thallium(III), or commonly called thallic, thallium resembles aluminum, although the ion Tl^{3+} appears to be too large to form alums. In the monovalent state, thallium(I) displays properties similar to those of both the heavier alkali metals and silver. The very close similarity in size of the thallium(I) ion, Tl^+, and the rubidium ion, Rb^+, makes many thallium(I) salts, such as the chromate, sulfate, nitrate, and halides, isomorphous (*i.e.*, have an identical crystal structure) to the corresponding rubidium salts; also the ion Tl^+ is able to replace the ion Rb^+ in the alums. Thus, thallium does form an alum; but in doing so it replaces the M^{I} ion, rather than the expected metal atom M^{III}, in the formula $M^{I}M^{III}(SO_4)_2 \cdot 12H_2O$.

Thallium imparts a brilliant green coloration to a bunsen flame. Thallous chromate, formula Tl_2CrO_4, is best used in the quantitative analysis of thallium, after any thallic ion present in the sample has been reduced to the thallous state. (A.G.M.)

Carbon group elements

The carbon group of five chemical elements consists of carbon (C), silicon (Si), germanium (Ge), tin (Sn), and lead (Pb); they comprise Group IVa in the periodic table (see Figure 10). Except for germanium, all of these elements are familiar in daily life either as the pure element or in the form of compounds, although, except for silicon, none is particularly plentiful in the Earth's crust. Carbon forms an almost infinite variety of compounds, in both the plant and animal kingdoms. Silicon and silicate minerals

Occurrence

are fundamental components of the Earth's crust; silica (silicon dioxide) is sand. Tin and lead, with abundances in the crust lower than those of some so-called rare elements, are nevertheless common in everyday life. They occur in highly concentrated mineral deposits, can be obtained easily in the metallic state from those minerals, and are useful as metals and as alloys in many applications. Germanium, on the other hand, forms few characteristic minerals and is most commonly found only in small concentrations in association with the mineral zinc blende and in coals. Although germanium is indeed one of the rarer elements, it assumed importance upon recognition of its properties as a semiconductor (*i.e.,* limited ability to conduct electricity).

HISTORY

Carbon as an element was discovered by the first man to handle charcoal from his fire; thus, together with sulfur, iron, tin, lead, copper, mercury, silver, and gold, carbon was one of the small group of elements well known in the ancient world. Modern carbon chemistry dates from the development of coals, petroleum, and natural gas as fuels and from the elucidation of synthetic organic chemistry, both substantially developed since the 1800s.

Amorphous elemental silicon was first obtained in a state of purity in 1824 by the Swedish chemist Jöns Jacob Berzelius; impure silicon had already been obtained in 1811. Crystalline elemental silicon was not prepared until 1854, when it was obtained as a product of electrolysis. In the form of rock crystal, however, silicon was familiar to the predynastic Egyptians, who used it for beads and small vases; to the early Chinese; and probably to many others of the ancients. The manufacture of glass containing silica was carried out both by the Egyptians—at least as early as 1500 BC—and by the Phoenicians. Certainly, many of the naturally occurring compounds called silicates were used in various kinds of mortar for construction of dwellings by the earliest men.

Mendeleyev's prediction

Germanium is one of three elements the existence of which was predicted in 1871 by the Russian chemist Dmitry Ivanovich Mendeleyev when he first devised his periodic table. Not until 1886, however, was germanium identified as one of the elements in a newly found mineral.

The origins of tin also are lost in antiquity. Apparently, bronzes, which are copper–tin alloys, were used by man in prehistory long before pure tin metal itself was isolated. Bronzes were common in early Mesopotamia, the Indus Valley, Egypt, Crete, Israel, and Peru. Much of the tin used by the early Mediterranean peoples apparently came from the Scilly Islands and from Cornwall in the British Isles, where tin mining dates to at least 300–200 BC. Tin mines were operating in both the Inca and Aztec domains of South and Central America before the Spanish conquest.

Lead is mentioned often in early Biblical accounts. The Babylonians used the metal as plates on which to record inscriptions. The Romans used it for tablets, water pipes, coins, and even cooking utensils; indeed, as a result of the last use, lead poisoning was recognized in the time of Augustus Caesar. The compound known as white lead was apparently prepared as a decorative pigment at least as early as 200 BC. Modern developments date to the exploitation in the late 1700s of deposits in the Missouri–Kansas–Oklahoma area in the United States.

COMPARATIVE CHEMISTRY

In the periodic table, the elements with eight electrons outermost form the group known as the noble gases (Group 0), the least reactive of the elements. The carbon group elements (Group IVa), with four electrons, occupy a middle position. Elements to the left of Group IVa have fewer than four electrons in the valence shell and tend to lose them (with their negative charges) to become positively charged ions, represented by the symbol for the element with a superscript indicating the number and sign of the charges; such elements are called metals. The nonmetals (except boron) are in the groups to the right of Group IVa; each has more than four electrons in its outermost shell and tends to acquire electrons to complete its octet, forming negatively charged ions.

Chemical reactions result from the exchange of electrons among atoms. In general, if a metal loses its few valence electrons to a nonmetal, the resulting oppositely charged ions are attracted to one another and form a bond, classified as ionic or electrovalent. Two nonmetals, neither of which can actually lose its valence electrons in chemical reaction, may nevertheless share them in pairs in such a way that what is called a covalent bond results. Metal atoms will bond to one another in a third type of bond, which releases their valence electrons in a way that allows them to conduct electricity.

Formation of covalent bonds with non-metals

All the carbon group atoms, having four valence electrons, form covalent bonds with nonmetal atoms; carbon and silicon cannot lose or gain electrons to form free ions, whereas germanium, tin, and lead do form metallic ions but only with two positive charges. Even lead, the most metallic of the carbon group atoms, cannot actually lose all four of its valence electrons, because, as each one is removed, the remainder are held more strongly by the increased positive charge. Because the distinction between covalent and electrovalent (ionic) bonds is often a matter of convenience for the chemist, and because the actual bond structure within a molecule may be quite complicated, it is often useful instead simply to count the total number of electrons an element gains or loses in bonding without regard to the nature of the bonds. This number is called the oxidation number, or oxidation state, of the element; many elements have more than one oxidation state possible, each oxidation state being found in different compounds. The oxidation state of an element is written as a Roman numeral following the name of the element in a compound—*e.g.,* lead(II) means lead in oxidation state plus two; with the chemical symbol of the element, the oxidation state may be written as a superscript, as in Pb^{II}. Covalent bonds generally are considered to be formed by interaction of the orbitals (generally, only the *s, p,* and *d* orbitals) in specific and varied ways. The most common are called sigma and pi bonds, written σ and π, respectively. The sigma bonds are symmetrical with respect to the axis of the bond, whereas the pi bonds are not. Examples of sigma and pi bonding as well as ionic bonding are found among the compounds of the elements of the carbon group. (For a full general discussion and further information useful to an understanding of the following sections, see ATOMS; MOLECULES; and CHEMICAL REACTIONS.)

GENERAL PROPERTIES OF THE GROUP

Metals and nonmetals of the group

The properties of the carbon group elements and those of their compounds are intermediate between properties associated with the elements of the adjacent boron and nitrogen groups. In all groups the metallic properties, resulting from the tendency to hold valence electrons more loosely, increase with atomic number. Within the carbon group, more than in any other, the change from nonmetallic to metallic character with increasing atomic number is particularly apparent. Carbon is a true nonmetal in every sense. Lead is a true metal. Silicon is almost completely nonmetallic; tin is almost completely metallic. Germanium is metallic in appearance and in a number of its other physical properties (see Table 17), but the properties of many of its compounds are those of derivatives of nonmetals. These changes are consequences of increase in atomic size with substantial screening of the larger nuclear charge by intervening electronic shells, as evidenced by decrease in ionization energy (energy required to remove an electron) and electronegativity power to attract electrons with increasing atomic number.

Crystal structure. In the solid state, elemental carbon, silicon, germanium, and gray tin (defined as alpha [α] tin; see Table 17) exist as cubic crystals, based upon a three-dimensional arrangement of bonds. Each atom is covalently bonded to four neighbouring atoms in such a way that they form the corners of a tetrahedron (a solid consisting of four three-sided faces). A practical result is that no discrete small molecules of these elements, such as those formed by nitrogen, phosphorus, or arsenic, can be distinguished; instead, any solid particle or fragment of one of these elements, irrespective of size, is uniformly

Table 17: Some Properties of the Carbon Group Elements

	carbon	silicon	germanium	tin	lead
Atomic number	6	14	32	50	82
Atomic weight	12.011	28.086	72.59	118.69	207.19

bonded throughout, and, therefore, the whole fragment can be considered as a giant molecule. Decreasing melting points, boiling points, and decreasing heat energies associated with fusion (melting), sublimation (change from solid to gas), and vaporization (change from liquid to gas) among these four elements, with increasing atomic number and atomic size, indicate a parallel weakening of the covalent bonds in this type of structure. The actual or probable arrangement of valence electrons is often impossible to determine, and, instead, relative energy states of the electrons, in the ground, or least energetic, state of the atom are considered. Thus, the same trend of nonmetallic toward metallic states is indicated by decreasing hardness and decreasing single-bond energy between atoms. Carbon crystallizes in two forms, as diamond and as graphite; diamond stands apart from all other elemental forms in the extreme stability of its crystal structure, whereas graphite has a layer structure. As may be expected, cleavage between layers of graphite is much easier to effect than rupture within a layer. The crystal structures of white beta (β) tin and elemental lead are clearly metallic structures. In a metal, the valence electrons are free to move from atom to atom, and they give the metal its electrical conductivity.

Uses. All the carbon group elements and many of their compounds have important uses. Carbon as diamond, for example, is the most expensive and brilliant of all the natural gemstones and also the hardest of abrasives; carbon as graphite is important as electrodes in electrochemical cells, as a lubricant, and, in microcrystalline and nearly amorphous form, as a black pigment, an adsorbent, a fuel, a filler for rubber, and in pencils. Coals are elemental carbon mixed with varying amounts of carbon compounds; coke and charcoal are nearly pure carbon. All organic compounds, such as proteins, carbohydrates, and fats, contain carbon, and all plant and animal cells consist of carbon compounds and their polymers. (Polymers are macromolecules consisting of many simple molecules bonded together in specific ways.) Carbonate minerals are important sources of various metals, such as sodium, magnesium, calcium, copper, and lead.

Elemental silicon is important largely as a semiconductor. Silica (silicon dioxide) is useful as an abrasive, in the production of glass and other ceramic bodies, as an adsorbent, and as sand in mortars and concretes; and these are only a few of its applications. Both naturally occurring and synthetically produced silicates are important in ceramics, building materials, absorbents, and ion exchangers.

Applications of germanium have been limited to semiconducting devices, indicating its weak metallic nature.

Tin-plating of iron protects the latter from corrosion; tin piping and valves maintain purity in water and beverages; molten tin is the base for (float) plateglass production; and tin is a significant component of such alloys as bronzes, pewter, bearing metals, type metals, and lead-based solders. Tin exists in two oxidation states; tin(IV) oxide is useful in making ceramic bodies opaque, as a mild abrasive, and as a weighting agent for fabrics; tin(II) fluoride and tin(II) pyrophosphate are used in dentifrices. Organic tin compounds act as stabilizers in certain plastics and as wood preservatives.

Oxidation states of lead

Elemental lead finds extensive use. Together with the compound lead(IV) oxide and with lead–antimony or lead–calcium alloys, it is employed in common storage batteries. Type metals, bearing alloys, shot metal, and fusible alloys all contain lead. Tetraethyllead is the most important antiknock additive to motor fuels.

Electron configurations. The ground-state electronic configurations (see Table 17) of atoms of these carbon group elements show that each has four electrons in its outermost shells. As has been explained, if *n* represents the outermost shell (*n* being two for carbon, three for silicon, etc.), then these four electrons are represented by the symbols ns^2np^2. Such a configuration suggests the importance of referring to the relatively stable noble-gas-atom configuration preceding each element in determining the properties of the element, in particular its chemical properties. The loss of four electrons by either a carbon atom or a silicon atom to give ions having a positive charge of four (or +4, written C^{4+} or Si^{4+}) with the electron configurations of the preceding noble-gas atoms is precluded by the sizable ionization energies as shown in Table 1. Ions of +4 charge do not exist, nor is there any evidence that carbon or silicon ions of charge +2 can form by the loss of only two unpaired (*np*, or outermost) electrons. Electron loss by atoms of the heavier elements of the family is easier, but it cannot lead to ions with noble-gas-atom configurations because of the presence of underlying (*i.e.*, d^{10}) arrangements of electrons inside the outermost shell. It is again unlikely that the +4 ions of germanium, tin, and lead (in symbols Ge^{4+}, Sn^{4+}, and Pb^{4+}) exist in known compounds, but it is true that the inertness of the ns^2 pair of electrons (which are, in terms of energy states, closer to the nucleus than the np^2 pair) increases substantially with increasing atomic number in the family and thus allows the np^2 electrons to be removed separately, to form at least the ions, Sn^{2+} and Pb^{2+}. Positive two and four oxidation states can be assigned in covalent unions of each of these elements with elements that are more electronegative (*i.e.*, having greater affinity for electrons).

Catenation. Carbon is unique among the elements in the almost infinite capacity of its atoms to bond to each other in long chains, a process called catenation. This characteristic reflects the strength of the bond between adjacent carbon atoms in the molecule, both in relationship to similar bonds involving other elements of the carbon family and in relationship to bonds between carbon atoms and atoms of many other elements. Only the carbon–hydrogen, carbon–fluorine, and carbon–oxygen single bonds (C—H, C—F, and C—O) are stronger than the carbon–carbon single bond (C—C), and each of these is weaker than the carbon–carbon multiple bonds ($C{=}C$ or $C{\equiv}C$). On the other hand, the silicon–silicon single bond (Si—Si) is weaker than other single bonds involving an atom of other elements with the silicon atom. The same is undoubtedly true of the germanium–germanium and tin–tin single bonds (Ge—Ge, Sn—Sn) in relationship to single covalent bonds between atoms of these elements and atoms of other elements. Experimentally, there appears to be no practical upper limit to catenation involving carbon. This phenomenon in three dimensions produces the diamond and in two dimensions the layers in graphite. Catenation is also exhibited to a high degree by elemental silicon, germanium, and tin, but it is strictly limited in compounds of these elements; silicon may have up to 14 atoms in a chain; germanium, 9; and tin, 2 or 3 only, largely in hydrides (compounds containing hydrogen). Double and triple bonds in catenated arrangements are limited to carbon.

Silicon chains

Catenation, via single or multiple bonds or both, combined with several other factors allows carbon to form more compounds than any other element. These factors are: (1) the stability of certain carbon bonds, in particular of the C—H bond; (2) the existence of carbon in both sp^2 and sp^3 hybridizations; (3) the ability of carbon to form both chain and cyclic compounds (in which the chain of atoms is joined end to end to form a ring) based upon either carbon atoms alone or carbon atoms in combination with those of other nonmetals (*e.g.*, oxygen, sulfur, nitrogen) and either upon single- or multiple-bond arrangements; and (4) the capability of many carbon compounds to exist in isomeric forms (isomers are molecules with identical numbers of the same atoms bonded in different arrangements; such molecules have quite different properties). All but a very few carbon compounds are called organic compounds, and they are discussed in the article CHEMICAL COMPOUNDS.

Atomic size. Reference has been made to some of the physical properties of the carbon group elements (Table 17). Most of the variations in properties from carbon through lead parallel increase in atomic size and are comparable with elements in the boron, nitrogen, oxygen, and fluorine groups. The general trends apparent in Table 17 are roughly those found for the adjacent boron group and nitrogen group elements. The significantly higher melting and boiling points of the carbon group elements reflect their tendency to exist as giant molecules, as opposed to the tendencies of elements in the adjacent families to exist as smaller, discrete molecules.

Special physical properties of carbon

As is true of the lightest element in each group of elements, the physical properties of carbon differ substantially from those of the other members of its family. To a large degree, these differences reflect the substantially higher concentration of the positive charge on the carbon nucleus relative to the size of the carbon atom. That is, the nucleus of carbon holds only six electrons in two shells and, therefore, holds them close; the nucleus of lead, on the other hand, has 82 electrons distributed in six shells. The attraction between the nucleus of lead and its outermost electrons is less than in carbon, because intervening shells in lead shield the outer electrons. Structural differences between diamond and graphite produce profound differences between them in hardness, conductivity, density, heat capacity, and other properties. Inasmuch as graphite is a unique crystalline formation among the elements, its properties should not be compared directly with those of the other elements in the family.

Reactions. Certain of the more common chemical reactions of the carbon group elements are summarized in Table 18. With a given reagent, diamond is generally less reactive than graphite and, thus, requires more rigorous conditions for reaction, such as a higher temperature; the ultimate products, however, are the same. Crystalline silicon is less reactive than finely divided and, possibly, amorphous silicon. Elemental germanium resembles silicon quite closely. Tin and lead behave in general as metals and thus yield at least some ionic products in reactions that are quite different from those of the other elements. Elemental carbon is of particular importance as a high-temperature reducing agent (a reagent that donates electrons) in metallurgical processing for metal oxides, a reaction that frees the metal. Thus to cite only a few of carbon's more important applications, carbon is used directly in the production of elemental phosphorus, arsenic, bismuth, tin, lead, zinc, and cadmium, and indirectly, as carbon monoxide, in the production of iron. Elemental silicon, in the iron–silicon alloy ferrosilicon, is also a strong reducing agent and has been used as such to liberate magnesium from its oxide.

Carbon in metallurgy

Biological and physiological significance. The biological implications of carbon are so extensive that they can be discussed here only very briefly. All biological substances are based upon compounds in which carbon is combined with other elements, the nature of the combination determining the characteristics, function, and relative importance of the substance. To begin with the inorganic compounds of carbon, elemental carbon is nontoxic. Carbon monoxide (CO) is both more readily absorbed and more firmly bound to the hemoglobin of the blood than is oxygen and is thus, even in small concentrations, a dangerous asphyxiant. Carbon dioxide (CO_2) is an asphyxiant of significance only in relatively large concentrations; in small concentration, it stimulates breathing. Hydrogen cyanide (HCN) and its derivatives (cyanogen compounds, cyanides) are all very toxic as protoplasmic poisons through the inhibition of tissue oxidation. Carbon tetrachloride (CCl_4) and other chlorinated hydrocarbons damage the nervous system. Among organic compounds, the most toxic are derivatives that contain the halogen

elements (fluorine, chlorine, bromine and iodine), sulfur, selenium, tellurium, nitrogen, phosphorus, arsenic, lead, and mercury. Most organometallic compounds are toxic, while oxygen-containing derivatives of the hydrocarbons are usually less toxic.

Elemental silicon and most silicon-containing compounds appear to be nontoxic. Indeed, human tissue often contains 6 to 90 milligrams of silica (SiO_2) per 100 grams dry weight, and many plants and lower forms of life assimilate silica and use it in their structures. Inhalation of dusts containing alpha SiO_2, however, produces a serious lung disease called silicosis, common among miners, stonecutters, and ceramic workers, unless protective devices are used.

The toxicology of germanium and its compounds is poorly defined.

Elemental tin is apparently nontoxic, and quantities of tin up to 300 parts per million, as dissolved by foods packaged in tin-plated containers and cooking utensils, are not harmful. Organic tin compounds, however, commonly used as biocides and fungicides, are toxic to human beings.

etra-
thyllead

Although elemental lead and difficultly soluble lead compounds are not absorbed by human tissue and are, therefore, quite innocuous, any soluble lead compound is toxic, with toxicity increasing as solubility increases. Symptoms of lead poisoning include abdominal pain and diarrhea followed by constipation, nausea, vomiting, dizziness, headache, and general weakness. Elimination of contact with a lead source is normally sufficient to effect a cure. The elimination of lead from insecticides and paint pigments and the use of respirators and other protective devices in areas of exposure have reduced lead poisoning materially. Low-level atmospheric and water pollution, stemming largely from the use of tetraethyllead, $[Pb(C_2H_5)_4]$ in motor fuels, has been receiving increasing attention.

INDIVIDUAL CARBON GROUP ELEMENTS

Carbon. The word carbon probably derives from the Latin *carbo,* meaning variously "coal," "charcoal," "ember." The term diamond, a corruption of the Greek word *adamas,* "the invincible," aptly describes the permanence of this crystallized form of carbon, just as graphite, the name for the other crystal form of carbon, derived from the Greek verb *graphein,* "to write," reflects its property of leaving a dark mark when rubbed on a surface. Before the discovery in 1779 that graphite when burned in air forms carbon dioxide, graphite was confused with both the metal lead and a superficially similar substance, the mineral molybdenite.

Occurrence and distribution. On a weight basis, carbon is 19th in order of elemental abundance in the crust of the Earth, and there are estimated to be 3.5 times as many carbon atoms as silicon atoms in the universe. Only hydrogen, helium, oxygen, neon, and nitrogen are atomically more abundant in the Cosmos than carbon. Carbon is the cosmic product of the "burning" of helium in which three helium nuclei, atomic number 4, fuse to produce a carbon nucleus, atomic number 12. In the crust of the Earth, elemental carbon is a minor component: carbon compounds (*i.e.,* carbonates of magnesium and calcium) form common minerals (*e.g.,* magnesite, dolomite, marble, or limestone). Coral and the shells of oysters and clams are primarily calcium carbonate. Carbon is widely distributed as coal and in the organic compounds that constitute petroleum, natural gas, and all plant and animal tissue. A natural sequence of chemical reactions called the carbon cycle—involving conversion of atmospheric carbon dioxide to carbohydrates by photosynthesis in plants, the consumption of these carbohydrates by animals and oxidation of them through metabolism to produce carbon dioxide and other products, and the return of carbon dioxide to the atmosphere—is one of the most important of all biological processes.

Carbon
in all
living
tissue

Production of elemental carbon. Elemental carbon is best considered in terms of its several crystalline forms—diamond, graphite, and "amorphous carbon"—since the widely different properties of these three substances require different approaches. (When an element exists in more than one crystal form, each is called an allotrope.)

Until 1955, all diamonds were obtained from natural deposits, most significant in southern Africa but occurring also in Brazil, Venezuela, British Guiana (now Republic of Guyana), and Siberia. The single known source in the United States, in Arkansas, has no commercial importance, nor is India, once historically a source of fine diamonds, a significant present-day supplier. The primary source of diamonds is a soft, bluish-coloured peridotic rock called kimberlite (after the famous deposit at Kimberley, South Africa), found in volcanic structures called pipes; but many diamonds occur in alluvial deposits presumably resulting from the weathering of primary sources. Isolated finds around the world in regions where no sources are indicated have not been uncommon. Natural deposits are worked by crushing, by gravity and flotation separations, and by removal of diamonds by their adherence to a layer of grease on a suitable table. The following products result: (1) diamond proper—distorted cubic-crystalline, gem-quality stones varying from colourless to red, pink, blue, green, and yellow; (2) bort—minute, dark crystals of abrasive but not gem quality; (3) ballas—randomly oriented crystals of abrasive quality; (4) macles—triangular, pillow-shaped crystals that are industrially useful; and (5) carbonado—mixed diamond–graphite crystallites containing other impurities.

Artificial
diamonds

The successful laboratory conversion of graphite to diamond was made in 1955. The procedure involved the simultaneous use of extremely high pressure and temperature with iron as a solvent or catalyst. Subsequently, chromium, manganese, cobalt, nickel, and tantalum were substituted for iron. Synthetic diamonds are now manufactured in several countries and are being used increasingly in place of natural materials as industrial abrasives.

Graphite occurs naturally in many areas, the deposits of major importance being in the Republic of Korea, Austria, China, Mexico, Madagascar, Germany, Sri Lanka, and the Soviet Union. Both surface- and deep-mining techniques are used, followed by flotation, but the major portion of commercial graphite is produced by heating petroleum coke in an electric furnace. A better crystallized form, known as pyrolytic graphite, is obtained from the decomposition of low-molecular-weight hydrocarbons by heat. Graphite fibres of considerable tensile strength are obtained by carbonizing natural and synthetic organic fibres.

Amorphous carbon, which is solid but not clearly crystallized, probably consists of microcrystals of graphite; it is common in commerce as coke; lampblack, or carbon black; and charcoal. These products are obtained by heating coal (to give coke), natural gas (to give blacks), or carbonaceous material of vegetable or animal origin, such as wood or bone (to give charcoal), at elevated temperatures in the presence of insufficient oxygen to allow combustion. The volatile by-products are recovered and used separately.

Structure of carbon allotropes. The crystal structure of diamond is an infinite three-dimensional array of carbon atoms, each of which forms a structure in which each of the bonds makes equal angles with its neighbours. If the ends of the bonds are connected, the structure is that of a tetrahedron, a three-sided pyramid of four faces (including the base). Every carbon atom is covalently bonded at the four corners of the tetrahedron to four other carbon atoms. The distance between carbon atoms along the bond is 1.54×10^{-8} centimetre, and this is called the single-bond length. The space lattice of the diamond can be visualized as carbon atoms in puckered hexagonal (six-sided) rings that lie roughly in one plane, the natural cleavage plane of the crystal; and these sheets of hexagonal, puckered rings are stacked in such a way that the atoms in every fourth layer lie in the same position as those in the first layer. The layer arrangement sequence is thus ABCABCA.... Such a crystal structure can be destroyed only by the rupture of many strong bonds: thus the extreme hardness, high sublimation temperature, the presumed extremely high melting point (extrapolated from known behaviour), and reduced chemical reactivity and insulating properties are all reasonable consequences of the crystal structure. Because of both the sense and the direction of the tetrahedral axis, four spatial orientations of carbon atoms exist, leading to two tetrahedral and two octahedral (eight-faced) forms of diamond.

Crystal structure of graphite

The crystal structure of graphite amounts to a parallel stacking of layers of carbon atoms. Within each layer the carbon atoms lie in fused hexagonal rings that extend infinitely in two dimensions. The stacking pattern of the layers is ABABA . . . ; that is, each layer separates two identically oriented layers. Within each layer the carbon–carbon bond distance is 1.42×10^{-8} centimetre, which is intermediate between the single bond and double (1.33×10^{-8} centimetre) bond distances. All carbon–carbon bonds within a layer are the same (an observation that is interpreted in terms of complete π-bonding). The interlayer distance (3.37×10^{-8} centimetre) is sufficiently large to preclude localized bonding between the layers; the bonding between layers is probably by van der Waals interaction (*i.e.,* the result of attraction between electrons of one carbon atom and the nuclei of neighbouring atoms). Ready cleavage, as compared with diamond, and electrical conductivity are consequences of the crystal structure of graphite. Other related properties are softness and lubricity (smoothness, slipperiness). A less common form of graphite, which occurs in nature, is based upon an ABCABCA . . . stacking, in which every fourth layer is the same. The amorphous varieties of carbon are based upon microcrystalline forms of graphite.

The greater degree of compactness in the diamond structure as compared with graphite suggests that by the application of sufficient pressure on graphite it should be converted to diamond. At room temperature and atmospheric pressure, diamond is actually less stable than graphite. The rate of conversion of diamond to graphite is so slow, however, that a diamond persists in its crystal form indefinitely. As temperature rises, the rate of conversion to graphite increases substantially, and at high temperatures it becomes (thermodynamically) favourable if the pressure is sufficiently high. At the same time, however, the rate of conversion decreases as the (thermodynamic) favourability increases. Thus, graphite does not yield diamond when heated under high pressure, and it appears that direct deformation of the graphite structure to the diamond structure in the solid state is not feasible. The occurrence of diamonds in iron–magnesium silicates in the volcanic structures called pipes and in iron–nickel and iron sulfide phases in meteorites suggests that they were formed by dissolution of carbon in those compounds and subsequent crystallization from them in the molten state at temperatures and pressures favourable to diamond stability. The successful synthesis of diamond is based upon this principle.

Diamonds in meteorites

The temperature and pressure relationships of any substance can be plotted to show how, for example, the boiling point changes as pressure is changed; such graphs are called phase diagrams (see MATTER). They reveal conditions under which rearrangements in the atomic or molecular structure of a substance take place.

The crystal structure of graphite is of a kind that permits the formation of many compounds, called lamellar or intercalation compounds, by penetration of molecules or ions. Graphitic oxide and graphitic fluoride are nonconducting lamellar substances not obtained in true molecular forms that can be reproduced, but their formulas do approximate, respectively, the compositions of carbon dioxide and carbon monofluoride.

A type of chemical reaction in which one substance (an oxidizing agent) accepts electrons from another substance (a reducing agent) and is thereby reduced (while the reducing agent is oxidized) is frequently observed with carbon and its compounds. Although carbon is usually a reducing agent, under acidic conditions elemental carbon is a moderately strong oxidizing agent. The large energy of the carbon–carbon bond makes activation energy requirements for the reaction so high that direct reduction of carbon—*e.g.,* to methane (formula CH_4)—is impractical. Reduction of carbon monoxide to elemental carbon and oxidation of carbon monoxide to carbon dioxide are both feasible but impractical in solution. Under alkaline conditions, only the oxidation of formate ion (HCO_2^-) to carbonate ion (CO_3^{2-}) is a reasonable process.

Nuclear properties. The notation used for the nucleus of atoms places the atomic mass as a presuperscript to the symbol of the element and the atomic number as a presubscript; thus, the isotope carbon-12 is symbolized ${}^{12}_{6}C$. Of the stable nuclides (Table 17), the isotope carbon-13 is of particular interest in that its nuclear spin imparts response in a device called a nuclear magnetic resonance spectrometer, which is useful when investigating the molecular structures of covalently bonded compounds containing carbon. This isotope is also useful as a label in compounds that are to be analyzed by mass spectrometry, another device that is used extensively to identify atoms and molecules. Of the unstable nuclides, only carbon-14 is of sufficiently long half-life to be important. It is formed by the interaction of neutrons, produced by cosmic radiation, with nitrogen (N) in the atmosphere in a reaction that may be written as follows (neutron is symbolized as ${}^{1}_{0}n$, the nitrogen atom as ${}^{14}_{7}N$, and a hydrogen nucleus, or proton, as ${}^{1}_{1}H$):

$${}^{14}_{7}N + {}^{1}_{0}n \longrightarrow {}^{14}_{6}C + {}^{1}_{1}H$$

The carbon-14 atoms from this reaction are converted to carbon dioxide by reaction with atmospheric oxygen and mixed and uniformly distributed with the carbon dioxide containing stable carbon-12. Living organisms use atmospheric carbon dioxide, whether with stable or radioactive carbon, through processes of photosynthesis and respiration, and thus their systems contain the constant ratio of carbon-12 to carbon-14 that exists in the atmosphere.

Death of an organism terminates this equilibration process; no fresh carbon dioxide is added to the dead substance. The carbon-14 present in the dead substance decays in accordance with its 5,730-year (± 40 years) half-life, while the carbon-12 remains what it was at death. Measurement of the carbon-14 activity at a given time thus allows calculation of the time elapsed after the death of the organism. Measurement of the carbon-14 activity in a cypress beam in the tomb of the Egyptian Pharaoh Snefru, for example, established the date of the tomb as *c.* 2600 BC. Many items of archaeological significance have been dated similarly.

The nuclides carbon-12 and carbon-13 are of importance in the carbon cycle of energy creation in certain stars. The cycle can be summarized in terms of nuclear equations, the separate steps being:

$${}^{12}_{6}\mathrm{C} + {}^{1}_{1}\mathrm{H} \longrightarrow {}^{13}_{7}\mathrm{N} + \text{energy}$$

$${}^{13}_{7}\mathrm{N} \longrightarrow {}^{13}_{6}\mathrm{C} + {}^{0}_{+1}e$$

$${}^{13}_{6}\mathrm{C} + {}^{1}_{1}\mathrm{H} \longrightarrow {}^{14}_{7}\mathrm{N} + \text{energy}$$

$${}^{14}_{7}\mathrm{N} + {}^{1}_{1}\mathrm{H} \longrightarrow {}^{15}_{8}\mathrm{O} + \text{energy}$$

$${}^{15}_{8}\mathrm{O} \longrightarrow {}^{15}_{7}\mathrm{N} + {}^{0}_{+1}e$$

$${}^{15}_{7}\mathrm{N} + {}^{1}_{1}\mathrm{H} \longrightarrow {}^{12}_{6}\mathrm{C} + {}^{4}_{2}\mathrm{He}.$$

Summation of the equations allows the fusion process to be written as a reaction among four atoms of hydrogen to yield one atom of helium (He), two positrons (${}^{0}_{+1}e$), and energy:

$$4\,{}^{1}_{1}\mathrm{H} \longrightarrow {}^{4}_{2}\mathrm{He} + 2\,{}^{0}_{+1}e + \text{energy};$$

this equation does not show that the process uses up and regenerates the carbon-12. In a sense, carbon acts as a catalyst for this mode of converting mass to energy.

Biological implications. The biological implications of the element and its simple compounds have been discussed earlier; the most significant implications are associated with organic compounds, which are discussed in such articles as CHEMICAL COMPOUNDS; BIOCHEMICAL COMPONENTS OF ORGANISMS.

Analysis. Carbon, either elemental or combined, is usually determined quantitatively by conversion to carbon dioxide gas, which can then be absorbed by other chemicals to give either a weighable product or a solution with acidic properties that can be titrated.

Silicon. The name silicon derives from the Latin *silex* or *silicis,* meaning "flint" or "hard stone."

Occurrence and distribution. On a weight basis, the abundance of silicon in the crust of the Earth is exceeded only by oxygen. Estimates of the cosmic abundance of other elements often are cited in terms of the number of their atoms per 10^6 atoms of silicon. Only hydrogen, helium, oxygen, neon, nitrogen, and carbon exceed silicon in cosmic abundance. Silicon is believed to be a cosmic product of alpha-particle absorption, at a temperature of about 10^9 K, by the nuclei of carbon-12, oxygen-16, and neon-20. The energy binding the particles that form the nucleus of silicon is about 8.4 million electron volts (MeV) per nucleon (proton or neutron). Compared with the maximum of about 8.7 million electron volts for the nucleus of iron, almost twice as massive as that of silicon, this figure indicates the relative stability of the silicon nucleus. The pure element silicon is too reactive to be found in nature. In compounds, the oxidized form, as silicon dioxide and particularly as silicates, is common in the Earth's crust

Silicon minerals

and is an important component of the Earth's mantle. Silicon dioxide occurs both in crystalline minerals (*e.g.,* quartz, cristobalite, tridymite) and amorphous or seemingly amorphous minerals (*e.g.,* agate, opal, chalcedony) in all land areas. The natural silicates are characterized by their abundance, wide distribution, and structural and compositional complexities. Most of the elements of the following groups in the periodic table are found in silicate minerals: groups Ia, IIa, IIIa, IIIb, IVb, Vb, VIb, VIIa. These elements are said to be lithophilic, or stone-loving. Important silicate minerals include the clays, feldspar, olivine, pyroxene, amphiboles, micas, and zeolites.

Production of elemental silicon. Elemental silicon is produced commercially by the reduction of silica (SiO_2) with coke in an electric furnace, and the impure product is then refined. Almost pure silicon is obtained by the reduction of silicon tetrachloride or trichlorosilane. For use in electronic devices, single crystals are grown by slowly withdrawing seed crystals from molten silicon.

Properties of the element. The more important physical and chemical properties of silicon have been summarized and related to the ground-state electronic configuration of the silicon atom and the position of silicon in the periodic table. Because silicon forms chains similar to those formed by carbon, silicon has been studied as a possible base element for silicon organisms. Another property resulting from the electronic structure of silicon is that it functions as an intrinsic semiconductor (see MATTER). Addition of an element such as boron, an atom of which can be substituted for a silicon atom in the crystal structure but which provides one less valence electron (boron is an acceptor atom) than silicon, allows silicon atoms to lose electrons to it. The positive holes created by the shift in electrons allow extrinsic semiconduction of a type referred to as positive (*p*). Addition of an element such as arsenic, an atom of which can also be substituted for a silicon atom in the crystal but which provides an extra valence electron (arsenic is a donor atom), releases its electron within the lattice. These electrons allow semiconduction of the negative (*n*) type. If *p*-silicon and *n*-silicon wafers are joined, in a manner called the *p–n* junction, and placed in sunlight,

The solar cell

the absorbed energy causes electrons to move across the junction and an electric current to flow in an external circuit connecting the two wafers. Such a solar cell is a source of energy for space devices.

Unlike carbon, the only crystalline form in which silicon exists is an octahedral form based upon atoms in the diamond-type arrangement. The amorphous forms of silicon contain micro crystals of this type. The reduced bond energy in crystalline silicon renders the element lower melting, softer, and chemically more reactive than diamond.

Only the 0 and +4 oxidation states of silicon are stable in aqueous systems.

As is true with carbon, the bonds in elemental silicon are strong enough to require large energies to activate, or promote, reaction in an acidic medium, and the oxidation–reduction reactions do not appear to be reversible at ordinary temperatures.

Germanium. The name germanium derives from the Latin word Germania (Germany) and was given to the element by its German discoverer, Clemens Winkler, in 1886.

Occurrence and distribution. On a weight basis, germanium is a scarce but not an extremely rare element in the crust of the Earth, equalling in abundance beryllium, molybdenum, and cesium and exceeding the elements arsenic, cadmium, antimony, and mercury. In the Cosmos, the atomic abundance of germanium is 50.5 (based upon $Si = 1 \times 10^6$), a value roughly equal to those for krypton and zirconium and only slightly less than that for selenium. The cosmic abundance is much less than those of a number of the heavier elements; *e.g.,* bromine, strontium, tin, barium, mercury, and lead. All of the elements of lower nuclear charge than germanium, except beryllium, boron, scandium, and gallium, are cosmically more abundant than germanium. Cosmically, germanium is believed to be one of the many elements formed by neutron absorption after the initial processes of hydrogen and helium burning and alpha-particle absorption.

Natural sources of germanium

Germanium is widely distributed in nature but is too reactive to occur free. Primary minerals include argyrodite, germanite, renierite, and canfieldite, all of them rare; only germanite and renierite have been used as commercial sources for the element. Trace quantities of germanium are found in certain zinc blendes, in sulfidic ores of copper and arsenic, and in coals, the latter possibly a consequence of the concentration of the element by plants of the Carboniferous Period in geologic history. Certain present-day plants are known to concentrate germanium. Both zinc-process concentrates and ash and flue dusts from coal-burning installations provide commercial sources of germanium.

Production of germanium. Pure germanium is obtained from these sources in a complicated process that finally yields billets or blocks, which may be purified by further refining to the quality required for the manufacture of semiconductors. Single crystals of germanium are grown in an atmosphere of nitrogen or helium from the molten material. These are then transformed into semiconductors by being doped (infused) with electron donor or acceptor atoms, either by incorporating the impurities in the melt during growth of the crystal or by diffusing the impurities into the crystal after it has been formed.

Properties of the element. The physical and chemical properties of germanium have been summarized earlier. Like silicon, germanium crystallizes in the diamond type of structure. The trend in properties noted with silicon and related to reduced bond energy continues with germanium. The electrical and semiconducting characteristics of germanium are comparable to those of silicon.

Germanium(II) compounds are well characterized as solids, and in general they are readily oxidized. Elemental germanium can be electrodeposited from many solutions and melts of its compounds. It is of interest that as little as one milligram of dissolved germanium per litre seriously interferes with the electrodeposition of zinc.

Tin. The symbol Sn for tin is an abbreviation of the Latin word for tin, *stannum.*

Occurrence and distribution. On a weight basis, tin is a scarce but not rare element in the crust of the Earth, its abundance being of the same order of magnitude as such technically useful elements as cobalt, nickel, copper, cerium, and lead, and it is essentially equal to the abundance of nitrogen. In the Cosmos, there are 1.33 atoms of tin per 1×10^6 atoms of silicon, an abundance roughly equal to that of niobium, ruthenium, neodymium, or platinum. Cosmically, tin is a product of neutron absorption. Its richness in stable isotopes is noteworthy.

Tin in Phoenician times

The only mineral of commercial significance is cassiterite (SnO_2). No high-grade deposits are known. The major sources are alluvial deposits, averaging about 0.01 percent tin. Lode deposits, containing up to 4 percent, are found in Bolivia and Cornwall. The latter were worked at least as early as Phoenician times but are no longer of major consequence. Some 90 percent of world production comes from Malaysia, Thailand, Indonesia, Bolivia, Congo (Brazzaville), Nigeria, and China. The United States has no significant deposits. (For commercial production see INDUSTRIES, EXTRACTION AND PROCESSING: *Production of other important industrial metals.*)

Properties of the element. The major physical and chemical properties of tin have been summarized earlier. The relationships among the allotropic modifications of tin can be represented as transformations from one crystal type to another at specific temperatures:

$$\underset{\text{(cubic-diamond crystals)}}{\text{gray or alpha } (\alpha) \text{ tin}} \xrightleftharpoons{13.2^\circ \text{ C } (55.8^\circ \text{ F})} \underset{\text{(tetragonal crystals)}}{\text{white or beta } (\beta) \text{ tin}}$$

$$\xrightleftharpoons{161^\circ \text{ C } (322^\circ \text{ F})} \underset{\text{(rhombic crystals)}}{\text{brittle tin}} .$$

(The double arrows signify that the transformation occurs in both directions, as tin is heated or as it is cooled.) Gray tin is easily crumbled, whereas white tin is malleable and ductile. The spontaneous conversion of the bright metal to a gray powder at low temperatures ("tin pest") seriously hampers the use of the metal in very cold regions. This change is rapid only below −50° C, unless catalyzed by gray tin or tin(IV). As a consequence of internal friction, white tin emits a characteristic sound ("tin cry") when bent. Elemental tin is readily oxidized to the dipositive ion in acidic solution, but this tin(II) ion is converted to tin(IV) ion by many mild oxidizing agents, including elemental oxygen. Oxidation under alkaline conditions normally gives the tetrapositive (Sn^{4+}) state. In an alkaline medium, dipositive tin (Sn^{2+}) disproportionates readily to tetrapositive tin and the free element.

Lead. The symbol Pb for lead is an abbreviation of the Latin word for lead, *plumbum.*

Occurrence and distribution. On a weight basis, lead has nearly the same abundance in the Earth's crust as tin. Cosmically, there is 0.47 lead atom per 10^6 silicon atoms. The cosmic abundance is comparable with those of cesium, praseodymium, hafnium, and tungsten, each of which is regarded as a reasonably scarce element. Lead is formed both by neutron-absorption processes and the decay of radionuclides of heavier elements. Stable lead nuclides are the end products of radioactive decay in the three natural decay series: uranium (decays to lead-206), thorium (decays to lead-208), and actinium (decays to lead-207).

Although lead is not abundant, natural concentration processes have resulted in substantial deposits of commercial significance, particularly in the United States, but also in Canada, Africa, Australia, Spain, Germany, and South America. Significant deposits are found in the U.S. in the western states and the Mississippi Valley. Elemental lead is only rarely found in nature. The major minerals are galena (PbS), anglesite ($PbSO_4$), and cerussite ($PbCO_3$). (For commercial production see INDUSTRIES, EXTRACTION AND PROCESSING: *Lead production.*)

Useful physical properties of lead

Properties of the element. The major physical and chemical properties of lead and their relationships to electronic configuration and position in the periodic table have been summarized earlier. Only a single crystalline modification, with a close-packed metallic lattice, is known. Properties that are responsible for the many uses of elemental lead include its ductility, ease of welding, low melting point, high density, and ability to absorb gamma radiation and X-radiation. Molten lead is an excellent solvent and collector for elemental silver and gold. The structural applications of lead are limited by its low tensile and fatigue strengths and its tendency to flow even when only lightly loaded. Elemental lead can be oxidized to lead(II) ion by hydrogen ion, but the insolubility of most lead(II) salts makes lead resistant to attack by many acids. Oxidation under alkaline conditions is easier to effect and is favoured by the formation of the soluble lead(II) species. Lead(IV) oxide is among the stronger oxidizing agents in acidic solution, but it is comparatively weak in alkaline solution. The ease of oxidation of lead is enhanced by complex formation. The electrodeposition of lead is best effected from aqueous solutions containing lead(II) hexafluorosilicate(IV) and hexafluorosilicic acid.

Nuclear properties. Of the radionuclides of lead, the following appear as members of the three natural decay series: (1) thorium series: lead-212; (2) uranium series: lead-214 and lead-210; (3) actinium series: lead-211. The atomic weight of natural lead varies from source to source, depending on its origin by heavier element decay.

(T.Mo./Ed.)

Nitrogen group elements

In the formal classification of the chemical elements known as the periodic table, the nitrogen group elements, consisting of nitrogen (N), phosphorus (P), arsenic (As), antimony (Sb), and bismuth (Bi), form a vertical file commonly designated group Va (see Figure 10). These elements share certain general similarities in chemical behaviour, though they are clearly differentiated from one another chemically, and these similarities reflect common features of the electronic structures of their atoms.

Probably no other group of the elements is more familiar to the layman than this group. Although the five elements together make up less than 0.2 percent by weight of the Earth's crust, they assume an importance far out of proportion to their abundance. This is especially true of the elements nitrogen and phosphorus, which comprise 2.4 and 0.9 percent, respectively, of the total weight of the human body.

The nitrogen elements have, perhaps, the widest range in physical state of any group in the periodic table. Nitrogen, for example, is a gas that liquefies at about −200° C, whereas bismuth is a solid melting at 271° C and boiling at about 1,560° C. Chemically, too, the range in properties is wide, nitrogen and phosphorus being typical nonmetals; arsenic and antimony, metalloids; and bismuth, a metal. Even in appearance these elements exhibit great variety. Nitrogen is colourless both as a gas and as a liquid. Phosphorus exists in a variety of physical modifications, or allotropic forms, including the familiar white, highly

Physical appearance

reactive form that must be stored under water to prevent it from igniting in the air; a much less reactive red or violet form; and a black modification that, although least known, appears to be the most stable of all. Arsenic exists mainly as a dull gray metallic solid, but a more reactive yellow, solid form is also known, and there are indications that other forms exist under certain conditions. Antimony is a silver, metallic appearing, but somewhat brittle solid; and bismuth is a silver-white metal with a trace of pink in its lustre.

Together with carbon, hydrogen, oxygen, and sulfur, the first two members of this group, nitrogen and phosphorus, are the principal chemical elements incorporated into living systems. Nitrogen and phosphorus are readily removed from the soil by plant growth, and therefore they are immensely important components of plant foods. Such designations as "5–10–5" on commercial fertilizers represent the respective weight percentage composition of the material in terms of nitrogen, phosphoric oxide, and potassium oxide (potassium being the third principal element needed for healthy plant growth). Nitrogen in fertilizers may be in the form of sodium or potassium nitrates, ammonia, ammonium salts, or various organic combinations. Phosphorus is supplied chiefly as inorganic phosphate.

These same elements, nitrogen and phosphorus, can also be used in ways less helpful to man. The explosives in conventional warfare are heavily dependent on their content of nitrogen compounds, and the deadly nerve gases are composed of organic compounds of phosphorus.

On the other hand, arsenic, which is notorious for its toxicity, is most useful in agriculture, where its compounds are an aid in controlling harmful insect pests. Antimony and bismuth are used chiefly in metal alloys, because they impart unique and desirable properties to these alloys.

HISTORY

Early theories of air

Nitrogen. About four-fifths of the Earth's atmosphere is nitrogen, which was isolated and recognized as a specific substance during early investigations of the air. Carl Wilhelm Scheele, a Swedish druggist, showed in 1772 that air is a mixture of two gases, one of which he called "fire air," because it supported combustion, and the other "foul air," because it was left after the "fire air" had been used up. The "fire air" was, of course, oxygen, and the "foul air" nitrogen. At about the same time nitrogen also was recognized by a Scottish botanist, Daniel Rutherford, and by the controversial British clergyman, Joseph Priestley, who, with Scheele, is given credit for the discovery of oxygen. Later work showed the new gas to be a constituent of nitre, a common name for potassium nitrate (KNO_3); and, accordingly, it was named nitrogen by the French chemist Jean-Antoine-Claude Chaptal in 1790. Nitrogen also was considered a chemical element by Antoine-Laurent Lavoisier, whose explanation of the role of oxygen in combustion eventually overthrew the phlogiston theory, an erroneous view of combustion that became popular in the early 18th century. The inability of nitrogen to support life led Lavoisier to name it *azote,* still the French equivalent of nitrogen.

Phosphorus. Arabian alchemists of the 12th century may have isolated elemental phosphorus by accident, but the records are unclear. Phosphorus appears to have been discovered in 1669 by Henning Brand, a German merchant whose hobby was alchemy. Brand allowed 50 buckets of urine to stand until they putrified and "bred worms." He then boiled the urine down to a paste and heated it with sand, thereby distilling elemental phosphorus from the mixture. Brand reported his discovery in a letter to Gottfried Wilhelm Leibniz, and, thereafter, demonstrations of this element and its ability to glow in the dark, or "phosphoresce," excited public interest. Phosphorus, however, remained a chemical curiosity until about a century later when it proved to be a component of bones. Digestion of bones with nitric or sulfuric acid formed phosphoric acid, from which phosphorus could be distilled by heating with charcoal. In the late 1800's, James Burgess Readman of Edinburgh developed an electric furnace method for producing the element from phosphate rock, which is essentially the method employed today.

Arsenic. Arsenic was known in the form of certain of its compounds long before it was clearly recognized as a chemical element. In the 4th century BC Aristotle wrote of a substance called *sandarachē,* now believed to have been the mineral realgar, a sulfide of arsenic. Then, in the 1st century AD, the writers Pliny the Elder and Pedanius Dioscorides both described *auripigmentum,* a substance now thought to have been the dyestuff orpiment, As_2S_3. By the 11th century AD three species of "arsenic" were recognized: white (As_4O_6), yellow (As_2S_3), and red (As_4S_4). The element itself possibly was first observed in the 13th century by Albertus Magnus, who noted the appearance of a metallike substance when *arsenicum,* another name for As_2S_3, was heated with soap. It is not certain, however, that this natural scientist and scholar actually observed the free element. The first clearly authentic report of the free substance was made in 1649 by Johann Schroeder, a German pharmacist, who prepared arsenic by heating its oxide with charcoal. Later, Nicolas Lêmery, a French physician and chemist, observed the formation of arsenic when heating a mixture of the oxide, soap, and potash. By the 18th century, arsenic was well known as a unique semimetal.

Antimony. The ancients were familiar with antimony both as a metal and in its sulfide form. Fragments of a Chaldean vase made of antimony have been estimated to date from about 4000 BC. The Old Testament tells of Queen Jezebel using the naturally occurring sulfide of antimony to beautify her eyes. Pliny, during the 1st century AD, wrote of seven different medicinal remedies using *stibium* or antimony sulfide. Early writings of Dioscorides, dating from about the same time, mention metallic antimony. Records of the 15th century show the use of the substance in alloys for type, bells, and mirrors. In 1615 Andreas Libavius, a German physician, described the preparation of metallic antimony by the direct reduction of the sulfide with iron; and a later chemistry textbook by Lêmery, published in 1675, also describes methods of preparation of the element. In the same century, a book summarizing available knowledge of antimony and its compounds was purportedly written by a Basil Valentine, allegedly a Benedictine monk of the 15th century, whose name appears on chemical writings over a span of two centuries. The name antimony appears to be derived from the Latin *antimonium,* in a translation of a work by the alchemist Geber, but its real origin is uncertain.

Bismuth. Bismuth evidently was known in very early times, since it occurs in the native state as well as in compounds. For a long period, however, it was not clearly recognized as a separate metal, being confused with such metals as lead, antimony, and tin. Miners during the Middle Ages apparently believed bismuth to be a stage in the development of silver from baser metals and were dismayed when they uncovered a vein of the metal thinking they had interrupted the process. In the 15th-century writings of Basil Valentine this element is referred to as *wismut.* The name may have been derived from the German words *wis mat,* meaning white mass. In any case it was latinized to *bisemutum* by the mineralogist Georgius Agricola, who recognized its distinctive qualities and described how to obtain it from its ores. Bismuth was accepted as a specific metal by the middle of the 18th century, and works on its chemistry were published in 1739 by the German chemist Johann Heinrich Pott and in 1753 by the Frenchman Claude-François Geoffroy.

COMPARATIVE CHEMISTRY

Electronic configurations. *Similarities in orbital arrangement.* In the periodic table, each of the nitrogen group elements occupies the fifth position among the main group elements of its period, a position designated Va. In terms of the electronic configuration of its atoms, each nitrogen group element possesses an outermost shell of five electrons. In each case, these occupy an outer *s* orbital completely (with two electrons) and contribute one electron to each of the three outer *p* orbitals (the orbitals being electron regions within the atom and the letter designations, *s, p, d,* and *f,* being used to designate different classes of orbital). The arrangement of outer electrons in the atoms of the nitrogen elements thus provides three half-filled outer orbitals that, by interaction with half-filled orbitals of the atoms of other elements, can form three covalent bonds. The other atoms may attract the shared electrons either more or less strongly than do the nitrogen group atoms; therefore the latter may acquire either positive or negative charges and exist in oxidation states of +3 or −3 in their compounds. In this respect, the nitrogen elements are alike.

Lone pairs

Another similarity among the nitrogen elements is the existence of an unshared, or lone, pair of electrons, which remains after the three covalent bonds, or their equivalent, have been formed. This lone pair permits the molecule to act as an electron pair donor in the formation of molecular addition compounds and complexes. The availability of the lone pair depends upon various factors, such as the relative size of the atom, its partial charge in the molecule, the spatial characteristics of other groups in the molecule, and the as-yet poorly understood phenomenon called the "inert pair effect." This effect consists of a tendency for the paired *s* electrons in the outermost shell of the heavier atoms of a major group to remain chemically unreactive. Because of it, the electron pair-donating ability of the nitrogen group elements is not uniform throughout the group; it is probably greatest with nitrogen, less with the intermediate elements, and nonexistent with bismuth.

Variations in bonding capacity. Significant differences in electronic configurations also occur among the elements of the nitrogen group with respect both to the underlying shell and to the outer *d* orbitals. Since the latter first appear with the third period of the table, they are present in all elements of the group but nitrogen. The possibility of utilizing these outer *d* orbitals for bonding thus exists for phosphorus, arsenic, antimony, and bismuth, but not for nitrogen.

Utilization of *d* orbitals

There are three principal ways in which the outer *d* orbitals can be used to increase the number of bonds or expand the valence octet. One is by providing a space to which one of the *s* electrons can be promoted. This creates two additional half-filled orbitals (one *d* and one *s* orbital), and it therefore generates the capacity to form two additional covalent bonds. This is exemplified by the production of phosphorus pentafluoride, PF_5, by further fluorination of the trifluoride, PF_3. Such promotion appears to be greatly assisted by the increase in outer *d*-orbital stability that results from the withdrawal of part of the screening electron and the attendant increase of the effective nuclear charge of the central atom. In PF_5, for example, the fluorine atoms, being much more electronegative than the phosphorus atom, draw away a portion of the phosphorus electrons, leaving the outer *d* orbitals more exposed to the phosphorus nucleus and therefore more stable.

A second way in which the outer *d* orbitals can become involved in the bonding is by their becoming sufficiently stable to attract a lone pair of electrons from a donor. For example, PF_5 can serve as an electron pair acceptor through an outer *d* orbital to coordinate a fluoride ion donor and form the complex ion PF_6^-.

A third way of involving *d* orbitals in bonding is for them to become partially occupied in accommodating lone-pair electrons from another atom, which is already attached by a single bond, thereby strengthening the bond. The phosphorus oxyhalides, of general formula POX_3, appear to be examples of this; their phosphorus–oxygen bonds are observed to be shorter and stronger than expected for ordinary single bonds.

Alternation of properties

The +5 oxidation state. It thus is possible for an atom of phosphorus, arsenic, antimony, or bismuth to expand its valence octet to form five covalent bonds and one additional coordinate covalent bond. This is not possible for nitrogen, which exhibits a maximum coordination number of four: three single covalent bonds and a coordinate covalent bond with nitrogen acting as donor (through its lone pair). Nevertheless, the +5 oxidation state is formally applicable to nitrogen, so that all five elements can be found in this state. When compounds in the +5 oxidation state are studied, however, it is observed that their properties do not exhibit a uniform trend within the group. Rather, a certain degree of alternation is observed, the +5 states of nitrogen, arsenic, and bismuth appearing less stable and more strongly oxidizing than the corresponding states of phosphorus and antimony. In part this alternation may find explanation in the electronic differences among the atoms with respect to their underlying shells. The number of electrons in the shell just below the outermost level, is two for nitrogen, eight for phosphorus, and 18 for arsenic, antimony, and bismuth.

Increasing the nuclear charge by 18 from phosphorus to arsenic may be accompanied by incomplete shielding of this extra charge by the ten 3*d* electrons also added. This would imply smaller size and a greater electronegativity for arsenic than for phosphorus and thus a greater similarity between the phosphorus and antimony atoms. This subject, however, is still controversial, and the widely used scale of electronegativities devised by Linus Pauling fails to make this distinction.

An interesting anomaly is presented by the fact that nitrogen as a free element is in the form of gaseous diatomic molecules, while the elements immediately preceding it in its period of the table are solids, as are the other elements in its group. In surveying the elements of the second period, the most obvious difference in atomic structure found on reaching nitrogen is the appearance for the first time in compounds of the element of a lone pair of electrons not used in bonding with other atoms. Calculations suggest that the presence of this lone pair of electrons is associated with a considerable weakening of nitrogen to nitrogen single bonds in compounds where these bonds occur. In the diatomic nitrogen molecule, however, the bonding is of a different variety—triple bonds being found between the atoms. It is thought that the triple bond is unaffected (unweakened) by the lone pairs of electrons on the nitrogen atoms, and this is assumed to be the reason why nitrogen "prefers" to exist as triply bonded gaseous diatomic molecules rather than as a condensed singly bonded solid polymer.

Bond weakening by lone pairs

The same effect might be expected to be operable with the other elements of the nitrogen group, all of which also contain lone electron pairs in their outermost shells. Further calculations disclose, however, that the bond-weakening effect of the lone pair is far less pronounced with these elements than it is with nitrogen. As a result, with these elements, single bonds are favoured over multiple bonds, and the diatomic state of the molecules is not the preferred form.

Relative electronegativities. It might also be expected that the weakening effect of the lone pair would be observed in compounds of the nitrogen group elements. The picture is more complicated here because the bonds under discussion are formed between different types of atoms. Since different elements differ in electronegativity, bonds between the atoms of different elements are inevitably polar. For purposes of discussion it can be assumed that polar bonds consist of blends of nonpolar covalent bonds and completely polar, ionic bonds. It can then be shown that a relatively small amount of ionic character will contribute a disproportionate share to the overall bond strength. Since the weakening effect of the lone pair is felt only on the covalent portion of the polar bond, rather than on the ionic portion, the less polar bonds will exhibit the greater lone-pair weakening effects.

Comparison of nitrogen group elements. These considerations become important in comparing the chemical behaviour of the nitrogen group elements. The electronegativity of nitrogen itself, although lower than that of oxygen, is substantially higher than that of any of the other elements of this group. Bonds between nitrogen and oxygen, therefore, will be considerably less polar than those between oxygen and phosphorus, or oxygen and arsenic, antimony, or bismuth. Consequently, for this reason alone, the covalent contribution to the nitrogen–oxygen bond energy will be relatively more important than is the case with the bonds between oxygen and the heavier elements of the group. Thus, single-bond weakening by the lone pair—and a corresponding tendency toward bond multiplicity—is likely to be much greater with oxides of nitrogen than with oxides of the heavier nitrogen group elements.

For a list of some of the chief properties of the nitrogen group elements, see Table 19.

INDIVIDUAL NITROGEN GROUP ELEMENTS

Nitrogen. *Occurrence and distribution.* The atmosphere of the Earth consists of 78.03 weight percent of nitrogen; this is the principal source of nitrogen for commerce and industry. The atmosphere also contains varying small amounts of ammonia and ammonium salts, as well as nitrogen oxides and nitric acid (the latter substances being formed in electrical storms and in the internal combustion engine). Nitrogen occurs also in mineral deposits of nitre or saltpetre (potassium nitrate, KNO_3) and Chile saltpetre (sodium nitrate, $NaNO_3$), but these deposits exist in quantities that are wholly inadequate for man's needs. Another material rich in nitrogen is guano, found in bat caves and in dry places frequented by birds. Nitrogen constitutes on the average about 16 percent by weight of the complex organic compounds known as proteins, present in all living organisms. The natural abundance of nitrogen in the earth's crust is 0.3 parts per 1,000. The cosmic abundance—the estimated total abundance in the universe—is between three and seven atoms per atom of silicon, which is taken as the standard.

Commercial production and uses. Commercial production of nitrogen is largely by fractional distillation of liquefied air. The boiling temperature of nitrogen is −195.8° C, about 13° below that of oxygen, which is therefore left behind. Nitrogen can also be produced on a large scale by burning carbon or hydrocarbons in air and separating the resulting carbon dioxide and water from the residual nitrogen. Various laboratory reactions that yield nitrogen include heating ammonium nitrite (NH_4NO_2) solutions, oxidation of ammonia by bromine water, and oxidation of ammonia by hot cupric oxide.

$$NH_4^+ + NO_2^- \rightarrow N_2 + 2\ H_2O$$
$$8\ NH_3 + 3\ Br_2 \rightarrow N_2 + 6\ NH_4^+ + 6\ Br^-$$
$$2\ NH_3 + 3\ CuO \rightarrow N_2 + 3\ H_2O + 3\ Cu$$

Uses of molecular nitrogen

Elemental nitrogen can be used as an inert atmosphere for reactions requiring the exclusion of oxygen. In the liquid state, nitrogen has valuable cryogenic applications; except for the gases hydrogen, methane, carbon monoxide, fluorine, and oxygen, practically all chemical substances have negligible vapour tensions at the boiling point of nitrogen and exist, therefore, as crystalline solids at that temperature.

In the chemical industry, nitrogen is used as a preventive of oxidation or other deterioration of a product, as an inert diluent of a reactive gas, as a carrier to remove heat or chemicals and as an inhibitor of fire or explosions. In the food industry nitrogen gas is employed to prevent spoilage through oxidation, mold, or insects, and liquid nitrogen is used for freeze drying and for refrigeration systems. In the electrical industry nitrogen is used to prevent oxidation and other chemical reactions, to pressurize cable jackets, and to shield motors. Nitrogen finds application in the metals industry in welding, soldering, and brazing, where it helps prevent oxidation, carburization, and decarburization. As a nonreactive gas, nitrogen is employed to make foamed—or expanded—rubber, plastics, and elastomers, to serve as a propellant gas for aerosol cans, and to pressurize liquid propellants for reaction jets. In medicine rapid freezing with liquid nitrogen may be used to preserve blood, bone marrow, tissue, bacteria, and semen.

Nitrogen fixation

Although the other applications are important, by far the greatest bulk of elemental nitrogen is consumed in the manufacture of nitrogen compounds. The bond between atoms in the nitrogen molecules is so strong (226 kilocalories per mole; more than twice that of molecular hydrogen) that it is difficult to cause molecular nitrogen to enter into other combinations. Most living organisms cannot utilize nitrogen directly and must have access to its compounds. Therefore the fixation of nitrogen, the incorporation of elemental nitrogen into compounds, is vitally important. In nature, two principal processes of nitrogen fixation are known. One is the action of electrical energy on the atmosphere, which dissociates nitrogen and oxygen molecules, allowing the free atoms to form nitric oxide, NO, and nitrogen dioxide, NO_2. Nitrogen dioxide then reacts with water as follows:

$$3\ NO_2 + H_2O \rightarrow 2\ HNO_3 + NO.$$

The nitric acid, HNO_3, dissolves and comes to Earth with rain as a very dilute solution. In time it becomes part of the combined nitrogen of the soil. The other principal process of natural nitrogen fixation is that of certain plants and vegetables called legumes. Through a cooperative action with bacteria, legumes are able to convert atmospheric nitrogen directly into nitrogen compounds. Certain bacteria alone, such as *Azotobacter chroococcum* and *Clostridium pasteurianum,* are also capable of fixing nitrogen.

The chief commercial method of fixing nitrogen is the Haber process for synthesizing ammonia. This process was developed during World War I to lessen the dependence of Germany on Chilean nitrate. It involves the direct synthesis of ammonia from its elements.

Properties and reaction. Nitrogen is a colourless, odour-

less gas, which condenses at −195.8° C to a colourless, mobile liquid. The element exists as N_2 molecules, represented as :N:::N:, for which the bond energy of 226 kilocalories per mole is exceeded only by that of carbon monoxide, 256 kilocalories per mole. Because of this high bond energy the activation energy for reaction of molecular nitrogen is usually very high, causing nitrogen to be relatively inert to most reagents under ordinary conditions. Furthermore, the high stability of the nitrogen molecule contributes significantly to the thermodynamic instability of many nitrogen compounds, in which the bonds, although reasonably strong, are far less so than those in molecular nitrogen. For these reasons, elemental nitrogen appears to conceal quite effectively the truly reactive nature of its individual atoms.

A relatively recent and unexpected discovery is that nitrogen molecules are able to serve as ligands in complex coordination compounds. The observation that certain solutions of ruthenium complexes can absorb atmospheric nitrogen has led to hope that one day a simpler and better method of nitrogen fixation may be found.

Atomic nitrogen

An active form of nitrogen, presumably containing free nitrogen atoms, can be created by passage of nitrogen gas at low pressure through a high-tension electrical discharge. The product glows with a yellow light and is much more reactive than ordinary molecular nitrogen, combining with atomic hydrogen and with sulfur, phosphorus, and various metals, and capable of decomposing nitric oxide, NO, to N_2 and O_2.

A nitrogen atom has the electronic structure represented by $1s^2$, $2s^2$, $2p^3$, or alternatively, 2–5. The five outer shell electrons screen the nuclear charge quite poorly, with the result that the effective nuclear charge felt at the covalent radius distance is relatively high. Thus nitrogen atoms are relatively small in size and high in electronegativity, being intermediate between carbon and oxygen in both of these properties. The electronic configuration includes three half-filled outer orbitals, which give the atom the capacity to form three covalent bonds. The nitrogen atom should therefore be a very reactive species, combining with most other elements to form stable binary compounds, especially when the other element is sufficiently different in electronegativity to impart substantial polarity to the bonds. When the other element is lower in electronegativity than nitrogen, the polarity gives partial negative charge to the nitrogen atom, making its lone-pair electrons available for coordination. When the other element is more electronegative, however, the resulting partial positive charge on nitrogen greatly limits the donor properties of the molecule. When the bond polarity is low (due to the electronegativity of the other element being similar to that of nitrogen), multiple bonding is greatly favoured over single bonding. If disparity of atomic size prevents such multiple bonding, then the single bond that forms is likely to be relatively weak, and the compound is likely to be unstable with respect to the free elements. All of these bonding characteristics of nitrogen are observable in its general chemistry.

Analytical chemistry. Often the percentage of nitrogen in gas mixtures can be determined by measuring the volume after all other components have been absorbed by chemical reagents. Decomposition of nitrates by sulfuric acid in the presence of mercury liberates nitric oxide, which can be measured as a gas. Nitrogen is released from organic compounds when they are burned over copper oxide, and the free nitrogen can be measured as a gas after other combustion products have been absorbed. The well-known Kjeldahl method for determining the nitrogen content of organic compounds involves digestion of the compound with concentrated sulfuric acid (optionally containing mercury, or its oxide, and various salts, depending on the nature of the nitrogen compound). In this way, the nitrogen present is converted to ammonium sulfate. Addition of an excess of sodium hydroxide releases free ammonia, which is collected in standard acid; the amount of residual acid, which has not reacted with ammonia, is then determined by titration.

The Kjeldahl method

Biological and physiological significance. As might be expected in view of the importance of the presence of nitrogen in living matter, most—if not all—organic nitrogen compounds are physiologically active.

The bends

Nitrogen itself, being inert, is innocuous except when breathed under pressure, in which case it dissolves in the blood and other body fluids in higher than normal concentration. This in itself produces a narcotic effect, but if the pressure is reduced too rapidly, the excess nitrogen evolves as bubbles of gas in various locations in the body. These can cause muscle and joint pain, fainting, partial paralysis, and even death. These symptoms are referred to as "the bends." Divers, and others forced to breathe air under pressure, must therefore be extremely careful that the pressure is reduced to normal very slowly following exposure. This enables the excess nitrogen to be released harmlessly through the lungs without forming bubbles. A better alternative is to substitute mixtures of oxygen and helium for air. Helium is much less soluble in body fluids, and the dangers are thus diminished.

Isotopes of nitrogen. Nitrogen exists as two stable isotopes, ^{14}N and ^{15}N. These can be separated by chemical exchange or by thermal diffusion. Artificial radioactive isotopes have masses of 12, 13, 16, and 17. The most stable has a half-life of only about 10 minutes.

Phosphorus. *Occurrence and distribution.* Phosphorus is a very widely distributed element—12th most abundant in the Earth's crust, to which it contributes about 0.10 weight percent. Its cosmic abundance is estimated to be about one atom per 100 atoms of silicon, the standard. Its high chemical reactivity assures that it does not occur in the free state. The principal combined forms in nature are the phosphate salts. Nearly 190 different minerals have been found to contain phosphorus, but, of these, the principal source of phosphorus is the apatite series in which calcium ions exist along with phosphate ions and variable amounts of fluoride, chloride, or hydroxide ions, according to the formula $[Ca_{10}(PO_4)_6(F, Cl, \text{or } OH)_2]$. Commonly such metal atoms as magnesium, manganese, strontium, and lead substitute for calcium in the mineral; and silicate, sulfate, vanadate, and similar anions substitute for phosphate ions. Very large sedimentary deposits of fluoroapatite are found in many parts of the Earth. The phosphate of bone and tooth enamel is hydroxyapatite. (The principle of lessening tooth decay by fluoridation depends upon the conversion of hydroxyapatite to the harder, more decay resistant, fluoroapatite.)

Estimates of the total phosphate rock in the Earth's crust average about 50,000,000,000 tons, of which north Africa contains two-thirds, and the U.S.S.R. and the United States most of the remaining third. This estimate includes only ore that is sufficiently rich in phosphate for conversion to useful products by present methods. Vast quantities of material lower in phosphorus content also exist.

Acidulation and reduction

Commercial production and uses. Two principal techniques for converting phosphate rock to usable materials are practiced. One involves acidulation of the crushed rock—with either sulfuric or phosphoric acids—to form crude calcium hydrogen phosphates that, being water soluble, are valuable additions to fertilizer. The other method is the reduction of the phosphate with carbon in an electric furnace to give elemental phosphorus. The latter reaction is extremely complex, and its precise details depend upon the composition of the mineral phosphate. A charge of sand, coke, and phosphate rock is melted at about 1,500° C in an electric furnace. The calcium and impurities are left in the form of a complex fluorosilicate slag, and elemental phosphorus vapour, at about 300° C, distills out and is collected, condensed, and stored underwater as the white allotropic form of the element. More than half a million tons of phosphorus are made annually in the United States in this way. Most of the output is burned to phosphoric anhydride and subsequently treated with water to form phosphoric acid, H_3PO_4.

Only about 5 percent of the 2,000,000 tons of phosphorus consumed per year in the United States is used in the elemental form. Pyrotechnic applications of the element include tracers, incendiaries, fireworks, and matches. Some is used as an alloying agent, some to kill rodents, and the rest is employed in chemical synthesis. A large amount is converted to sulfides used in matches and in the manufacture of insecticides and oil additives. Most of the remainder is converted to halides or oxides for subsequent use in synthesizing organic phosphorus compounds.

Properties and reactions. The electronic configuration of the phosphorus atom can be represented by $1s^2$, $2s^2$, $2p^6$, $3s^2$, $3p^3$, or 2–8–5. The outer shell arrangement therefore resembles that of nitrogen, with three half-filled orbitals each capable of forming a single covalent bond and an additional lone-pair of electrons. Depending on the electronegativity of the elements with which it combines, phosphorus can therefore exhibit oxidation states of +3 or −3, just as does nitrogen. The principal differences between nitrogen and phosphorus are that the latter is of considerably lower electronegativity and has larger atoms, with outer *d* orbitals available. For these reasons, the similarities between nitrogen and phosphorus chemistry are largely formal ones, tending to conceal the actual, wide differences. The outer *d* orbitals in phosphorus permit an expansion of the octet, which leads to the +5 state, with five actual covalent bonds being formed in compounds, a condition impossible for nitrogen to achieve.

Allotropic forms

The first striking difference in chemistry of the two elements is that elemental phosphorus exists under ordinary conditions in any of several modifications, or allotropic forms, all of which are solid. Phosphorus molecules of formula P_2, structurally analogous to N_2 molecules and evidently also triply bonded, exist only at very high temperatures. These P_2 molecules do not persist at lower temperatures—below about 800°—because of the fact that three single bonds in phosphorus, in contrast to the situation with nitrogen, are favoured over one triple bond. On cooling, the triply bonded P_2 molecules condense to form tetrahedral P_4 molecules, in which each atom is joined to three others by single bonds. These molecules further condense to form either hexagonal- or cubic-structured molecular solids, both called "white phosphorus." Because of the relatively weak intermolecular attractions (van der Waals forces) between the separate P_4 molecules, the solid melts easily at 44.1° C and boils at about 280° C. Formation of tetrahedra requires bond angles of 60° instead of the preferred 90°–109° angles, so that white phosphorus is a relatively unstable, or metastable, form. It changes spontaneously, but slowly, at temperatures around 200° or higher, to a polymeric form called "red phosphorus." This substance is amorphous when formed at lower temperatures, but it can become crystalline, with a melting point of about 590° C. At higher temperatures and pressures, or with the aid of a catalyst, at ordinary pressures and a temperature of about 200° C, phosphorus is converted to a black crystalline form, which somewhat resembles graphite. This may prove to be the most stable form of phosphorus, despite the relative difficulty in its preparation. In both the red and the black forms, each phosphorus atom forms three single bonds, which are spread apart sufficiently to be relatively strain free.

Consistent with the metastable condition of the white modification, and the crowding of its covalent bonds, this form is far more reactive chemically than the others. It is highly toxic, reacts vigorously with most reagents, and inflames in air at only 35° C, so that it must be stored under water or other inert liquid. White phosphorus dissolves readily in solvents such as carbon disulfide, in which it maintains the composition P_4. In contrast, red phosphorus is insoluble and relatively inert, although large quantities of the usual commercial form can ignite spontaneously in air and react with water to form phosphine and phosphorus oxyacids. Black phosphorus is more inert and is capable of conducting electricity. Both these polymeric forms are insoluble and are very much less volatile than white phosphorus.

Analytical chemistry. Elemental phosphorus can be detected by its phosphorescence. It can also be converted to phosphine with boiling sodium hydroxide solution or with zinc and sulfuric acid; the phosphine is identified by means of test paper containing either silver nitrate or mercuric chloride, both of which are reduced to the free metal by phosphine, thereby darkening the paper. Phosphorus vapour also readily darkens silver nitrate test paper. Phosphorus is determined quantitatively by oxidation to phosphate, followed by any of several standard procedures. Phosphate, for example, may be precipitated as the magnesium ammonium salt, $MgNH_4PO_4$, converted by ignition to magnesium pyrophosphate, $Mg_2P_2O_7$, and weighed. Alternatively, phosphate may be precipitated as ammonium phosphomolybdate; this can be weighed as such, converted to magnesium pyrophosphate and weighed, or titrated directly with sodium hydroxide solution.

Biological and physiological significance. Phosphorus is an important constituent of bones and teeth, and it is essential to the growth of living organisms. In organisms the element usually appears as phosphate. In its other forms phosphorus is likely to prove very toxic. White phosphorus attacks the skin and, when ingested, causes a necrosis of the jawbone, called "phossy jaw." Certain organic esters of phosphoric acid, used as lubricating-oil additives, have been found to cause permanent paralysis when accidentally ingested. Phosphine is extremely toxic, as are its organic derivatives. Some of the most toxic substances known to man, collectively termed nerve gas, are organic derivatives of phosphorus.

Nerve gas

Isotopes of phosphorus. The only naturally occurring isotope of phosphorus is that of mass 31. The other isotopes from mass 29 to mass 34 have been synthesized by appropriate nuclear reactions. All of these are radioactive with relatively short half-lives. The isotope of mass 32 has a half-life of about 14 days and has proven extremely useful in tracer studies involving the absorption and movement of phosphorus in living organisms.

Arsenic. *Occurrence and distribution.* The abundance of arsenic in the Earth's crust is about five grams per ton; the cosmic abundance is estimated as about four atoms per million atoms of silicon. The element is widely distributed. A small amount exists in the native state, in 90–98 percent purity. Most, however, is combined in more than 150 different minerals, as sulfides, arsenides, sulfoarsenides, and arsenites. Mispickel, or arsenopyrite, FeAsS, is among the most common of arsenic-bearing minerals; others are realgar, As_4S_4; orpiment, As_2S_3; loellingite, $FeAs_2$; and enargite, Cu_3AsS_4. Most commercial arsenic is recovered as a by-product of the smelting of copper, lead, cobalt, and gold ores.

Commercial production and uses. Metallic arsenic forms when arsenopyrite is heated at 650°–700° C in the absence of air. The arsenic in arsenopyrite and the arsenic impurities in other metal ores unite readily with oxygen when heated in air, forming the easily sublimed oxide, As_4O_6, also known as "white arsenic." The vapour of the oxide is collected and condensed in a series of brick chambers and later purified by resublimation. Most arsenic is prepared by carbon reduction of the arsenious oxide dust thus collected.

World consumption of metallic arsenic is relatively small, only a few hundred tons per year. Most of what is consumed comes from Sweden. It is used in metallurgical applications because of its metalloid properties. About one percent arsenic content is desirable in the manufacture of lead shot, for example, because it improves the roundness of the molten drops. Bearing alloys based on lead are improved in both thermal and mechanical properties when they contain about 3 percent arsenic. A small amount of arsenic in lead alloys hardens them for use in batteries and cable sheathing. Small concentrations of arsenic improve the corrosion resistance and thermal properties of copper and brass. Very highly purified arsenic finds applications in semiconductor technology, where it is used with silicon and germanium, as well as in the form of gallium arsenide, GaAs, for diodes, lasers, and transistors.

In contrast to the small use of metallic arsenic, tens of thousands of tons of the element are consumed annually in the form of its compounds. These are used primarily in agriculture.

Properties and reactions. In its most stable free state, arsenic is a steel-gray, brittle solid with low thermal and electrical conductivity. Other forms have been reported but are not well characterized, including especially a yellow, metastable form, which may consist of As_4 molecules analogous to white phosphorus, P_4. Arsenic sublimes at 613° C, and in the vapour it exists as As_4 molecules, which do not begin to dissociate until about 800° C; dissociation to As_2 molecules becomes complete at about 1,700° C.

Electronic structure

The electronic structure of the arsenic atom, 2–8–18–5, resembles those of nitrogen and phosphorus in that there are five electrons in the outermost shell, but it differs from them in having 18 electrons in the penultimate shell instead of two or eight. The addition of ten positive charges to the nucleus during the filling of the five $3d$ orbitals frequently causes a general contraction of the electronic cloud and a concomitant increase in electronegativity of the elements. In other groups of the periodic table this is clearly shown. Thus, it seems generally accepted that zinc is more electronegative than magnesium and, similarly, that gallium is more electronegative than aluminum. The difference diminishes, however, in the next groups, and many authorities do not agree that germanium is more electronegative than silicon, although an abundance of chemical evidence appears to indicate that this is so. The similar transition from penultimate 8-shell to 18-shell element in passing from phosphorus to arsenic might also produce an increase in the electronegativity of arsenic over phosphorus, but this remains controversial.

Bonding properties

The outer-shell similarity of the two elements suggests that arsenic, like phosphorus, can form three covalent bonds per atom, with an additional lone pair of electrons left unbonded. The oxidation state of arsenic should, therefore, be either +3 or −3 depending on the electronegativity of arsenic and that of the elements with which it is combined. The possibility should also exist of utilizing the outer d orbitals to expand the octet, thereby allowing arsenic to form five bonds. This possibility is realized only in compounds with fluorine. The availability of the lone pair for complex formation (through electron donation) appears much less in the arsenic atom than in phosphorus and nitrogen, as evidenced by the chemistry of the element.

Arsenic itself is stable in dry air, but in moist air it tends to become coated with a black oxide. Sublimed arsenic vapour readily burns in air to form arsenious oxide. The free element is essentially unaffected by water, bases, or nonoxidizing acids, but it can be oxidized by nitric acid to the +5 state. Halogens attack arsenic, as does sulfur, and the element will combine directly with many metals forming arsenides.

Tests for arsine

Analytical chemistry. Qualitatively, arsenic may be detected by precipitation as the yellow arsenious sulfide from hydrochloric acid of 25 percent or greater concentration. Trace amounts of arsenic are usually determined by conversion to arsine. The latter can be detected by the so-called Marsh test, in which arsine is thermally decomposed, forming a black arsenic mirror inside a narrow tube, or by the Gutzeit method, in which a test paper impregnated with mercuric chloride darkens when exposed to arsine because of the formation of free mercury.

Biological and physiological significance. The toxicity of arsenic and its compounds varies widely, ranging from the exceedingly poisonous arsine—and its organic derivatives—to elemental arsenic itself, which is relatively inert. Arsenical compounds in general are skin irritants, which easily cause dermatitis. Protection against inhalation of arsenic-containing dusts is recommended, but most poisoning appears to come from ingestion. The maximum tolerable concentration of arsenic in dusts during an eight-hour day is 0.5 milligrams per cubic metre. For arsine, exposure of similar duration requires that the concentration be less than 0.05 parts per million in the air. In addition to the many uses of arsenic compounds as herbicides and pesticides, they have in several instances been employed as pharmacological agents. The first successful antisyphilitic agent, for example, was an arsenic compound, "Salvarsan," or "606," or 3,3′-diamino-4,4′-dihydroxyarsenobenzene dihydrochloride.

Isotopes of arsenic. Only one stable isotope of arsenic, that of mass 75, occurs in nature. Among the artificial radioactive isotopes is one of mass 76, which has a half-life of 26.4 hours.

Antimony. *Occurrence and distribution.* Antimony is about one-fifth as abundant as arsenic, contributing on the average about one gram to every ton of the Earth's crust. Its cosmic abundance is estimated as about one atom to every 5,000,000 atoms of silicon. Small deposits of native metal have been found, but most of the antimony occurs in the form of more than 100 different minerals. The most important of these is stibnite, Sb_2S_3. Small stibnite deposits are found in Algeria, Bolivia, China, Yugoslavia, Mexico, Peru, and South Africa. Some economic value also attaches to kermesite ($2Sb_2S_3 \cdot Sb_2O_3$), argentiferous tetrahedrite [$(Cu,Fe)_{12}Sb_4S_{13}$], livingstonite ($HgSb_4S_7$), and jamesonite ($Pb_4FeSb_6S_{14}$). Small amounts are also recoverable from the production of copper and lead. About half of all the antimony produced is reclaimed from scrap lead alloy from old batteries, to which antimony had been added to provide hardness.

Stibnite

Commercial production and uses. High-grade or enriched stibnite reacts directly with scrap iron in the molten state, liberating antimony metal. The metal can also be obtained by conversion of stibnite to the oxide, followed by reduction with carbon. Sodium sulfide solutions are effective leaching agents for the concentration of stibnite from ores. Electrolysis of these solutions produces antimony. After further purification of the crude antimony, the metal, called regulus, is cast into cakes.

About half of this antimony is used metallurgically, principally in alloys. It improves the hardness and corrosion resistance of lead. Most of the metal is used for lead alloys, largely for storage batteries, but also for chemical equipment such as tanks, pipes, and pumps. With tin, antimony forms such alloys as britannia metal and pewter, used for utensils and Babbitt metal for bearings. Other applications of antimony alloys are in solder, type metal, and other special materials. Highly purified antimony is used in semiconductor technology to prepare the intermetallic compounds indium, aluminum, and gallium antimonide for diodes and infrared detectors.

Properties and reactions. The most stable form of antimony is a brittle, silvery solid of high metallic lustre. Electrolytic deposition of antimony under certain conditions produces an unstable, amorphous form called "explosive antimony," because, when bent or scratched, it will change in a mildly explosive manner to the more stable, metallic form. There is also an amorphous black form of antimony that results from sudden quenching of the vapour, and a yellow form produced by low temperature oxidation of stibine, SbH_3, with air or chlorine. Metallic antimony is not affected by air or moisture under ordinary conditions, but it can be oxidized easily by oxygen, sulfur, and the halogens, especially when heated.

Electronic structure

The electronic structure of antimony closely resembles that of arsenic. It is represented as 2–8–18–18–5, with three half-filled orbitals in the outermost shell. Thus it can form three covalent bonds and exhibit +3 and −3 oxidation states. The electronegativity of antimony, like that of arsenic, remains somewhat controversial. It is generally agreed to be lower than that of arsenic, but whether it is lower also than that of phosphorus is undecided. It can act as an oxidizing agent and reacts with many metals to form antimonides that, in general, resemble nitrides, phosphides, and arsenides, but are somewhat more metallic. The promotion of one of the lone-pair electrons to an outer d orbital apparently occurs more easily with antimony than with arsenic, since antimony exhibits the +5 oxidation state in forming both the pentafluoride and the pentachloride.

Analytical chemistry. Antimony may be separated and weighed for analysis as the sulfide, Sb_2S_3. Alternatively, the sulfide may be converted to the oxide and, after careful ignition, weighed as Sb_4O_6. Numerous volumetric methods are also available, including several methods of oxidizing Sb(III) with potassium permanganate, potassium bromate, or iodine. In the absence of arsenic, small amounts of antimony may be determined by a modified Gutzeit method.

Biological and physiological significance. Antimony and a number of its compounds are highly toxic. In fact, the use of antimony compounds for medicinal purposes was temporarily outlawed several centuries ago because of the number of fatalities they had caused. A hydrated potassium antimonyl tartrate called "tartar emetic" is currently used in medicine as an expectorant, diaphoretic,

Tartar emetic

and emetic. The maximum tolerable concentration of antimony dust in air is about the same as for arsenic, 0.5 milligrams per cubic metre.

Isotopes of antimony. Two stable isotopes, nearly equal in abundance, occur in nature. One has mass 121 and the other mass 123. Radioactive isotopes of masses 120, 122, 124, 125, 126, 127, 129, and 132 have been prepared.

Bismuth. *Occurrence and distribution.* Bismuth is about as abundant as silver, contributing about 2×10^{-5} weight percent of the Earth's crust. Its cosmic abundance is estimated as about one atom to every 7,000,000 atoms of silicon. It occurs both native and in compounds. In the native state, it is found in veins associated with lead, zinc, tin, and silver ores in Bolivia, Canada, England, and Germany. Its naturally occurring compounds are chiefly the oxide (bismite or bismuth ochre), the sulfide (bismuthinite or bismuth glance), and two carbonates (bismutite and bismutosphaerite). Commercial bismuth, however, is produced largely as a by-product in the smelting and refining of lead, tin, copper, silver, and gold ores. Thus, it comes—for example—from tungsten ores in South Korea, lead ores in Mexico, copper ores in Bolivia, and both lead and copper ores in Japan.

Commercial production and uses. Bismuth is volatile at high temperature, but it usually remains with the other metals after smelting operations. Electrolytic refining of copper leaves bismuth behind as one component of the anode sludge. Separation of bismuth from lead by the Betterton–Kroll process involves the formation of highmelting calcium or magnesium bismuthide (Ca_3Bi_2 or Mg_3Bi_2), which separates and can be skimmed off as dross. The dross may be chlorinated to remove the magnesium or calcium, and finally the entrained lead. Caustic soda treatment then produces highly pure bismuth. An alternative separation, the Betts process, involves electrolytic refining of lead bullion (containing bismuth and other impurities) in a solution of lead fluosilicate and free fluosilicic acid, bismuth being recovered from the anode sludge. Separation of bismuth from its oxide or carbonate ores can be effected by leaching with concentrated hydrochloric acid. Dilution then precipitates the oxychloride, BiOCl. This—heated with lime and charcoal—produces metallic bismuth.

Alloys of bismuth

Metallic bismuth is used principally in alloys, to many of which it imparts its own special properties of low melting point and expansion on solidification. Bismuth is thus a useful component of type-metal alloys, which make neat, clean castings; and it is an important ingredient of lowmelting alloys, called fusible alloys, which have a large variety of applications, especially in fire-detection equipment. A bismuth–manganese alloy has been found effective as a permanent magnet. Small concentrations of bismuth improve the machinability of aluminum, steel, stainless steels, and other alloys and suppress the separation of graphite from malleable cast iron. Thermoelectric devices for refrigeration make use of bismuth telluride, Bi_2Te_3, and bismuth selenide, Bi_2Se_3. Liquid bismuth has been used as a fuel carrier and coolant in the generation of nuclear energy.

The principal chemical application of bismuth is in the form of bismuth phosphomolybdate, which is an effective catalyst for the air oxidation of propylene and ammonia to acrylonitrile. The latter is used to make acrylic fibres, paints, and plastics. Pharmaceutical uses of bismuth have been practiced for centuries. It is effective in indigestion remedies and antisyphilitic drugs. Slightly soluble or insoluble salts are utilized in the treatment of wounds and gastric disorders, and bismuth is sometimes injected in the form of finely divided metal, or as suspensions of its insoluble salts. Substantial quantities of the oxychloride, BiOCl, have been used to impart a pearlescent quality to lipstick, nail polish, and eye shadow.

Properties and reactions. Bismuth is a rather brittle metal with a somewhat pinkish, silvery metallic lustre. It undergoes a 3.3 percent expansion when it solidifies from the molten state. Its electrical conductivity is very poor, but somewhat better in the liquid state than in the solid. With respect to thermal conductivity, it is the poorest of all metals except mercury. Bismuth is quite resistant to corrosion by air and moisture, but it is oxidized rapidly at its boiling point of 1,560° C. It is oxidized and dissolved by concentrated nitric acid.

Bismuth atoms have the same electronic structure in their outermost shell as do the other elements of the nitrogen group. They can, therefore, form three single covalent bonds, exhibiting either a +3 or −3 oxidation state. The element has a somewhat lower electronegativity than the others, and its lone pair of electrons is evidently quite inert, causing the +5 state of bismuth to be rare and unstable.

Analytical and physiological chemistry. Bismuth is usually determined gravimetrically, being precipitated and weighed as the phosphate or the oxychloride, BiOCl. To produce the latter, a suitable amount of hydrochloric acid is added to a nitric acid solution containing the bismuth, and the resulting solution is poured into a large volume of water, causing the oxychloride to precipitate. Volumetric and colorimetric methods of determination are also available.

Bismuth is relatively nontoxic, the least so of the heavy metals. It is generally not an industrial hazard. Although bismuth and certain of its compounds find considerable therapeutic use, some authorities recommend that other remedies be substituted. Soluble inorganic bismuth compounds are toxic.

Isotopes of bismuth. Bismuth forms only one stable isotope, that of mass 209. A large number of radioactive isotopes are known, as shown in the table, most of them being very unstable. (R.T.S./Ed.)

Oxygen group elements

Oxygen, sulfur, selenium, tellurium, and polonium comprise the family referred to in the periodic classification of the chemical elements as Group VIa, or the chalcogens (see Figure 10). A relationship among the first three members of the group was recognized as early as 1829; tellurium was assigned its place by 1865, and the discovery of polonium in 1898 completed the group. By the early 1970s, the possibility of finding element 116, the next member of Group VIa, in nature appeared to be negligible.

Estimates of the proportions of the various kinds of atoms in the universe put oxygen fourth in abundance, after hydrogen, helium, and neon, but the importance of such a ranking is slight since hydrogen atoms account for almost 94 percent of the total and helium for most of the rest. About three atoms out of 10,000 are oxygen, but because the mass of an oxygen atom is approximately 16 times that of a hydrogen atom, oxygen constitutes a larger fraction of the mass of the universe, though still only about 0.5 percent. In the regions ordinarily accessible to man, however—*i.e.,* within a few kilometres of the surface of the Earth—oxygen is the most abundant element: in mass, it makes up about 20 percent of the air, about 46 percent of the solid crust of the Earth, and about 89 percent of the water.

Oxygen is represented by the chemical symbol O. In the air, oxygen exists mostly as molecules each made up of two atoms (O_2), although small amounts of ozone (O_3), in which three atoms of oxygen make up each molecule, are present in the atmosphere. Oxygen is a colourless, odourless, tasteless gas essential to living organisms, being taken up by animals, which convert it to carbon dioxide; plants, in turn, utilize carbon dioxide as a source of carbon and return the oxygen to the atmosphere. Oxygen forms compounds by reaction with practically any other element, as well as by reactions that displace elements from their combinations with each other; in many cases, these processes are accompanied by the evolution of heat and light and in such cases are called combustions.

Cosmic abundance of sulfur

In cosmic abundance, sulfur ranks ninth among the elements, accounting for only one atom of every 20,000–30,000. Sulfur occurs in the uncombined state as well as in combination with other elements in rocks and minerals that are widely distributed, although it is classified among the minor constituents of the Earth's crust, in which its proportion is estimated to be between 0.03 and 0.06 percent. On the basis of the finding that certain meteorites contain about 12 percent sulfur, it has been suggested that deeper layers of the Earth contain a much larger proportion. Seawater contains about 0.09 percent sulfur in the form of sulfate. The most important source is underground deposits of very pure sulfur present in domelike geologic structures where the sulfur is believed to have been formed by the action of bacteria upon the mineral anhydrite, in which sulfur is combined with oxygen and calcium. Deposits of sulfur in volcanic regions probably originated from gaseous hydrogen sulfide generated below the surface of the Earth and transformed into sulfur by reaction with the oxygen in the air.

Sulfur exists under ordinary conditions as a pale yellow, crystalline, nonmetallic solid; it is odourless and tasteless, combustible, and insoluble in water. Its chemical symbol is S. It reacts with all metals except gold and platinum, forming sulfides; it also forms compounds with several of the nonmetallic elements. Several million tons of sulfur are produced each year, mostly for the manufacture of sulfuric acid, which is widely used in industry.

The element selenium (symbol Se) is much rarer than oxygen or sulfur, comprising approximately 90 parts per billion of the crust of the Earth. It is occasionally found uncombined, accompanying native sulfur, but is more often found in combination with heavy metals (as copper, mercury, lead, or silver) in a few minerals. The principal commercial source of selenium is as a by-product of copper refining; its major uses are in the manufacture of electronic equipment, in pigments, and in making glass. The gray, metallic form of the element is the most stable under ordinary conditions; this form has the unusual property of greatly increasing in electrical conductivity when exposed to light. Selenium compounds are toxic to animals; plants grown in seleniferous soils may concentrate the element and become poisonous.

Tellurium is a silvery-white element (symbol Te) with properties intermediate between those of metals and nonmetals; it makes up approximately one part per billion of the Earth's crust. Like selenium, it is less often found uncombined than as compounds of metals such as copper, lead, silver, or gold, and is obtained chiefly as a by-product of the refining of copper or lead. No large use for tellurium has been found.

Polonium (symbol Po) is an extremely rare, radioactive element found in minerals containing uranium. It has some scientific applications as a source of alpha radiation.

HISTORY

Oxygen. Although several substances now recognized as elements were known in their uncombined states in ancient times, the presently accepted idea of chemical elements dates from 1661, when the English natural philosopher Robert Boyle set forth their nature as simple, primitive, perfectly unmixed bodies, not formed from each other nor from any other bodies. Despite its terrestrial abundance, oxygen was not recognized as belonging to this class before the 1770s. Two chemists, Carl Wilhelm Scheele, in about 1772, and Joseph Priestley, in 1774, both obtained oxygen by heating certain metal oxides. Antoine-Laurent Lavoisier, with remarkable insight, interpreted the role of oxygen in respiration as well as combustion, discarding the phlogiston theory, which had been accepted up to that time; he noted its tendency to form acids by combining with many different substances and accordingly named the element *oxygen* (*oxygène*) from the Greek words for "acid former."

Boyle's definition of chemical elements

Sulfur. The history of sulfur is part of antiquity. The name itself probably found its way into Latin from the language of the Oscans, an ancient people who inhabited the region including Vesuvius, where sulfur deposits are widespread. Prehistoric man used sulfur as a pigment for cave painting; one of the first recorded instances of the art of medication is in the use of sulfur as a tonic.

The combustion of sulfur had a role in Egyptian religious ceremonials as long as 4,000 years ago. "Fire and brimstone" references in the Bible are related to sulfur, suggesting that "hell's fires" are fuelled by sulfur. The beginnings of practical and industrial uses of sulfur are credited to the Egyptians, who used sulfur dioxide for bleaching cotton as early as 1600 BC. Greek mythology includes sulfur chemistry: Homer tells of Odysseus' use of sulfur dioxide to fumigate a chamber in which he had slain his wife's suitors. The use of sulfur in explosives and fire displays dates to about 500 BC in China, and flameproducing agents used in warfare (Greek fire) were prepared with sulfur in the Middle Ages. Pliny the Elder in AD 50 reported a number of individual uses of sulfur and ironically was himself killed, in all probability by sulfur fumes, at the time of the great Vesuvius eruption (AD 79). Sulfur was regarded by the alchemists as the principle of combustibility. Lavoisier recognized it as an element in 1777, although it was considered by some to be a compound of hydrogen and oxygen; its elemental nature was established by the French chemists Joseph Gay-Lussac and Louis Thenard.

Selenium. In 1817 a Swedish chemist named Jöns Jacob Berzelius noted a red substance resulting from sulfide ores from mines of Fahlun (Falun), Sweden. When this red material was investigated in the following year, it proved to be an element and was named after the Moon or the Moon goddess Selene. An ore of unusually high selenium content was discovered by Berzelius only days before he made his report to the scientific societies of the world on selenium. His sense of humour is evident in the name he gave the ore, *eucairite,* meaning "just in time."

Tellurium. The element tellurium was isolated before it was actually known to be an elemental species. About 1782 Franz Joseph Müller von Reichenstein, an Austrian mineralogist, worked with an ore referred to as German gold. From this ore he obtained a material that defied his attempts at analysis and was called by him *metallum problematicum.* In 1798 Martin Heinrich Klaproth confirmed Müller's observations and established the elemental nature of the substance. He named the element after man's "heavenly body" Tellus, or Earth.

Polonium. The fifth member of Group VIa, polonium, was the first to be found by taking advantage of the phenomenon of radioactivity, discovered by Henri Becquerel in the last part of the 19th century. Pierre and Marie Curie isolated the element while carrying out analyses on a uranium ore, pitchblende. The very intense radioactivity not attributable to uranium was ascribed to a new element, named by them after Mme Curie's homeland, Poland. The discovery was announced in July 1898.

Intense radioactivity of polonium

COMPARISON OF PROPERTIES

The elements belonging to Group VIa of the periodic table are characterized by electron configurations in which six electrons occupy the outermost shell. An atom having such an electronic structure tends to form a stable shell of eight electrons by adding two more, producing an ion that has a double negative charge. This tendency to form negatively charged ions, typical of nonmetallic elements, is quantitatively expressed in the properties of electronegativity (the assumption of partial negative charge when present in covalent combination) and electron affinity (the ability of a neutral atom to take up an electron, forming a negative ion). Both these properties decrease in intensity as the elements increase in atomic number and mass proceeding down column VIa of the periodic table. Oxygen has, except for fluorine, the highest electronegativity and electron affinity of any element; the values of these properties then decrease sharply for the remaining members of the group to the extent that tellurium and polonium are regarded as predominantly metallic in nature, tending to lose rather than gain electrons in compound formation.

As is the case within all groups of the table, the lightest element—the one of smallest atomic number—has extreme or exaggerated properties. Oxygen, because of the small size of its atom, the small number of electrons in its underlying shell, and the large number of protons in the nucleus relative to the atomic radius, has properties uniquely different from those of sulfur and the remaining chalcogens. Those elements behave in a reasonably predictable and periodic fashion, as will be shown.

Although even polonium exhibits the oxidation state −2 in forming a few binary compounds of the type MPo (in which M is a metal), the heavier chalcogens do not form the negative state readily, favouring positive states such as +2 and +4. All the elements in the group except oxygen may assume positive oxidation states, with the even values predominating, but the highest value, +6, is not a very stable one for the heaviest members. When this state is achieved, there is a strong driving force for the atom to return to a lower state, quite often to the elemental form. This tendency makes compounds containing Se(VI) and Te(VI) more powerful oxidizing agents than S(VI) compounds. Conversely, sulfides, selenides, and tellurides, in which the oxidation state is −2, are strong reducing agents, easily oxidized to the free elements.

Neither sulfur nor selenium, and most certainly not oxygen, forms purely ionic bonds to a nonmetal atom. Tellurium and polonium form a few compounds that are somewhat ionic; tellurium(IV) sulfate, $Te(SO_4)_2$, and polonium(II) sulfate, $PoSO_4$, are examples.

Another feature of the Group VIa elements that parallels trends generally shown in columns of the periodic table is the increasing stability of molecules having the composition $X(OH)_n$ as the size of the central atom, X, increases. There is no compound HO—O—OH, in which the central oxygen atom would have a positive oxidation state, a condition that it resists. The analogous sulfur compound HO—S—OH, although not known in the pure state, does have a few stable derivatives in the form of metal salts, the sulfoxylates. More highly hydroxylated compounds of sulfur, $S(OH)_4$ and $S(OH)_6$, also do not exist, not because of sulfur's resistance to a positive oxidation state but rather because of the high charge density of the S(IV) and S(VI) states (the large number of positive charges relative to the small diameter of the atom), which repels the electropositive hydrogen atoms, and the crowding that attends covalent bonding of six oxygen atoms to sulfur, favouring loss of water:

$$S(OH)_6 \longrightarrow (HO)_2SO_2 + 2H_2O.$$

orthosulfuric acid   sulfuric acid   water

As the size of the chalcogen atom increases, the stability of the hydroxylated compounds increases: the compound orthotelluric acid, $Te(OH)_6$, is capable of existence.

Catenation. One of the most unusual properties of this family of elements is that of catenation or the bonding of an atom to another identical atom. Although oxygen shows this property only in the existence of ozone, sulfur is second only to carbon in exhibiting this mode of combination; the chalcogens beyond sulfur show it to diminishing degrees, polonium having no tendency to catenate. This type of bonding is found in the many ring systems of sulfur and selenium as well as in long zigzag chain structures. Catenation also occurs in the sulfanes and the metal polysulfides, compounds that have the formulas H_2S_x and M_2S_x, in which x may take the values of 2, 3, 4, or more, and M represents a singly charged metal ion. In comparing the catenation of sulfur atoms with that of carbon atoms, it may be noted that the number of molecular species having $(-S-)_x$ structures is very large, as is that of the analogous hydrocarbon compounds $(-CH_2-)_x$. The analogy between molecules containing rings of sulfur atoms and cyclic hydrocarbons is limited because only S_6 and S_8 have sufficient stability to permit proper comparison to be made. The general similarity extends to molecules of the form $Z(-S-)_xZ$ and $Z(-CH_2-)_xZ$, which are represented by compounds in which Z is H, SO_3H, and CF_3.

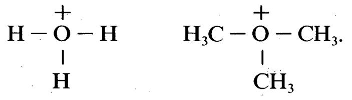
Covalent links between sulfur atoms have some of the character of multiple bonds—that is, more than one pair of electrons is shared, at least to some extent. Such interactions may involve overlap of p orbitals of one sulfur atom with d orbitals of another. Although not all investigators feel alike on the subject of d-orbital participation in the bonding of sulfur compounds, partial occupation of these orbitals is consistent with certain properties such as the colours of S_8 and S_2 molecules, the rigidity of chains and rings of sulfur atoms, and other features of the chemistry of sulfur compounds.

Manifestations of the similarities between sulfur and oxygen

Similarities of sulfur and oxygen are exhibited in certain compounds in which these elements interchange for one another. Examples include sulfates and thiosulfates (such as Na_2SO_4 and $Na_2S_2O_3$), phosphates and thiophosphates (containing the ions PO_4^{3-}, PO_3S^{3-}, $PO_2S_2^{3-}$, POS_3^{3-}, and PS_4^{3-}), and a similar series of arsenates and thioarsenates.

Ores of heavy metals often are found as both sulfides, MS, and selenides, MSe, or even with MS_xSe_y structures. The similarity in structures as well as properties accounts for the chalcogens' being found together in nature.

The number of atoms to which an element of Group VIa can form covalent bonds increases from oxygen to sulfur. An oxygen atom usually combines with two other atoms, as in the compounds water (H_2O), oxygen fluoride (OF_2), or dimethyl ether ($H_3C-O-CH_3$); the unshared pairs of electrons and the partial negative charge on the oxygen atom in most of these compounds allows bonding to another atom, as in the hydronium ion or trimethyloxonium ion:



$$\overset{+}{H-O-H} \quad \text{with } H \text{ below O} \qquad H_3C-\overset{+}{O}-CH_3. \text{ with } CH_3 \text{ below O}$$

hydronium ion   trimethyloxonium ion

Heavier members of the group associate or coordinate with other atoms or groups of atoms in numbers commensurate with the size of both the chalcogen and the coordinating group. Thus, sulfur tetrafluoride (SF_4) and sulfur hexafluoride (SF_6) are stable compounds, although sulfur hexaiodide (SI_6) is not known because of the very large size of the iodine atom. A closely related property is that of anionic complex formation: there is little evidence for the ion SF_6^{2-}, but there are ions such as $TeCl_6^{2-}$, TeF_6^{2-}, and PoI_6^{2-}.

Isotopes. The known isotopes of each of the Group VIa elements are listed in Table 20. Consistent with a generality observed throughout the periodic system, isotopes of even mass number are more abundant than those of odd mass number. Each member of the group except polonium has several stable isotopes; oxygen-18 and sulfur-35 have been used as tracers in chemical analysis, and polonium-210 serves as a convenient source of alpha particles (nuclei of helium atoms) for nuclear reactors and nuclear batteries.

INDIVIDUAL CHALCOGENS

Oxygen. *Natural occurrence and distribution.* As mentioned earlier, oxygen makes up about 46 percent of the mass of the crust of the Earth. In rocks, it is combined with metals and nonmetals in the form of oxides that are acidic (such as those of sulfur, carbon, aluminum, and phosphorus) or basic (such as those of calcium, magnesium, and iron) and as saltlike compounds that may be regarded as formed from the acidic and basic oxides, as sulfates, carbonates, silicates, aluminates, and phosphates. Plentiful as they are, these solid compounds are not useful as sources of oxygen, because separation of the element from its tight combinations with the metal atoms is too expensive.

Allotropy. Oxygen has two allotropic forms, diatomic (O_2) and triatomic (O_3, ozone). The properties of the diatomic form suggest that six electrons bond the atoms and two electrons remain unpaired, accounting for the paramagnetism of oxygen. The three atoms in the ozone molecule do not lie along a straight line.

Ozone may be produced from oxygen according to the equation:

$$3O_2 \longrightarrow 2O_3.$$

oxygen   ozone

Production of ozone

The process, as written, is endothermic (energy must be provided to make it proceed); conversion of ozone back into diatomic oxygen is promoted by the presence of transition metals or their oxides. Pure oxygen is partly transformed into ozone by a silent electrical discharge; the reaction is also brought about by absorption of ultraviolet light of wavelengths around 250 nanometres (nm, the nanometre, equal to 10^{-9} metre); occurrence of this process in the upper atmosphere removes radiation that

*No stable isotopes. †Two isotopes.

would be harmful to life on the surface of the Earth. The pungent odour of ozone is noticeable in confined areas in which there is sparking of electrical equipment, as in generator rooms. Ozone is light blue; its density is 1.658 times that of air, and it has a boiling point of −112° C at atmospheric pressure.

Ozone is a powerful oxidizing agent, capable of converting sulfur dioxide to sulfur trioxide, sulfides to sulfates, iodides to iodine (providing an analytical method for its estimation), and many organic compounds to oxygenated derivatives such as aldehydes and acids. The conversion by ozone of hydrocarbons from automotive exhaust gases to these acids and aldehydes contributes to the irritating nature of smog. Commercially, ozone has been used as a chemical reagent, as a disinfectant, in sewage treatment, water purification, and bleaching textiles.

Preparative methods. Production methods chosen for oxygen depend upon the quantity of the element desired. Laboratory procedures include the following:

1. Thermal decomposition of certain salts, such as potassium chlorate or potassium nitrate:

$$\begin{array}{ccccc} 2KClO_3 & \longrightarrow & 2KCl & + & 3O_2 \\ \text{potassium chlorate} & & \text{potassium chloride} & & \text{oxygen} \end{array}$$

$$\begin{array}{ccccc} 2KNO_3 & \longrightarrow & 2KNO_2 & + & O_2. \\ \text{potassium nitrate} & & \text{potassium nitrite} & & \text{oxygen} \end{array}$$

The decomposition of potassium chlorate is catalyzed by oxides of transition metals; manganese dioxide (pyrolusite,-MnO_2) is frequently used. The temperature necessary to effect the evolution of oxygen is reduced from 400° C to 250° by the catalyst.

2. Thermal decomposition of oxides of heavy metals:

$$\begin{array}{ccccc} 2HgO & \longrightarrow & 2Hg & + & O_2 \\ \text{mercury(II) oxide} & & \text{mercury} & & \text{oxygen} \end{array}$$

$$\begin{array}{ccccc} 2Ag_2O & \longrightarrow & 4Ag & + & O_2. \\ \text{silver(I) oxide} & & \text{silver} & & \text{oxygen} \end{array}$$

Scheele and Priestley used mercury(II) oxide in their preparations of oxygen.

3. Thermal decomposition of metal peroxides or of hydrogen peroxide:

$$\begin{array}{ccccc} 2BaO & + & O_2 & \xrightarrow{\text{heat}} & 2BaO_2 \\ \text{barium oxide} & & \text{oxygen (from air)} & & \text{barium peroxide} \end{array}$$

$$\begin{array}{ccccc} 2BaO_2 & \xrightarrow{\text{heat}} & 2BaO & + & O_2 \\ \text{barium peroxide} & & \text{barium oxide} & & \text{oxygen} \end{array}$$

$$\begin{array}{ccccccc} BaO_2 & + & H_2SO_4 & \longrightarrow & H_2O_2 & + & BaSo_4 \\ \text{barium peroxide} & & \text{sulfuric acid} & & \text{hydrogen peroxide} & & \text{barium sulfate} \end{array}$$

$$\begin{array}{ccccc} 2H_2O_2 & \xrightarrow[\text{catalyst}]{\text{heat or}} & 2H_2O & + & O_2 \\ \text{hydrogen peroxide} & & \text{water} & & \text{oxygen} \end{array}$$

An early commercial procedure for isolating oxygen from the atmosphere or for manufacture of hydrogen peroxide depended on the formation of barium peroxide from the oxide as shown in the equations.

4. Electrolysis of water containing small proportions of salts or acids to allow conduction of the electric current:

$$\begin{array}{ccccc} 2H_2O & \xrightarrow[\text{electric current}]{H_2SO_4} & 2H_2 & + & O_2. \\ \text{water} & & \text{hydrogen} & & \text{oxygen} \end{array}$$

Oxygen from the air

Commercial production and use. When required in tonnage quantities, oxygen is prepared by the fractional distillation of liquid air. The process takes advantage of the fact that when a compressed gas is allowed to expand, it cools. Major steps in the operation include the following: (1) Air is filtered to remove particulates; (2) moisture and carbon dioxide are removed by absorption in alkali; (3) the air is compressed and the heat of compression removed by ordinary cooling procedures; (4) the compressed and cooled air is passed into coils contained in a chamber; (5)

a portion of the compressed air (at about 200 atmospheres pressure) is allowed to expand in the chamber, cooling the coils; (6) the expanded gas is returned to the compressor with multiple subsequent expansion and compression steps resulting finally in liquefaction of the compressed air at a temperature of −196° C; (7) the liquid air is allowed to warm to distill first the light rare gases, then the nitrogen, leaving liquid oxygen. Multiple fractionations will produce a product pure enough (99.5 percent) for most industrial purposes.

The steel industry is the largest consumer of pure oxygen in "blowing" high carbon steel—that is, volatilizing carbon dioxide and other nonmetal impurities in a more rapid and more easily controlled process than if air were used. The treatment of sewage by oxygen holds promise for more efficient treatment of liquid effluents than other chemical processes. Incineration of wastes in closed systems using pure oxygen has become important. The so-called LOX of rocket oxidizer fuels is liquid oxygen; the consumption of LOX depends upon the activity of space programs. Pure oxygen is used in a multitude of breathing devices, submarines, diving bells, and in hospitals.

Chemical properties and reactions. The large values of the electronegativity and the electron affinity of oxygen are typical of elements that show only nonmetallic behaviour. In all of its compounds, oxygen assumes a negative oxidation state as is expected from the two half-filled outer orbitals. When these orbitals are filled by electron transfer, the oxide ion O^{2-} is created. In peroxides (species containing the ion O_2^{2-}) it is assumed that each oxygen has a charge of −1. This property of accepting electrons by complete or partial transfer defines an oxidizing agent. When such an agent reacts with an electron-donating substance, its own oxidation state is lowered. The change (lowering), from the zero to the −2 state in the case of oxygen, is called a reduction. Oxygen may be thought of as the "original" oxidizing agent, the nomenclature used to describe oxidation and reduction being based upon this behaviour typical of oxygen.

As described in the section on allotropy, oxygen forms the diatomic species, O_2, under normal conditions and, as well, the triatomic species ozone, O_3. There is some evidence for a very unstable tetratomic species, O_4. In the molecular diatomic form there are two unpaired electrons that lie in antibonding orbitals. The paramagnetic behaviour of oxygen confirms the presence of such electrons.

Reactivity of ozone

The intense reactivity of ozone is sometimes explained by suggesting that one of the three oxygen atoms is in an "atomic" state; on reacting, this atom is dissociated from the O_3 molecule, leaving molecular oxygen.

The molecular species, O_2, is not especially reactive at normal (ambient) temperatures and pressures. The atomic species, O, is far more reactive. The energy of dissociation ($O_2 \rightarrow 2O$) is large at 117.2 kilocalories per mole.

Sulfur. *Natural occurrence and distribution.* Many important metal ores are compounds of sulfur, either sulfides or sulfates. Some important examples are galena (lead sulfide, PbS), blende (zinc sulfide, ZnS), pyrite (iron disulfide, FeS_2), chalcopyrite (copper iron sulfide, $CuFeS_2$), gypsum (calcium sulfate dihydrate, $CaSO_4 \cdot 2H_2O$) and barite (barium sulfate, $BaSO_4$). The sulfide ores are valued chiefly for their metal content, although a process developed in the 18th century for making sulfuric acid utilized sulfur dioxide obtained by burning pyrite.

Allotropy. In sulfur, allotropy arises from two sources: (1) the different modes of bonding atoms into a single molecule and (2) packing of polyatomic sulfur molecules into different crystalline and amorphous forms. Some 30 allotropic forms of sulfur have been reported, but some of these probably represent mixtures. Only eight of the 30 seem to be unique; five contain rings of sulfur atoms and the others contain chains.

In the rhombohedral allotrope, designated ρ-sulfur, the molecules are composed of rings of six sulfur atoms. This form is prepared by treating sodium thiosulfate with cold, concentrated hydrochloric acid, extracting the residue with toluene, and evaporating the solution to give hexagonal crystals. ρ-sulfur is unstable, eventually reverting to orthorhombic sulfur (α-sulfur).

A second general allotropic class of sulfur is that of the eight-membered ring molecules, three crystalline forms of which have been well characterized. One is the orthorhombic (often improperly called rhombic) form, α-sulfur. It is stable at temperatures below 96° C. Another of the crystalline S_8 ring allotropes is the monoclinic or β-form, in which two of the axes of the crystal are perpendicular, but the third forms an oblique angle with the first two. There are still some uncertainties concerning its structure; this modification is stable from 96° C to the melting point, 118.9° C. A second monoclinic cyclooctasulfur allotrope is the γ-form, unstable at all temperatures, quickly transforming to α-sulfur.

An orthorhombic modification, S_{12} ring molecules, and still another unstable S_{10} ring allotrope are reported. The latter reverts to polymeric sulfur and S_8. At temperatures above 96° C, the α-allotrope changes into the β-allotrope. If enough time is allowed for this transition to occur completely, further heating causes melting to occur at 118.9° C; but if the α-form is heated so rapidly that the transformation to β-form does not have time to occur, the α-form melts at 112.8° C.

Effects of heating sulfur

Just above its melting point, sulfur is a yellow, transparent, mobile liquid. Upon further heating, the viscosity of the liquid decreases gradually to a minimum at about 157° C, but then rapidly increases, reaching a maximum value at about 187° C; between this temperature and the boiling point of 444.6° C, the viscosity decreases. The colour also changes, deepening from yellow through dark red, and, finally, to black at about 250° C. The variations in both colour and viscosity are considered to result from changes in the molecular structure. A decrease in viscosity as temperature increases is typical of liquids, but the increase in the viscosity of sulfur above 157° C probably is caused by rupturing of the eight-membered rings of sulfur atoms to form reactive S_8 units that join together in long chains containing many thousands of atoms. The liquid then assumes the high viscosity characteristic of such structures. At a sufficiently high temperature, all of the cyclic molecules are broken, and the length of the chains reaches a maximum. Beyond that temperature, the chains break down into small fragments. Upon vaporization, cyclic molecules (S_8 and S_6) are formed again; at about 900° C, S_2 is the predominant form; finally, monatomic sulfur is formed at temperatures above 1,800° C.

Commercial production. Elemental sulfur is found in volcanic regions as a deposit formed by the emission of hydrogen sulfide, followed by aerial oxidation to the element. Underground deposits of sulfur associated with salt domes in limestone rock provide a substantial portion of the world's supply of the element. These domes are located in the Louisiana swamplands of the United States and offshore in the Gulf of Mexico.

Frasch process

Herman Frasch, a German-born U.S. chemist, developed a process, subsequently known by his name, for extracting and raising pure sulfur from these deposits, which may be situated anywhere from a few hundred to several thousands of metres below the suface. Ordinary underground mining procedures are inapplicable since highly poisonous hydrogen sulfide gas accompanies the element in the domes.

The Frasch process takes advantage of the low melting point of sulfur, about 112° C. Water heated above this temperature (under pressure) is pumped down one of three concentric pipes, melting the sulfur. Compressed air is then forced down an inner pipe forming a froth of the molten sulfur, which is then forced up through the middle concentric pipe to the surface, where it is either pumped into bins for storage or into barges or ships for transporting to industrial areas for conversion, for the most part, to sulfuric acid. The availability of cheap, very pure sulfur from this process eliminated much of the need to mine sulfur from sulfides and volcanic sulfur-bearing rock for many years. By the mid-20th century the purification of sour (high sulfur-content) petroleum and improved methods for obtaining sulfur from metal sulfides had increased sulfur production from non-Frasch sources.

A few of the non-Frasch processes for sulfur production may be mentioned.

Other recovery processes

(1) Sulfur-bearing rock is piled into mounds. Shafts are bored vertically and fires set at the top of the shafts. The burning sulfur provides sufficient heat to melt the elemental sulfur in the rock layers below, and it flows out at the bottom of the pile. This is an old process, still used to some extent in Sicily. The product is of low purity and must be refined by distillation. The air pollution in the area of the process is so great that its operation is limited to certain times of the year when prevailing winds will carry the fumes away from populated areas.

(2) Rock bearing sulfur is treated with superheated water in retorts, melting the sulfur, which flows out. This process is a modification of the Frasch method.

(3) Sulfates (such as gypsum or barite) may be treated with carbon at high temperatures, forming the metal sulfides, CaS or BaS (the Chance–Claus process). The metal sulfides can be treated with acid, generating hydrogen sulfide, which in turn can be burned to give elemental sulfur.

(4) Tremendous tonnages of sulfur are available from smelter operations and from power production by combustion of fossil and sour petroleum fuels, some of which contain as much as 4 percent sulfur. Thus, generation of electrical power and heat represent a major source of atmospheric pollution by sulfur dioxide. Unfortunately, recovery and purification of sulfur dioxide from stack gases are expensive operations.

Wherever such metals as lead, zinc, copper, cadmium, or nickel (among others) are processed, much of the sulfuric acid needed in the metallurgical operations may be obtained on the site by converting sulfur dioxide, produced by roasting the ores, to sulfur trioxide, SO_3, and thence to sulfuric acid.

Sulfur available in bulk from commercial production usually is more than 99 percent pure, and some grades contain 99.9 percent sulfur. For research purposes, the proportion of impurities has been reduced to as little as one part in 10,000,000 by the application of procedures such as zone melting, column chromatography, electrolysis, or fractional distillation.

Conversion into sulfuric acid

Uses of sulfur. Sulfur is so widely used in industrial processes that its consumption often is regarded as a reliable indicator of industrial activity and the state of the national economy. Approximately six-sevenths of all the sulfur produced is converted into sulfuric acid, for which the largest single use is in the manufacture of fertilizers (phosphates and ammonium sulfate). Other important uses include the production of pigments, detergents, fibres, petroleum products, sheet metal, explosives, and storage batteries; hundreds of other applications are known. Sulfur not converted to sulfuric acid is used in making paper, insecticides, fungicides, dyestuffs, carbon disulfide (a solvent employed in making rayon, cellophane, and industrial chemicals), and numerous other products.

Selenium. *Occurrence and distribution.* The proportion of selenium in the Earth's crust is about 10^{-5} to 10^{-6} percent. It has been obtained mainly from the anode slimes (deposits and residual materials from the anode) in electrolytic refining of copper and nickel. Other sources are the flue dusts in copper and lead production and the gases formed in roasting pyrites. Selenium accompanies copper in the refining of that metal: about 40 percent of the selenium present in the original ore may concentrate in copper deposited in electrolytic processes. About 1.5 kilograms of selenium can be obtained from a ton of smelted copper.

Allotropy. The allotropy of selenium is not as extensive as that of sulfur, and the allotropes have not been studied as thoroughly. Only two crystalline varieties of selenium are composed of cyclic Se_8 molecules: designated α and β, both exist as red monoclinic crystals. A gray allotrope having metallic properties is formed by keeping any of the other forms at 200°–220° C.

An amorphous (noncrystalline), red, powdery form of selenium results when a solution of selenious acid or one of its salts is treated with sulfur dioxide. If the solutions are very dilute, extremely fine particles of this variety yield a transparent red colloidal suspension. Clear red glass results from a similar process that occurs when molten glass containing selenites is treated with carbon. A glassy, almost black variety of selenium is formed by rapid cooling of other modifications from temperatures above 200° C. Conversion of this vitreous form to the red, crystalline allotropes takes place upon heating it above 90° C or upon keeping it in contact with organic solvents, such as chloroform, ethanol, or benzene.

Preparation. Pure selenium is obtained from the slimes and sludges formed in producing sulfuric acid. The impure red selenium is dissolved in sulfuric acid in the presence of an oxidizing agent, such as potassium nitrate or certain manganese compounds. Both selenious acid, H_2SeO_3, and selenic acid, H_2SeO_4, are formed and can be leached from residual insoluble material. Other methods utilize oxidation by air (roasting) and heating with sodium carbonate to give soluble sodium selenite, $Na_2SeO_3 \cdot 5H_2O$, and sodium selenate, Na_2SeO_4. Chlorine may also be employed: its action upon metal selenides produces volatile compounds including selenium dichloride, $SeCl_2$; selenium tetrachloride, $SeCl_4$; diselenium dichloride, Se_2Cl_2; and selenium oxychloride, $SeOCl_2$. In one process, these selenium compounds are converted by water to selenious acid. The selenium is finally recovered by treating the selenious acid with sulfur dioxide.

Selenium is a common component of ores valued for their content of silver or copper; it becomes concentrated in the slimes deposited during electrolytic purification of the metals. Methods have been developed to separate selenium from these slimes, which also contain some silver and copper. Melting the slime forms silver selenide, Ag_2Se, and copper(I) selenide, Cu_2Se. Treatment of these selenides with hypochlorous acid, HOCl, gives soluble selenites and selenates, which can be reduced with sulfur dioxide. Final purification of selenium is accomplished by repeated distillation.

Photoconductivity of selenium

Physical–electrical properties. The most outstanding physical property of crystalline selenium is its photoconductivity: on illumination, the electrical conductivity increases more than 1,000-fold. This phenomenon results from the promotion or excitation of relatively loosely held electrons by light to higher energy states (called the conduction levels), permitting electron migration and, thus, electrical conductivity. In contrast the electrons of typical metals are already in conduction levels or bands, able to flow under the influence of an electromotive force.

The electrical resistivity of selenium varies over a tremendous range, depending upon such variables as the nature of the allotrope, impurities, the method of refining, temperature, and pressure. Most metals are insoluble in selenium, and nonmetallic impurities increase the resistivity.

Illumination of crystalline selenium for 0.001 second increases its conductivity by a factor of 10 to 15 times. Red light is more effective than light of shorter wave length.

Advantage is taken of these photoelectric and photosensitivity properties of selenium in the construction of a variety of devices that can translate variations in light intensity into electric current and thence to visual, magnetic, or mechanical effects. Alarm devices, mechanical opening and closing devices, safety systems, television, sound films, and xerography depend upon the semiconducting property and photosensitivity of selenium. Rectification of alternating electrical current (conversion into direct current) has for years been accomplished by selenium-controlled devices. Many photocell applications using selenium have been replaced by other devices using materials more sensitive, more readily available, and more easily fabricated than selenium.

Tellurium. *Occurrence and preparation.* The demand for tellurium does not match that for selenium. The two elements are found together in many ores; they may be isolated by employing the processes described in connection with selenium, obtaining solutions containing salts of both selenious and tellurous acids, H_2SeO_3 and H_2TeO_3. Upon treatment of these solutions with sulfuric acid, tellurium dioxide, TeO_2, separates because of its low solubility, while the selenious acid remains dissolved. The tellurium dioxide can be converted into elemental tellurium by treatment with sulfur dioxide; an electrolytic process is used to purify the product.

Physical and chemical properties. In tellurium, the covalent bonding necessary to provide large ring- and chain-molecules by catenation is almost nonexistent. The element crystallizes in the rhombohedral form. It is silvery white and isomorphous with gray selenium—that is, the structure and dimensions of the crystals are very similar. It is brittle but not very hard. The tellurium atoms form spiral chains in the crystal with Te–Te distances of 3.74 Å. There are no good solvents for tellurium, although certain compounds oxidize or reduce the element to soluble substances. The photoconductivity of tellurium is not as pronounced as that of selenium, and tellurium does not have major industrial uses.

Polonium. The existence of polonium in pitchblende, an ore of uranium, was noted by the Curies. Polonium is extremely rare, even in pitchblende: 1,000 tons of the ore must be processed to obtain 40 milligrams of polonium. In the chemical isolation, the ore is treated with hydrochloric acid, and the resulting solution is heated with hydrogen sulfide to precipitate polonium monosulfide, PoS, along with other metal sulfides, such as that of bismuth, Bi_2S_3, which resembles polonium monosulfide closely in chemical behaviour, though it is less soluble. Because of the difference in solubility, repeated partial precipitation of the mixture of sulfides concentrates the polonium in the more soluble fraction, while the bismuth accumulates in the less soluble portions. The difference in solubility is small, however, and the process must be repeated many times to achieve a complete separation. Purification is accomplished by electrolytic deposition.

Purification process

Two modifications of polonium are known, an α- and a β-form, both of which are stable at room temperature and possess metallic character. The fact that its electrical conductivity decreases as the temperature increases places polonium among the metals rather than the metalloids or nonmetals. (R.C.Br./Ed.)

Halogen elements

Fluorine (F), chlorine (Cl), bromine (Br), iodine (I), and astatine (At) are the members of the family of halogen elements, and they constitute Group VIIa of the periodic table (see Figure 10). They were given the name halogen from the Greek roots *hal-* ("salt") and *gen* ("to produce"), because they all produce sodium salts of similar properties, of which sodium chloride, table salt, is the best known. Because of their great reactivity, the free halogen elements are not found in nature. In combined form, fluorine is the most abundant of the halogens in the Earth's crust. The percentages of the halogens in the igneous rocks of the Earth's crust are 0.06 fluorine, 0.031 chlorine, 0.00016 bromine, and 0.00003 iodine. Astatine does not occur in nature because it consists only of short-lived radioactive isotopes.

The halogen elements show great resemblances to one another in their general chemical behaviour and in the properties of their compounds with other elements. There is, however, a progressive change in properties from fluorine through chlorine, bromine, and iodine to astatine—the difference between two successive elements being most pronounced with fluorine and chlorine. Fluorine is the most reactive of the halogens and, in fact, of all elements, and it has certain other properties that set it apart (see below *General properties of the halogens*).

Chlorine is the best known of the halogen elements. The free element is widely used as a water purification agent, and it is employed in a number of chemical processes. Sodium chloride, of course, is one of the most familiar of chemical compounds. Fluorides are known chiefly for the controversy over their addition to public water supplies to prevent tooth decay, but organic fluorides are also used as refrigerants and lubricants. Iodine is most familiar as an antiseptic, and bromine is used chiefly to prepare a gasoline additive (ethylene dibromide) that prevents deposits of lead in engines.

HISTORY

Rock salt (common salt, sodium chloride) has been known for several thousand years; it is the main constituent of the salts dissolved in seawater, from which it was obtained in ancient Egypt by evaporation. In 1648 the German chemist Johann Rudolf Glauber obtained a strong acid, which he called spirit of salt, by heating moist salt in a charcoal furnace and condensing the fumes in a receiver. Later he obtained the same product, now known to be hydrochloric acid, by heating salt with sulfuric acid.

In 1774 the Swedish chemist Carl Wilhelm Scheele treated powdered black oxide of manganese with hydrochloric acid and obtained a greenish-yellowish gas, which he failed to recognize as an element. The true nature of the gas as an element was recognized in 1810 by Sir Humphry Davy, who later named it chlorine and provided an explanation for its bleaching action.

In 1811 the French chemist Bernard Courtois obtained a violet vapour by heating seaweed ashes with sulfuric acid. This vapour condensed to a black crystalline substance, which he called "substance X." In 1813 Davy, who was passing through Paris on his way to Italy, recognized substance X as an element analogous to chlorine; he suggested the name iodine.

Discovery of bromine

Bromine was discovered in 1826 by the French chemist Antoine-Jérôme Balard in the residues from the manufacture of sea salt at Montpellier. He liberated the element by passage of chlorine through aqueous solution of the residues, which contained magnesium bromide. Distillation of the material with manganese dioxide and sulfuric acid produced red vapours, which were condensed to a dark liquid. The similarity of this procedure to that for making chlorine suggested to Balard that he had obtained a new element similar to chlorine. (The German chemist Justus von Liebig appears to have obtained the element before Balard, but he wrongly considered it to be iodine chloride.)

The fluorine-containing mineral fluorspar (fluorite) was described in 1529 by Georg Bauer, the German physician and mineralogist better known as Agricola. It appears likely that crude hydrofluoric acid was first prepared by an unknown English glassworker in 1720. In 1771 Scheele obtained hydrofluoric acid in an impure state by heating fluorspar with concentrated sulfuric acid in a glass retort, which was greatly corroded by the product; as a result, vessels made of metal were used in subsequent experiments with the substance. The nearly anhydrous acid was prepared in 1809, and two years later the French physicist André-Marie Ampère suggested that it was a compound of hydrogen with an unknown element, analogous to chlorine, for which he suggested the name fluorine. Fluorspar was then recognized to be calcium fluoride.

Isolation of fluorine

The isolation of fluorine was for a long time one of the chief unsolved problems in inorganic chemistry, and it was not until the year 1886 that the French chemist Henri Moissan prepared the element by electrolyzing a solution of potassium hydrogen fluoride in hydrogen fluoride. The difficulty in handling the element and its toxic properties contributed to the slow progress in fluorine chemistry. Indeed, up to the time of World War II the element appeared to be a laboratory curiosity. Then, however, the use of uranium(VI) fluoride in the separation of uranium isotopes and the development of organic fluorine compounds of industrial importance made fluorine an industrial chemical of considerable use. Astatine was prepared for the first time in 1940 by bombarding bismuth with alpha particles.

GENERAL PROPERTIES OF THE GROUP

Oxidizing property. Probably the most important generalization that can be made about the halogen elements is that they are all oxidizing agents; *i.e.,* they raise the oxidation state, or oxidation number, of other elements—a property that used to be equated with combination with oxygen but that is now interpreted in terms of transfer of electrons from one atom to another. In oxidizing another element, a halogen is itself reduced—*i.e.,* its oxidation number is reduced from 0, the typical state for a free element, to -1. In this state the halogens combine with other elements to form compounds known as halides—namely, fluorides, chlorides, bromides, iodides, and astatides. Many of the halides may be considered to be salts of the respective hydrogen halides, which are colourless

Formation of saltlike compounds

gases at room temperature and atmospheric pressure and which are known to exhibit acidic properties. Indeed the general term salt is derived from rock salt, or table salt (sodium chloride). The tendency of the halogen elements to form saltlike compounds increases in the following order: astatine, iodine, bromine, chlorine, and fluorine.

This order is also that of increasing oxidizing properties of the free halogen elements. Fluorides are usually more stable than the corresponding chlorides, bromides, or iodides. (Often astatine is omitted from general discussions of the halogens because it is less well known than the other elements.) Conversely, of the halogen elements, fluorine is prepared in the free state with the greatest difficulty and iodine with the least. As a class, the halogen elements are nonmetals, but astatine shows certain properties resembling those of the metals.

Electronic structure. The chemical behaviour of the halogen elements can be discussed most conveniently in terms of their position in the periodic table of the elements. In the periodic table the halogens comprise Group VIIa, the group immediately preceding the noble gases. It is characteristic of the atoms of the halogen elements that each carries seven electrons in its outermost orbitals. The seven outermost electons of an atom of a halogen element are in two different kinds of orbitals, designated *s* (with two electrons) and *p* (with five). Potentially, a halogen atom could hold one more electron (in a *p* orbital), which would give the electrons the same arrangement (configuration) as that of the noble gas next to it in the periodic table, the noble gases all having exceptionally stable configurations of electrons in their atoms. It is in acquiring such an electron that an atom of a halogen element acts as an oxidizing agent (or is itself reduced). In the process, the atom acquires an electrical charge (in this case a negative one) and becomes a charged particle or ion. Halogen elements exist in their salts as halide ions, which are relatively large ions, colourless and extremely stable.

Diatomic halogen molecules

At room temperature and atmospheric pressure the halogen elements in their free states exist as diatomic molecules—molecules composed of two atoms each. In molecular fluorine the atoms are held together by a bond made from the union of a *p* orbital from each atom, such a bond being classed as a sigma bond. Beginning with chlorine, however, the halogen atoms are able to make use of different orbitals, called *d* orbitals—an option that is not open to the fluorine atoms. By forming partial bonds with their *d* orbitals, chlorine and the other halogens (with the exception of fluorine) form diatomic molecules held in part by multiple bonds (called pi bonds), which are stronger than single bonds, such as those that hold together the atoms in a fluorine molecule.

Relative reactivity. The great reactivity of fluorine largely stems from the relatively low energy of the fluorine–fluorine bond (37.7 kilocalories per mole, a standard measure for bond energies). The chlorine–chlorine bond is considerably stronger (57 kilocalories per mole) because of its partial multiple-bond character.

Fluorine and chlorine are gases at room temperature. Bromine is a reddish-brown liquid at room temperature, and is—apart from mercury—the only element that is liquid at 20° C and atmospheric pressure. Iodine forms dark-violet crystals under these conditions. In the solid state the halogen elements form molecular lattices—extended weblike structures including a great many separate units. The lattice energies increase with increasing size of the molecules. The principal properties of the halogen elements are noted in Table 21.

Electron affinities

The energy released in the formation of an ion from a free atom and an electron (brought up from an infinite distance) is called the electron affinity. The electron affinities for the halogen elements are all high and show only slight differences from one another. It is known, however,

Table 21: Properties of the Halogen Elements

	fluorine	chlorine	bromine	iodine	astatine
Atomic number	9	17	35	53	85
Atomic weight	18.9984	35.453*	79.904*	126.904	(210)

*Variation of isotopic abundance in terrestrial samples limits the precision of the atomic weight given. †Estimated.

that the oxidizing properties (ability to take up an electron) increase from astatine to fluorine, and this increase is reflected in the position of the respective oxidation–reduction systems in the electromotive series (a standard arrangement of oxidation–reduction systems in water in order of oxidizing strength).

The fluoride ion is extremely stable toward oxidation; the iodide ion is a mild reducing agent. This difference between the ions is caused by two factors: (1) a decreasing tendency for the halide ion to act as an electron-pair donor (a so-called Lewis base) in the series fluoride, chloride, bromide, iodide, and astatide, leading to a decrease in stability of the hydrated form of the ion (*i.e.,* the free ion surrounded by water molecules) in the same order; and (2) a decrease in electron pair acceptor (Lewis acid) properties of the free halogens in the reverse order, namely, astatine, iodine, bromine, chlorine, and fluorine.

Within a molecule in which atoms are held together by a shared electron pair—*i.e.,* by a covalent or nonionic bond—the tendency of an atom to attract the shared electrons may be expressed by an electronegativity value. Fluorine has the greatest electronegativity value (is the most electronegative) of all elements (not just the halogens), and there is a decrease in electronegativity within the family of the halogen elements from fluorine through chlorine, bromine, and iodine to astatine.

Fluorine replaces any other halide ion from its compounds, as shown in the following equations (in which atoms of the elements are represented by their chemical symbols; number of atoms of a given kind in a molecule are indicated by subscripts; and positive and negative charges on ions are indicated by superscript plus and minus signs; as is customary in chemical equations the reactants are written to the left and the products to the right; the double arrows indicate that both the forward reaction and the reverse reaction occur). Chlorine, however, replaces only bromide, iodide, and astatide ions, and bromine only iodide and astatide ions. Free fluorine, chlorine, bromine, and iodine are expected to replace astatide ions.

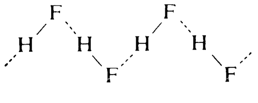
$$F_2 + 2Cl^- \rightleftharpoons 2F^- + Cl_2$$

$$F_2 + 2Br^- \rightleftharpoons 2F^- + Br_2$$

$$F_2 + 2I^- \rightleftharpoons 2F^- + I_2$$

$$F_2 + 2At^- \rightleftharpoons 2F^- + At_2.$$

The halogen elements all form compounds with hydrogen—the hydrogen halides. The energy of the hydrogen–halogen bond increases strongly from iodide to fluoride. Hydrogen fluoride in the crystalline state consists of infinite zigzag chains, as shown in the diagram



in which H represents the hydrogen atoms and (as before) F the fluorine atoms; the solid lines represent covalent bonds between the hydrogen and fluorine atoms within the molecules, and the dotted lines represent secondary bonds, called hydrogen bonds. The hydrogen bonds between hydrogen fluoride molecules are considerably weaker (seven kilocalories per mole) than those within the molecules (135 kilocalories per mole), yet they are retained to a great extent in the liquid state. Similar hydrogen bonding exists in the other hydrogen halides, but it is considerably weaker. The large difference in hydrogen bonding between hydrogen fluoride and the other hydrogen halides accounts for the relatively high melting and boiling points of hydrogen fluoride as compared to those of hydrogen chloride and the other hydrogen halides. The hydrogen–halogen bond energies also decrease considerably in going from hydrogen fluoride to hydrogen iodide.

Ionization potentials of halogens

The ionization potentials of the halogens are generally high, but they fall markedly with atomic number. Fluorine is the only halogen that does not form compounds with positive oxidation states—*i.e.,* states in which it has lost, rather than gained, electrons. This property is related to the inability of the fluorine atom to use *d* orbitals in bonding (see above), an inability not shared by the other halogen elements. Iodine forms an appreciable number of compounds in which a unipositive iodine ion is stabilized by coordination (surrounding with other groups); for example, with the coal-tar base, pyridine. The same situation has also been found with astatine.

Whereas fluorine exhibits only the single oxidation state of −1, the principal oxidation states of chlorine, bromine, and iodine are −1, +1, +3, +5, and +7. The oxo acids are compounds in which halogen atoms are joined to oxygen atoms and show large positive oxidation numbers. The oxo acids are all powerful oxidizing agents, being reduced to the corresponding aqueous hydrogen halides—the oxidation numbers passing from +5 or +7 to −1 in the process. The oxidizing properties of the oxo acids, however, fall with increasing oxidation number of the halogen because the coordination number increases with increasing oxidation number and the ion is stabilized by the coordination.

All the molecules and ions in which halogen atoms employ four electron pairs in bonding are basically tetrahedral in shape—as is, for example, the perchlorate ion $(ClO_4)^-$. Those employing five electron pairs are square pyramidal in structure, such as iodine(V) fluoride (IF_5)—the roman numeral in the name being used to indicate the oxidation number of the element it follows. Those with six electron pairs are octahedral; *e.g.,* the paraperiodate ion, $(IO_6)^{5-}$. The unique binary compound iodine(VII) fluoride (IF_7) is believed to have a pentagonal bipyramidal arrangement of fluorine atoms.

The maximum coordination number of chlorine(VII) toward oxygen is 4 (*i.e.,* the chlorine atom is surrounded by four oxygen atoms) in the perchlorate ion, $(ClO_4)^-$, whereas that of iodine(VII) is 6 in the paraperiodate ion, $(IO_6)^{5-}$. Analagous behaviour is found in the elements preceding the respective halogen in the periodic table, sulfur and tellurium.

INDIVIDUAL HALOGEN GROUP ELEMENTS

Fluorspar—source of fluorine

Fluorine. *Occurrence and distribution.* The fluorine-containing mineral fluorspar has been used for centuries as a flux (cleansing agent) in various metallurgical processes. The name fluorspar is derived from the Latin *fluere,* "to flow." The mineral subsequently proved to be a source of the element, which was named fluorine accordingly. The colourless, transparent crystals of fluorspar exhibit a bluish tinge when illuminated, and this property is accordingly known as fluorescence.

Fluorine is found in nature only in the form of its chemical compounds, except for trace amounts of the free element in fluorspar that has been subjected to the action of radiation from radium. The principal fluorine-containing minerals are: (1) fluorspar (fluorite, CaF_2), deposits of which occur in Illinois, Kentucky, Derbyshire, southern Germany, the south of France, and the Soviet Union; (2) cryolite (Na_3AlF_6), chiefly from Greenland; (3) fluoroapatite $(Ca_5[PO_4]_3[F,Cl])$, widely distributed and containing variable amounts of fluorine and chlorine; (4) topaz $Al_2SiO_4[F,OH]_2)$, the gemstone; and (5) lepidolite, a mica as well as a component of animal bones and teeth.

Production and use. Fluorspar is the most important source of fluorine. In the manufacture of hydrogen fluoride, powdered fluorspar is distilled with concentrated sulfuric acid in a lead or cast-iron apparatus. The hydrogen fluoride is obtained in a fairly anhydrous state by fractional distillation in copper or steel vessels and stored in steel cylinders. The usual impurities in commercial hydrogen fluoride are sulfurous and sulfuric acids as well as fluorosilicic acid, arising from the presence of silica in the fluorspar. Traces of moisture may be removed by electrolysis with platinum electrodes.

The preparation of the free element is carried out by electrolytic procedures in the absence of water. Generally these take the form of electrolysis of a melt of potassium fluoride–hydrogen fluoride (in a ratio of 1 to 2.5–5) at temperatures between 30° and 70° C, 80° and 120° C, or at 250° C. During the process the hydrogen fluoride content of the electrolyte is decreased and the melting point rises; it is therefore necessary to add hydrogen fluoride. In the high-temperature cell the electrolyte is replaced when the melting point reaches over 300° C. Fluorine can be safely stored under pressure in cylinders of stainless steel if the valves of the cylinders are free from traces of organic matter.

Uses in fluorination

The element is used for the preparation of various fluorides, such as chlorine trifluoride, sulfur(VI) fluoride, or cobalt(III) fluoride. The cobalt compound and certain other metal fluorides are important fluorinating agents for organic compounds. With appropriate precautions, the element itself may be used for the fluorination of organic compounds. Fluorine derivatives of hydrocarbons (compounds of carbon and hydrogen) are useful as refrigerants and as lubricants. The element is also used for the preparation of uranium(VI) fluoride, which is important in the process of separation of uranium-235 from natural uranium. Its outstanding oxidizing properties make elemental fluorine of possible interest as an oxidizer in rocket propulsion. Hydrogen fluoride and boron(III) fluoride are produced commercially because they are good catalysts for the alkylation reactions used to prepare organic compounds of many kinds. The addition of sodium fluoride to drinking water to reduce the incidence of dental caries in children is a matter of some controversy.

Chemical properties. At room temperature fluorine is a pale-yellow gas with an irritating odour. Inhalation of the gas is dangerous except in very low concentration. There is only one stable isotope of the element—fluorine-19.

Because fluorine is the most electronegative of the elements, atomic groupings rich in fluorine are negatively charged. Methyl iodide (CH_3I) and trifluoroiodomethane (CF_3I) have different properties for that reason. The charge distributions in these molecules are shown in the following formulas, in which the Greek symbol δ (delta) indicates a partial charge:

$$\overset{\delta+}{CH_3}\overset{\delta-}{I} \qquad\qquad \overset{\delta-}{CF_3}\overset{\delta+}{I}.$$

The ionization potential of fluorine is very high (402 kilocalories per gram atom), giving a standard heat formation for fluoride ion of 420 kilocalories per mole.

The small size of the fluorine atom makes it possible to pack a relatively large number of fluorine atoms or fluoride ions around a given coordination centre—*i.e.,* around a central atom. Fluorine is the most powerfully oxidizing element. No other substance, therefore, is able to reduce the fluoride ion to the free element, and for this reason the element is not found in the free state in nature. Furthermore, all chemical methods have failed to produce the element, success having been achieved only by the use of electrolytic methods. The high oxidizing properties of fluorine allow the element to produce the highest oxidation numbers possible in other elements, and many higher fluorides of elements are known for which there are no other corresponding halides—*e.g.,* silver(II) fluoride, cobalt(III) fluoride, rhenium(VII) fluoride, bromine(V) fluoride, and iodine(VII) fluoride.

Fluorine reacts with nearly all other elements at room temperature. Some metals, such as nickel, are quickly covered by a fluoride layer, which prevents further attack of the metal by the element. When dry, certain metals, such as mild steel, copper, aluminum, or Monel metal, are not attacked by fluorine to any extent at ordinary temperatures. For work with fluorine at temperatures up to 600° C Monel metal is suitable; sintered alumina is resistant up to 700° C. When lubricants are required, fluorocarbon oils are most suitable.

Fluorine reacts violently with organic matter (such as rubber, wood, and cloth), and controlled fluorination of organic compounds by the action of elemental fluorine is not possible unless special precautions are taken.

Analysis. The accurate quantitative determination of the amount of fluorine in compounds is difficult. Free fluorine may be detected by its oxidizing action on chlorides such as sodium chloride, as shown:

$$F_2 + 2NaCl \rightleftharpoons 2NaF + Cl_2.$$

The chlorine evolved may be determined by measurement of the volume of gas produced. The principal qualitative tests for the presence of fluorine are: (1) liberation of hydrogen fluoride by the action of sulfuric acid, (2) formation of a precipitate of calcium fluoride upon addition of a calcium chloride solution, and (3) decoloration of a yellow solution prepared from titanium(IV) oxide and hydrogen peroxide in sulfuric acid. Quantitative methods for analyzing fluorine are: (1) precipitation of calcium fluoride in the presence of sodium carbonate and treatment of the precipitate with acetic acid; (2) precipitation of lead chlorofluoride by addition of sodium chloride and lead nitrate; and (3) titration (determination of concentration of a dissolved substance) with thorium nitrate [$Th(NO_3)_4$] solution using sodium alizarin sulfonate as indicator, according to the equation.

Qualitative tests for fluorine

$$Th(NO_3)_4 + 4KF \rightleftharpoons ThF_4 + 4KNO_3.$$

Chlorine. *Occurrence and distribution.* When Sir Humphry Davy in 1810 recognized the elementary nature of the yellowish-green gas that had first been obtained by Scheele in 1774, he suggested the name chlorine from the Greek *chloros,* meaning "yellowish-green." Apart from very small amounts of free chlorine in volcanic gases, chlorine is found only in the form of chemical compounds. It constitutes 0.031 percent of the Earth's crust. The most common compound of chlorine is sodium chloride, which is found in nature as crystalline rock salt, often discoloured by impurities. Sodium chloride is also present in seawater, which has an average concentration of about 3 percent of that salt. Certain landlocked seas, such as the Dead Sea, contain up to 7.2 percent of dissolved salt. Besides sodium chloride, other metal halides, such as magnesium chloride, magnesium bromide, and—in small amount—certain sulfates, are contained in seawater. Small quantities of sodium chloride are present in blood and in milk. Other chlorine-containing minerals are sylvite (potassium chloride, KCl), bischofite ($MgCl_2 \cdot 6H_2O$), carnallite ($KCl \cdot MgCl_2 \cdot 6H_2O$), and kainite ($KCl \cdot MgSO_4 \cdot 3H_2O$). Free hydrochloric acid is present in the stomach.

Present-day salt deposits must have been formed by evaporation of prehistoric seas, the salts with the least solubility in water crystallizing first, followed by those with greater solubility. Because potassium chloride is more soluble in water than sodium chloride, certain rock salt deposits—such as those at Stassfurt, East Germany—were covered by a layer of potassium chloride. In order to gain access to the sodium chloride, the potassium salt, important as a fertilizer, is removed first.

Mining of rock salt deposits

Production and use. Rock salt deposits are usually mined; occasionally water is pumped down and brine, containing about 25 percent sodium chloride, is brought to the surface. When the brine is evaporated, impurities separate first and can be removed. In warm climates salt is obtained by evaporation of shallow seawater by the sun, to give bay salt.

Chlorine is produced on a large scale by any of a number of different methods:

1. By electrolysis of a concentrated solution of sodium chloride in water. Hydrogen is evolved at the cathode and chlorine at the anode. At the same time, an alkali metal hydroxide is produced in the electrolyte, and hence this process is often referred to as chlorine-alkali-electrolysis.

The chemical reactions occurring at each electrode and the overall cell process are given in the equations below:

cathode process: $2H_2O + 2e^- \longrightarrow 2OH^- + H_2$
(cathode of iron)
anode process: $2Cl^- \longrightarrow Cl_2 + 2e^-$
(anode of graphite)
cell process: $2H_2O + 2Cl^- \longrightarrow 2OH^- + H_2 + Cl_2$

in which the symbol e^- represents a single electron. In the reaction vessel free chlorine and hydroxide ions must not come in contact with each other because chlorine would be consumed according to the reaction:

$$Cl_2 + 2OH^- \rightarrow (ClO)^- + Cl^- + H_2O.$$

To accomplish the separation of chlorine gas and the hydroxide ion, a porous wall is inserted between the electrodes (diaphragm process), or the iron cathode is replaced by a cathode consisting of liquid mercury (mercury cathode process) which avoids the production of hydroxide ions at the electrode. Instead, free sodium is discharged at the cathode, and this metal is readily dissolved in the mercury forming an amalgam, as follows:

$$2Na^+ + 2e^- \rightleftharpoons 2Na(\text{amalgam}).$$

The amalgam is allowed to react with water outside the cell:

$$2Na(\text{amalgam}) + 2H_2O \longrightarrow 2Na^+ + 2OH^- + H_2.$$

The overall process is equivalent to the cell process given above.

2. By electrolysis of fused sodium chloride, which also produces metallic sodium; chlorine is again evolved at the anode.

3. By electrolysis of fused magnesium chloride, in which chlorine is formed as a by-product in the manufacture of metallic magnesium.

4. By oxidation of hydrogen chloride. In this process gaseous hydrogen chloride mixed with air or oxygen is passed over pumice in contact with cupric chloride as a catalyst, as shown in the following equation:

$$4HCl + O_2 \xrightarrow{\text{catalyst}} 2H_2O + 2Cl_2.$$

The equilibrium constant for this reaction decreases with increase of temperature; *i.e.,* the reaction proceeds less extensively at higher temperatures. In practice, however, a temperature of 400° C is required to achieve a reasonable rate of conversion.

5. Of historical interest is the process in which a mixture of almost any solid chloride and manganese dioxide (MnO_2) yields chlorine when heated with concentrated sulfuric acid (H_2SO_4). The reaction occurs, as follows:

$$2NaCl + 3H_2SO_4 + MnO_2 \rightarrow MnSO_4 + 2NaHSO_4 + 2H_2O + Cl_2.$$

Laboratory preparations of chlorine

In the laboratory chlorine is frequently prepared by the oxidation of concentrated hydrochloric acid with permanganate or dichromate salts:

$$2MnO_4^- + 10Cl^- + 16H^+ \rightarrow 2Mn^{2+} + 5Cl_2 + 8H_2O$$

$$Cr_2O_7^{2-} + 6Cl^- + 14H^+ \rightarrow 2Cr^{3+} + 3Cl_2 + 7H_2O.$$

Similarly, chlorine may be prepared on a small scale by addition of any dilute acid to bleaching powder, a mixture of dry calcium salts, including the hydroxide, chloride, and hypochlorite.

Most of the chlorine produced is used for chemical processes involving the introduction of chlorine into organic compounds, yielding carbon tetrachloride (used as a solvent, a fire extinguisher, and a dry-cleaning agent) and glycols (used as antifreeze), and other organic compounds for the manufacture of plastics (polyvinyl chloride) and synthetic rubber. Sulfur chloride, made by the action of chlorine on carbon disulfide or by combining sulfur and chlorine, is used in the vulcanization of rubber and as a chlorinating agent in organic synthesis. Chlorine and carbon monoxide form carbonyl chloride, or phosgene, which has been employed as a war gas and is used in metallurgy to transform certain oxides into chlorides. Much chlorine is used to sterilize water and wastes; and the substance is employed either directly or indirectly as a bleaching agent for paper or textiles. Chlorine is applied in the manufacture of hydrochloric acid, the extraction of titanium with formation of titanium(IV) chloride, the removal of tin from old tinplate, and in the production of antiknock materials for gasolines, such as tetraethyl lead. Anhydrous aluminum chloride is made by the reaction of chlorine with scrap aluminum or with aluminum oxide and carbon. Chlorine is also used to prepare silicon(IV) chloride and methyl chloride, which are employed in the synthesis of silicon materials. Chlorine enters directly, or indirectly as an intermediate, into many organic syntheses of industrial importance.

Physical and chemical properties. Chlorine is a greenish-yellow gas at room temperature and atmospheric pressure. It is considerably heavier than air. It has a choking smell, and inhalation causes suffocation, constriction of the chest, tightness in the throat, and—after severe exposure—edema (filling with fluid) of the lungs. As little as 2.5 milligrams per litre in the atmosphere causes death within a few minutes, but less than 0.0001 percent by volume may be tolerated. Chlorine was the first gas used in chemical warfare in World War I. The gas is easily liquefied by cooling or by pressures of a few atmospheres at ordinary temperature.

Toxicity of chlorine

Chlorine has a high electronegativity and a high electron affinity, the latter being even slightly higher than that of fluorine. The affinity of chlorine for hydrogen is so great that the reaction proceeds with explosive violence in light, as in the following equation:

$$H_2 + Cl_2 \xrightarrow{h\nu} 2HCl.$$

In the presence of charcoal, the combination of chlorine and hydrogen takes place rapidly (but without explosion) in the dark. A jet of hydrogen will burn in chlorine with a silvery flame. Its high affinity for hydrogen allows chlorine to react with many compounds containing hydrogen. Chlorine reacts with hydrocarbons, for example, substituting chlorine atoms for the hydrogen atoms successively. If the hydrocarbon is saturated, however, chlorine atoms readily add to the double or triple bond.

Chlorine reacts with many elements of both metals and nonmetals to give chlorides. Only toward carbon, nitrogen, and oxygen is it fairly inert. The products of reaction with chlorine usually are chlorides with high oxidation numbers, such as iron(III) chloride ($FeCl_3$), tin(IV) chloride ($SnCl_4$), or antimony(V) chloride ($SbCl_5$), but it should be noted that the chloride of highest oxidation number of a particular element is frequently in a lower oxidation state than the fluoride of highest oxidation number. Thus, vanadium forms a pentafluoride, whereas the pentachloride is unknown, and sulfur gives a hexafluoride but no hexachloride. With sulfur, even the tetrachloride is unstable.

Chlorine displaces the less electronegative halogens from compounds. The displacement of bromides, for example, occurs according to the following equation:

$$2Br^- + Cl_2 \rightleftharpoons Br_2 + 2Cl^-.$$

Furthermore, it converts several oxides into chlorides. An example is the conversion of iron(III) oxide to the corresponding chloride:

$$2Fe_2O_3 + 6Cl_2 \rightleftharpoons 4FeCl_3 + 3O_2.$$

With carbon monoxide chlorine gives carbonyl chloride; and with sulfur dioxide, sulfuryl chloride:

$$CO + Cl_2 \rightleftharpoons COCl_2$$

$$SO_2 + Cl_2 \rightleftharpoons SO_2Cl_2.$$

Chlorine water

Chlorine is moderately soluble in water, yielding chlorine water, and from this solution a solid hydrate of ideal composition $Cl_2 \cdot 7.66H_2O$ is obtained. This hydrate is characterized by a structure that is more open than that of ice; the unit cell contains 46 molecules of water and six cavities suitable for the chlorine molecules. When the hydrate stands, disproportionation takes place—that is, one chlorine atom in the molecule is oxidized and the other is reduced. At the same time, the solution becomes acidic, as shown in the following equation:

$$\overset{0}{Cl_2} + H_2O \rightleftharpoons H\overset{+1}{Cl}O + H\overset{-1}{Cl}$$

in which the oxidation numbers are written above the atomic symbols. Chlorine water loses its efficiency as an oxidizing agent on standing, because hypochlorous acid gradually decomposes. The reaction of chlorine with alkaline solutions yields salts of oxo acids (see below).

The ionization potential of chlorine is high. Although ions in positive oxidation states are not very stable, high oxidation numbers are stabilized by coordination, mainly with oxygen and fluorine. In such compounds bonding is predominantly covalent, and chlorine is capable of exhibiting the oxidation numbers +1, +3, +4, +5, +6, and +7.

Analysis. Free chlorine may be recognized by its smell, its colour, and its characteristic reaction with mercury to produce white mercury(II) chloride. Tests for chloride ions are:

1. The formation of a white precipitate of silver chloride on addition of silver nitrate in dilute nitric acid. (This precipitate is soluble in the presence of ammonia.)
2. The formation of chromyl chloride, a red gas, by heating a solid sample with potassium dichromate and concentrated sulfuric acid. When chromyl chloride is passed into water, a yellow chromate solution forms (bromides and iodides do not form analogous compounds).
3. The evolution of free chlorine by heating the sample with manganese dioxide and concentrated sulfuric acid.

The following methods are available for the quantitative determination of free chlorine:

Quantitative determination of chlorine

1. The chlorine-containing gas is shaken with an aqueous solution of potassium iodide, and the resulting iodine is determined by titration.
2. Chlorine is reduced in alkaline solution by an alkali arsenite. Back-titration of excess arsenite is carried out with potassium bromate.
3. In the presence of an alkali hydroxide, chlorine is reduced to the chloride ion by hydrogen peroxide, and the excess alkali hydroxide is back-titrated with acid.
4. With sulfur dioxide or sodium thiosulfate, chlorine is reduced to chloride, and the latter is analyzed as silver chloride (see below).
5. Colorimetric measurements are carried out in the presence of *o*-toluidine in hydrochloric acid.

For the determination of chloride ions, one of the following methods may be recommended: (1) gravimetric analysis (analysis by weight of a given product) as silver chloride; (2) titration of neutral chloride solution with silver nitrate in the presence of potassium chromate; and (3) potentiometric titration (measurement of voltage changes) with silver nitrate, a process that can be carried out in the presence of bromide and iodide ions.

Most insoluble chlorides can be melted with soda, and the resulting melt is then usually soluble in water. Organic compounds containing chlorine are heated with alkali peroxide, and the product is dissolved in water.

Bromine. *Occurrence and distribution.* Because of the bad odour of the element, the French Academy of Science suggested the name bromine, from the Greek word *bromos,* meaning "bad smell," or "stench." Bromine occurs only in compounds and is considerably less abundant than chlorine. Apart from silver bromide (bromyrite), which is found in Mexico and Chile, the element is mainly found in seawater or in salt deposits. The bromide content of seawater is about 0.07 grams per litre, but the Dead Sea contains much more—up to five grams per litre. Natural salt deposits are the main source of bromine and its compounds in the United States. In Germany it is available as a by-product of the manufacture of potassium.

Bromine from seawater

Production and use. Bromine is produced on a large scale from seawater by treatment with chlorine in the presence of sulfuric acid, according to the following equation:

$$2Br^- + Cl_2 \rightleftharpoons Br_2 + 2Cl^-.$$

The product of the reaction is a dilute solution of bromine, from which the element is removed by blowing air through it. The free bromine is then mixed with sulfur dioxide, and the mixed gases are passed up a tower down which water is trickling. The following reaction takes place in the tower:

$$SO_2 + Br_2 + 2H_2O \rightarrow 2HBr + H_2SO_4,$$

resulting in a mixture of acids that is much richer in bromide ion than seawater. Treatment with chlorine again liberates bromine, which is freed from chlorine and purified by passage over moist iron filings. In Germany most bromine produced comes from the mother liquor obtained in the production of potassium salts. This mother liquor, which contains mainly magnesium bromide, is treated with chlorine in a continuous process to release the bromine.

Commercial bromine generally contains up to 0.3 percent chlorine. It is usually stored in glass bottles or, in the United States, in barrels coated with lead or Monel metal.

Much of the bromine produced is converted to ethylene dibromide ($C_2H_4Br_2$), which is added to gasoline with tetraethyl lead to prevent deposition of lead in the engine. Bromine is also used for the preparation of silver bromide, which is employed in photography, and in the production of catalysts, such as aluminum bromide, as well as of organic dyestuffs and various other organic compounds.

Physical and chemical properties. Free bromine is a reddish-brown liquid with an appreciable vapour pressure at room temperature. Both liquid bromine and the vapour are highly toxic and produce painful burns on the skin. Like the other halogens, bromine exists as diatomic molecules in all aggregation states.

Bromine water

About 3.41 grams of bromine dissolve in 100 millilitres of water at room temperature. The solution is known as bromine water. Like chlorine water, it is a good oxidizing agent, and it is more useful because it does not decompose so readily. It liberates free iodine from iodide-containing solutions and sulfur from hydrogen sulfide. Sulfurous acid is oxidized by bromine water to sulfuric acid. In the sunlight bromine water decomposes, with release of oxygen, as in the following equation:

$$H_2O + Br_2 \longrightarrow 2HBr + \tfrac{1}{2}O_2.$$

From bromine water a hydrate can be isolated that contains 172 water molecules and 20 cavities capable of accommodating the bromine molecules. Bromine dissolves in aqueous alkali hydroxide solutions, giving bromides, hypobromites, or bromates, depending on the temperature. Bromine is readily extracted from water by organic solvents such as carbon tetrachloride, chloroform, or carbon disulfide, in which it is very soluble. In the organic solvents it gives an orange solution.

The electron affinity of bromine is high and similar to that of chlorine. It is, however, a less powerful oxidizing agent, chiefly because of the weaker hydration of the bromide ion as compared with the chloride ion. Similarly, a metal–bromine bond is weaker than the corresponding metal–chlorine bond, and this difference is reflected in the chemical reactivity of bromine, which lies between that of chlorine and that of iodine.

Bromine combines violently with the alkali metals and with phosphorus, arsenic, and antimony but less violently with certain other metals. Bromine displaces hydrogen from saturated hydrocarbons and adds to unsaturated hydrocarbons, though not as readily as chlorine does.

The ionization potential of bromine is high, and compounds containing bromine in positive oxidation numbers are stabilized by appropriate ligands, mainly oxygen and fluorine. Compounds with the oxidation numbers +1, +3, +4, +5, and +7 are known; they all contain covalent bonds.

Analysis. A sensitive test for bromine is the reaction with fluorescein to give a deep red colour caused by bromination of the organic molecule, or by its reaction with fuchsine dyes in the presence of sulfurous acid, to give a deep blue colour. A more common test involves heating of the sample with dilute sulfuric acid in the presence of potassium dichromate; the bromine is then extracted with chloroform, and, upon addition of potassium iodide, the pink colour of iodine appears. The presence of bromine may also be recognized by the evolution of hydrogen bromide containing some brown bromine vapour when a solid sample is treated with concentrated sulfuric acid. Alternatively, chlorine may be added to an aqueous solution of a sample containing bromide, with development of a brown colour (free bromine).

For the quantitative determination of bromine the following methods are recommended:

$$Br_2 + 2(S_2O_3)^{2-} \rightleftharpoons (S_4O_6)^{2-} + 2Br^-.$$

1. Free bromine is titrated with sodium thiosulfate in the presence of potassium iodide:

$$Br^- + Ag^+ \rightleftharpoons AgBr.$$

2. Bromides may be determined either gravimetrically (by weight analysis) or by titration with silver nitrate:
3. In the presence of chloride and iodide, the potentiometric method may be used (as with chlorine).
4. In the absence of iodide, bromide may be oxidized to bromine, which is then determined in the distillate. Alternatively, bromide may be oxidized to bromate by hypochlorous acid. The excess of the oxidizing agent is destroyed by sodium formate, and iodine is liberated by addition of potassium iodide and acid, the free iodine being titrated by thiosulfate.
5. For the determination of bromine in an organic compound, the latter is oxidized by nitric acid, and the bromine is determined as silver bromide.

Iodine. *Occurrence and distribution.* Because of its violet-coloured vapours, the element was given the name iodine from the Greek word *ioeides,* "violet coloured." Iodine occurs to a small extent in seawater and is formed in seaweeds, oysters, and cod livers. Sodium iodate ($NaIO_3$) is contained in crude Chile saltpetre (sodium nitrate, $NaNO_3$). The human body contains iodine in the compound thyroxine, which is produced in the thyroid gland. It occurs in small quantities in much animal and vegetable matter.

Iodine from brines

Production and use. Iodine is produced commercially either from Chile saltpetre or from iodine-containing brines. In the former process, the salt is dissolved in hot water and the saltpetre allowed to crystallize on cooling. The mother liquor is used for further extractions until the extracts contain up to nine grams of iodine per litre. Sodium hydrogen sulfite is then added in order to reduce all iodate to iodide, and the solution is nearly neutralized with sodium carbonate. Fresh mother liquor is then added until all iodide is oxidized by the iodate to free iodine, according to the equation:

$$2NaIO_3 + 5NaHSO_3 \rightleftharpoons 3NaHSO_4 + 2Na_2SO_4 + H_2O + I_2.$$

The solid, containing up to 80 percent iodine, is collected, washed with water, and pressed into cheeselike blocks. These are heated to distill off both iodine and water.

Natural brines, or brines extracted from oil wells containing up to 150 milligrams of iodine per litre, are found in Java, California, and northern Italy. Impurities, such as clay, sand, and oil, are removed by filtration, and the solution is passed through a stream of sulfur dioxide and then through a number of containers containing bundles of copper wire. The copper(I) iodide that forms is removed by filtration, washed with water, dried, and finely ground. The product is heated with potassium carbonate to give potassium iodide, which is then oxidized to the free element with dichromate and sulfuric acid:

$$Cu_2I_2 + K_2CO_3 \rightleftharpoons 2KI + Cu_2O + CO_2$$

$$6KI + Na_2Cr_2O_7 + 7H_2SO_4 \rightleftharpoons 3I_2 + Cr_2(SO_4)_3 + Na_2SO_4 + 3K_2SO_4 + 7H_2O.$$

In an alternate process, chlorine is used as the oxidizing agent:

$$2KI + Cl_2 \rightleftharpoons 2KCl + I_2.$$

Iodine from seaweed

For a long time, iodine has been recovered on a commercial scale from seaweed. This is dried and burnt; the ash is leached with water; sodium sulfate and sodium chloride are removed by crystallization; and the remaining solution is concentrated by evaporation of water. The final solution, which contains 30 to 100 grams of iodine per litre, is treated with sulfuric acid in order to decompose any sulfite, and sulfide and manganese dioxide are added to release iodine, which is vapourized and purified by sublimation. Alternatively, addition of cupric sulfate gives cuprous iodide.

Iodine is widely used as a disinfectant and antiseptic, frequently in a solution of alcohol and water containing potassium iodide. Several compounds of iodine, such as iodoform (CHI_3), also serve as antiseptics.

Because iodine is converted to thyroxine in the thyroid gland, a small amount of iodine is essential for the body. In many places drinking water contains sufficient iodine for this purpose. In the absence of iodine in the water supply, however, goitre is prevalent, and a small quantity of iodine is frequently added to table salt in order to ensure against iodine deficiency.

Iodine and its compounds are used extensively in analytical chemistry, many analytical procedures being based on the release or uptake of iodine and its subsequent titration with sodium thiosulfate (iodometry). Unsaturation of fats (that is, the number of double bonds between carbon atoms) is determined by addition of free iodine (iodine number). Iodine compounds are also employed as catalysts in certain classes of organic reactions. Iodine, silver iodide, and potassium iodide are used in photography. Silver iodide is also used to seed clouds to induce rain. Iodine has been introduced into metallurgical processes for the production of certain transition metals in a high state of purity, among them titanium, zirconium, thorium, chromium, and cobalt. Electronic equipment, such as scintillation counters or neutron detectors, contain single-crystal prisms consisting of alkali metal iodides.

Solid iodine

Physical and chemical properties. Iodine is solid at room temperature, dark coloured, and with a glittering crystalline appearance. The molecular lattice contains discrete diatomic molecules, which are also present in the molten and the gaseous states. Above 700° C dissociation into iodine atoms becomes appreciable.

Iodine has a moderate vapour pressure at room temperature and in an open vessel slowly sublimes (sublimation is vaporization of a solid—comparable to distillation of a liquid). For this reason, iodine is best weighed in a stoppered bottle; for the preparation of an aqueous solution the bottle may contain a solution of potassium iodide, which considerably decreases the vapour pressure of iodine, a complex (triiodide) being readily formed.

Molten iodine may be used as a nonaqueous solvent for iodides. The electrical conductivity of molten iodine has in part been ascribed to the following self-ionization equilibrium:

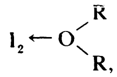
$$2I_2 \rightleftharpoons I^+ + I_3^-.$$

The alkali iodides are soluble in molten iodine and give conducting solutions typical of weak electrolytes. Alkali iodides react with compounds containing iodine with the oxidation number +1, such as iodine bromide, as in the following equation:

$$KI_3 + IBr \rightleftharpoons KBr + 2I_2.$$

In such reactions the alkali iodides may be regarded as bases.

The iodine molecule can act as a Lewis acid in that it combines with various Lewis bases. The interaction is weak, however, and few solid complex compounds have been isolated. The complexes are easily detected in solution and are referred to as charge-transfer complexes. Iodine, for example, is slightly soluble in water to give a yellowish-brown solution. Brown solutions are also formed with alcohol, ether, ketones, and other compounds acting as Lewis bases through an oxygen atom, as in the following example:



in which the R groups represent various organic groups.

Iodine gives a red solution in benzene, which is regarded as the result of a different type of charge-transfer complex. In inert solvents, such as carbon tetrachloride or carbon disulfide, violet-coloured solutions are obtained that contain uncoordinated iodine molecules. Iodine reacts also with iodide ions, because the latter can act as Lewis bases, and for this reason the solubility of iodine in water is greatly enhanced in the presence of an iodide. When cesium iodide is added, crystalline cesium triiodide may be isolated from the reddish-brown, aqueous solution. Iodine forms a blue complex with starch, and this colour test is used to detect small amounts of iodine.

The electron affinity of the iodine atom is not much different from those of the other halogen atoms. Iodine is a weaker oxidizing agent than bromine, however, because the iodide ion is a weaker Lewis base than the bromide ion and is hydrated to a smaller extent. In fact, the oxidizing properties of iodine are considerably weaker than those of bromine, chlorine, or fluorine. The following reaction—oxidation of arsenite, $(AsO_3)^{3-}$—in aqueous solution proceeds only in the presence of sodium hydrogen carbonate, which acts as a buffer:

$$(AsO_3)^{3-} + I_2 + 2OH^- \rightleftharpoons (AsO_4)^{3-} + 2I^- + H_2O.$$

In acidic solution, arsenate is reduced to arsenite, whereas, in strongly alkaline solution, iodine is unstable, and the reverse reaction occurs.

Volumetric determination of iodine

The most familiar oxidation by iodine is that of the thiosulfate ion, which is oxidized quantitatively to tetrathionate, as shown:

$$2(S_2O_3)^{2-} + I_2 \rightleftharpoons (S_4O_6)^{2-} + 2I^-.$$

This reaction is used to determine iodine volumetrically. The consumption of iodine at the end point is detected by the disappearance of the blue colour produced by iodine in the presence of a fresh starch solution.

Iodine combines directly with many elements. Silver and aluminum are easily converted into the respective iodides. White phosphorus unites readily with iodine, but no compounds of sulfur and iodine are known. The ionization potential of the iodine atom is considerably smaller than that of the lighter halogen atoms, and this is in accord with the existence of various compounds containing iodine in a positive oxidation number.

Analysis. Free iodine is detected (1) by the violet colour of the vapour or of its solution in carbon tetrachloride or carbon disulfide or (2) by the bright-blue colour produced in the presence of fresh starch solution in water, a very sensitive test.

Detection of iodide ions

Iodide ions may be detected in water (1) by the yellow precipitate of silver iodide, insoluble in water and ammonia solution, which is produced by addition of silver nitrate in the presence of dilute nitric acid, (2) by the formation of iodine on addition of chlorine or bromine water, (3) by the formation of iodine in the presence of other oxidizing agents, such as hydrogen peroxide or potassium dichromate, or (4) by the scarlet precipitate of mercury(II) iodide formed on addition of mercury(II) chloride, as in the equation below:

$$2I^- + HgCl_2 \rightleftharpoons HgI_2 + 2Cl^-.$$

This precipitate is dissolved by excess of iodide ions because of formation of a complex ion:

$$HgI_2 + 2I^- \rightleftharpoons (HgI_4)^{2-}.$$

Iodate or periodate is reduced by sulfurous acid to iodide and may be detected as such.

For the quantitative determination of iodine, one of the following methods may be recommended: (1) gravimetrically, by precipitation as silver iodide; (2) volumetrically, by titrating iodine with a standardized solution of sodium thiosulfate (using starch as an indicator); or (3) potentiometric titration with silver nitrate, which is applicable in the presence of both chloride and bromide. The second method is applied in the determination of many oxidizing substances. Dichromate, for example, reacts with excess potassium iodide in the presence of sulfuric acid, as shown:

$$(Cr_2O_7)^{2-} + 6I^- + 14H^+ \rightleftharpoons 2Cr^{3+} + 3I_2 + 7H_2O.$$

The iodine liberated is treated with standard thiosulfate solution.

Astatine. Because the element astatine has no stable or long-lived isotopes, it was given its name from the Greek word *astatos,* meaning "unstable." Minute amounts of the very short-lived isotopes, astatine-215, -218, and -219, occur in nature in radioactive equilibrium with certain long-lived, naturally occurring radioelements. In the body, astatine is concentrated in the thyroid gland. A substantial portion, however, distributes throughout the body, where it acts as an internal radiation source.

Preparation of astatine

Production and use. The only practical way of obtaining astatine is by synthesizing it through nuclear reactions. The first synthesis was effected in 1940 by the bombardment of bismuth with alpha particles to obtain astatine-211.

Astatine is usually prepared according to the general equation:

$$^{209}\mathrm{Bi}\,(a, xn)\,^{(213-x)}\mathrm{At},$$

which indicates that bismuth-209 takes up one alpha particle and emits x neutrons to form an isotope of astatine, whose atomic weight depends on the number of neutrons lost. Metallic bismuth may be used as a target material. From this, astatine may readily be removed by distillation in air from a stainless-steel tube. The free element begins to distill at 271° C (the melting point of bismuth), but the operation is best carried out at 800° C with subsequent redistillation. If an aqueous solution of astatine is desired, the element may be separated by washing with an appropriate aqueous solution. Alternatively, the halogen may be removed from the target by chemical methods, such as dissolving in nitric acid, the latter being removed by boiling.

Another procedure involves the use of a metallic thorium target, which—after bombardment—is dissolved in concentrated hydrochloric acid containing hydrogen fluoride and chlorine.

Use of iodine as a carrier in experiments

Analysis. With the exception of a few spectrographic and mass-spectrographic studies, all investigations of astatine chemistry have utilized tracer techniques at extreme dilution—concentrations around or below 10^{-10} molar, molarity being the number of moles (gram molecular weight) per litre of solution. At such concentration, the effects of impurities can be very serious, especially for a halogen such as astatine, which exists in several oxidation states and can form many organic compounds. Iodine has been used as a carrier in most experiments. Techniques applied include coprecipitation, solvent extraction, ion exchange, and other forms of chromatography (separation by adsorption differences), electrodeposition (deposition by an electric current), electromigration (movement in an electric field), and diffusion. A direct identification of some astatine compounds has been made by mass spectrography.

Except for nuclear properties, the only physical property of astatine to be measured directly is the spectrum of atomic astatine. Other physical properties have been predicted from theory and by extrapolation from the properties of other elements.

Chemical properties. The astatide ion, At^-, is quantitatively coprecipitated with insoluble iodides, such as silver iodide or thallium(I) iodide. The diffusion coefficient of the iodide ion is 1.42 times that of the astatide ion, which moves more slowly toward the anode than the former under given conditions. The ion is formed by reduction of the element, using, for example, zinc and acid. It is oxidized to the zero valence state by ferric ion, Fe^{3+}, iodine (I_2), and dilute nitric acid. Thus, the astatide ion is a stronger reducing agent than the iodide ion, and free iodine is a stronger oxidizing agent than astatine.

Free astatine is characterized by volatility from solution and by extractability into organic solvents. It undergoes disproportionation in alkaline media. Astatine is coprecipitated with cesium iodide and thus appears to form polyhalide anions. Astatine extracted into chloroform has been shown to coprecipitate homogeneously with iodine when a portion of the latter is crystallized. Astatine seems to be present as the iodide, which appears to be more polar (*i.e.,* showing separation of electrical charge) in character than iodine bromide.

Astatine is known to occur in positive oxidation numbers. The astatate ion, $(AtO_3)^-$, is coprecipitated with insoluble iodates, such as silver iodate $(AgIO_3)$, and it is obtained by oxidation of lower oxidation states with hypochlorite, periodate, or persulfate. So far no evidence for perastatate has been found, but this may be because the ion, $(AtO_6)^{5-}$, may show little tendency to coprecipitate with potassium iodate (KIO_4).

Astatine in the $+1$ state is stabilized by complexation, and complexes formulated as dipyridine astatine(I) perchlorate $[At(py)_2]$ $[ClO_4]$ and dipyridine astatine(I) nitrate $[At(py)_2]$ $[NO_3]$ have been prepared. Compounds with the formulas $(C_6H_5)AtCl_2$, $(C_6H_5)_2AtCl$, and $(C_6H_5)AtO_2$ have also been obtained. A variety of methods may be used to synthesize astatobenzene, C_6H_5At. (V.G./Ed.)

Noble gases

The so-called noble gases consist of a group of six chemical elements that exist under ordinary conditions as colourless, odourless, tasteless, nonflammable gases: helium (He), neon (Ne), argon (Ar), krypton (Kr), xenon (Xe), and radon (Rn). They traditionally have been labelled Group 0 in the periodic table (see Figure 10) because for decades after their discovery it was believed that they had a valence of zero; that is, that their atoms could not combine with those of other elements to form chemical compounds. Their electronic structures and the finding that some of them do indeed form compounds suggest that a more appropriate designation would be Group VIIIa.

When the members of the group were discovered and identified they were thought to be exceedingly rare, as well as chemically inactive, and therefore were called the rare gases or the inert gases. It is now known, however, that several of these elements are quite abundant on Earth and in the rest of the universe, so the designation rare is misleading. Similarly, use of the term inert has the drawback that it often is applied to gases such as nitrogen and carbon dioxide to connote their nonflammability. In chemistry and alchemy, the word noble long has signified the passivity toward oxygen of a group of metals, such as gold and platinum; it applies in the same sense to the group of gases covered here.

The abundances of the noble gases decrease as their atomic numbers increase; helium is, in fact, the most plentiful element in the universe except hydrogen. All the noble gases are present in the Earth's atmosphere and, except for helium and radon, their major commercial source is the air, from which they are obtained by liquefaction and fractional distillation. Most helium is produced commercially from certain natural gas wells. Radon usually is isolated as a product of the radioactive decomposition of dissolved radium compounds (the nuclei of radium atoms spontaneously decay by emitting energy and particles; the particles are the nuclei of helium and radon atoms).

Important industrial applications

Several important uses of the noble gases rest on their marked lack of chemical reactivity. Their indifference toward oxygen, for example, confers utter nonflammability upon all six noble gases. Although helium is not quite as buoyant as hydrogen, its incombustibility makes it a safer lifting gas for lighter-than-air aircraft. The noble gases—most often helium and argon, the least expensive—are used to provide chemically unreactive environments for such operations as cutting, welding, and refining of metals (atmospheric oxygen and, in some cases, nitrogen or carbon dioxide would react with the hot metal) and in the handling of other easily attacked materials.

The noble gases absorb and emit electromagnetic radiation in a much less complex way than do other substances. The absorption and emission behaviour is utilized in the employment of these gases in discharge lamps and fluorescent lighting devices: if any of them is confined at low pressure in a glass tube and an electrical discharge is passed through it, the gas glows. Neon produces the familiar orange-red colour of advertising signs; xenon emits a beautiful blue.

The very low boiling points and melting points of the noble gases make them useful as refrigerants in the study of matter at extremely low temperatures. The low solubility of helium in fluids leads to its use in admixture with oxygen for breathing by deep-sea divers: because helium does not dissolve in the blood, it does not form bubbles upon decompression (as nitrogen does, leading to the condition known as bends). Xenon has been used as an anesthetic; although it is costly, it is nonflammable and readily eliminated from the body. Radon is highly radioactive; its only uses have been those that exploit this property, as, for example, in radiotherapy.

The compounds of the noble gases are powerful oxidizing agents (substances that tend to remove electrons from others) and have potential value as reagents in the synthesis of chemical compounds.

HISTORY

Discovery of argon

In 1785 Henry Cavendish, an English chemist and physicist, found that air contains a small proportion (slightly less than 1 percent) of a substance that is chemically less active than nitrogen. A century later Lord Rayleigh, an English physicist, isolated from the air a gas that he thought was pure nitrogen but found that it was denser than nitrogen prepared chemically by liberating it from its compounds. He reasoned that his aerial nitrogen must contain a small amount of a denser gas. Sir William Ramsay, a British chemist, collaborated with Rayleigh in isolating (1894) this gas, which proved to be a new element, argon.

After the discovery of argon, and at the instigation of other scientists, Ramsay undertook to investigate the gas evolved upon heating the mineral clevite, which was thought to be a source of argon. The gas proved (1895) instead to be helium, which in 1868 had been detected spectroscopically in the Sun but had not been found on Earth. Ramsay and his co-workers searched for related gases and by fractional distillation of liquid air discovered krypton, neon, and xenon, all in 1898. Radon, first identified in 1900, was established as a member of the noble-gas group in 1904.

In 1895 the French chemist Henri Moissan failed in an attempt to bring about a reaction between fluorine and argon. In fact, all late 19th- and early 20th-century efforts to prepare chemical compounds of argon failed. The lack of chemical reactivity implied by these failures was of significance in the development of theories of atomic structure. In 1913 the Danish physicist Niels Bohr proposed that the electrons in atoms are arranged in successive shells having characteristic energies and capacities and that the capacities of the shells determine the numbers of elements in the periods of the periodic table. On the basis of experimental evidence relating chemical properties to electron distributions, it was suggested that in the atoms of each noble gas beyond helium the electrons are arranged in these shells in such a way that the outermost shell always contains eight electrons, no matter how many others (in the case of radon, 78 others) were arranged inside those of eight.

Octet theory

In a theory of chemical bonding advanced by others in 1916, this octet of electrons was taken to be the most stable arrangement for the outermost shell of any atom. Although only the noble-gas atoms possessed this arrangement, it was the condition toward which the atoms of all other elements tended in their chemical bonding. Certain elements satisfied this tendency by either gaining or losing electrons outright, becoming ions; other elements shared electrons, forming stable combinations linked together by covalent bonds. The valences of elements—that is, the proportions in which their atoms combined to form ionic or covalent compounds—were thus controlled by the behaviour of their outermost electrons, which for this reason were called the valence electrons. This theory rationalized the chemical bonding of the reactive elements as well as the relative inactivity of the noble gases, which is their chief characteristic. (Additional information appears in the article MOLECULES.)

The outer electrons of the atoms of the heavier noble gases, screened from the nucleus by intervening electrons, are held less firmly and can be removed more easily from the atoms than can the electrons of the lighter noble gases. This fact had been known for a long time from experiments using electrical and magnetic fields; the energy required for removal of one electron is called the first ionization potential. In 1962 it was discovered that platinum hexafluoride would oxidize molecular oxygen to form a salt. Knowledge that the first ionization potential of xenon is very close to that of oxygen led to the suggestion that a salt of xenon might be formed similarly. In the same year it was established that it is indeed possible to remove electrons from xenon by chemical means—that is, to oxidize xenon—when two teams of chemists independently prepared fluorides of that element. This achievement was followed by the preparation of other xenon compounds and of the fluorides of radon (1962) and krypton (1963).

GENERAL PROPERTIES OF THE GROUP

Each noble-gas element is situated in the periodic table between an element of the most electronegative group, the halogens (Group VIIa, the atoms of which add electrons to achieve the octet and thereby become negative ions), and an element of the most electropositive group, the alkali metals (Group Ia, the atoms of which lose electrons to become positive ions). The noble gases thus form a dramatic transition group in the periodic table of the elements and are neither electropositive nor electronegative but, relatively speaking, neutral, neither gaining nor losing electrons easily.

The sizes of the atoms of noble gases increase smoothly with the increase in atomic number, partially because repulsion between the electrons prevents them from occupying the same region of space and forces each successive shell to extend into a larger concentric spherical volume. In the largest atoms, the weaker attraction of the nucleus for the electrons in the most distant shell explains the greater ease with which the outer electron clouds of these atoms are distorted by other charged bodies, or polarized. A polarized atom as a whole remains electrically neutral but the distribution of charge within it becomes unsymmetrical, the centre of gravity, so to speak, of the negative charge being displaced from that of the positive charge. The polarizability of the noble gases increases markedly through the group from helium to radon as the ionization potential decreases.

Clathrates

Generally speaking, a polarizable substance is attracted more strongly to surfaces and dissolves in fluids more extensively than a nonpolarizable one. Because the polarizability of helium is minimal, it shows little or no tendency to adsorb upon surfaces and it is not very soluble in fluids. These properties may account for the fact that helium does not induce narcosis when it is breathed by divers at high pressures and that it does not form clathrates. (Clathrates—from a Latin word meaning "enclosed by a lattice"—are substances in which the molecules of one compound, called the host, form a cagelike crystalline lattice within which there are open spaces that may be occupied by molecules of a second compound or element, called the guest, although no chemical bonds are formed between the host and the guest. The stability of a clathrate is influenced by the closeness with which the guest particles fit into the holes as well as by the polarizability of the guest.) The properties of small size and low polarizability make helium a highly mobile gas; *i.e.,* one that is not trapped by various structures of other atoms. The greater polarizability of argon and the heavier noble gases accounts for their formation of clathrates, including those in which water is the host—hydrates—and also accounts for the ready adsorption of these gases on surfaces. The narcotic activity of the noble gases also parallels their polarizability. The noble gases reduce the sensitivity of living cells to attack by oxygen under the influence of radiation; the heavier gases are more effective than the lighter ones in this action, perhaps simply as a result of their greater solubility in fluids, but possibly also as a consequence of their greater ability to absorb neutrons.

INDIVIDUAL NOBLE GASES

Helium. Because the first evidence of the existence of helium was the presence of certain wavelengths in the yellow region of the spectrum of the light emitted from the Sun, the name of the element was derived from the Greek word *hēlios,* "sun." Helium constitutes about 23 percent of the mass of the universe, but only about eight parts per 1,000,000,000 of the Earth's crust; ordinary air contains about five parts per 1,000,000 of helium.

The nucleus of every helium atom contains two protons but, as is the case with all elements, isotopes of helium exist. The known isotopes of helium contain from one to six neutrons, so their mass numbers range from three to eight. Of these six isotopes, only the two having mass numbers of three (helium-3, symbolized ^{3}He) and four (helium-4, ^{4}He) are stable; all the others are radioactive, decaying very rapidly into other substances. Helium-4 is by far the more plentiful of the stable isotopes: helium-4 atoms outnumber those of helium-3 about 700,000 to one in atmospheric helium and about 7,000,000 to one in certain helium-bearing minerals.

Most of the helium of commerce is derived from natural gas produced in the southwestern United States. The helium, which comprises between 1.5 and 7 percent of the gas, is separated by continuous processes involving several steps. A portion of the helium market is supplied from plants that liquefy air on a large scale; the amount of helium obtainable from 1,000 tons of air is about 112 cubic feet, measured at room temperature and atmospheric pressure.

Liquid and solid helium

The boiling and freezing points of helium are lower than those of any other known substance. Helium is the only element that cannot be solidified by sufficient cooling at normal atmospheric pressure; it is necessary to apply pressure of 25 atmospheres at a temperature of 1 K (−272.15° C) to convert it to its solid form.

The isotope helium-4 is unique in having two liquid forms. The form designated I exists at temperatures from its boiling point of 4.21 K down to 2.18 K (−270.97° C); form II exists at still lower temperatures. Liquid helium II exhibits the property called superfluidity: its viscosity, or resistance to flow, is so low that it has not been measured. This liquid spreads in a thin film over the surface of any substance it touches, and this film flows without friction even against the force of gravity.

A liquid mixture of the two isotopes helium-3 and helium-4 separates at temperatures below about 0.8 K into two layers. One layer is practically pure helium-3; the other is mostly helium-4, but retains about 6 percent helium-3 even at the lowest temperatures achieved. Dissolving helium-3 in helium-4 is accompanied by a cooling effect that has been utilized in the construction of cryostats (devices for production of very low temperatures) that can attain—and maintain for periods of days—temperatures as low as 0.01 K.

Neon. Neon, the name of which is derived from the Greek word *neos,* "new," is present in some minerals, but its only commercial source is the atmosphere, of which it comprises 18 parts per 1,000,000 by volume. Because its boiling point is −246° C, neon remains, along with helium and hydrogen, in the small fraction of air that resists liquefaction upon cooling to −196° C. Neon is isolated from this cold, gaseous mixture by bringing it into contact with activated charcoal, which adsorbs the neon and hydrogen; removal of hydrogen is effected by adding enough oxygen to convert it all to water, which, along with any surplus oxygen, condenses upon cooling.

Neon was the first element shown to consist of more than one stable isotope. In 1913 application of the technique of mass spectrometry revealed the existence of neon-20 and neon-22, which comprise 90.92 and 8.82 percent, respectively, of the naturally occurring mixture. The third stable isotope, neon-21, which makes up 0.26 percent of natural neon, was detected later. Five radioactive isotopes of neon also have been identified.

Argon. The first of the noble gases to be discovered, argon was named from the Greek word *argos,* "lazy," because of its chemical inertness. In cosmic abundance, argon ranks approximately 12th among the 100-odd chemical elements; although the stable isotopes argon-36 and argon-38 make up all but a trace of this element in the universe, the third stable isotope, argon-40, comprises 99.60 percent of the argon found on Earth. The terrestrial preponderance of argon-40 presumably arose from the formation of this isotope by the radioactive decay of potassium-40.

Argon is the most plentiful of the noble gases on Earth, comprising 0.934 percent by volume, or 1.288 percent by weight, of the atmosphere. The element is obtained from air by liquefaction and fractional distillation; although the boiling points of argon, oxygen, and nitrogen all lie within a few degrees of each other, efficient processing provides each gas in a purity of more than 99.9 percent.

Krypton. Krypton is named from the Greek word *kryptos,* "hidden." Traces of krypton are present in minerals and meteorites, but the usual commercial source is the atmosphere, which contains 1.14 parts per 10^6 by volume. Krypton also is formed by the nuclear fission of uranium triggered by slow neutrons: this source may be expected to become increasingly important because of the growing number of fission-power plants. Krypton has isotopes of every mass number from 74 through 95; six, with mass numbers 78, 80, 82, 83, 84, and 86, are stable. After it has been stored a few days, krypton obtained by nuclear fission contains only one radioactive isotope, krypton-85, which has a half-life of about 10 years, because all the other radioactive isotopes have half-lives of three hours or less. (The half-life is the length of time during which one-half of any original amount of an unstable substance decays.)

Because its boiling point is about 30° C higher than those of the major constituents of air, krypton is readily separated from liquid air by fractional distillation; it accumulates along with xenon in the least volatile portion. These two gases are further purified by adsorption onto silica gel, redistillation, and passage over hot titanium metal, which removes all impurities except other noble gases.

Krypton is the lightest of the noble gases that has been converted into chemical compounds.

Principal source

Xenon. The name xenon is derived from the Greek word *xenos,* "strange" or "foreign." Like several other noble gases, xenon is present in meteorites and certain minerals, but its only useful source has been the atmosphere, of which it composes 86 parts per 10^9 by volume. Nuclear reactors may become an important source of xenon, because the fission of uranium produces several isotopes of xenon.

The mass numbers of the known isotopes of xenon range from 118 to 144; nine of these numbers correspond to stable isotopes. The xenon isotopes produced in the greatest amount by nuclear fission are xenon-131, -132, -134, and -136, which are stable, and xenon-133, which is radioactive, having a half-life of 9.2 hours.

Xenon is the least volatile of the noble gases obtainable from the ir. Its purification has been mentioned above (see *Krypton*). Numerous compounds of xenon have been prepared since the discovery of the noble-gas compounds in 1962. Although xenon itself is an unusually safe anesthetic, its compounds appear to be toxic.

Radon. Radon was originally called radium emanation: it is the radioactive gas formed, along with helium, as radium decays. The term radon sometimes has been restricted to the isotope of mass 222, other isotopes being referred to as thoron (symbolized Tn, now called radon-220), formed from thorium; and actinon (An, now radon-219), formed from actinium. The name emanation, symbolized Em, has been used to denote the entire family now recognized as radon isotopes. Radon has no stable isotope; radioactive isotopes having masses ranging from 204 through 224 have been identified, the longest-lived of these being radon-222, which has a half-life of 3.82 days. All the isotopes decay, the stable end-products being helium and isotopes of heavy metals, in most cases lead. (Ed.)

Transition elements

The so-called transition elements constitute a group of 56 (the majority of the 107 known elements); while the term transition has no particular chemical significance, it is a convenient name by which to distinguish the similarity of the atomic structures and resulting properties of the elements so designated. They occupy the middle portions of the long periods of the periodic table of elements (see Figure 10) between the groups on the left-hand side and the groups on the right. Specifically, they form Groups IIIb, IVb, Vb, VIb, VIIb, VIII, and Ib. Of these 56 transition elements only 24 are treated here (see Table 23 for list of names), the others being dealt with in subsequent sections as explained below.

GENERAL PROPERTIES OF THE GROUP

The most striking similarities shared by the 24 elements in question are that they are all metals and that most of them are hard, strong, and lustrous, have high melting and boiling points, and are good conductors of heat and electricity. The range in these properties is considerable, therefore the statements are comparative with the general properties of all the other elements.

Table 23: Abundance of the Transition Elements in the Earth's Solid Crust
(in grams per ton)

Titanium	5.7×10^2	Ruthenium	0.001
Vanadium	135	Rhodium	0.001
Chromium	102	Palladium	0.01

Molybdenum	1.5	Platinum	0.005
Technetium	~0	Gold	0.004

Many of the elements are technologically important: titanium, iron, nickel, and copper, for example, are used structurally and in electrical technology. Second, the transition elements form many useful alloys, with one another and with other metallic elements. Third, most of these elements dissolve in mineral acids although a few, such as platinum, silver, and gold, are called "noble"—that is, are unaffected by simple (nonoxidizing) acids.

Without exception, the elements of the main transition series (*i.e.,* excluding the lanthanides and actinides as specified below) exhibit variable valence and form stable compounds in two or more formal oxidation states (valence and oxidation states are explained in the following section).

The transition elements may be subdivided into two main types according to the electronic structures of their atoms, which are simply indicated here but fully explained in the section immediately following.

The three main transition series are called the first, second, and third transition series. The first series begins with either scandium (symbol Sc, atomic number 21) or titanium (symbol Ti, atomic number 22) and ends with copper (symbol Cu, atomic number 29). The second series includes the elements yttrium (symbol Y, atomic number 39) to silver (symbol Ag, atomic number 47). The third series extends from lanthanum (symbol La, atomic number 57) to gold (symbol Au, atomic number 79). These three main transition series are included in the set of 27 elements often called the *d*-block transition elements. Because scandium, yttrium, and lanthanum actually do not form compounds analogous to those of the other transition elements and because their chemistry is quite homologous to that of the lanthanides, they are excluded from the present discussion of the main transition elements. The *d*-block transition elements and some of their characteristic properties are listed in Table 24.

The lanthanides and the actinides comprise two other categories of transition elements. The first of these inner transition series includes the elements from cerium (symbol Ce, atomic number 58) to lutetium (symbol Lu, atomic number 71). These elements are called the lanthanides because the chemistry of each closely resembles that of lanthanum. Lanthanum itself is often regarded as one of the lanthanides. The actinide series consists of 15 elements from actinium (symbol Ac, atomic number 89) to lawrencium (symbol Lr, atomic number 103). These inner transition series are covered in the sections *Rare-earth elements* and *Actinide elements.* For elements 104 through 106, see below *Transuranium elements.*

(F.A.C./Ed.)

Electronic structure and position in the periodic table. The relative locations of the transition elements in the periodic table and their chemical and physical properties can best be understood by considering their electronic structures and the way in which those structures vary as atomic numbers increase.

Atomic orbitals. As noted earlier, the electrons associated with an atomic nucleus are localized, or concentrated, in various specific regions of space called atomic orbitals, each of which is characterized by a set of symbols (quantum numbers) that specify the volume, the shape, and orientation in space relative to other orbitals. An orbital may accommodate no more than two electrons. The en-

ergy involved in the interaction of an electron with the nucleus is determined by the orbital that it occupies, and the electrons in an atom distribute themselves among the orbitals in such a way that the total energy is minimum. Thus, by electronic structure, or configuration, of an atom is meant the way in which the electrons surrounding the nucleus occupy the various atomic orbitals available to them. The simplest configuration is the set of one-electron orbitals of the hydrogen atom. The orbitals can be classified, first, by principal quantum number, and the orbitals have increasing energy as the principal quantum number increases from 1 to 2, 3, 4, etc. (The sets of orbitals defined by the principal quantum numbers 1, 2, 3, 4, etc., are often referred to as shells designated *K, L, M, N,* etc.) For principal quantum number 1 there is but a single type of orbital, called an *s* orbital. As the principal quantum number increases, there are an increasing number of different types of orbitals, or subshells, corresponding to each: *s, p, d, f, g,* etc. Moreover, the additional orbital types each come in larger sets. Thus, there is but one *s* orbital for each principal quantum number, but there are three orbitals in the set designated *p,* five in each set designated *d,* and so on. For the hydrogen atom, the energy is fully determined by which orbital the single electron occupies. It is especially notable that the energy of the hydrogen atom is determined solely by the principal quantum number of the orbital occupied by the electron (except for some small effects that are not of concern here); that is, in hydrogen, the electron configurations of the third shell, for example, are equi-energic (of the same energy, whichever one the electron occupies), which is not the case with any of the other atoms, all of which contain two or more electrons.

To understand the electron configurations of other atoms, it is customary to employ the *Aufbau* (German: "building up") principle, the basis of which is that, to achieve a multi-electron configuration, the required number of electrons must be added to the orbitals one at a time, filling the most stable orbitals first, until the total number has been added. There is one restriction upon this conceptualization, namely, the Pauli exclusion principle, which states that only two electrons may occupy each orbital. Thus there can be no more than two electrons in any *s* orbital, six electrons in any set of *p* orbitals, ten electrons in any set of *d* orbitals, etc. In carrying out this process, however, one cannot simply use the ordering of electron orbitals that is appropriate to the hydrogen atom. As electrons are added they interact with each other as well as with the nucleus, and as a result the presence of electrons in some orbital causes the energy of an electron entering another orbital to be different from what it would be if this electron were present alone. The overall result of these interelectronic interactions (sometimes referred to as shielding) is that the relative order of the various atomic orbitals is different in many-electron atoms from that in the hydrogen atom; in fact, it changes continuously as the number of electrons increases.

Shielding

As multi-electronic atoms are built up, the various subshells *s, p, d, f, g,* etc. of a principal quantum number cease to be equi-energic; they all drop, although not by equal amounts, to lower energies. Overall lowering of energy occurs because the shielding from the nuclear charge that an electron in a particular orbital is given by all of the other electrons in the atom is not sufficient to prevent a steady increase in the effect that the charge in the nucleus has on that electron as the atomic number increases. In other words, each electron is imperfectly shielded from the nuclear charge by the other electrons. In addition the different types of orbitals in each principal shell, because of their different spatial distributions, are shielded to different degrees by the core of electrons beneath them; accordingly, although all of them decrease in energy, they decrease by different amounts, and thus their relative order in energy continuously changes. In order to specify the electron configuration of a particular atom, it is necessary to use the order of orbitals appropriate to the specific value of the atomic number of that atom. The behaviour of the various *d* and *f* orbitals is to be especially noted in regard to where the transition elements occur in the periodic table.

The argon atom (atomic number 18) has an electron configuration $1s^2\ 2s^2\ 2p^6\ 3s^2\ 3p^6$ (*i.e.,* it has two electrons in the *s* orbital of the first shell; two in the *s* and six in the *p* orbitals of the second shell; two in the *s* and six in the *p* orbitals of the third shell: this expression often is abbreviated [Ar] especially in specifying the configurations of elements between argon and krypton, because it represents a common part of the configurations of all these elements). The 3*d* orbitals are more shielded from the nuclear charge than is the 4*s* orbital, and, consequently, the latter orbital has lower energy. The next electrons to be added enter the 4*s* orbital in preference to the 3*d* or 4*p* orbitals. The two elements following argon in the periodic table are potassium, with a single 4*s* electron, and calcium, with two 4*s* electrons. Because of the presence of the 4*s* electrons, the 3*d* orbitals are less shielded than the 4*p* orbitals; therefore, the first regular transition series begins at this point with the element scandium, which has the electron configuration [Ar] $4s^2 3d^1$. Through the next nine elements, in increasing order of atomic number, electrons are added to the 3*d* orbitals until, at the element zinc, they are entirely filled and the electron configuration is [Ar] $3d^{10} 4s^2$. The 4*p* orbitals are then the ones of lowest energy, and they become filled through the next six elements, the sixth of which is the next noble gas, krypton, with the electron configuration $1s^2\ 2s^2\ 2p^6\ 3s^2\ 3p^6\ 4s^2\ 3d^{10}\ 4p^6$, or [Kr].

First transition series

Throughout the next period the pattern of variation of the orbital energies is similar to that immediately preceding. When the configuration of the noble gas, krypton, has been achieved, the 5*s* orbital is more stable than the 4*d* orbitals. The next two electrons therefore enter the 5*s* orbital, but then the 4*d* orbitals fall to lower energy than the 5*p* orbitals, and the second regular transition series commences with the element yttrium. Electrons continue to be added to the 4*d* orbitals until those orbitals are entirely filled at the position of the element cadmium, which has an electron configuration [Kr] $4d^{10} 5s^2$. The next six electrons enter the 5*p* orbitals until another noble gas configuration is attained at the element xenon. Analogously to the two preceding periods, the next two electrons are added to the next available orbital, namely, the 6*s* orbital, producing the next two elements, cesium and barium. At this point, however, the ordering of orbitals becomes more complex than it previously had been, because there are now unfilled 4*f* orbitals as well as the 5*d* orbitals, and the two sets have approximately the same energy. In the next element, lanthanum (atomic number 57), an electron is added to the 5*d* orbitals, but the immediately following element, cerium (atomic number 58), has two electrons in the 4*f* orbitals and none in the 5*d* orbitals. Through the next 12 elements the additional electrons enter the 4*f* orbitals, although the 5*d* orbitals are of only slightly higher energy. This set of elements, spanning the range from lanthanum, where the 4*f* orbitals were still vacant or about to be filled, through lutetium, in which the 4*f* orbitals are completely filled by 14 electrons, makes up the lanthanides, mentioned above.

Second transition series

At this point the next available orbitals are the 5*d* orbitals, and the elements hafnium through gold, the third regular transition series, correspond to the successive filling of these 5*d* orbitals. Following this series there are again *p* orbitals (6*p*) to be filled, and when this is accomplished the noble gas radon is reached.

Third transition series

Molecular orbitals. If two atoms are close together, some of their orbitals may overlap and participate in the formation of molecular orbitals. Electrons that occupy a molecular orbital interact with the nuclei of both atoms: if this interaction results in a total energy less than that of the separated atoms, as is the case if the orbital lies mainly in the region between the two nuclei, the orbital is said to be a bonding orbital and its occupancy by electrons constitutes a covalent bond that links the atoms together in compound formation and in which the electrons are said to be shared. If the occupation of an orbital by electrons raises the energy of the system, as is the case if the orbital lies mainly outside the region between the two nuclei, that orbital is said to be antibonding; the presence of electrons in such orbitals tends to offset the attractive force derived from the bonding electrons.

A bonding or an antibonding molecular orbital may be disposed along the line passing through the two nuclei (Figure 13A), in which case it is designated by the Greek letter σ (sigma); or it may occupy regions approximately parallel to that line (Figure 13B and 13C) and be designated π (pi).

DISCOVERY OF THE TRANSITION ELEMENTS

The most abundant transition element in the Earth's solid crust is iron, which is fourth among all elements and second (to aluminum) among metals in crustal abundance. The elements titanium, manganese, zirconium, vanadium, and chromium also have abundances in excess of 100 grams (3.5 ounces) per ton. Some of the most important and useful transition elements have very low crustal abundances—*e.g.,* tungsten, platinum, gold, and silver. Table 23 lists the abundances of the transition elements.

Four of the regular transition elements were known to the ancients: iron (*ferrum*), copper (*cuprum*), silver (*argentum*), and gold (*aurum*). Their chemical symbols (Fe, Cu, Ag, Au), in fact, are derived from their alchemical (Latin) names rather than their contemporary names. The other regular transition elements were discovered (or recognized as elements) after the early 18th century. The transition element most recently discovered in nature is rhenium (atomic number 75), which in 1925 was detected in platinum ores and in the niobium mineral columbite.

Technetium (atomic number 43) is the only *d*-block element that has not been isolated from the Earth's crust. All isotopes of technetium are radioactive; the half-life of even the stablest isotope, technetium-97, is too short to permit the survival of primordial technetium in the Earth's crust, and claims that it has been isolated or detected there must be considered erroneous. Technetium can be isolated in considerable quantities, however, from the fission products of nuclear reactors, and it is at least as readily available for chemical study as the naturally occurring similar element rhenium, of which there are no concentrated ores.

TRANSITION-METAL CATALYSTS

Types of transition-metal catalysts

One important use of transition metals and their compounds is as catalysts for a variety of industrial processes, mostly in the petroleum and polymer (plastics, fibres) industries, in which organic molecules are isomerized, built up from simple molecules, oxidized, hydrogenated, or caused to polymerize. Only a few of the most important such processes and their catalysts can be mentioned here. Catalysts are of two physical types: homogeneous (*i.e.,* dissolved in the reaction mixture) and heterogeneous (*i.e.,* constituting a solid phase separate from and insoluble in the reaction mixture). Both types are represented on the industrial scene, but the latter are much more common.

The introduction of catalysts that allow polymerization to be carried out at relatively low temperatures and pressures revolutionized the production of polyethylene and polypropylene. Previously polyethylene had to be made by a process requiring pressures of about 1,000 atmospheres, and polypropylene of useful properties was not commercially important. The catalysts devised and applied during the early 1950s are prepared from titanium tetrachloride and an aluminum alkyl such as triethylaluminum: the precipitated, titanium-containing solid, plus the excess aluminum alkyl in solution, constitutes the catalyst. A very different sort of catalyst, consisting of chromium(VI) oxide dispersed on silica-alumina, performs similarly in polymerizing ethylene but cannot produce a useful form of polypropylene.

Chromium in the form of chromium(III) oxide on alumina is the major industrial catalyst for transforming saturated hydrocarbons (*i.e.,* those in which all available valence bonds of the atoms are attached to other atoms) to useful olefins (unsaturated organic compounds), chiefly *n*-butane to butylene and butadiene.

Ammonia synthesis

Iron-containing catalysts are used in various processes of which the most notable is that for producing ammonia from nitrogen and hydrogen. This process, developed early in the 20th century, represents the first major industrial application of transition metal catalysis. The catalyst is magnetic triiron tetroxide (Fe_3O_4), "promoted" by the addition of small quantities of potassium oxide, aluminum oxide, calcium oxide, and silica.

Molybdenum in molybdenum(VI) oxide–aluminum oxide mixtures or in cobalt oxide–molybdenum oxide–aluminum oxide mixtures finds many applications, such as desulfurizing gases and liquids; removing lead, nickel, and vanadium from petroleum refinery feed stocks; and in modifying, or "reforming," crude petroleum fractions to increase their octane rating.

Olefins that are free of such impurities as carbon monoxide, sulfur, halogen, and compounds of arsenic or lead (catalyst poisons), can be hydrogenated (*i.e.,* combined with hydrogen) at atmospheric pressure and room temperature, using various types of active nickel preparations as catalysts.

Copper is a component of a variety of catalysts, of which the copper chromites, used for selective hydrogenation of carbonyl groups (compounds containing the divalent organic radical $>$CO), are perhaps the most important. Fats and oils can also be hydrogenated to alcohols using copper catalysts. Palladium chloride together with copper(I) salts forms a homogeneous catalyst for oxidizing ethylene to acetaldehyde (Wacker process), but commercial use of this process has been abandoned. Metallic platinum has a broad spectrum of catalytic activities. One of the most important in terms of tonnage production is in catalytic reforming of petroleum fractions to improve antiknock quality of gasoline. Silver oxide, on an inactive, refractory support, catalyzes oxidation of ethylene to ethylene oxide.

The oxo process (also called hydroformylation), in which certain olefins react with carbon monoxide and hydrogen to give aldehydes (a class of organic compounds that contain the group —CHO), requires a homogeneous catalyst containing a transition metal. The first practicable one was hydrogen tetracarbonylcobaltate(-I), $HCo(CO)_4$, which is formed in the reaction mixture by action of hydrogen on octacarbonyldicobalt, $Co_2(CO)_8$. More recently rhodium complexes have been found to have greater activity at lower temperatures and pressures and to be more easily recovered. The net reaction in the oxo process is represented by

$$\underset{\text{a terminal olefin}}{RCH{=}CH_2} + \underset{\text{carbon monoxide}}{CO} + \underset{\text{hydrogen}}{H_2} \longrightarrow \underset{\text{an aldehyde}}{RCH_2CH_2CHO.}$$

BIOLOGICAL FUNCTIONS OF TRANSITION METALS

Several transition elements are important to the chemistry of living systems, the most familiar examples being iron, cobalt, copper, and molybdenum. Iron is by far the most widespread and important transition metal that has a function in living systems; proteins containing iron participate in two main processes, oxygen transport and electron transfer (*i.e.,* oxidation–reduction) reactions. There are also a number of substances that act to store and transport iron itself.

Vitamin B_{12}

Though cobalt is understood to be an essential trace element in animal nutrition, the only detailed chemical knowledge of its biochemical action has to do with vitamin B_{12} and related co-enzymes. These molecules contain one atom of cobalt bound in a macrocyclic ring (*i.e.,* one consisting of many atoms) called corrin, which is similar to a porphyrin ring. Copper is found in both plants and animals, and numerous copper-containing proteins have been isolated. The blood of many lower animals, such as mollusks, cephalopods, gastropods, and decapods, contains respiratory proteins called hemocyanins, which contain copper atoms (but no heme) and appear to bind one oxygen molecule per two copper atoms. Human serum contains a glycoprotein called ceruloplasmin, the molecule of which contains eight copper atoms; its biological function is still uncertain. Other proteins, called cerebrocuprein, erythrocuprein, and hepatocuprein, that are found in the mammalian brain, erythrocytes, and liver, respectively, contain about 60 percent of the total copper in those tissues; their functions are still unknown. There are a number of copper-containing enzymes; examples are (1) ascorbic acid oxidase (an oxidase is an oxidizing enzyme), which contains eight atoms of copper per molecule; it is widely distributed in plants and microorganisms; (2) cytochrome oxidase, which contains heme and copper in a 1 : 1 ratio; (3) tyrosinases, which catalyze the formation of melanin (brownish-black pigments occurring in hair, skin, and retina of higher animals) and were the first enzymes in which copper was shown to be essential to function.

Nitrogen fixation

Vanadium occurs widely in petroleum, notably that from Venezuela, and can be isolated as porphyrin complexes, the origin of which is not known. Vanadium is present in high concentrations in blood cells (vanadocytes) of certain ascidians (sea squirts), apparently in a curious, complex, and poorly understood protein-containing substance called hemovanadin, thought to serve in oxygen transport. Molybdenum is believed to be a necessary trace element in animal diets, but its function and the minimum levels have not been established. Nitrogen-fixing bacteria utilize enzymes that contain both molybdenum and iron. One such enzyme, or at least a part of it that has been isolated in the crystalline state, contains two atoms of molybdenum and 40 atoms of iron. This protein in association with another, which contains only iron, can catalyze the reduction of nitrogen gas to nitrogen compounds.

THEORIES OF TRANSITION-METAL COMPLEXES

As has been noted, partially filled *d* orbitals account for the characteristic chemical properties of the regular transition elements, both as a class and as individuals. The interpretation and understanding of the chemical and physical properties of these elements thus depends heavily upon the description of these d^n (*n* is one or more but fewer than ten) electron configurations. The five orbitals of each *d* shell, regardless of principal quantum number, have the shapes and designations shown in Figure 14. The radial extent or size changes with principal quantum number, but the shapes are characteristic for all sets.

d-orbital subsets

For an atom or ion in free space and not subject to any electromagnetic field, the five orbitals of a set have equal energies; but in chemical compounds, the surrounding atoms cause the set to separate into subsets, differing in energy. This separation has a profound influence upon the spectroscopic properties (including colour) and magnetic properties of the substance, and the analysis of such effects has stimulated a great deal of theoretical and experimental effort. The most common situations to be considered are those in which a transition-metal ion occurs in an octahedron or a tetrahedron of surrounding anions or other ligands. Such cases illustrate the handling of the problem of the electronic structure of transition-metal ions in compounds.

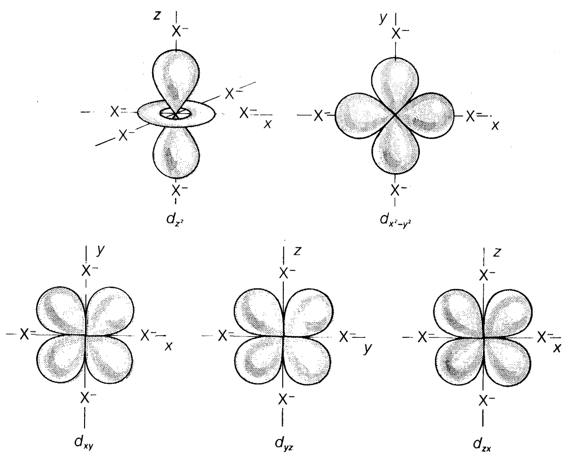

Figure 14: The shapes of the *d* orbitals and their conventional designations. The symbols X^- represent some or all of a set of six octahedrally located anions.

Three different theoretical approaches have been used: (1) the valence-bond treatment, pioneered in the United States by Linus Pauling; (2) the crystal-field theory or its more sophisticated form, the ligand-field theory, first proposed by Hans Bethe and developed extensively by the U.S. physicist J.H. Van Vleck; and (3) the molecular orbital theory, the application of which to transition-metal complexes was first discussed by Van Vleck. The second and third methods are used almost exclusively, and only those two will be outlined here.

Crystal-field and ligand-field theories. The crystal-field theory (CFT) employs an extreme electrostatic model, in which the ligands are treated as point charges (*i.e.,* as if the entire negative charge were concentrated at a single point in space) if they are anions or as point dipoles (*i.e.,* pairs of particles having equal and opposite charges that are separated by a finite distance) if they are neutral molecules. These extreme approximations are useful because they preserve certain essential features of the actual physical condition and yet reduce the mathematical problem to one that can be solved. Since the CFT treatment makes no allowance for covalence in the metal–ligand bonds, it necessarily does not account for all aspects of the electronic structures of complexes, even the most ionic ones. It can be amended, however, by empirical adjustment of certain parameters, to allow for some of the effects of covalence, without sacrificing mathematical convenience. This version of the theory, which can correlate much of the data on complexes of metals in their normal oxidation states, is called ligand-field theory (LFT).

Octahedral complexes

Orbital splitting patterns. Crystal-field theory treats the question of how the energies of a set of *d* electrons or orbitals are split when a set of ligands is placed around a central metal ion; it does so by treating the ligands as a set of negative charges. The simplest case to consider is that of an ion with a single *d* electron, surrounded by six negative charges at the vertices of an octahedron. This arrangement is defined, relative to a set of Cartesian axes, *x, y, z,* shown in Figure 15. By comparing the shapes of the *d* orbitals (see Figure 14) with this arrangement, it can be seen that the d_{xy}, d_{xz}, and d_{yz} orbitals have equivalent relationships to the set of charges. Thus, the electron will be repelled to the same extent by the negative charges regardless of which of the three orbitals it occupies. The

Tetrahedral complexes

three orbitals thus have equal energy and are called triply degenerate. It is not particularly obvious from a pictorial argument, but mathematical analysis shows that each of the other two orbitals, d_{z^2} and $d_{x^2-y^2}$, causes the electron to experience the same amount of electrostatic repulsion from the surrounding charges; they are described as doubly degenerate. Thus, the first important conclusion of the crystal-field theory is that the spatial relationships of the d orbitals to the surrounding charges cause the set of five d orbitals to be split into two subsets; the orbitals within each subset are equivalent to each other and are thus degenerate, but they are no longer degenerate with those in the other subset. Those in the subset consisting of the d_{xy}, d_{yz}, and d_{zx} orbitals are known as the t_{2g} orbitals; the d_{z^2} and $d_{x^2-y^2}$, pair are called the e_g orbitals. When the surrounding charges are located at the vertices of an octahedron, the two e_g orbitals are of higher energy than the three t_{2g} orbitals. When an ion is surrounded by a tetrahedrally arranged set of four negative charges, the d orbitals also split into a set of three and a set of two, but the energy order is the reverse of that in the octahedral case. Beginning with these splitting patterns it is possible to elaborate a detailed account of the magnetic and spectroscopic properties of transition-metal ions in their compounds.

Factors influencing magnetic properties

Magnetic and spectroscopic properties. Discussion of magnetic properties must begin with the basic question of how many unpaired electrons will be present. This is decided by the competition between two factors: (1) the electrons tend to occupy separate orbitals since this minimizes repulsions between them; and (2) the electrons also tend to occupy orbitals of lower energy in preference to higher ones. For ions with one, two, and three d electrons in octahedral fields, the first factor dictates, without opposition from the second, that the electrons occupy separate t_{2g} orbitals; such ions therefore always have 1, 2, and 3 unpaired electrons. Similarly, for configurations of eight and nine d electrons, the only possibilities are six electrons in t_{2g} orbitals and two in e_g orbitals, and six electrons in t_{2g} orbitals and three in e_g orbitals ($t_{2g}^6e_g^2$ and $t_{2g}^6e_g^3$), and such ions must always have 2 and 1 unpaired electrons, respectively. For cases of d^4, d^5, d^6, and d^7 configurations, the number of unpaired electrons depends on which of the two factors dominates. If the splitting (the energy difference between e_g and t_{2g} orbitals) is relatively small, control by the first factor produces the high-spin configurations, $t_{2g}^3e_g$, $t_{2g}^3e_g^2$, $t_{2g}^4e_g^2$, and $t_{2g}^5e_g^2$, which have 4, 5, 4, and 3 unpaired electrons, respectively. When the difference is relatively large, control by the second factor produces the low-spin configurations t_{2g}^4, t_{2g}^5, t_{2g}^6, and $t_{2g}^6e_g$, with 2, 1, 0, and 1 unpaired electrons, respectively. In tetrahedral complexes the splitting is always sufficiently small so that the first factor dominates and high-spin states are always obtained. Once the number of unpaired eletrons is known, numerical values of the magnetic moments are calculated by taking account of the interaction of the orbital-angular momentum with the spin-angular momentum.

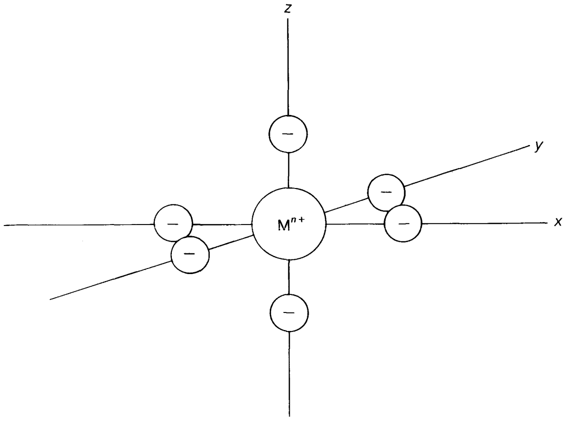

Figure 15: An octahedrally arranged set of negative charges in relation to a set of Cartesian coordinates with a positively charged metal ion (M^{n+} at the centre).

The spectra emitted by the electronic structures of transition-metal ions, which are responsible for their colours, can be understood in terms of the CFT splitting patterns. For a d^1 ion in an octahedral field, a single electronic transition, $t_{2g} \rightarrow e_g$, is expected; that is, the absorption of light raises the energy of an electron and causes it to pass from the low-energy t_{2g} orbital to the high-energy e_g orbital. The titanium(III), Ti^{3+}, ion, for example, has just a single absorption band in the visible region of the spectrum, at a wavelength of about 5,000 nanometres, corresponding to an energy of 20,000 cm^{-1}, which is assigned to this transition. This says that the orbital energy difference for Ti^{3+} in $[Ti(H_2O)_6]^{3+}$ is 20,000 per centimetre. For configurations with more than one d electron, electronic interactions require that an elaborate treatment, which cannot be explained here, be used.

The difference in the colours of hexaquonickel(II) ion, $[Ni(H_2O)_6]^{2+}$ (green), and tris (ethylenediamine) nickel(II) ion, $[Ni(H_2NCH_2CH_2NH_2)_3]^{2+}$ (purple), reflects the fact that the six nitrogen atoms cause a greater splitting than the six oxygen atoms.

In general, the relative magnitudes of d orbital splittings for a given ion with different ligand sets fall in a consistent order. This ordering of ligands according to their ability to split the d orbitals was discovered empirically in the 1930s and is called the spectrochemical series. A short list of ligands in order of their splitting power is fluoride (weakest), water, thiocyanate, pyridine or ammonia, ethylenediamine, nitrite, cyanide (strongest).

Jahn-Teller effect. According to the Jahn-Teller theorem, any molecule or complex ion in an electronically degenerate state will be unstable relative to a configuration of lower symmetry in which the degeneracy is absent. The chief applications of this theorem in transition-metal chemistry are in connection with octahedrally coordinated metal ions with high-spin d^4, low-spin d^7, and d^9 configurations; in each of these cases the t_{2g} orbitals are all equally occupied (either all half filled or all filled) and there is a single electron or a single vacancy in the e_g orbitals. Either an e_g or an e_g^3 configuration gives rise to a doubly degenerate (E) ground state, and thus a distortion of the octahedron is expected. In other words, high-spin d^4, low-spin d^7, and d^9 ions should be found in distorted, not regular, octahedral environments. It has been found by experiment that, with few possible exceptions, this is the case. The exceptions do not necessarily constitute violations of the Jahn-Teller theorem, because the slightness of the distortions may be within experimental error.

Distorted complexes

By far the most common form of distortion in the three cases given above is an elongation of the octahedron along one of its fourfold axes. Thus, two opposite ligands are farther from the metal ion than the other, coplanar (*i.e.,* lying in one plane) set of four. Such effects have been observed in compounds and complexes of high-spin chromium(II) and manganese(III) ions, ($t_{2g}^3e_g$); low-spin cobalt(II) and nickel(III) ions, ($t_{2g}^6e_g$); and copper(II) and silver(I) ions ($t_{2g}^6e_g^3$). The greatest body of data available is for copper(II) compounds, and some representative sets of copper–ligand distances are copper(II) chloride, four chloride ions at 2.30 Å and two at 2.95 Å; copper(II) bromide, four bromide ions at 2.40 Å and two at 3.18 Å.

Molecular-orbital theory. The molecular-orbital (MO) treatment of the electronic structures of transition-metal complexes is, in principle, a more flexible approach than the CFT or LFT treatments. Because a great many complexes and compounds in the ordinary oxidation states (II, III) of the transition metals are substantially ionic, the CFT and LFT treatments are useful though not exact. In the MO method, the ligand-atom orbitals and all of the valence-shell orbitals of the metal atom are presumed to interact to form molecular orbitals.

The interaction of a metal ion from the first transition series and an octachedral set of ligands that interact only through orbitals directed toward the metal ion results in the separation of the d orbitals of the metal ion into two sets of molecular orbitals; a t_{2g} set and a higher energy e_g set. This is the same pattern as that obtained in the

CFT treatment, but the difference is that now the t_{2g} and e_g orbitals are regarded not as pure d orbitals but as molecular orbitals, having both metal d orbital and ligand orbital components. Thus, the modifications of CFT that lead to LFT—that is, inclusion of covalence effects—are in harmony with the basic ideas of the MO treatment.

THE ELEMENTS OF THE FIRST TRANSITION SERIES

General chemical trends of the first transition series

Although the transition elements have many general chemical similarities, each one has a detailed chemistry of its own. The closest relationships are usually to be found among the three elements in each vertical group in the periodic table, although within each group the element of the first series usually differs more from the other two than they differ from each other. Most of the first series elements are more familiar and technically important than the heavier members of their vertical group. Thus, it is convenient to discuss first each of the metals of the first transition series and then to discuss the remaining ones in pairs.

Before considering each of the individual elements, a few of the chemical trends to be found in the first transition series may be capsulized.

1. From titanium to manganese the highest valence exhibited, which usually is found only in oxo compounds, fluorides, or chlorides, corresponds to the total number of $3d$ and $4s$ electrons in the atom. The stability of this highest oxidation state decreases from titanium(IV) to manganese(VII). Following manganese—that is, for iron, cobalt, and nickel—oxidation states corresponding to the loss of all $3d$ and $4s$ electrons do not occur; higher oxidation states in general become progressively more difficult to attain because the increasing nuclear charge causes the $3d$ electrons to be more tightly bound. Very high oxidation states occur only for chromium(V, VI), manganese(V, VI, VII), and iron(V, VI) and apart from the fluorides, such as chromium(V) fluoride, CrF_5, and chromium (VI) fluoride, CrF_6, and oxofluorides such as manganese(VII) trioxide fluoride, MnO_3F, the main chemistry in these oxidation states is that of oxo anions such as manganate(VII), MnO_4^-; chromate(VI), CrO_4^{2-}; and ferrate(VI), FeO_4^{2-}. All of these compounds are powerful oxidizing agents.
2. The oxides of each element become more acidic with increasing oxidation number, and the halides become more covalent and susceptible to hydrolysis.
3. In the oxo anions characteristic of the higher valence states the metal atom is tetrahedrally surrounded by oxygen atoms, whereas in the oxides formed in the lower valence states the atoms are usually octahedrally coordinated.
4. In the oxidation states II and III, complexes in aqueous solution or in crystals are usually four-, five- or six-coordinated.
5. Oxidation states lower than II are not found in the ordinary chemistries of the transition elements, except for copper. The lower oxidation states are, however, attainable for all the elements using ligands of the carbon monoxide type.

Titanium. The preparation of pure titanium is difficult because of its reactivity. Titanium cannot be obtained by the common method of reducing the oxide with carbon because a very stable carbide is readily produced and, moreover, the metal is quite reactive toward oxygen and nitrogen at elevated temperatures. Therefore, special processes have been devised. One of the ores, such as ilmenite ($FeTiO_3$) or rutile (TiO_2), is treated at red heat with carbon and chlorine to yield titanium tetrachloride, $TiCl_4$, which is fractionally distilled to eliminate impurities such as ferric chloride, $FeCl_3$. The $TiCl_4$ is then reduced with molten magnesium at about 800° C in an atmosphere of argon, and metallic titanium is produced as a spongy mass from which the excess of magnesium and magnesium chloride can be removed by volatilization at about 1,000° C. The sponge may then be fused in an atmosphere of argon or helium in an electric arc and be cast into ingots. On the laboratory scale, extremely pure titanium can be made by vaporizing the tetraiodide, TiI_4, in very pure form and decomposing it on a hot wire in vacuum.

itanium
roduction

The atoms are arranged in a hexagonal, close-packed lattice in titanium, which resembles other transition metals such as iron and nickel in being hard, refractory, and a good conductor of heat and electricity. It is quite light in comparison to other metals of similar mechanical and thermal properties, however, as well as unusually resistant to certain types of corrosion, and therefore it has come into demand for special applications in engineering.

Although titanium is rather unreactive at ordinary temperatures, it combines directly with many nonmetals, such as hydrogen, the halogens, oxygen, nitrogen, carbon, boron, silicon, and sulfur at elevated temperatures. The resulting nitride (TiN), carbide (TiC), and borides (TiB and TiB_2) are interstitial compounds that are very stable, hard, and refractory. Titanium is not attacked by mineral acids at room temperature or by hot aqueous alkali; it dissolves in hot hydrochloric acid, giving trivalent titanium species, and hot nitric acid converts it into a hydrous oxide that is rather insoluble in acid or base. The best solvents for the metal are hydrofluoric acid or other acids to which fluoride ions have been added; such mediums dissolve titanium and hold it in solution because of the formation of fluoro complexes.

Preparation and uses of vanadium

Vanadium. The preparation of very pure vanadium is difficult because the metal is quite reactive toward oxygen, nitrogen, and carbon at elevated temperatures. Because the major commercial use of vanadium is in steel and cast iron, to which it lends ductility and shock resistance, vanadium is produced commercially mainly in the form of an iron alloy called ferrovanadium. When the very pure metal is required, it may be obtained by processes described in the foregoing discussion of titanium. Very pure vanadium metal resembles titanium in being quite corrosion resistant, hard, and steel gray in colour. In the massive state it is not attacked by air, water, alkalies, or nonoxidizing acids other than hydrofluoric acid. It dissolves in nitric acid, concentrated sulfuric acid, or aqua regia and at high temperatures will combine with nearly all nonmetals. For vanadium the important oxidation states are II, III, IV, and V.

Chromium. The name of the element chromium (from Greek *chrōmos,* "colour") connotes the pronounced and varied colorations of chromium compounds. The red colour of ruby and the green colour of emerald, to mention only gems, are due to small amounts of chromium. The free metal is never found in nature; most ores consist of the mineral chromite, the ideal formula of which is $FeCr_2O_4$. Natural deposits are usually contaminated with magnesium, aluminum, and silica and their chromium content varies from 42 to 56 percent. One of the chief uses of chromium is in ferrous alloys, for which the pure metal is not required. Accordingly, chromite is often reduced with carbon in a furnace, producing the alloy ferrochromium, which contains iron and chromium in an atom ratio of approximately 1 to 2. To obtain pure chromium, chromite is first treated with molten alkali and oxygen, converting all of the chromium to the alkali chromate, and the latter is dissolved in water and eventually precipitated as sodium dichromate, $Na_2Cr_2O_7$. The dichromate is then reduced with carbon to chromium(III) oxide, Cr_2O_3, and that oxide in turn reduced with aluminum to give the chromium metal.

The metal is white, hard, lustrous, and brittle and is extremely resistant to ordinary corrosive reagents; this resistance accounts for its extensive use as an electroplated protective coating. Chromium metal dissolves rather readily in nonoxidizing mineral acids—for example, hydrochloric or sulfuric acids; it does not dissolve in cold aqua regia or in nitric acid because of a curious phenomenon known as passivation, in which the metal presumably becomes covered with a thin unreactive coating. At elevated temperatures chromium unites directly with the halogens or with sulfur, silicon, boron, nitrogen, carbon, or oxygen.

Manganese. As in the case of titanium, vanadium, and chromium, the highest oxidation state (+7) of manganese corresponds to the total number of $3d$ and $4s$ electrons. That state occurs only in the oxo species manganate (VII) (MnO_4^-), manganese(VII) oxide (Mn_2O_7), and manganese(VII) trioxide fluoride (MnO_3F), which show some similarity to corresponding compounds of the halogens—for example, in the instability of the oxide. Manganese in oxidation state +7 is powerfully oxidizing, usually being reduced to divalent manganese. The intermediate oxidation states are known, but, except for some compounds in the +3 and +4 states, they are not particularly important.

Manganese, first recognized as an element by the Swedish chemist Carl Wilhelm Scheele in 1774, is second only to iron among the transition elements in its abundance in the Earth's crust and is roughly similar to iron in its physical and chemical properties but is harder and more brittle. Although it is widely distributed, manganese occurs in a number of substantial deposits, mainly the oxides, of which the mineral pyrolusite (manganese(IV) oxide, MnO_2) is the most important. Manganese is quite electropositive, dissolving very readily in dilute non-oxidizing acids. Although relatively unreactive toward nonmetals at room temperature, it reacts with many at elevated temperatures. Thus, manganese burns in chlorine to give manganese(II) chloride, $MnCl_2$; reacts with flourine to give manganese(II) and (III) fluorides, MnF_2 and MnF_3; and burns in nitrogen at about 1,200° C to give manganese (II) nitride, Mn_3N_2, and in oxygen to give trimanganese tetroxide Mn_3O_4. Manganese also combines directly with boron, carbon, sulfur, silicon, or phosphorus, but not with hydrogen. The most important oxidation states for manganese are +2, +3, +7.

Iron. Hundreds of mineral species contain iron as a constituent, and igneous rocks average about 5 percent iron content. The major iron ores are the minerals hematite [iron(III) oxide, Fe_2O_3], magnetite [triiron tetroxide, Fe_3O_4], limonite [iron(III) oxide hydroxide, FeO(OH)], and siderite [iron(II) carbonate, $FeCO_3$].

For the element iron the trends already noted in the relative stabilities of oxidation states among elements of the first transition series are continued, except that there is no compound or chemically important circumstance in which the oxidation state of iron is equal to the total number of its valence shell electrons, eight; the highest known oxidation state is +6, which is rare and unimportant. Even the trivalent state, which is important at the position of chromium in the periodic table, loses ground to the divalent state at the position of iron. This trend continues in the remaining elements with the sole exception of trivalent cobalt, which is stable in a host of complexes.

The Mössbauer effect

Iron compounds are amenable to study by taking advantage of a phenomenon known as the Mössbauer effect (the phenomenon of a gamma ray being absorbed and reradiated by a nucleus without recoil). Although the Mössbauer effect has been observed for about one-third of the elements, it is particularly for iron (and to a lesser extent tin) that the effect has been a major research tool for the chemist. In the case of iron the effect depends on the fact that the nucleus of iron-57 can be excited to a high energy state by the absorption of gamma radiation of very sharply defined frequency that is influenced by the oxidation state, electron configuration, and chemical environment of the iron atom and can thus be used as a probe of its chemical behaviour.

Pure iron is a white, lustrous metal that is not particularly hard and is quite reactive. As commonly available, however, iron almost always contains small amounts of carbon, which modify its properties greatly. In a very finely divided state metallic iron is pyrophoric (*i.e.,* it ignites spontaneously). It combines vigorously with chlorine on mild heating and also with a variety of other nonmetals, including all of the halogens, sulfur, phosphorus, boron, carbon, and silicon (the carbide and silicide phases play major roles in the technical metallurgy of iron). Metallic iron dissolves readily in dilute mineral acids. With nonoxidizing acids and in the absence of air divalent iron is obtained; with air present or when warm dilute nitric acid is used, some of the iron goes into solution as the iron(III) ion, Fe^{3+}. Very strongly oxidizing mediums, for example, concentrated nitric acid or acids containing dichromate, passivate iron (*i.e.,* cause it to lose its normal chemical activity), however, much as they do chromium (see above). Air-free water and dilute air-free hydroxides have little effect on the metal, but it is attacked by hot concentrated sodium hydroxide.

Rusting of iron

Under normal atmospheric conditions iron rusts to form hydrated oxides, a process that occurs in two steps: first, iron dissolves in the acid solution produced by the moisture and the carbon dioxide of the air, to form ferrous iron—*i.e.,* iron(II)—and liberate hydrogen; second, oxygen from the air oxidizes the ferrous iron to form hydrated iron(III) oxide.

The stable structure of iron up to 766° C is that of a crystal form called body-centred cubic, and it is ferromagnetic (*i.e.,* capable of being permanently magnetized). Above this temperature the structure is retained but the magnetic properties change to simple paramagnetic (*i.e.,* capable of being only weakly magnetized and only as long as the magnetizing field is present). At 906° C the structure changes to a crystal form called cubic close-packed; but there is another structural change at 1,401° C, and iron reverts to the body-centred cubic structure.

Cobalt. The trends toward decreased stability for very high oxidation states and increased stability of the +2 state relative to the +3 state, which have been evident through the series titanium, vanadium, chromium, manganese, iron, persist with cobalt. In fact there is a complete absence of oxidation states higher than +4 under chemically significant conditions, and even the latter may be represented by only a few incompletely characterized compounds. The +3 state is relatively unstable in simple compounds, but forms a host of low-spin complexes, most of them involving ammonia or amines as ligands. The oxidation state +1 is perhaps better known for cobalt than for any other element in the first transition series except copper.

The abundance of cobalt in the Earth's crust is relatively low, and the element is widely distributed; even the best cobalt ores contain only low concentrations of the element and require complex processing to concentrate and extract it. In general, little cobalt ore is mined for the cobalt content: the metal is recovered as a by-product from the ores of other metals, particularly copper and nickel.

Cobalt is a hard, bluish-white metal and, along with iron and nickel, is one of the three metals that are ferromagnetic at room temperature. It dissolves slowly in dilute mineral acids, does not combine directly with either hydrogen or nitrogen, but will combine, on heating, with carbon, phosphorus, or sulfur. Cobalt is also attacked by oxygen and by water vapour at elevated temperatures, with the result that cobalt(II) oxide, CoO, is produced.

Nickel. Typical compounds of nickel in nature, in which it occurs primarily as minerals in combination with arsenic, antimony, and sulfur, are nickel(II) sulfide, NiS; nickel (III) arsenide, NiAs; nickel(III) antimonide, NiSb; nickel (III) diarsenide, $NiAs_2$; nickel(III) thioarsenide, NiAsS; and nickel(III) thioantimonide, NiSbS. Some commercially important deposits contain the mineral garnierite, a magnesium–nickel silicate of variable composition. Also certain varieties of the iron mineral pyrrhotite contain 3 to 5 percent nickel. Elemental nickel is found alloyed with iron in many meteors, and the central regions of the Earth are believed to contain considerable quantities. The free metal is never found in the Earth's crust. The metallurgy of nickel is complicated in its details, many of which vary widely, according to the particular ore being processed. In general the ore is transformed to nickel(III) sulfide, Ni_2S_3, which is roasted in air to give nickel(II) oxide, NiO, which is then reduced with carbon to obtain the metal. Some high-purity nickel is made by the carbonyl process mentioned earlier.

Properties and reactions of nickel

Nickel is a silver-white metal with high electrical and thermal conductivity and it can be fabricated readily by the use of standard hot and cold working methods. The metal is fairly resistant to attack by air or water at ordinary temperatures when compact and is therefore often electroplated as a protective coating. Nickel reacts only slowly with fluorine, eventually developing a protective coating of the fluoride, and therefore is used as the pure metal or in the form of alloys such as Monel metal (which contains some 60 to 70 percent nickel, 30 to 40 percent copper, and small amounts of other metals such as iron) in equipment for handling fluorine gas and corrosive fluorides. Nickel is ferromagnetic at ordinary temperatures, although not as strongly so as iron, and is less electropositive than iron but dissolves readily in dilute mineral acids.

Copper. Copper is distributed widely in nature in the form of the free metal, sulfides, arsenides, chlorides, and carbonates. It is extracted by oxidative roasting and smelting, followed by electrodeposition from sulfate solutions, and it is technologically important, particularly in alloys, as an electroplated coating and as an exceptionally good

Properties and reactions of copper

conductor of heat and electricity. The pure metal is soft, tough, ductile, and characteristically reddish in colour and is second only to silver in thermal and electrical conductivity. Metallic copper is only superficially oxidized in air, sometimes acquiring a green coating that is a mixture of hydroxo-carbonate, hydroxosulfate, and small amounts of other compounds.

Copper is a moderately noble metal, being unaffected by nonoxidizing or noncomplexing dilute acids in the absence of air; it will, however, dissolve readily in nitric acid and in sulfuric acid in the presence of oxygen and is also soluble in aqueous ammonia or potassium cyanide in presence of oxygen, because of the formation of very stable cyano complexes upon dissolution. The metal will react at red heat with oxygen to give copper(II) oxide, CuO, and, at higher temperatures, copper(I) oxide, Cu_2O. It reacts on heating with sulfur to give copper(I) sulfide, Cu_2S.

Copper forms compounds in the oxidation states +1 and +2 in its normal chemistry, although under special circumstances some compounds of trivalent copper can be prepared.

THE ELEMENTS OF THE SECOND AND THIRD TRANSITION SERIES

Differences in properties of elements in the second and third series from those of the first

While the elements in the second and third transition series for a given group have chemical properties similar to those of the element in the first series, they nevertheless show definite differences from the lighter element of the group. The following examples illustrate this point: (1) Although cobalt (of the first series) forms a considerable number of tetrahedral and octahedral complexes in its divalent state, and that valence state is characteristic in ordinary aqueous chemistry, divalent states of rhodium (second series) and iridium (third series) are rare and relatively unimportant. (2) The manganese(II) ion (Mn^{2+}) is very stable and of principal importance in the chemistry of manganese, but for technetium and rhenium the oxidation state +2 is little more than a laboratory curiosity. (3) Trivalent chromium forms a great number of complexes, which make up one of the best known aspects of the chemistry of the element; whereas trivalent molybdenum and tungsten are not particularly stable states under any conditions and form only a few complexes. (4) The oxy anions of the first-row elements in their higher oxidation states—for example, chromate(VI) and manganate(VII)—are powerful oxidizing agents the chemistry of which is essentially restricted to that function; whereas their stoichiometric analogues, such as molybdate(VI), tungstate (VI), technetate(VII), and rhenate(VII), are quite stable and have an extensive and diverse chemistry. There are, however, some cases in which quite valid and useful analogies can be found between the chemistry of the lighter element and the two heavier elements of the group. For instance, the chemistry of trivalent rhodium complexes is, in general, quite similar to that of trivalent cobalt complexes. On the whole, however, there are differences more consistently than there are similarities between the first element and the heavier elements of each group.

For the heavier transition elements, higher oxidation states are generally more stable than is the case for the elements in the first transition series; this is true not only, as has been mentioned, for the properties of the oxo anions but for the higher halides as well. Thus the heavier elements form compounds such as ruthenium(VIII) oxide, RuO_4; tungsten(VI) chloride, WCl_6; platinum(VI) fluoride, PtF_6, etc., which have no analogues among the first-row elements, whereas the chemistry of aquo ions of lower valence states, especially +2 and +3, which is such a dominant part of the chemistry of the lighter elements, is relatively unimportant for most of the heavier ones.

One of the reasons for the generally close similarity in chemistry between the second and third transition series elements of a given group is the so-called lanthanide contraction. As already described, the series of elements known as the lanthanides comes between the second and third regular transition series and is formed by the filling of the 4*f* orbitals. The 5*d* and 6*s* orbitals, which are the valence shell orbitals for the third transition series elements, are imperfectly shielded by the 4*f* electrons from the increased nuclear charge. There is consequently, a steady contraction in the size of these orbitals through the lanthanide series of elements, with the net result that the atomic and ionic radii of hafnium, which immediately follows the lanthanide series, are almost identical to the corresponding radii of the zirconium atom, which lies just above it in Group IV. Because the zirconium and hafnium atoms have almost identical sizes as well as analogous electron configurations in all of their oxidation states, their chemistry and the properties of their compounds are exceedingly similar; indeed, it is very difficult to separate the two elements because of the great similarity in properties of their compounds. In moving along the third transition series, there is a steady but slow divergence in the properties of the second and third elements in each group so that, at the end, considerable differences exist between those of palladium and platinum and of silver and gold. The differences are not as great, however, as might have been expected had the lanthanide contraction not intervened to preclude greater disparity in the orbital sizes. Although niobium and tantalum are not quite as similar as zirconium and hafnium, the differences between them are slight, and, similarly, molybdenum and tungsten, technetium and rhenium, ruthenium and osmium, and rhodium and iridium show marked similarities in their chemistries.

Zirconium and hafnium. Zirconium occurs widely in the Earth's crust, but not in concentrated deposits. The mineral zircon, $ZrSiO_4$ (zirconium orthosilicate), which is generally found in alluvial deposits in stream beds, ocean beaches, or old lake beds, is the only commercial source of zirconium. Baddeleyite, which is essentially pure zirconium(IV) oxide, ZrO_2, is the only other important zirconium mineral. These zirconium minerals generally have a hafnium content that varies from a few tenths of 1 percent to several percent. For some purposes separation of the two elements is not important: zirconium containing about 1 percent of hafnium is as acceptable as pure zirconium. In the case of the largest single use of zirconium, however, namely, as a structural and cladding material in atomic reactors, it is essential that the zirconium be essentially free of hafnium, because the usefulness of zirconium in reactors is based on its extremely low absorption cross section for neutrons. Hafnium, on the other hand, has an exceptionally high cross section, and accordingly even slight hafnium contamination nullifies the intrinsic advantage of the zirconium. Pure hafnium in fact is also used in some atomic reactors as a control element material because of its high neutron-capture cross section.

Separation of hafnium and zirconium is generally accomplished by a liquid–liquid countercurrent-extraction procedure. In the procedure, crude zirconium(IV) chloride is dissolved in an aqueous solution of ammonium thiocyanate and methyl isobutyl ketone is passed countercurrent to the aqueous mixture, with the result that the hafnium(IV) chloride is preferentially extracted.

Either of the metals, or a mixture of the two, is produced by the same process as that described in the section *Titanium* (see above). Both the metals have extremely high melting points: zirconium 1,850° C and hafnium 2,230° C. Hafnium and zirconium are fairly resistant to acids and are best dissolved in hydrofluoric acid, in which procedure the formation of anionic fluoro complexes is important in stabilizing the solution. At normal temperatures neither metal is particularly reactive, but both become quite reactive with a variety of nonmetals at elevated temperatures.

The atomic radii of zirconium and hafnium are 1.45 and 1.44 Å, respectively, while the radii of the ions are Zr^{4+}, 0.74 Å, and Hf^{4+}, 0.75 Å. The virtual identity of atomic and ionic sizes, resulting from the lanthanide contraction, has the effect of making the chemical behaviour of these two elements more similar than for any other pair of elements known. Although the chemistry of hafnium has been studied less than that of zirconium, the two are so similar that only very small quantitative differences—for example, in solubilities and volatilities of compounds—would be expected in cases that have not actually been investigated.

The most important respect in which these two elements differ from titanium is that lower oxidation states are of minor importance; there are relatively few compounds of hafnium or zirconium in other than their tetravalent states. The increased size of the atoms makes the oxides more basic and the aqueous chemistry somewhat more extensive, and permits the attainment of coordination numbers 7 and, quite frequently, 8 in a number of zirconium and hafnium compounds.

Close association in nature

Niobium and tantalum. Although not quite as similar to each other as are hafnium and zirconium, niobium and tantalum differ but little in their chemistry, and, thus, separation problems are significant. Due to their great chemical similarity and consequent close association in nature, in fact, the establishment of the individual identities of the two elements was very difficult. Niobium was probably first discovered in 1801, in an ore sample from Connecticut, by an English chemist, Charles Hatchett, who named the element columbium in honour of the country of its origin, Columbia being a synonym for the United States. In 1844 a German chemist, Heinrich Rose, discovered what he considered to be a new element occurring along with tantalum and named it niobium after Niobe, the mythological goddess who was the daughter of Tantalus. After considerable controversy it was decided that columbium and niobium were the same element, and eventually international agreement was reached to adopt the name niobium. The name columbium is often seen, however, even today, especially in the metallurgical literature.

Niobium is roughly ten times more abundant in the crust of the Earth than is tantalum. The main commercial sources of both elements are the columbite–tantalite series of minerals, in which columbite ($FeNb_2O_6$) and tantalite ($FeTa_2O_6$) occur in highly variable ratios. Niobium is also obtainable from pyrochlore, a calcium sodium niobate. The production procedures for the metals are complex, the major problem being separation of the two elements, which is solved mainly by use of a liquid–liquid extraction process. The metals themselves are obtained by either electrolysis of fused salts or reduction of fluoro complexes with a very reactive metal such as sodium. Both metals are bright, have high melting points (niobium, 2,468° C, tantalum, 2,996° C), and are quite resistant to acids. They can best be dissolved in a mixture of nitric and hydrofluoric acids.

Molybdenum and tungsten. Molybdenum (Mo) and tungsten (W) are very similar chemically, although there are some differences that are not easy to explain. They have similar abundances and occur in nature in the same sorts of compounds; neither occurs as a free metal. For molybdenum the chief ore is molybdenite—molybdenum(IV) sulfide, MoS_2—but molybdates such as lead molybdate, $PbMoO_4$ (wulfenite), and $MgMoO_4$ are also found. Although tungsten occurs as tungstenite—tungsten(IV) sulfide, WS_2—the most important ores in this case are the tungstates such as scheelite (calcium tungstate, $CaWO_4$), stolzite (lead tungstate, $PbWO_4$), and wolframite—a solid solution or a mixture or both of the isomorphous substances iron(II) tungstate, $FeWO_4$, and maganese(II) tungstate, $MnWO_4$.

The small quantities of molybdenite in molybdenum ores are concentrated by foam flotation processes and roasted to give molybdenum(VI) oxide, MoO_3, which, after purification, can be reduced with hydrogen to the metal. For tungsten the ores are concentrated by magnetic and mechanical processes and the concentrate then fused with alkali. The crude melts are leached with water to give solutions of sodium tungstate, from which hydrous tungsten(VI) oxide is precipitated upon acidification, and the oxide is then dried and reduced to metal with hydrogen. The metals are quite refractory, the melting points being 2,610° C for molybdenum and 3,410° C for tungsten. Both metals are rather resistant to attack by acids, except for mixtures of concentrated nitric and hydrofluoric acids, and both can be attacked rapidly by alkaline oxidizing melts, such as fused mixtures of potassium nitrate and sodium hydroxide or sodium peroxide; aqueous alkalies, however, are without effect. The metals are inert to oxygen at normal temperature, but combine with it readily at red heat, to give the trioxides, and are attacked by fluorine at room temperature, to give the hexafluorides. Both elements form hard, refractory, and chemically inert interstitial compounds with boron, carbon, nitrogen, and silicon upon direct reaction with those elements at high temperatures. Tungsten carbide is extensively used for high-speed cutting tools; tungsten metal itself has wide application as a lamp filament, and molybdenum is used in a number of small-scale applications in which high resistance to erosion at high temperatures is required—*e.g.,* in jet engines, combustion liners, and afterburner parts.

Technetium and rhenium. As has been noted, technetium does not occur in nature; nor does rhenium occur free in nature or as a compound in any distinct mineral; instead it is widely distributed in small amounts in other minerals. Rhenium is generally isolated from flue dusts and gases obtained on the roasting of molybdenites that contain rhenium. Such gases can be leached or scrubbed with water to dissolve the oxide, Re_2O_7, which in turn can be converted to ammonium rhenate(VII) (perrhenate), NH_4ReO_4, and then reduced to the metal with hydrogen. The melting point of rhenium, 3,170° C, is exceeded only by those of tungsten and carbon.

Technetium and rhenium are very similar chemically and differ greatly from manganese. Their most characteristic and important compounds are formed in the oxidation states $+4$ and $+7$, although compounds are known in all formal oxidation states from -1 to $+7$. Rhenium has only minor uses; for example, as an alloy with tungsten in flash bulb filaments; technetium has essentially none.

Ruthenium and osmium. Both ruthenium and osmium have low crustal abundances of about 0.001 part per million. They occur in nature along with the other platinum metals, and processes for isolating them are an integral part of the metallurgical art that applies to all of them.

High resistance to chemical attack

Ruthenium and osmium are hard, bright metals having high melting points and resistance to chemical attack. They are the most noble of the platinum metals, and cold and hot acids, even including aqua regia, are without effect on them. They can be dissolved by fused alkalies, especially if an oxidizing agent such as sodium chlorate is present. Osmium will react at 200° C with air or oxygen to form the volatile tetroxide, OsO_4. Although ruthenium tetroxide, RuO_4, has similar stability and volatility to osmium tetroxide, OsO_4, it differs in that it cannot be formed from the elements.

The chemistries of ruthenium and osmium are generally similar and differ markedly from that of iron. The higher oxidation states $+6$ and $+8$ are much more readily obtained than for iron, and there is an extensive chemistry of the tetroxides, oxohalides, and oxo anions. For both elements there is little, if any, evidence that simple aquo ions exist, and virtually all their aqueous solutions, whatever the anions present, may be considered to contain complexes. In addition to carbonyl and organometallic compounds in the low oxidation states -2, 0, and $+1$, both elements form compounds in every oxidation state from $+2$ to $+8$. The most important oxidation states, however, are $+2$, $+3$, $+4$, $+6$, and $+8$.

Rhodium and iridium. Rhodium and iridium occur in nature in association with the other platinum metals, and their separation and refinement form part of the overall metallurgical processing of the group, which is discussed elsewhere. These metals are somewhat more reactive than ruthenium and osmium. Rhodium will dissolve in hot concentrated sulfuric acid and both dissolve in concentrated hydrochloric acid containing sodium perchlorate at 125°–150° C. Both will dissolve in aqua regia.

For both elements, the most important chemistry is that of the oxidation states $+1$ and $+3$, although iridium forms some complexes in oxidation state $+4$ and rhodium forms the dirhodium tetraacetate, $Rh_2(O_2CCH_3)_4$ and various derivatives containing two additional ligands—*e.g.,* water, pyridine, or triphenylphosphine—in oxidation state $+2$. Complexes in oxidation state $+1$ chiefly contain carbon monoxide, olefins, and phosphines as ligands. Hexachloroiridate(IV), $IrCl_6^{2-}$, and hexabromoiridate(IV), $IrBr_6^{2-}$, are the only notable chemical species containing tetravalent iridium.

Palladium and platinum. Platinum and palladium are more abundant than any of the other platinum metals. Platinum is by far the best known and technologically the most important. Both palladium and platinum are more reactive than the other platinum metals. Palladium is readily attacked by concentrated nitric acid and in its sponge form will dissolve even in hydrochloric acid in presence of chlorine or oxygen. Platinum is not attacked by any single mineral acid, but it dissolves readily in aqua regia and slowly in hydrochloric acid in presence of air. Both metals are rapidly attacked by fused alkali oxides and peroxides and also by fluorine and chlorine at about 500° C. They also combine with a number of nonmetallic elements on heating, such as phosphorus, arsenic, antimony, silicon, sulfur, and selenium.

Both metals, but especially palladium, are capable of absorbing large volumes of hydrogen. At 80° C and one atmosphere, palladium will absorb up to 900 times its own volume. The absorption causes both the electrical conductivity and magnetic susceptibility to decrease. These and other observations have led some investigators to conclude that there is a definite palladium hydride phase, although its structure and ideal composition are not firmly established.

Silver and gold. Silver and gold are two of the noblest—that is, least chemically reactive—of the transition elements, and both are found in nature in the free state. For silver the more important deposits commercially are such compounds as the mineral argentite (silver sulfide, Ag_2S), which is usually associated with other sulfides such as those of lead and copper, as well as several other sulfides, some of which contain antimony as well. Silver is found generally in lead ores, copper ores, and cobalt arsenide ores and is also frequently associated with gold in nature. Most silver is derived as a by-product from ores that are mined and processed to obtain these other metals. Gold is most commonly found free, the only compounds of gold in nature being various tellurides.

Silver is a white, lustrous metal and is among the most ductile and malleable ones known. Pure silver has the highest electrical and thermal conductivities of all metals. Gold is a soft, yellow metal that has the highest ductility and malleability of any element.

Reactivity of silver and gold

Silver is less reactive chemically than copper except toward sulfur and hydrogen sulfide, which rapidly blacken silver surfaces. The metal will dissolve in oxidizing acids and in solutions containing cyanide ions in the presence of oxygen or peroxides. Gold is much less reactive and is not attacked by oxygen or sulfur, although it will react readily with halogens or with solutions containing or generating chlorine, such as aqua regia. It also will dissolve in cyanide solutions in presence of air or hydrogen peroxide. Dissolution in cyanide solutions is attributable to the formation of the very stable dicyanoargentate(I), $Ag(CN)_2-$, and dicyanoaurate(I), $Au(CN)_2-$, ions.

As does copper, the elements silver and gold have a single *s* electron outside a completed *d* shell, but in spite of the similarity in electronic structures and ionization potentials there are few close resemblances between silver and gold on the one hand and copper on the other.

Both silver and gold find their chief applications in the form of the metals themselves, but silver is also of unique utility as silver chloride in photographic emulsions. Despite the relatively high cost of the material no satisfactory substitute has ever been found.

For silver the pre-eminently important oxidation state in all of its ordinary chemistry is the state +1, although the states +2 and +3 are known. With gold, on the other hand, the state +1 is generally quite unstable, and most of the chemistry of gold involves the state +3.

(F.A.C./Ed.)

Rare-earth elements

The rare-earth elements form a series of 17 chemically similar metals, all but one of which occur in nature. Often they are called simply rare earths, but this is a misnomer because the term earth properly is applied to the oxide of a metal rather than to the element itself. The rare-earth elements are not even particularly rare, though for a long time they were thought to be.

The 17 rare-earth elements are: scandium (Sc), yttrium (Y), lanthanum (La), cerium (Ce), praseodymium (Pr), neodymium (Nd), promethium (Pm), samarium (Sm), europium (Eu), gadolinium (Gd), terbium (Tb), dysprosium (Dy), holmium (Ho), erbium (Er), thulium (Tm), ytterbium (Yb), and lutetium (Lu).

Until the mid-20th century, there was not much use for pure rare-earth elements or compounds except cerium and lanthanum; mixtures of the rare earths, however, had found metallurgical and other uses. By the 1970s three of these elements, yttrium, gadolinium, and europium, were being used in the red phosphors for colour television.

Position in the periodic table

In the periodic table of the elements (see Figure 10), the rare-earth elements comprise three members of Group IIIb and all 14 members of one of two series of elements generally written apart from the main table. This long series is known collectively as the lanthanide series because it directly follows lanthanum in a different form of the table. The rare-earth elements all have certain common features in the electronic structure of their atoms, which is the fundamental reason for their chemical similarity.

The aqueous chemistry of all the rare earths is very similar and changes only slightly in progressing along the lanthanide series. Because of this similarity, it is difficult to separate individual rare earths. In the few cases in which the rare-earth ion can be oxidized or reduced to another valency, however, chemical separations can be carried out readily. Also, artificial mixtures of elements far apart in the series can be separated easily.

All of these elements form trivalent compounds, and in the crystal lattices (the regular arrangement of atoms in the solid forms) of such compounds, one rare-earth ion readily replaces another. The rare-earth metals when heated react strongly with nonmetallic elements to form very stable compounds. They are never found as the free metals in the Earth's crust. Pure minerals of individual rare earths do not exist in nature; all their minerals contain mixtures of the rare-earth elements.

Promethium is never found in the Earth's crust since it has no stable isotopes and is produced only by nuclear reactions; it can, however, be obtained in quantity from the fission products formed in nuclear reactors.

The chemical properties of scandium differ sufficiently from those of other rare-earth elements for it to have become segregated from them by the action of geological processes. Scandium seldom is associated with the rare earths in minerals.

HISTORY

The early Greeks defined earths as materials that could not be changed further by the sources of heat then available. Until late in the 18th century, this Greek conception remained strong in chemistry, and oxides of metals such as calcium, aluminum, and magnesium were known as earths and were thought to be elements.

Discovery of the first rare earth

In 1794, Johan Gadolin, a Finnish chemist, while investigating a rare Swedish mineral, discovered a new earth in impure form, which he believed to be a new element and to which he gave the name ytterbia, from Ytterby, the village where the ore was found. The name, however, was soon shortened to yttria. In 1803, from the same mineral, later named gadolinite in Gadolin's honour, another new earth was reported in the literature independently by several chemists. The new earth became known as ceria, from the asteroid Ceres, which had just been discovered (1801). Since yttria and ceria had been discovered in a rare mineral, and they closely resembled other known earths, they were referred to as the rare earths. Not until 1808 did Sir Humphry Davy demonstrate that the earths as a class were not elements themselves but were compounds of oxygen and metallic elements. Later, a number of chemists verified the existence of ceria and yttria in gadolinite and found that these oxides were also present in a wide variety of other rare minerals. The elements of which yttria and ceria were the oxides were then given the names yttrium and cerium, respectively.

In the period from 1839 to 1843, Carl Gustaf Mosander, a Swedish chemist (and student of Berzelius), found that yttria and ceria were not even the oxides of single elements but were, in fact, mixtures. He reported that if the oxides were dissolved in strong acid and the resulting solution subjected to a long series of fractional precipitations as various salts (oxalates, hydroxides, and nitrates), two new elemental substances could be split off from the main component of each oxide. The two new oxides found in ceria he called lanthana and didymia, and the elements contained in them were named lanthanum and didymium. The new elements found (as their oxides) in yttria he called erbium and terbium, and the oxides were referred to as erbia and terbia. Mosander also was the first to obtain the rare-earth metals themselves from their oxides, although only in impure form. Mosander's researches puzzled the scientists of his time. He seemed to be finding a new group of elements of an entirely different type from any known previously. All formed the same classes of compounds with almost the same properties, and the elements could be distinguished from one another—at that time—only by slight differences in the solubilities and molecular weights of the various compounds.

In the next few years the literature on the rare earths became confused. There was, for example, considerable controversy for a number of years over the existence of didymium. The situation was considerably clarified in 1859 when an instrument called the spectroscope was introduced into the study of the rare earths. This instrument indicated the patterns of light emission or absorption characteristic of the elements, and, with it, didymium was shown to have a characteristic absorption spectrum. From then on determination of spectra of various types became one of the most important tools in following the progress of the fractionation of rare earths. Somehow during this period the names used for the various fractions differed from laboratory to laboratory. Around 1860, by general agreement, it was decided to interchange the names of Mosander's earths, erbia and terbia.

Scandium and the periodic table

In 1869, when Mendeleyev first proposed the periodic table, he found it necessary to leave a blank at the position now occupied by scandium. He predicted, however, that a new element would be found to fit that blank in the table, and he also predicted certain properties of the element. The discovery of scandium a few years later (1879) and the agreement of its properties with those predicted by Mendeleyev helped to bring about general scientific acceptance of Mendeleyev's periodic table. Interestingly enough, one of the greatest weaknesses in the table was that it provided no logical place for the lanthanides, a difficulty that was not resolved for some years.

From 1843 to 1939 chemical fractionation of the mixed rare-earth salts obtained from many minerals was intensively investigated in both Europe and North America. Mosander's didymia was resolved into several oxides—samaria (samarium; 1879), praseodymia (praseodymium; 1885), neodymia (neodymium; 1885), and europia (europium; 1901). His terbia and erbia were resolved into holmia (holmium; 1878), thulia (thulium; 1879), dysprosia (dysprosium; 1886), ytterbia (ytterbium; 1876), and lutetia (lutetium; 1907).

During this period many of these elements were discovered independently by more than one investigator, but the credit for the discovery was usually given to the man who first separated sufficient quantities of the oxide to determine some of its properties and who published his results first.

As the scientists carried out their fractionations, they frequently observed changes in colour, apparent molecular weight, and spectra of the substances. Such changes were mainly responsible for the more than 70 claims for the discovery of new rare-earth elements during this period. Many of the observed changes were brought about by the concentration of different impurities, particularly the transition elements, in various fractions of the series. It is now known that such trace impurities in the rare-earth oxides can give rise to such colour changes and that such oxides can be made to fluoresce strongly and exhibit unique spectra.

Contributions of Welsbach

Shortly after Auer von Welsbach isolated praseodymia and neodymia in 1885 he invented an illuminating device that bears his name (Welsbach gas mantle), and a little later he produced a practical lighter flint. Both devices depended upon rare-earth elements. Although minerals rich in rare earths had up to that time been thought to be very rare, the demand for rare earths that developed as a result of Auer von Welsbach's inventions resulted in a worldwide search for rare-earth minerals, and it was found that one of them, monazite, existed in extensive deposits. Monazite, a phosphate of several rare-earth elements, was ideal for Auer von Welsbach's purposes, because it contained a high percentage of the element thorium, which was also used for the mantles. These were prepared by impregnating a cloth fabric with a solution of about 90 percent thorium nitrate, 10 percent cerium trinitrate, and minor amounts of other salts. When heated by a gas flame, these salts were converted to their oxides, which, when heated by the flame, gave off an intense white light. Cerium and iron form an alloy that emits sparks when struck. The discovery of this alloy by Auer von Welsbach started the flint industry. In 1913 about 3,300 tons of monazite were refined to produce the thorium and cerium used in gas mantles and the mixed rare-earth metals for flints and related products.

Atomic numbers of the rare-earth elements

The British physicist H.G.J. Moseley, while studying the X-ray emission spectra of the elements in 1913–14, found a direct relationship between the X-ray frequencies and the atomic numbers of the elements. This relationship made it possible to assign unambiguous atomic numbers to the elements and to verify their locations in the periodic table. In this way, Moseley was able to show clearly that there could be only 14 lanthanides, starting with cerium and ending at lutetium, and, at that time, all of the rare-earth elements had been discovered except for element 61. Because no stable isotopes (forms of the element with differing mass) of this substance exist in nature, it was not isolated until 1945, when one of its radioactive isotopes was separated from atomic fission products produced in a nuclear reactor. The element was named promethium after the Greek Titan who stole fire from the gods and gave it to mankind.

As in most fields of science, the present state of knowledge concerning the rare earths is the result of hundreds of scientists publishing thousands of papers and of the individual scientist making his advances based on the work that had been previously published. There were, of course, a number of men whose outstanding contributions changed the direction of the researches, but space does not permit referring to them by name.

OCCURRENCE AND ABUNDANCE

The rare-earth elements are not rare in nature. They are found in low concentrations widely distributed throughout the Earth's crust and in high concentrations in a considerable number of minerals. In addition, they are also found in many meteorites, on the Moon, and in the Sun. The spectra of many types of stars indicate that the rare-earth elements are much more abundant in these systems than they are in our solar system. Even promethium-147, which has a half-life (time required for one-half the material to undergo radioactive decay) of only a few years, has been observed in certain stars.

Cerium is reported to be more abundant in the Earth's crust than tin, and yttrium and neodymium more abundant than lead. Even the relatively scarce lutetium is said to be more abundant than mercury or iodine.

Widespread distribution on Earth

The rare-earth elements are found as mixtures in almost all massive rock formations, in concentrations of from ten to a few hundred parts per million by weight. The fact that these elements have not been separated into minerals containing individual members of the family at any time in the Earth's history—even after eons of repeated melting and resolidifying, mountain formation and erosion, exposure to hot vapour, and immersion in seawater—attests to the great similarity in properties of these elements. Nevertheless, rock formations resulting from some of these geological processes become enriched or depleted in rare earths at one end of the series or the other, so that an analysis of the relative content of the rare-earth elements is never exactly the same, even for similar rocks taken from different locations. In general, it has been found that the more basic (or alkaline) rocks contain smaller amounts of rare earths than do the more acid rocks, and it is believed that as these molten basic rocks intrude into the more acidic rocks, the rare earths are partially extracted into the more acidic rocks. Also, as this extraction takes place, the rare-earth elements of lower molecular weight (lanthanum, cerium, praseodymium, and neodymium) are taken up to a greater extent than the heavier elements.

Analytical methods involving activation analysis (production of artificial radioactivity) and mass spectroscopy (separation of atoms on the basis of mass) have made it possible to make accurate measurements of the relative abundances of these elements, even when they are present in extremely small amounts. Such measurements are of great interest to geophysicists because they supply valuable information about the development of geological formations. The cooling of molten rocks and superheated water solutions that have percolated through rock under great pressure frequently produces minerals containing up to 50 percent rare earths. (For uniformity, these percentages are calculated as if the entire rare-earth content of the mineral were present in the form of oxides.) From the presence and composition of such minerals, geochemists can learn a great deal about the conditions, such as temperature and pressure, to which the rock mass was subjected. Similarly, the relative abundance of rare earths in the rocks on the Moon is of great interest because of what it is expected to reveal about how the Moon was formed and whether all or part of the Moon was molten at any time.

The average content of rare-earth elements found in certain meteorites (chondrites) and in three types of common rocks is listed in Table 25. Included also is an estimate of the relative abundance of the elements in terms of the overall rank of all known elements and of their concentration in the Earth's crust. It is now generally accepted that the relative values of the rare-earth elements in chondritic (granular) meteorites represent their overall relative abundance in the Cosmos. The elements with even atomic numbers are much more abundant than the odd-numbered elements. Such information, together with the relative abundance of their isotopes, is of critical importance to astrophysicists because it bears on theories of the origin of the universe and the genesis of the chemical elements.

GENERAL PROPERTIES OF THE GROUP

Location of lanthanide elements in the periodic table

Electronic structure. The 14 lanthanide elements—from cerium through lutetium—are much alike because the differences in their electronic structures chiefly involve the inner 4*f* electrons, whereas it is the outer *s* and *p* (and sometimes *d*) electrons that are involved in chemical bonding with other atoms and thereby determine the chemical behaviour of the elements. Although lanthanum atoms contain no 4*f* electrons, they resemble the atoms of the lanthanide elements closely, and it is not surprising that lanthanum should behave much as the lanthanides do (the name lanthanide, in fact, merely means lanthanum-like). Scandium and yttrium are elements in the same vertical file in the periodic table as lanthanum, and their atoms, too, have somewhat the same electronic structure but fewer filled shells, the outermost electrons in scandium being two 4*s* electrons and one 3*d*. In the case of yttrium, however, the outermost electrons are 5*s* and 4*d* electrons, respectively.

Because of their general similarity in atomic structure, scandium, yttrium, lanthanum, and the 14 lanthanides are very similar chemically. This similarity is the reason they are found together in nature and also the reason they are so frequently classed together as the rare-earth elements.

Table 26 lists the lowest energy electronic configurations of the rare-earth elements in gaseous and in condensed states, *i.e.*, as the free metal or in a crystalline or solution form as a compound. In a compound the $5d6s^2$ electrons (the superscript indicating the number of electrons in the subshell) are the valence, or bonding, electrons. These electrons are involved in the chemical bond and are usually paired with the electrons of the anion (the negative ion included with the rare-earth ion in the compound), with the result that they are no longer closely associated with the rare-earth atom. In the case of the metal, these electrons are free to wander throughout the crystal, being able to carry an electrical current and known, therefore, as conducting electrons. In the case of lanthanides in the gaseous state, the valence electrons are localized at the individual atoms, but in many cases the 5*d* electron can switch to the 4*f* subshell, giving rise to a state of different energy and different electronic configuration.

Lanthanide contraction

As the charge on the nucleus increases across the lanthanide series, it pulls the various subshells, especially the 5*s* and 5*p* subshells, closer to the nucleus. As a result, the radii of the lanthanide ions decrease as the atomic number increases. This effect is known as the lanthanide contraction.

Physical properties. The pure rare-earth metals are bright and silvery. A bar of europium will tarnish almost immediately when exposed to air and will be entirely converted to the powdered oxide in a few days. Lanthanum, cerium, praseodymium, and neodymium also corrode readily in air; bars of these metals become encrusted with a thick layer of oxide in several weeks. Metallic yttrium, gadolinium, and lutetium, on the other hand, remain bright and shiny for years.

The properties of the rare-earth metals are frequently quite sensitive to the presence of impurities; for example, the light lanthanide metals will corrode much more rapidly if small amounts of calcium or magnesium or rare-earth oxides are present in the metal. The melting points and transition temperatures between different crystal forms (allotropic forms) can be changed drastically, frequently by several hundred degrees, when the metals are alloyed with other elements.

Small amounts of nonmetallic impurities also effect many of the properties of the rare-earth elements. Several thousand parts per million by weight of oxygen and even smaller amounts of nitrogen in the metals make them brittle. The effect of nonmetallic impurities on physical properties is determined by atomic percentages (that is, by the relative numbers of atoms present) and not by weight percentages; thus, in lutetium 300 parts per million by weight of hydrogen is about 5 percent on an atomic basis, whereas 1,000 parts per million of oxygen in lutetium by weight represents only 1 percent oxygen on the atomic scale.

In determining properties of the rare-earth metals it is obviously essential to work with well-characterized samples. The amount of each individual impurity present should be accurately known, as well as the previous history of the sample with regard to temperature and work. If the reported values of physical properties are to have much meaning, this information concerning the samples used must be given. Unfortunately, because of a lack of appreciation of the importance of impurities or a lack of proper equipment to adequately characterize the sample, there is a wide variation in the numbers reported in the literature for certain properties. In Table 26 are the values of the properties that—in the author's opinion—are the best values known. Some properties, such as elastic constants, resistivity, and effective magnetic moments, are very sensitive to temperature and show marked anomalies at and in the neighbourhood of crystal or magnetic transformations. Also, some properties depend on the angle at which they are measured with respect to the principal crystal axes in the metal.

In fact, the rare-earth metals do not resemble one another as closely as was generally believed in the early part of the 20th century. Physical properties differ as much across the lanthanide series as they do for most other series in the periodic table. The melting point of lutetium, for example, is almost twice that of lanthanum, and the vapour pressures of ytterbium and europium at 1,000° C are millions of times greater than those of lanthanum and cerium. Lanthanum is a superconductor of electricity at 6 K (−267° C) and gadolinium is a stronger ferromagnet at 0 K than iron. The properties of adjacent pairs of lanthanide elements do, however, differ in a predictable and usually regular manner. This behaviour makes these metals uniquely valuable in studying theories of the metallic state, the formation of alloys, and the existence of intermetallic compounds. Each of the rare-earth metals readily combines with almost any other metallic element, and the resulting alloys exhibit a wide variety of properties: they can be hard or soft, brittle or ductile, and they can have high or low melting points. Some are extremely pyrophoric (ignite spontaneously), whereas others cause a coating to be formed on the surface of metals such as magnesium that protects the alloys from corrosion at elevated temperatures.

Rare-earth metals absorb hydrogen to form stable alloylike hydrides in which percentages of the divalent compounds MH_2 range from zero to 100. These hydrides, brittle and metallic in appearance, have a bluish tinge. After absorption of hydrogen to yield the composition MH_2, further absorption occurs, finally yielding trivalent hydrides MH_3. During the change from MH_2 to MH_3, the properties become more saltlike. The amount of hydrogen per unit volume in yttrium hydride is considerably greater than that in water or liquid hydrogen, and this hydride does not develop a partial pressure of hydrogen gas equal to one atmosphere until the alloy has been heated to a white heat. Cerium metal, once the oxide surface film has been broken, absorbs hydrogen at room temperature and decomposes water vapour at higher temperatures, absorbing the hydrogen and reacting with the oxygen to form a layer of sesquioxide on the surface. The oxides, nitrides, and carbides of the rare-earth elements are soluble in the molten metals, as are the elements oxygen, nitrogen, and carbon. The exact form in which the dissolved substances are present is not known, but it is generally believed that the nonmetallic elements are present as interstitial atoms (atoms inserted in spaces left in the crystal structure). These dissolved nonmetallic elements remain in solid solution over a considerable composition range at temperatures near the melting point. As the metal is slowly cooled, however, the solubility decreases, and the dissolved elements precipitate as a second phase, probably as the sesquioxides, nonstoichiometric nitrides, and carbides. The diffusion rate (rate of movement) for nonmetallic elements in the metal is low below 800° C and becomes progressively lower as the temperature is lowered. The properties of the metals containing these impurities, therefore, are dependent upon the heat treatment to which they have been subjected.

Heat
reatment
and crystal
structure

Anisotropy. Rare-earth metals often exhibit anisotropy—differences in properties depending on which direction in the crystal they are measured—and the heat treatment of the sample is important in producing polycrystalline metal. It is possible by certain heat treatments to produce large grains oriented preferentially in a given direction. When properties that depend on crystal direction are measured on such polycrystalline samples, the results have little meaning unless the amount of preferred orientation is known.

Energy states of lanthanides. The spark and arc spectra (patterns of emitted light) of the gaseous lanthanides are extremely complicated. There are literally tens of thousands of frequencies of light emitted by each of the lanthanides, and it requires very powerful instruments (spectrographs) to resolve them. This complexity arises from the fact that the lanthanides have an incomplete inner subshell, and the angular moments (spins and orbital motions) of the electrons in this subshell can combine in many ways to give many different energy states. In the most complicated case, that of gadolinium, there are 3,432 different states. Any of these states can combine with the many states arising from the three valence electrons, and this condition results in an incredible number of excited energy levels. The emitted frequencies represent transitions between any of these states. The situation is further complicated by the fact that the ionization potentials of these elements are extremely low, with the result that in the arc- and spark-light sources there are a great many ionized atoms, and their complicated spectra fall on top of those of the neutral atoms. Many thousands of these lines remain to be identified. A start has been made on this task, however, and a few levels—including the basic ones—have been identified. A thorough understanding of the energy levels of the rare-earth atoms will be of great value in arriving at a complete theory by which all the properties of an atom can be calculated from basic principles. Furthermore, the complete identification of the spectral lines of the rare-earth elements will be of great assistance to astronomers in identifying the many lines observed in stellar spectra that are believed to indicate the presence of rare-earth elements.

The first ionization potentials (the energy required to remove an electron from the neutral atom) of these elements are also difficult to determine accurately because of the complexity of the rare-earth spectra.

Rare-earth ions in solids and liquids. The sharp bands in spectra of solid rare-earth elements and compounds are much better understood. These bands arise from transitions between different energy states of the $4f$ subshell, and the position of the bands seems to be little affected by the atoms surrounding the lanthanide atoms. For this reason, scientists have been able to use these bands for more than a century to determine whether particular rare-earth ions are present in solids or liquids. The fine line structure of the bands, which can be resolved at low temperatures, is sensitive to the environment, and this effect makes such spectra a valuable tool for studying the forces that exist in solids and liquids.

Magnetic
properties

The $4f$ electrons also are responsible for the strong magnetism exhibited by the metals and compounds of the lanthanides. In the incomplete $4f$ subshell the magnetic effects of the different electrons do not cancel out each other as they do in a completed subshell, and this factor gives rise to the interesting magnetic behaviour of these elements. At higher temperatures, all the lanthanides except lutetium are paramagnetic (weakly magnetic), and this paramagnetism frequently shows a strong anisotropy. As the temperature is lowered, many of the metals exhibit a point below which they become antiferromagnetic (*i.e.,* magnetic moments of the ions are aligned but some are opposed to others), and, as the temperatures are lowered still further, many of them go through a series of spin rearrangements, which may or may not be in conformity with the regular crystal lattice. Finally, at still lower temperatures, a number of these elements become ferromagnetic (*i.e.,* strongly magnetic, like iron). Some of the metals have saturation moments (magnetism observed when all the magnetic moments of the ions are aligned) greater than iron, cobalt, or nickel. They also show a strong anisotropy in their magnetic behaviour depending on the crystal direction. Study of the magnetism of rare-earth elements has had great influence on present-day theories of magnetism.

Electrical conductivity. The rare-earth metals, with the exceptions of cerium, ytterbium, and europium, have three electrons available for carrying electrical current. The space occupied by these electrons apparently represents more than 85 percent of the volume associated with the atom of each metal. Cerium is reported to have an average of 3.1 conducting electrons, presumably as the result of the existence of some of its atoms in a state in which four electrons are free to move through the metal. Pure cerium under high pressure or at low temperature assumes a high-density form in which the four-electron state assumes more importance. Europium and ytterbium are much less dense than the other lanthanides, and they have only two conducting electrons; the third valence electron has moved to an inside subshell ($4f$). In europium this electron half fills this subshell, and in ytterbium it completes it, the two configurations $4f^7$ and $4f^{14}$ being particularly stable. The electrical and chemical properties of these two metals therefore resemble those of magnesium, calcium, strontium, and barium (metals with two conducting electrons) more closely than those of the other lanthanides.

Nuclear properties. As a group the rare-earth elements are rich in total numbers of isotopes, averaging about 20 each. The elements with odd atomic numbers have only one, or at most two, stable isotopes, but those with even atomic numbers have from four to seven stable isotopes. Some of the unstable isotopes are feebly radioactive, having extremely long half-lives. The unstable radioactive isotopes can be produced in many ways; *e.g.,* by fission, neutron bombardment, radioactive decay of neighbouring elements, and bombardment of neighbouring elements with charged particles. The lanthanide isotopes are of particular interest to nuclear scientists because they offer a rich field for testing theories about the nucleus, especially because many of these nuclei are nonspherical, a property that has a decided influence on nuclear stability. When either the protons or neutrons complete a nuclear shell (that is, arrive at certain fixed values), the nucleus is exceptionally stable—the number of protons or neutrons required to complete a shell being called a magic number. One particular magic number—82 for neutrons—occurs in the lanthanide series.

PRODUCTION AND APPLICATION

Monazite

Sources and extraction. Though numerous minerals rich in rare earths are found in the Earth's crust, many are extremely rare, and many more are found only in small pockets in more massive rocks. Although such minerals are of considerable research interest they are not used commercially. Monazite, a mixed phosphate of calcium, thorium, cerium, and various lanthanides, occurs in extensive deposits and is one of the main sources used commercially to obtain the light rare-earth elements. Monazite contains about 50 percent by weight rare-earth elements, in the approximate proportions 50 percent cerium, 20 percent lanthanum, 20 percent neodymium, 5 percent praseodymium, and lesser amounts of samarium, gadolinium, and yttrium. It also contains small amounts of the heavy rare-earth elements. The actual amounts of each element in the mineral vary considerably, depending on the point of origin of the monazite, because the various metallic elements can substitute for one another in the crystal lattice. The mineral probably formed as small crystals in rocks as they cooled, but as the mountains eroded away and were washed into the sea, the monazite, being denser than most other materials, settled first, while the lighter materials were carried farther out to sea. Apparently as a result of this action, sandbars containing monazite are found along the coasts of Brazil and southwest India. Concentrated deposits are also found on certain uplands, which are thought to have been the beaches of ancient seas or oceans and which were later uplifted. Such deposits in massive amounts are found in Australia, the U.S.S.R., and South Africa, and in the United States in South Carolina, Florida, and Idaho, and in many other locations. The mineral is dredged or scooped up, pulverized if necessary, and concentrated by flotation methods. Sometimes a magnetic-belt separator is used to pull the more magnetic monazite to one side in order to separate it from the nonmagnetic materials. The monazite is then shipped to rare-earth chemical plants. The mineral xenotime, a phosphate of yttrium and various lanthanides, is frequently found associated with monazite and may comprise from 1 to 10 percent of the mixed minerals. It is similar to monazite except that the metallic atoms are about 50 to 60 percent yttrium, and it contains more heavy lanthanides than light ones. Xenotime is one of the main sources of the heavy rare earths, and it can be separated from monazite by the magnetic-belt process because it is more magnetic than monazite.

Another important source of light rare earths and europium is the mineral bastnaesite, a fluorocarbonate of lanthanum and cerium, with smaller amounts of neodymium and praseodymium. It is found in extensive deposits in eastern California. It contains almost no heavy rare earths, but there is enough europium (about 0.1 percent) to supply much of the world demand for this element. The mineral is also found in the U.S.S.R. and in parts of Africa. The rock is broken up by blasting and then is crushed and ground to a fine powder. The bastnaesite is separated from the other materials by the usual flotation methods and is then treated chemically so that it can be separated into europium, lanthanum, and cerium fractions by liquid–liquid extraction methods (see below *Liquid–liquid extraction*).

The niobium titanate minerals, such as fergusonite, euxenite, samarskite, and blomstrandine, are rich in the heavy rare-earth elements but are not used much commercially. The same is true of such silicates as gadolinite and allanite. Other commercial sources of rare-earth oxides are certain uranium- and apatite-mining operations in which the rare earths are obtained as a by-product even though the rare-earth content of the ores is low.

Very little scandium is found in rare-earth minerals. Most of the scandium produced commercially is a by-product from uranium processing—the scandium, which may be present in amounts up to five parts per million, being recovered from the uranium solution. There is, however, a rare mineral thortveitite—found in Norway—that contains up to 34 percent scandia, Sc_2O_3.

Purification of europium

Methods of separation and purification. Generally, the rare-earth elements exist in dilute solution as trivalent ions. Quite early, however, it was found that a number of the elements could also exist in tetravalent or divalent form—including cerium(IV), samarium(II), europium(II), and ytterbium(II). If an element could be oxidized (to the tetravalent state) or reduced (to the divalent), then it could be removed readily from the other rare earths. Between the years 1930 and 1935, for example, about two kilograms of extremely pure europium compounds were prepared by a separation process making use of the divalent form of europium. Although europium is one of the less abundant rare-earth elements, it was one of the first of the heavier rare earths to become generally available.

Fractionation. Because the ions of the rare-earth elements are surrounded by tightly bound water molecules in aqueous solution, compounds of the rare earths formed from aqueous solutions have properties much alike, and this similarity is particularly true for adjacent elements. The problem is still further complicated by the fact that one rare-earth ion can be substituted readily for another in crystal lattices, with the result that most precipitates consist of crystals of almost the same rare-earth mixture as the solution. Because of this behaviour, chemists of the 19th and early 20th centuries found it necessary to resort to laborious fractionation processes to isolate individual rare-earth elements. At the time, many different processes were used, such as fractional crystallization, fractional precipitation, fractional decomposition, and fractional extraction. All of these consisted of separating the mixed rare earths into two approximately equal fractions, one of which would be enriched in the lighter elements and the other in the heavier elements. Both fractions would then be put back into solution and the process repeated on each of them. Usually the adjacent inner fractions would be recombined before proceeding to the next stage. Gradually, the lighter rare earths were collected in the beakers toward one end of the system, with the heavier elements concentrated at the other end.

As the quantity of material in the end beakers became small, it was usually customary to combine equivalent fractions from other similar runs. At this point the first series would be split into several independent groups, and a new fractionation process more suited to the elements in each fraction started. Needless to say, the quantity of a relatively pure rare-earth compound obtained from the end beakers was distinctly limited.

Fractional separation methods

Fractional separation methods, particularly for adjacent heavy rare earths, are extremely slow and tedious. One investigator, for example, reported that he had recrystallized the bromate salt of a thulium fraction 15,000 times and could see little difference between the first and last fractions. It is now known that even the purest fractions he obtained contained some ytterbium and erbium. If the elements are far apart in the lanthanide series, however, the task is simplified. It takes only a few partial precipitations, for example, to obtain a lanthanum–cerium–praseodymium fraction completely free of erbium, thulium, ytterbium, and lutetium. The most basic (nonacidic) of the rare-earth elements, lanthanum, is very well situated in the series in this respect because it occurs at one end, and a few fractionations suffice to separate a lanthanum–cerium fraction from the other rare earths.

Since cerium in its tetravalent form has distinctly different chemical properties from a typical lanthanide in the trivalent state, it can be separated from lanthanum easily by ordinary chemical operations. Consequently, pure lanthanum and cerium compounds have been commercially available for many years, and even today several companies find the fractionation process the most economical method for producing compounds of these elements in ton quantities.

Ion exchange of fission products

Ion exchange. Ion exchange is a method of separation based on differential absorption and elution (washing off) of substances from certain solid supporting materials, often powdered or finely divided materials held in glass tubes. The technique was first used in the rare-earth field during World War II to separate fission products obtained from nuclear reactors. In December 1943 a research group at the Oak Ridge (Tennessee) national laboratory announced that they had separated the mixed rare-earth elements from certain fission products by ion exchange on an organic resin into three fractions. The first fraction was shown to have radioactivity associated with yttrium, and the final peak to have cerium activity. The middle peak was thought to be a combination of the neodymium and element-61 activities. The group at Oak Ridge continued to develop the elution technique for separating fission products both with and without carriers (nonradioactive materials added to carry with them the radioactive isotopes). By the end of the war, they had succeeded in developing the processes so that they could separate the individual rare-earth elements of the cerium group (cerium through element 61) and yttrium. The carriers usually consisted of a few milligrams of each of the corresponding natural rare earths. In the meantime, a group at Iowa State University applied the ion-exchange process to the separation of gram quantities of adjacent rare earths and succeeded in separating the difficult pair praseodymium and neodymium in fairly high purities in gram quantities.

The ion-exchange elution method

Rare-earth-element separation by the ion-exchange elution process is carried out as follows: At the start of the process, the resin is saturated with monovalent cations, such as ammonium ion, NH_4^+, or hydrogen ion, H^+. Next, a solution of mixed rare-earth ions accompanied by strong acid anions is poured onto the top of the column. When the rare-earth ion encounters the cation-containing resin, it replaces three monovalent cations, and these—along with the strong acid anions—will flow through the column in solution and out the bottom. A band of resin saturated with rare-earth ions forms at the top of the ion exchanger and grows in length as more rare-earth solution is added. There is, however, little separation of individual rare-earth ions as this band forms. An eluant solution containing an anion that complexes with the rare-earth ion is then prepared, for example, an ammonium citrate solution of controlled acidity. This solution is then started flowing through the column to elute the rare-earth band down the column and out the bottom. When the main ions present in ammonium citrate in acid solution, $HCit^{2-}$ or H_2Cit^-, encounter rare-earth ions on the resin, complex ions form; these enter the solution phase, and three monovalent ions deposit on the resin in their place. When the rare-earth complexes reach the ammonium or acid resin, in front of the rare-earth band, the rare-earth ions are again deposited, and the band progresses down the column. The formation constants of the individual rare-earth complexes increase slightly with increasing atomic number. Because the various rare-earth ions on the resin are in equilibrium with the rare-earth complexes in solution as they pass over the band, there is a slight enrichment of heavy rare earths at the front of the band. As the band progresses down the column, this enrichment continues. At the same time, the band grows in length, since ammonium and hydrogen ions are also in equilibrium with the resin and their ions will deposit along with the rare-earth ions. After the band has travelled many band lengths, each rare earth exhibits a bell-shaped elution curve (concentration of rare-earth ions versus volume of eluant leaving the column) and these individual rare-earth bands travel down the column at different rates. The bands overlap badly at first, but after travelling many band lengths, they pull completely apart. The area under each curve is, of course, constant, because the amount of each rare earth on the column does not change, but the concentration of the rare earth in the resin gets less and less relative to the ammonium and hydrogen ions on the resin.

Limitations of the elution technique

With this type of separation, the original mixed rare-earth band must be quite narrow because the band has to travel many band lengths on a given column. The ions in the eluant are constantly overrunning the bands, with the result that large quantities of solution are needed; and the solution coming out the bottom of the column containing the successive pure rare earths is extremely dilute in rare earths. Such a process is obviously ideal for separating radioactive tracers, which one can count by means of radioactivity, and this process is frequently used in analytical chemistry, where only small amounts of the rare earths are separated. When it is necessary to obtain large amounts of rare earths in high purity, this process is not effective. It has the disadvantage of requiring far more chemicals than the displacement method developed later and described below. Furthermore, this process is not particularly adaptable to being scaled up to produce large quantities of ultrapure rare earths, nor is it well suited for recycling the water and chemicals. It does not give the purity of the individual rare earth that displacement methods can achieve. Finally, the elution process is slow compared with the displacement method.

The ion-exchange displacement method

The band displacement method of separating individual rare-earth elements was first published in 1952. This process is capable of being scaled up to handle any quantity of rare earths. The mixture can be resolved so that 98 or 99 percent of each individual rare earth can be recovered with less than 0.1 percent of other rare-earth impurities; and, if the rare earths are taken from the middle third of the bands, the sum total of other rare earths can be kept as low as 0.0001 percent. The same resins and type of equipment are used in this process as in the elution technique. Two strong chemical constraints, however, are imposed at the top and bottom edges of the rare-earth band. The eluant contains a strong complexing ion—such as a chelating agent, an organic molecule that wraps itself around the rare-earth ion, replacing all or most of the adjacent water molecules. The first constraint requires that the formation constants of the rare-earth complexes formed should be large enough so that, when the chelating agent encounters the top edge of the rare-earth band, it complexes in a short distance all of the rare-earth ions, moving them into solution and replacing them with the cation of the eluant. (The formation constant, however, should not be so large as to remove all the rare-earth ions from the solution phase.) The second chemical constraint occurs at the bottom edge of the rare-earth band: the original resin bed, called the retaining bed, down which the rare-earth band is moving, must have cations on its exchange sites that form a much tighter soluble complex with the chelating ion than do the rare-earth ions. Under this constraint the rare-earth complex promptly breaks up at the point where it encounters the retaining bed, and the rare-earth ions completely deposit in the bed, simultaneously removing an equivalent amount of the retaining-bed cations. With these constraints, the rare-earth band, after spreading out slightly to reach equilibrium, remains of constant length, with sharp top and bottom edges, no matter how far down the column it travels. The elution curve is flat-topped (rare-earth concentration remains constant over almost the entire band when plotted against volume of elute leaving the bottom of the column), and the percentage of rare-earth ions in the rare-earth band on the active sites of the resin is close to 100 percent. Here again, there must be a slight difference in the formation constants of the rare-earth chelates, so that the rare-earth ions are constantly interchanging as the eluant flows by the rare-earth band. As the band moves, the individual rare earths separate into individual flat-topped bands, which ride head to tail and never pull apart. By the time the band has travelled a tenth of its length, most of the heavy rare earths are already to be found in the front segments of the total rare-earth band, and, by the time it has travelled one length, all the individual rare earths are in separate bands, which overlap only slightly to give a narrow region consisting of a binary mixture of adjacent elements. These mixed regions, of course, must be recycled. By having a series of columns, however, the original rare-earth band can be made very long, and, since the overlap regions are independent of band length, the bulk of each successive rare earth comes out the bottom of the column in high purity.

A number of companies have adopted the displacement process and, using it, have made available highly pure salts of the rare-earth elements of atomic number 59 and above (all the elements from praseodymium through lutetium) in any quantity at reasonable prices. This process has the distinct advantage of allowing the water and the eluting chemicals to be recycled and used over again. One long absorbed band can follow another down a series of columns if a short retaining-bed section is continually regenerated between the absorbed bands.

The first chelating agent used was ammonium citrate at such a low acidity that the citrate ion, Cit^{3-}, predominates in the solution. At this acidity the complex chelate ion, $MCit_2^{3-}$, forms. This process works well, but in 1954 it was improved by using a buffered ammonium solution of ethylenediaminetetraacetic acid (EDTA) with a cupric-ion retaining bed. A number of other chelating agents and types of retaining beds have also been investigated. Many of these work well, but none is markedly superior to EDTA. Some of these other systems, however, are used for certain regions of the rare-earth series because, for these regions, the processing is accomplished more quickly and cheaply.

Organic and aqueous phases

Liquid–liquid extraction. Liquid–liquid extraction methods also find important applications in the rare-earth industry. The basic principles involved are similar to those operating in the ion-exchange processes. An organic solvent, such as tributyl phosphate, flows countercurrent to an aqueous stream containing the mixed rare-earth salts. Rare-earth complexes are formed with formation constants that vary somewhat across the series. The rare-earth ions can complex with their own anions to form neutral molecules that are soluble in the organic phase, or they can complex with molecules of the organic solvent and thereby join the organic stream. If desired, an organic chelating agent can be added to form complexes with the rare-earth ions. These complexes should be soluble in the organic liquid. As the aqueous phase flows past the immiscible organic stream, an equilibrium is set up between the rare-earth ions in the aqueous solution and the complex ions in the organic solvent. As the two streams flow past each other, the heavy rare-earth elements concentrate in one stream and the lighter ones in the other.

The equilibrium constant for the exchange of one rare-earth ion for another is usually small, with the result that the ions have to exchange with the complex many times before a clear-cut separation between two rare-earth ions is achieved. This process necessitates that the two liquids be in contact with each other through many stages. If the equilibrium constant is equal to 1, no separation will take place, and for adjacent rare earths it is difficult to find complexes—except in special cases—that differ much from that value.

The liquid–liquid extraction process suffers from the disadvantage that for a given system only one cut is made in the rare-earth series, and if 15 pure rare earths were desired 14 cuts would have to be made. It also suffers from the disadvantage that the distance the rare-earth ions must travel in order to complete one exchange is many times that required in the ion-exchange columns. It has the advantages, however, that more concentrated solutions can be used and that the process is more economical for handling large quantities of materials. So far, it has found application mainly in special cases. It is used in some industries to concentrate the total rare earths where their abundance in the original materials is low. It is also used for separating certain elements, such as lanthanum, cerium, europium, and yttrium, with which favourable equilibrium constants are found. This is the case for cerium and europium, because they can be extracted in their tetravalent and divalent forms, respectively. Yttrium is not a lanthanide, and its position in the rare-earth series can be changed by using different organic solvents or complexing agents. First, a complex is used that separates the yttrium and heavy lanthanides from the light lanthanides, and then a different system is used whereby the yttrium is shifted with respect to the lanthanide series, so that it can be separated from the heavy lanthanides.

The liquid–liquid extraction system has not been successful in separating the adjacent heavy rare earths in the quantities desired. If ultrahigh-purity rare earths are required, it is common practice—even in those cases where liquid–liquid extraction methods have been used—to place the somewhat impure rare earth on an ion-exchange column and to use the displacement method for further purification.

Preparation of pure metals. *Early metal-reduction methods.* It is relatively easy to reduce anhydrous halides of the rare earths to metals. What is difficult, however, is to reduce them to high-purity metals in ingot form. The rare-earth metals have a great affinity for the nonmetallic elements—hydrogen, boron, carbon, nitrogen, oxygen, silicon, sulfur, phosphorus, chlorine, and bromine—and form very stable compounds with them. If a small amount of rare-earth metal is added to most other metals containing these elements present as impurities, it reacts with the impurities and removes them by gathering them together in nodules or transferring them to the slag phase. There has been a steady market for misch metal, a mixed rare-earth alloy, since Auer von Welsbach's time. A small addition of this alloy greatly improves the mechanical properties of many impure metals or alloys.

Also, hot rare-earth turnings (chips or curls from machining) can be used to produce extremely pure helium, neon, and argon by removing hydrogen, oxygen, nitrogen, carbon dioxide, and hydrocarbon vapours. As is often the case with the rare earths, however, other—and cheaper—materials perform this function equally well, and for this reason the rare-earth elements are seldom used for this purpose.

Finally, molten rare-earth metals dissolve almost all other metals and react with most compounds. They come close to being the hypothetical universal solvent of the ancients. The molten metal attacks any crucible in which it is melted, and the final product generally is a rare-earth-rich alloy of the crucible elements.

The metallothermic process

Mosander, in 1826, was the first to reduce a rare earth to a metal. He used a metallothermic reaction (heating with active metals) to reduce anhydrous chlorides made from his ceria with metallic sodium or potassium. His yields were low, 26 percent, and the metal existed as small nuggets in a solid slag, from which they could be separated only with difficulty. The metal was very impure; it contained considerable amounts of sodium or potassium and iron and other crucible materials. It also contained considerable amounts of hydrogen, oxygen, nitrogen, and carbon, as well as a mixture of the ceria group of rare earths.

During the next hundred years, as the individual rare earths were discovered and separated, a number of scientists reduced many of the lighter rare earths to the metallic form using the metallothermic process—but sometimes varying it by substituting calcium, magnesium, and aluminum as the reductants and anhydrous fluoride salts as the reactants. Because of the scarcity of pure rare earths, however, as well as the difficulty in finding suitable crucible materials and the poor equipment for keeping out atmospheric gases, the metals were still so impure that no extensive studies could be made of their properties.

In 1935, samples of the purest rare-earth chlorides available were reduced to metals at relatively low temperatures in glass capsules with potassium vapour. This process gave free metals in the form of fine powder imbedded in potassium chloride; no attempt was made to separate the metal from the potassium chloride, because only such properties as crystal structure, density, and magnetic susceptibility were under investigation. Potassium chloride acted as an internal standard in the X-ray investigations, and magnetic susceptibilities could be corrected for the potassium chloride present. Although these metals were not really pure by modern standards—they contained appreciable amounts of potassium and rare-earth impurities—they yielded values for the lattice constants and densities of most of the rare-earth metals that lie within 1 percent of the best modern values.

Electrolytic processes

In 1875, the first successful preparation of rare-earth metals by an electrolytic process was reported. About five grams each of cerium, lanthanum, and didymium (neodymium and praseodymium) in compact form were prepared by electrolyzing the fused chlorides covered with layers of ammonium chloride. The electrolytic technique was later improved, and, in the period 1902–05, misch metal, cerium, lanthanum, praseodymium, neodymium, and samarium were prepared. In 1906, Auer von Welsbach started the commercial production of lighter flints, for which the misch metal was electrolytically reduced. In the years 1923–26, several improvements in the cell designs were made, and somewhat purer samples of lanthanum, cerium, and neodymium were prepared, along with some yttrium, although most of the latter metal deposited as power.

The electrolytic process suffers from much the same difficulties as the metallothermic methods. It is difficult to find electrodes and cell materials that will stand up to molten rare earths and at the same time not introduce impurities into the ingot. It is also difficult to design cells that exclude all the atmospheric elements. The method works best for the low-melting rare earths, with which the cells can be kept sufficiently hot so that a molten pool of the metal forms in the bottom of the cell. With the higher melting rare earths, only powdered metal is formed, and it is difficult to separate it from the electrolyte in a pure form.

In 1931, a cell especially designed for producing much purer metals and also capable of reducing the halides of the heavier rare earths was employed to produce a quantity of cerium that contained only a small percentage of impurities and, somewhat later, the same apparatus was used to produce a number of other rare-earth metals, including europium, gadolinium, and yttrium.

By 1939 most of the rare-earth metals had been made in fair purity, and a number of their properties, such as magnetic behaviour, melting point, density, crystal structure, and chemical reactivity had been studied. All of these metals contained small amounts of metallic impurities and unknown amounts of nonmetallic impurities. Most of these impurities were not reported because analytical methods to determine them had not been developed at that time. Almost no work had been done on the properties of the rare-earth alloys except for those of cerium and lanthanum.

Importance of impurities

Modern techniques for producing ultrapure rare-earth metals. As purer rare-earth metals are produced, it is increasingly clear that many of their properties are extremely sensitive to small amounts of impurities. This phenomenon is particularly true with regard to magnetic and to nonmetallic impurities. For many industrial uses extreme purity is not required—nor even desired—since less pure metals can be produced much more cheaply. On the other hand, the presence of impurities can be critical in metal produced for research purposes, especially when experimental properties are being compared with predicted values, or in metal to be incorporated into solid-state devices. The processes described below are those used in making research-grade metal. If less pure metal is satisfactory, many of the steps described can be omitted, and the process can be terminated at the point where the desired purity is attained.

One especially favoured reduction process utilizes metallic calcium (Ca) and the rare-earth fluoride (MF_3). The reaction is as in the following equation:

$$3Ca + 2MF_3 \rightleftharpoons 2M + 3CaF_2.$$

Other metallothermic processes, however, can also be used, such as lithium (Li) metal and the rare-earth chloride (MCl_3):

$$3Li + MCl_3 \rightleftharpoons M + 3LiCl.$$

Variations of these methods, using lithium, sodium, potassium, or calcium as the reducing agent and any halide of the rare earth for the reactant, also are possible. For these alternative processes to succeed, however, the metal must be separable from the slag cleanly without introducing impurities, and all sources of contamination must have been eliminated.

The problem of obtaining sufficient quantities of highly pure individual rare-earth oxides has been solved by the development of the displacement-band method of separating rare earths on ion-exchange columns described above. If the oxides are obtained from the middle third of the pure rare-earth band, the total of other rare-earth impurities in the metals obtained from them does not exceed 10 parts per million. Fractions taken closer to the band edges contain somewhat larger proportions of such impurities. If the same equipment is used to prepare the different raw materials and to make the metals of a number of different rare earths, great care must be taken to prevent cross contamination of the rare earths.

Limiting contamination

Contamination from the crucible cannot be eliminated entirely. Tungsten and tantalum make the best crucibles: they are little attacked by molten rare-earth metals at temperatures below 1,000° C, and the crucible material introduced into the rare-earth metals at higher temperatures, if harmful, can be removed by special techniques. Both tungsten and tantalum are available commercially in the form of both crucibles and thin sheets: to prepare them for use, these materials are thoroughly cleaned and baked in a high vacuum to remove impurities that may be adsorbed on their surfaces.

Introduction of impurities from the atmosphere can be largely eliminated by carrying out all operations in an environment of purified helium and by the use of modern high-vacuum ion pumps instead of oil pumps.

Finally, if ultrapure metals are to be obtained, the raw materials from which they are made must also be ultrapure or their impurities will end up in the rare-earth ingot. Commercial calcium is doubly distilled at low pressure in an atmosphere of pure argon or helium to remove iron and various nonmetals that it contains, and thereafter is rigorously protected from carbon dioxide and water vapour. Anhydrous rare-earth halides form oxyhalides upon contact with water vapour; therefore, the preparation of an anhydrous fluoride is carried out in two steps. The first is the passage of dry hydrogen fluoride over the powdered oxide, immediately sweeping away any water formed; and the second is the passage of the pure, dry hydrogen fluoride over the molten fluorides. If this is done, the oxygen content of the fluoride can be kept below ten parts per million.

Groups for standardized operation

There are enough differences in the properties of the 17 rare-earth metals that the same reduction process does not work equally well for all of them. If metal containing less than 0.01 weight percent of impurities is desired, each element has to be treated somewhat differently. Many of the operations are the same for all reductions, and if the metals are divided into five groups, standardized operations can be applied for all metals in a group. The groups are as follows: Group I consists of those metals that have low melting points and high boiling points—lanthanum, cerium, praseodymium, and neodymium. Group II consists of those metals having high melting points and high boiling points—gadolinium, terbium, scandium, yttrium, and lutetium. Group III consists of those metals having high melting points, low boiling points, and, in addition, an appreciable vapour pressure at the melting point—dysprosium, holmium, erbium, and scandium. Group IV consists of those metals that have low boiling points—samarium, europium, ytterbium, and thulium. Group V, consisting only of promethium, would be included in Group II, except that serious difficulties result from the intense radioactivity of the metal. All operations with it must be carried out by remote controls, and this is usually done at special installations.

The calcium-reduction process works well for the metals of Groups I, II, III, and V, but not at all well for Group IV. Most of the trifluorides (SmF_3, EuF_3, YbF_3) of this group are reduced only to divalent fluorides, even when a large excess of calcium is used; the resulting material resembles, but is not, the metal. Thulium trifluoride is reduced to the metal, but the high vapour pressure of molten metallic thulium causes difficulty.

The standard procedure for producing the metal by calcium reduction is to load a tantalum container with enough rare-earth fluoride to yield a metal billet weighing about 300 grams. About 10 percent excess calcium is added to drive the reaction to completion. The crucible is then placed in a furnace with a helium atmosphere and heated above the melting point of the rare-earth metal or of the slag—whichever is greater—and held at that temperature until the reaction is complete and the metallic and slag layers have separated because of differences in their densities. After cooling to room temperature, the crucible is taken out of the furnace in the dry box, cut in two at the metal–slag interface, and all slag is knocked off the metal. Usually a bright metal surface can be obtained. The metal ingot, however, contains small amounts of calcium and rare-earth fluoride as impurities. Group I and Group II metals are then put in another tantalum crucible and replaced in the furnace for the boiling-off process. This time a high vacuum is used, and the metal is heated to about 1,400° to 1,500° C and held there for some time, so that any volatile impurities, particularly calcium and rare-earth fluoride, evaporate. At these temperatures considerable amounts (1 to 3 percent) of tantalum dissolve in the molten metal. The furnace temperature is then slowly lowered until it is just above the melting point of the pure metal, at which temperature it is held for a few minutes to allow most of the tantalum to precipitate onto the walls or sink to the bottom of the crucible. (For Group I metals, the solubility of tantalum is about 50 parts per million or less at the melting point.) The ingot is then removed from the cooled furnace in the dry box, and the tantalum crucible and precipitates are machined off. The resulting ingot usually contains less than 0.01 percent total impurities.

Removal of dissolved tantalum

The Group II metals, because of their higher melting points, still contain some tantalum as an impurity when they solidify; usually this tantalum appears as a second phase, showing up as black dots in the metallographic pictures of the metal. It is possible, however, to purify these metals further by distillation from a tantalum still. The still consists of a short tantalum crucible located in a high-vacuum furnace. Affixed to this crucible is an inverted crucible, which is out of the heating zone of the furnace, its upper part being 400° to 500° C cooler because of radiation losses. The rare-earth metal can then be slowly sublimed (changed from a solid into a gas without passing through the liquid state) and resolidified in the inverted crucible. Because volatile impurities usually have different boiling points and heats of sublimation, it is possible (by choosing the right temperature) to sublime the metal in such a manner that the impurities can be separated from the metal. The nonvolatile tantalum remains behind in the still. Finally, the condenser, with its rather porous crystalline mass of rare-earth metal, is removed from the furnace, and the tantalum (or tungsten) is machined off in the dry box. The porous mass is then arc-melted into a billet on a water-cooled copper hearth under an inert atmosphere.

The Group III elements cannot be held at their melting points for long: because of their volatility a considerable quantity of the metal is lost. The boiling process therefore is omitted, but sublimation or volatilization works well, and—by the right choice of temperature in the still—both the volatile and inert impurities can be eliminated.

For the Group IV metals, only a distillation process is used. The pure oxide of the rare earth is dissolved in acid and reprecipitated using ultrapure chemicals to remove traces of calcium and magnesium often introduced from the water and chemicals used in the ion-exchange process. The precipitate is again converted to the oxide and placed in the still. Pure metallic lanthanum, cerium, or misch metal, which has been subjected to the boiling-off process to remove volatile impurities, is added in excess.

The reaction of europium oxide with lanthanum metal ($Eu_2O_3 + 2La \rightarrow La_2O_3 + 2Eu\uparrow$) takes place when the mixture is heated. Because the vapour pressure of europium is millions of times greater than that of lanthanum or of the oxide of either element, the metal distills away from the oxides, and the reaction goes practically to completion. If ultrahigh-purity metal is desired, a second distillation is performed.

Problems with thulium

Thulium poses special problems. Its melting point is so high that the molten metal acquires a considerable amount of impurity from the crucible. On the other hand, it has such a high vapour pressure at the melting point that it is practically impossible to melt it without losing much of the metal. Thulium is never melted, therefore, but is sublimed to the condenser, on which it forms solid crystals but not compact metal. If a solid bar is desired, the porous metal can be pressed into a tantalum tube and reduced to about half its diameter. The tantalum covering can then be machined off and a bar of compact metal obtained.

Major industrial uses. The properties of the 17 rare-earth elements in the form of their metals, alloys, or compounds—or some combination thereof—are so varied as to make them valuable for many industrial uses. Many other somewhat less costly materials, however, often will perform just as well; and when this is the case, the rare-earth elements are seldom used for these purposes. Only when their properties are unique is the extra cost justified industrially.

Use as catalysts

Millions of tons of rare earths have been used annually in the United States to produce catalysts for the cracking of crude petroleum. The natural mixture of rare earths obtained from the minerals accounted for about 20 percent of that total, and the remaining 80 percent was made up of special mixtures of lanthanum, praseodymium, neodymium, and samarium. Rare-earth catalysts have been repeatedly recommended for use in numerous organic reactions, including the hydrogenation of ketones to form secondary alcohols, the hydrogenation of olefins to form alkanes, the dehydrogenation of alcohols and butanes, and the formation of polyesters. The extent to which these catalysts are used in industry seldom is made public, but there is no doubt that the rare earths show marked catalytic properties.

Another substantial use of rare-earth oxides is in the glass industry. Cerium oxide has been found to be a more rapid polishing agent for glass than rouge, and several million pounds a year are consumed in the polishing of lenses for cameras, binoculars, and eyeglasses, as well as in polishing mirrors and television faceplates. Glasses containing lanthanum oxide have very high refractive indexes and low dispersions. Such glasses are used in complex lenses for cameras, binoculars, and military instruments—for the purpose of correcting spherical and chromatic aberrations. Rare-earth oxides often are added to glass melts in order to produce special glasses. Neodymium is added to some glasses to counteract the yellowish tint caused by iron impurities. Very pure neodymium oxide, when added in sufficient quantities (1–5 percent), gives a beautiful purple glass. Praseodymium and neodymium are added to glass to make welders' and glassblowers' goggles, that absorb the bright-yellow light from the sodium flame. The same combination is sometimes added to the glass used in television faceplates to decrease the glare from outside light sources. A beautiful yellow ceramic stain results from the addition of about 3 percent praseodymium oxide to zirconium oxide. Cerium oxide increases the opacity of white porcelain enamels.

Use in metallurgy

The metallurgical industry is another heavy user of rare earths. Small amounts of misch metal and cerium have long been added to other metals or alloys to remove their nonmetallic impurities. Misch metal added to cast iron makes a more malleable nodular iron. Added to some steels, it makes them less brittle. The addition of misch metal to certain alloys has been reported to increase the tensile strength and improve the hot workability and the high-temperature oxidation resistance. The rare earths are particularly effective in iron–chromium and iron–chromium–nickel alloys to improve a number of their properties, especially their resistance to corrosion and oxidation. Yttrium metal is said to work even better than misch metal in removing impurities from certain materials. The flints of cigarette lighters are an alloy of misch metal and iron.

The addition of misch metal or pure rare-earth elements to magnesium increases its high-temperature strength and its creep resistance—that is, resistance to slow deformation under prolonged use. This alloy also makes better castings if small amounts of zirconium or other metals are added, and such alloys are used in jet-engine and precision castings. The addition of small amounts of rare-earth elements to aluminum has also been reported to give better castings.

Use in television screens

By far the heaviest user of ultrapure separated rare earths is the television industry. It has been found that if a small amount of europium oxide (Eu_2O_3) is added to yttrium oxide (Y_2O_3), it gives a brilliant-red phosphor. Colour television screens utilize red, green, and blue phosphors. In the past, a zinc–cadmium sulfide was used as the red phosphor, but it was not completely satisfactory because its fluorescent band was too wide, and it could not be made to fluoresce as intensely as the other phosphors. The Y_2O_3–Eu_2O_3 phosphor corrected these disadvantages and made possible much brighter and more natural coloured pictures. This use has been growing in many countries. Many of the early rare-earth screens used europium–yttrium orthovanadate phosphor, but the industry is shifting heavily toward the oxide phosphor. Some television companies have substituted gadolinium oxide for the yttrium oxide. The rare-earth phosphors are also finding use in mercury-arc lights, which are used for sporting events and special street lighting. Instead of the unhealthy-looking blue light of the mercury arc, the phosphors give an intense white radiation similar to daylight. Considerable amounts of mixed rare-earth fluorides are used to make cored carbon rods, which are used as arcs in searchlights and in some of the lights used by the motion-picture industry.

Yttrium-iron garnets are synthetic high-melting silicates that can be fabricated into special shapes for use as microwave filters in the communications industry. Yttrium-aluminum garnets also are being produced at an increasing rate for use both in electronics and as gemstones. Both of these synthetic minerals have much use in the jewelry business. These garnets have a high refractive index and a hardness approaching that of diamond. In a solid crystal form they are amazingly transparent, and they are being cut into imitation diamonds.

Another significant industrial application of rare earths is in the manufacture of strong permanent magnets. Alloys of cobalt with rare earths, such as cobalt–samarium, produce permanent magnets that are far superior to most of the varieties now on the market. Another relatively recent development is the use of a barium phosphate–europium phosphor in a sensitive X-ray film that forms satisfactory images with only half the exposure.

Nuclear applications

Europium, gadolinium, and dysprosium have large capture cross sections for thermal neutrons—that is, they absorb large numbers of neutrons per unit of area exposed. These elements, therefore, are incorporated into control rods used to regulate the operation of nuclear reactors or to shut them down should they get out of control. In addition, rare-earth elements are used as burnable neutron absorbers to keep the reactivity of the reactor more nearly constant. As uranium undergoes fission, it produces some fission products that absorb neutrons and tend to slow down the nuclear reaction. If the right amounts of rare-earth elements are present, they burn out at about the same rate that other absorbers are formed.

Yttrium dihydride is used as a moderator in reactors to slow down neutrons. Certain rare earths are also used in shielding materials because of their high nuclear cross sections. Scandium metal is used as a neutron filter that allows neutrons only of a certain energy (two kiloelectron volts) to pass through.

Complexes of europium, praseodymium, or ytterbium with derivatives of camphor are useful reagents for analysis of optically-active organic compounds, which often are obtained as mixtures containing unknown proportions of two components that differ only in that their molecular structures are mirror images of each other. Determination of these proportions can be very difficult, but the rare-earth complexes provide asymmetric environments in which each component absorbs electromagnetic radiation of a particular frequency in the presence of a strong magnetic field. Proportions then can be determined by measuring the intensities of the separate absorptions.

Low toxicities of the rare earths

The rare earths have low toxicities and can be handled safely with ordinary care. Solutions injected into the peritoneum will cause hyperglycemia (excess of sugar in the blood), decreased blood pressure, spleen degeneration, and fatty liver. If solutions are injected into muscle about 75 percent of the rare-earth element remains at the site, the remainder going to the liver and skeleton. When taken orally, only a small percentage of a rare-earth element is absorbed into the body. Organically complexed ions are somewhat more toxic than solids or inorganic solutions. As is true for most chemicals, dust and vapours should not be inhaled, nor should they be ingested. Solutions splashed into the eyes should be washed out, and splinters of metal should be removed.

When handling rare-earth ores or minerals, dust should be avoided because many minerals contain other toxic elements, such as beryllium, thorium, and uranium. Finely divided rare-earth metals can ignite spontaneously, somewhat as magnesium does. (F.H.S./Ed.)

Actinide elements

The actinide elements constitute a group of 15 consecutive elements in the periodic table from actinium, symbol Ac, with atomic number 89, to lawrencium, symbol Lr, and atomic number 103. As a group they are significant largely because of their radioactivity. Although several members of the group, including uranium (the most familiar), occur naturally, most are man-made. Both uranium and plutonium have been used in atomic bombs for their explosive power and currently are being employed in nuclear plants for the production of electrical power.

GENERAL COMPARISONS

The actinide elements follow one another in the seventh series of the periodic table (see Figure 10). Each has 86 electrons arranged as in the atoms of the noble gas radon (which precedes actinium by several spaces in the table), with three more electrons that may be positioned in the *6d* and *7s* orbitals (the seventh shell is outermost), and with additional electrons packing into inside orbitals. Specifically, the series is formed by the insertion of one more electron for each successive new element into an underlying *5f* orbital. The valence electrons, however, are found mainly in the *6d* and *7s* orbitals. Thus, the chief difference among the atoms of the elements of the series is the single additional electron deep within the electron cloud; but the fact is that, because of its position in the 5th shell, this distinguishing electron actually affects the chemical properties of the actinides only in a relatively minor way; *5f* electrons are not involved in the formation of chemical bonds with other atoms.

As is usual with the elements of any group, there are a number of exceptions to these generalities, particularly in the lower members of the series; but for most of these elements, the concept of a series of nearly identical actinide elements is a useful guide for predicting their chemical and physical properties.

Like all elements, each actinide has its own particular atomic number, equal to the number of protons in the nucleus and, consequently, to the number of electrons; at the same time the atoms of an element are capable of existing in a number of forms (isotopes), each of which has a different number of neutrons in its nucleus and hence a different atomic mass. Although isotopes of a given element behave alike chemically, they may have different stabilities in relation to radioactive decay, which is a property of the nucleus. No element beyond bismuth in the periodic classification—*i.e.,* no element that has an atomic number greater than 83—has any stable isotopes; radioactive isotopes of every element in the table can be produced in the laboratory. The actinides are unusual in forming a series of 15 elements having no stable isotopes; every actinide isotope undergoes radioactive decay, and, as a result, only a few of the lighter, more stable members of the series (such as thorium and uranium) are found in nature. The half-life, or the precise time required for one-half of any amount of a particular isotope to disappear due to radioactive decay, is a measure of the stability of that isotope. The naturally occurring isotopes in the actinide series have long half-lives, of the order of billions of years.

PRACTICAL APPLICATIONS OF THE ACTINIDES

Nuclear fission

The practical significance of the actinides arises from the fissionability, or potential for splitting, of certain of their isotopes. When an atomic nucleus breaks apart, or undergoes fission, a far more disruptive process than ordinary radioactive decay, enormous amounts of energy are liberated. This energy can be allowed to generate an atomic explosion, or it can be controlled and used as a fuel to generate heat for the production of electrical power. Nuclear processes for power production give off no smoke, smog, or noxious gases, as conventional coal- or gas-fueled plants do. Nuclear power plants, however, do yield waste heat that may be considered as thermal pollution, and they also yield useless and dangerous radioactive wastes which, although they are pollutants, may be less undesirable than those from fossil-fuel generators. For this and other reasons, such as economy of operation, there is a potential for an enormous electrical energy production inherent in nuclear energy generating technologies, and, since the actinide elements are the only known fissionable materials, the practical impact of their availability is great. The isotope of uranium with the atomic number 92 and mass 235, written as uranium-235 or, in chemical symbols, as ^{235}U, is present to the extent of only about 0.7 percent in ordinary uranium, but it is a necessary fissionable material in the operation of a nuclear reactor using natural uranium. Other fissionable isotopes of great importance are uranium-233, plutonium-239, and plutonium-241.

Fissionable plutonium isotopes are formed as by-products of fission in reactors using uranium; when neutrons are added to uranium-238, which is not itself fissionable, it is converted to the fissionable isotope plutonium-239. Thorium, also, is potentially of great economic value, because one of its isotopes, thorium-232, can be converted into the fissionable isotope uranium-233 in a nuclear breeder reactor (*i.e.,* one that produces more fissionable material than it consumes), thus increasing by many times available supplies of fissionable materials. Since thorium is about three times more plentiful than uranium, the potential use of this element to produce nuclear energy is significant.

The heavier actinides, those beyond plutonium in the periodic table, are of interest principally to research scientists, though they have some practical uses as sources of thermoelectric heat and neutrons. They are employed to some extent in cancer therapy.

Actinium, thorium, protactinium, and uranium are the only actinide elements found in nature to any significant extent. The remaining actinide elements, commonly called the transuranium elements, are all man-made by bombarding naturally occurring actinides with neutrons or with heavy ions (charged particles) in particle accelerators (such as cyclotrons). The actinides beyond uranium do not occur in nature (except, in some cases, in trace amounts), since the stability of their isotopes decreases with increase in atomic number and whatever quantities may be produced decay too fast to accumulate. The half-life of uranium-238, the most stable uranium isotope, is 4.5×10^9 years. Plutonium-239 has a half-life of 24,400 years and is produced in reactors in ton amounts; but nobelium and lawrencium, elements 102 and 103, with half-lives of seconds, are produced a few atoms at a time. The first of these synthetic actinide elements to be discovered (1940) was neptunium, symbol Np, atomic number 93, which was prepared by bombardment of uranium metal with neutrons (see below *Transuranium elements*).

PROPERTIES OF THE GROUP

Similar lanthanide and actinide series

Chemical properties. The chemistry of any element can be understood best in terms of atomic structure and its effect on the formation of chemical bonds. In the actinide series, just as in the lanthanides, added electrons (with increasing atomic number) go into internal *f* orbitals, where they are partially buried and consequently not chemically active. These two series occur in Group IIIb of the periodic table; because the outer, or valence, electrons of these elements are much the same, the chemical properties of the elements in the two series tend to resemble one another closely. A great deal is known about the lanthanides, all but one of which occur in nature as stable isotopes and, therefore, predictions about the chemistry of the actinides, some of which can be prepared only in minute quantities, can be made with some success by comparing their electron structures with those of the lanthanides. In the lanthanide series of elements, as indicated above, each added electron goes into the *f* orbital of the fourth shell; these orbitals are designated as 4*f.* In the actinide elements, the added electrons also go into an *f* orbital in a similar manner, but in the fifth shell, instead. Electrons with larger quantum numbers generally are farther from the nucleus than those with smaller quantum numbers, and are therefore usually less strongly held by it. As expected, then, electrons in the 5*f* orbitals, being farther from the nucleus, are much less tightly bound than are those in 4*f* orbitals and, in fact, sometimes are active enough to take part in chemical reactions. The result is that the actinide elements, in which the 5*f* orbitals are being filled, have more variable valences (number of electrons available for chemical bonds) than do the lanthanides, in which the 4*f* orbitals are being filled.

The similarities between many lanthanide and actinide compounds are striking and offer a useful comparison. Under certain conditions, for example, actinium, americium, curium, and berkelium metals have the same crystal structure, as do many of the lanthanides. It is not yet known whether californium or einsteinium, the only other actinide elements with sufficiently stable isotopes for chemical work, have the same structure. Several of the lighter actinide elements from thorium through plutonium have different and unusual metallic structures, presumably due to the mixing of 5*f* and 6*d* orbitals in their atoms, some electrons entering unfilled 6*d* orbitals rather than the expected 5*f* orbitals.

The +2 oxidation state

The actinides generally show multiple oxidation states. Compounds of americium and californium with an oxidation state of +2 are known; there are reasons for expecting the existence of this state in some of the elements heavier than californium. For example, spectroscopic evidence for einsteinium(II) in the presence of the fluoride ion has been obtained. Divalent actinides (that is, actinides in the +2 oxidation state) form compounds with nearly the same properties as those of the divalent lanthanides and, accordingly, iodides, bromides, and chlorides of divalent americium and californium have been found to be stable. If X symbolizes the nonactinide and M symbolizes the actinide element, then the general formula for these compounds would be one atom of actinide and two atoms of nonactinide: MX_2.

The +3 oxidation state

Great similarities in chemical behaviour are found in the actinides of oxidation state +3, from actinium to einsteinium; furthermore, they are much like the lanthanides of the same oxidation state. The crystal types and many physical properties of these trivalent actinides are dependent more on the size of the +3 ion (an atom that has given up three electrons and has become an ion with three positive charges, symbolized as Ac^{+3}, etc.) of the particular element that is involved. For instance, the solubility of the trifluorides formed by actinides with a +3 state (thorium and protactinium have no such state) is exceedingly low. The crystal-structure type for the actinide trifluorides is the same as that of lanthanum trifluoride, and, since the radius of the ion is a regular function of the atomic number, the circumstance allows extrapolation from the lanthanum compound to the actinide compound and interpolation between known compounds in the series to determine missing values. The hydroxides, phosphates, oxalates, and alkali double sulfates of the actinides are also insoluble, with many of each having identical crystal structures, or being isostructural. The chlorides, bromides, and iodides (*i.e.,* the halides) of the actinides are, for the most part, isostructural for any one halide, and the structure type can be predicted from a knowledge of the ionic radius. The solubility of these halides in water is generally great. The +3 oxides of actinides are also isostructural, with the general formula M_2O_3, in which M is any of the actinide elements; they form cubic (or hexagonal) crystals, and the sizes of the molecules are thus easily predictable. Generally, then, the chemistry of the actinides in the +3 oxidation state is similar, with the differences mainly due to ionic size. As a consequence of these similarities, separations of the elements and of their components are frequently difficult, necessitating the use of methods in which very slight physical differences of the atoms or ions serve to separate the chemically almost identical materials. Two methods are ion-exchange reactions, in which differences in ions and bonding are used to effect separation and solvent extraction, in which specific solvents are used to dissolve and withdraw from the mixture the desired element or its compound.

The +4 oxidation state

Actinides in the +4 oxidation state also are much alike (and also resemble the +4 lanthanides). The +4 actinides, thorium, protactinium, uranium, neptunium, plutonium, berkelium, and, to a lesser extent, americium and curium, are sufficiently stable to undergo chemical reactions in water solutions. Crystallized compounds in the +4 state exist for thorium, protactinium, uranium, neptunium, plutonium, americium, curium, berkelium, and californium. The oxides and many complex fluorides are known for all of these elements. The dioxides are all isostructural, as are the tetrafluorides. Most of these actinide compounds can be prepared in a dry state by igniting the metal itself, or one of its other compounds, in an atmosphere of oxygen or of fluorine. Some tetrachlorides, bromides, and iodides are known for thorium, uranium, and neptunium. The ease with which they can be formed decreases with increasing atomic number. Berkelium(IV) appears to be sufficiently stable to allow the preparation of the tetrachloride. Hydroxides of a number of these elements in the +4 state also are known; they are of very low solubility, as are the fluorides, oxalates, and phosphates. Again, many physical properties of the tetrafluorides are influenced more by ionic size than by atomic number, and isostructurality of these actinide and lanthanide compounds is the rule rather than the exception.

The similarities exhibited by the lanthanide and actinide compounds in the +3 and +4 oxidation states, as well as in some cases by the free elements, can be very useful. A great many individual differences, however, do arise. These are due, in part, to mixing of the orbitals (some electrons moving into *d* rather than *f* orbitals) and, in part, to the relative degrees of binding of the *f* electrons.

Special properties. *Chemical.* The metals thorium, protactinium, uranium, neptunium, and plutonium are for the most part different from one another. Uranium, neptunium, and plutonium have extremely dense metallic forms. Neptunium, for example, with a density of 20.45 grams per cubic centimetre when crystallized into the orthorhombic crystal form, is one of the densest metals known to man. A possible explanation for the fact that these metals show a number of different crystal forms is that the electrons in the 5*f* orbitals mix with those in the 6*d* orbitals and consequently form a number of hybrid electronic states of nearly the same energy. Beginning with americium, however, the electron energy levels seem to be sufficiently separated so that mixing does not occur.

The +5, +6, +7 oxidation states

The other main differences shown by the actinides is that some possess the +5, +6, and +7 oxidation states (no lanthanide element exceeds the +4 state). It appears that the 5*f* electrons of the actinides, being far enough from the positively charged nucleus, permit increasingly easier removal and consequent formation of higher oxidation states. The element protactinium shows the +5 state; uranium, neptunium, and americium exhibit the +5 and +6 states; only neptunium and plutonium have the +7 state.

There are two types of chemical reactions for the +5 and +6 states. If M symbolizes any actinide, and O, as usual, symbolizes oxygen, then the ions found both in aqueous (water) solution and in solids prepared from solution are represented by the general formulas MO_2^+ (meaning a molecule consisting of one atom of M with two of oxygen, the whole having a single positive charge) and MO_2^{2+}. In nonaqueous solution, and in solids prepared from them, compounds of M that do not contain oxygen are known. With the halogens (X being a general designation for a halogen—fluorine, chlorine, bromine, or iodine), compounds are known that can be represented as MX_5 (meaning a molecule consisting of one atom of an actinide with five atoms of a halide) and MX_6, as well as complexes of the type having the molecular formulas MX_6^-, MX_7^{2-}, and MX_8^{3-} for the +5 states, and MX_7^- and MX_8^{2-} for the +6 states. Neptunium(VII) and plutonium(VII) have been prepared in basic solution, and certain oxygenated ions (of the type represented by MO_5^{3-}) as well as a few solid compounds, have been identified with the same oxidation state. Complex oxides with alkali metals in which these two elements have the +7 state also have been prepared.

Physiological. All the actinide elements are heavy metals and, as such, are toxic, just as lead is toxic—relatively large amounts ingested over a long period cause serious illness. But, with the exception of the long-lived thorium and uranium isotopes, the real danger with the actinide elements lies in the radioactive properties of these elements. They are emitters of tissue-destroying and cancer-producing rays (alpha, beta, or gamma; see ATOMS: *Radioactivity*). Furthermore, the chemistry of many of these elements is such that, once ingested, they tend to remain in the body almost indefinitely. Several, such as plutonium and americium, migrate to the bone marrow, where their radiation interferes with the production of red blood cells. As a consequence, workers using these elements are required to take elaborate precautions to prevent ingestion. Less than one-millionth of a gram can be fatal.

Radioactive decay series

Nuclear. All of the actinide elements are unstable toward radioactive decay; the reason that actinium, thorium, protactinium, and uranium are found in nature at all is because some of their isotopes are unusually stable and others are being formed constantly by decay of the long-lived isotopes. It is convenient to divide the naturally occurring isotopes into families based on the relationships of their atomic masses to each other. The mass numbers of all isotopes of the so-called thorium series, for instance, turn out to be multiples of four, and the series is known as the 4n series. In the uranium series, masses have been shown to be such that they are represented by 4n + 2; and in the actinium series, by 4n + 3. Not found in nature to any significant extent, but which can be artificially produced by man, is the neptunium, or 4n + 1 series, named for its longest-lived member, neptunium-237.

In the various radioactive decay processes, several "rays" are emitted, the term ray being a holdover from the time when all of these emissions were thought to be rays. They are: (1) electrons, called beta particles to indicate their origin in radioactive decay, and designated as negative beta, or $\beta-$, particles; (2) helium nuclei, called alpha particles and designated as α particles, or as helium with a plus two charge, He^{+2}; (3) gamma rays, which are electromagnetic waves of very high frequency, designated as γ rays; (4) positrons, which are positively charged electrons and are designated as positive beta, or $\beta+$, particles. Finally, an orbital electron in a radioactive atom may be captured by the nucleus and taken into it. This radioactive event is called K-capture. Except for the emission of gamma rays, each of these processes leads to an isotope of a different element; that is, to a substance with a different atomic number. The emission of an alpha particle leads to a change in atomic weight as well, because this emission has significant mass. The changes occur in sequence, each decay process leading to still another unstable element, until a region of stable isotopes of the elements lead and bismuth is reached.

The most important nuclear reactions, however, involve the capture of neutrons by an actinide nucleus, followed by splitting, or fission, of that nucleus into two unequal parts, with the liberation of enormous quantities of energy plus two or more extra neutrons. Nuclear reactors and atomic bombs depend upon the chain reaction set up by this process: the resulting neutrons react further, inducing more fission reactions, which produce more neutrons, which lead to still more fission reactions, with the result that, without control, a great deal of energy is liberated very quickly.

One gram of burning coal yields fewer than 10,000 calories of heat. The fission of one gram of uranium-235 produces 2×10^{10} calories, or about 2,000,000 times as much energy. With adequate control the energy can be released in useful form.

Fissionable isotopes

The most important actinide by far, because of its fissionability, is uranium, which has several isotopes. Natural uranium consists mostly of uranium-238, a nonfissionable isotope; uranium-235 occurs to the extent of only seven-tenths of 1 percent; and there are even smaller amounts of uranium-234.

The fissionable isotope uranium-235 is the valuable substance that causes the chain reactions with neutrons. Methods that separate isotopes by virtue of their different masses are used to eliminate the unwanted isotopes in the naturally occurring mixture of uranium ores and thus enrich natural uranium with respect to uranium-235. Such enriched uranium was used in the first atomic bomb exploded over Japan.

Two other fissionable actinide isotopes are important and undoubtedly will be more so in the future. The first is the isotope plutonium-239 prepared by neutron bombardment of uranium-238. First, uranium-239 is formed by neutron capture; this isotope then undergoes negative beta decay, giving neptunium-239, which in turn reacts by negative beta decay to give plutonium-239. Plutonium-239 thus is formed as a by-product in uranium piles in which uranium-238 is exposed to neutrons; it can be used in place of uranium-235 in atomic weapons or in reactions. The second fissionable isotope is potentially even more important, because it is produced from the element thorium, of which there are enormous reserves on Earth. When the isotope thorium-232 is bombarded by neutrons, one of which it captures, it is converted to thorium-233. This substance decays by beta emission to protactinium-233, which again emits a beta particle to give uranium-233, also a fissionable isotope of uranium. Since uranium is a relatively scarce element, development of nuclear power on a large scale is expected to deplete rapidly the uranium that can be produced economically. The use of thorium thus could extend the supplies of fissionable material by about threefold, and the use of plutonium as well could more than double them. Breeder power reactors are designed so that very few neutrons are lost through the surface or from absorption by impurities, and more fissionable material (either uranium-233 or plutonium-239) is produced than is consumed. Should such breeder reactors be made practicable, never-ending supplies of fissionable isotopes would be available.

Thermoelectric power generators

Although no other fissionable isotopes of the actinides occur in significant amount, there are practical uses of the nonfissionable isotopes due to the amounts of heat they produce by nuclear decay. For special power sources that require great dependability, thermoelectric generators using these isotopes can be considered. Alpha-emitting isotopes with radioactive half-lives in the range of several months to 100 years or more are suitable candidates. (Beta- or gamma-emitting isotopes require too much shielding to be usable.) Curium-244, which has a half-life of 17.6 years, produces 2.9 watts of heat per gram. Another isotope, plutonium-238, produces 0.57 watt per gram and has the much longer half-life of 86 years. Such power sources have been planted on the Moon to provide electrical energy for transmitting messages back to Earth. Plutonium-238 also is being considered for use as a power source for artificial hearts. A thermoelectric power generator fueled by this radioisotope already has been implanted in the human body to power a heart pacemaker, which is not expected to need replacement for at least 10 years. (L.B.As./Ed.)

Transuranium elements

The transuranium elements are so called because they all lie beyond uranium; that is to say, they are elements with atomic numbers higher than 92 in the periodic table (see Figure 10). Eighteen elements, up to and including atomic number 110, have been discovered, although confirmation of the discovery of elements after 103 remains uncertain. Eleven of them, from neptunium to lawrencium, belong to the actinide series, described above. The other seven, which have atomic numbers higher than 103, are sometimes referred to as the transactinides. All of the transuranium elements are unstable, decaying radioactively, with half-lives that range from tens of millions of years to mere fractions of a second. Since only two of the 18 have been found in nature (neptunium and plutonium) and those only in trace amounts, the synthesis of these elements through nuclear reactions has been an important source of knowledge about them. That knowledge has expanded scientific understanding of the fundamental structure of matter and makes it possible to predict the existence and basic properties of elements much heavier than element number 110—*i.e.,* the so-called superheavy elements, those with atomic numbers from 110 to around 126. Since it is predicted that such elements should have significant nuclear stability and, therefore, may exist in nature, some of them are actively being sought. Elements with atomic numbers even higher, around 164, are also predicted, but with lesser nuclear stability; and present theory suggests that the maximum atomic number will be found to lie somewhere between 170 and 210. All these still unknown elements are included in the transuranium group.

DISCOVERY OF THE FIRST TRANSURANIUM ELEMENTS

First synthesis. The first attempt to prepare a transuranium element was made in 1934 in Rome where a team of Italian physicists headed by Enrico Fermi and Emilio Segrè bombarded uranium nuclei with free neutrons. Although transuranium species may have been produced, the results of the experiment were ultimately interpreted by the German physical chemists Otto Hahn and Fritz Strassman in terms of nuclear fission. Not until 1940 was a transuranium element first positively produced and identified by two American physicists, Edwin Mattison McMillan and Philip Hauge Abelson, who, in California, exposed uranium oxide to neutrons from a cyclotron target. The resulting element was found to have an atomic number of 93. It was named neptunium.

Transformations in atomic nuclei are represented by equations that balance all the particles of matter and the energy involved before and after the reaction. The above transformation of uranium into neptunium may be written as follows:

$$^{238}_{92}\mathrm{U}\,(n,\,\gamma)\,^{239}_{92}\mathrm{U} \xrightarrow{\beta^-} {}^{239}_{93}\mathrm{Np}$$

In this equation the atomic symbol of the particular isotope reacted upon, in this case U for uranium, is given with its mass number at upper left and its atomic number at lower left: $^{238}_{92}\mathrm{U}$. The symbols within the parentheses indicate, first, the species of matter or of energy (here *n,* for neutron) reacting with the nucleus and, second, the species (here γ, for a quantum of energy called a gamma ray) emitted by the nucleus during the reaction.

Equations for nuclear transformations

The resulting isotope is shown next, with its changed mass at the upper left ($^{239}_{92}\mathrm{U}$). Together, these symbols represent the transformation of a single uranium-238 nucleus, reacting with a neutron and releasing gamma radiation, to produce the isotope uranium-239. The next event is represented by an arrow showing a spontaneous loss of a beta particle (symbolized β), an electron with very high velocity, from the nucleus of uranium-239. What has happened is that a neutron within the nucleus has been transformed into a proton, with the emission of a beta particle which carries off a single negative charge; the nucleus, therefore, now has one more positive charge than it had before the event, when its atomic number was 92. The resulting isotope, as a result, has an atomic number of 93 but, because the beta particle has negligible mass, the mass number of the nucleus has not changed. It is still 239. The nucleus resulting from these events is an isotope of the element neptunium, atomic number 93 and mass number 239. The above is called negative beta-particle decay; a nucleus may also emit a positron, or positive electron, resulting in beta-particle decay. (In another type of decay the nucleus, instead of emitting a β-particle, "captures" or absorbs one of the electrons orbiting the nucleus, thus reducing the positive charge by one.)

The usual manner of writing nuclear reactions drops the atomic number from the symbol for the element and this rule will be followed in the rest of this article.

For further information on discoveries of transuranium elements, see Table 27.

SYNTHESIS OF TRANSURANIUM ELEMENTS

The most abundant isotope of neptunium is neptunium-237. Neptunium-237 has a half-life of approximately 2×10^6 years and decays by the emission of alpha particles. (Alpha particles are composed of two neutrons and two protons and are actually the very stable nucleus of helium.) Neptunium-237 is formed in kilogram quantities as a by-product of the large-scale production of plutonium in nuclear reactors. This isotope is synthesized from the reactor fuels, uranium-235 and uranium-238, by the following reactions:

$${}^{238}\mathrm{U}\ (n, 2n)\ {}^{237}\mathrm{U} \xrightarrow{\beta^-} {}^{237}\mathrm{Np}$$

$${}^{235}\mathrm{U}\ (n,\gamma)\ {}^{236}\mathrm{U}\ (n,\gamma)\ {}^{237}\mathrm{U} \xrightarrow{\beta^-} {}^{237}\mathrm{Np}$$

In the first reaction, uranium-238 captures one neutron but emits two, reducing the mass number by one. Plutonium, as the isotope plutonium-239, is produced in ton quantities in nuclear reactors by the reaction:

$${}^{238}\mathrm{U}\ (n,\gamma)\ {}^{239}\mathrm{U} \xrightarrow{\beta^-} {}^{239}\mathrm{Np} \xrightarrow{\beta^-} {}^{239}\mathrm{Pu}$$

The plutonium isotope plutonium-238, which is of secondary importance, is produced in kilogram quantities by the reaction:

$$^{237}\text{Np}(n,\gamma)^{238}\text{Np} \xrightarrow{\beta^-} {}^{238}\text{Pu}$$

The production of transuranium elements by a process of continuous, intensive irradiation with slow neutrons is illustrated in Figure 16, in which the heavy line indicates the principal path of neutron capture and negative beta-particle decay that results in successively heavier elements and higher atomic numbers. The lighter lines show subsidiary paths that augment the major path. The major path terminates at an isotope of fermium (fermium-257), because the short half-life of the next fermium isotope (fermium-258), for radioactive decay by spontaneous fission (360 microseconds), precludes its production and the production of isotopes of elements beyond fermium by this means. The lighter lines beyond indicate predictions only.

From G. Seaborg, "Elements Beyond 100, Present Status and Future Prospects," *Annual Review of Nuclear Science,* vol. 18, p. 119 (1968)

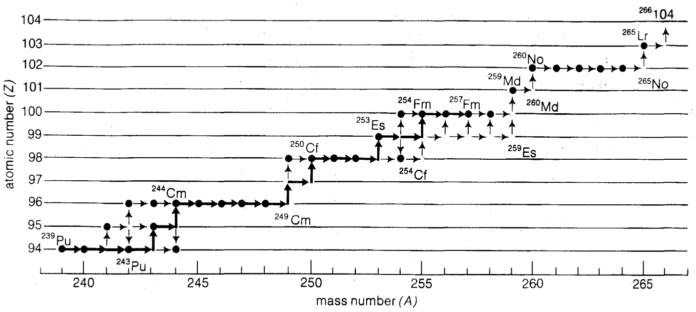

Figure 16: Nuclear reactions for the production of heavy elements by intensive slow neutron irradiation (see text).

Heavy isotopes of some transuranium elements are produced in nuclear explosions. Underground detonations of nuclear explosive devices during the late 1960s resulted in the production of significant quantities of einsteinium and fermium isotopes, which were separated from rock debris by mining techniques and chemical processing. Again, the heaviest isotope found was that of fermium-257. Why this is the case is not yet completely understood.

An important method of synthesizing transuranium isotopes, currently as well as historically, is by bombarding heavy element targets with charged particles, rather than neutrons, from accelerators. For the synthesis of elements with atomic numbers of 101 or greater, so-called heavy ions (*i.e.,* charged particles heavier than the helium nuclei, mentioned above as alpha particles) have been used.

Accelerators for superheavy elements

New accelerators, or modifications of existing ones, are necessary in order to accelerate the heavy ions needed to produce the superheavy elements. Targets and projectiles relatively rich in neutrons are required so that the resulting superheavy nuclei will have sufficiently high neutron numbers; too low a neutron number renders the nucleus extremely unstable and unobservable because of its resultingly short half-life.

NUCLEAR PROPERTIES

Isotopes of the transuranium elements are radioactive in the usual ways: they decay by emitting alpha particles, beta particles, gamma rays; and they also fission, or break up, spontaneously. In Table 28, significant nuclear properties of certain important isotopes are listed. Only the principal mode of decay is given, though in many cases other modes of decay also are exhibited by the isotope. In particular, with the isotope californium-252, alpha-particle decay is important because it determines the half-life, but the expected applications of the isotope exploit its spontaneous fission decay that produces an enormous neutron output. Other isotopes, such as plutonium-238, are useful because of their relatively large thermal power output during decay (given in Table 28 in watts per gram). Research on the chemical and solid-state properties of these elements and their compounds obviously requires that isotopes with long half-lives be used. Isotopes of plutonium and curium, for example, are particularly desirable from this point of view. The discovery of the mendelevium isotope, with a half-life of 54 days (for the emission of alpha particles) has raised hopes that all elements, at least through atomic number 101, will have some isotopes with half-lives long enough so that some of their macroscopic properties can be measured. In Table 28, the specific activities, such as disintegrations per minute per unit weight, are given for those elements that can be produced in nuclear reactors (formerly called atomic piles). Beyond element 100 the isotopes must be produced by charged-particle reactions using particle accelerators, with the result that only relatively few atoms can be made at any one time.

Nuclear structure and stability. Although the decay properties of the transuranium elements are important with regard to the potential application of the elements, these elements have been studied largely to develop a fundamental understanding of nuclear reactions and nuclear and atomic structure. Study of the known transuranium elements also helps in predicting the properties of yet undiscovered isotopes and elements as a guide to the researcher who can then design experiments to prepare and

Table 28: Nuclear Properties of Selected Transuranium Element Isotopes

name and mass	principal decay mode	half-life	specific activity	
			d/m/μg*	watts/gram
Neptunium-237	alpha	2.14×10^6 years	1.56×10^3	2.07×10^{-5}
Plutonium-238	alpha	86 years	3.86×10^7	0.570
Plutonium-239	alpha	2.44×10^4 years	1.36×10^5	$\sim 1.91 \times 10^{-3}$

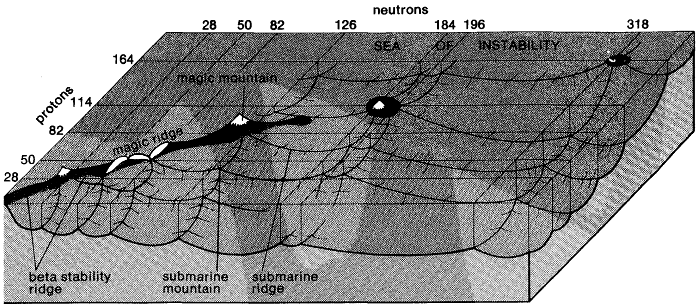

Figure 17: Known and predicted regions of nuclear stability, surrounded by a "sea" of instability.

From G. Seaborg, *Proceedings of The Robert A. Welch Foundation Conference XIII: Transuranium Elements* (November 17, 1969)

identify them. As shown in the allegorical Figure 17, the known isotopes of the elements can be represented graphically with the number of protons in the nucleus along the left-hand axis and the number of neutrons plotted on the axis along the bottom. The relative stabilities of the isotopes are indicated by their relative heights. In such representation, the known isotopes resemble a peninsula rising above a sea of instability. The most stable isotopes, appearing as mountain tops, occur at specific values called magic numbers.

Magic numbers

The magic numbers derive from calculations of the energy distribution based on the theoretical structure of the nucleus. According to theory, neutrons and protons (collectively, nucleons) are arranged within the nucleus in shells that are able to accommodate only fixed maximum numbers of them; when the shells are closed (*i.e.,* unable to accept any more nucleons) the nucleus is much more stable than when the shells are only partially filled. The number of nucleons in the closed shells yields the magic numbers. As the proton and neutron numbers depart further and further from the magic numbers, the nuclei are relatively less stable.

As the highest atomic numbers are reached, decay by alpha-particle emission and spontaneous fission sets in (see below). At some point the peninsula is terminated. With experimental methods available in the early 1980s, it appeared that the point at which the peninsula of stability disappeared lay in the vicinity of the element with atomic number 108. There has been, however, considerable speculation, based on a number of theoretical calculations, that two islands of stability might also exist. The first is expected to extend from about element 110 to element 126, while the second would be centred on element 164. With heavy-ion accelerators, experimenters might be expected to find such islands, especially the first.

Processes of nuclear decay. The correlation and prediction of nuclear properties in the transuranium region are based on systematics (that is, extensions of observed relationships) and on the development of theoretical models of nuclear structure. The development of structural theories of the nucleus has proceeded rather rapidly, in part because valid parallels with atomic and molecular theory can be drawn. At the same time, systematics has been successfully used in the case of alpha-particle decay by noting regularities in experimental alpha-particle decay energies and half-lives as a function of mass and atomic number. Similarly, for beta-particle decay, nuclear thermodynamics gives useful results. Half-lives for spontaneous fission also can be predicted by the application of systematics.

Alpha-particle decay. A nucleus can decay to an alpha particle (helium nucleus) plus a daughter product if the mass of the nucleus is greater than the sum of the mass of the daughter product and the mass of the alpha particle; *i.e.,* if some mass is lost during the transformation. The amount of matter defined by the difference between reacting mass and product mass is transformed into energy and is released with the alpha particle. The relationship is given by Einstein's equation: $E = mc^2$, in which the product of the mass (m) and the square of the velocity of light (c) equals the energy (E) produced by the transformation of that mass into energy. It can be shown that because of the inequality between the mass of a nucleus and the masses of the products, most nuclei beyond about the middle of the periodic table are likely to be unstable because of the emission of alpha particles. In practice, however, because of the reaction rate (*i.e.,* speed of reaction), decay by ejection of an alpha particle is important only with the heavier elements. Indeed, beyond bismuth (element 83) the predominant mode of decay is by alpha-particle emission, although at californium (element 98) an alternate process, called spontaneous fission, becomes possible (as a result of changes in energy balances) and begins to compete favourably with alpha-particle emission. In addition, with a number of transuranium nuclei, a third process, beta-particle decay (emission of a negative electron by the nucleus or the capture by the nucleus of an orbital electron) is of considerable importance.

Predicted half-lives

The regularities in the alpha-particle-decay process that have been noted from experimental data have been used to predict half-lives of as yet undiscovered isotopes. Such predicted half-lives are essential for experiments designed to discover new elements and new isotopes, because the experiment must take the expected half-life into account. The regularities in alpha-particle-decay energies can be plotted in a graph and, since the alpha-particle-decay half-life depends in a regular way on the alpha-particle-decay energy, the graph can be used to obtain the estimated half-lives of undiscovered elements and isotopes.

Beta-particle decay. In elements lighter than lead, beta-particle decay—emission of either negative electrons (usually called simply electrons) or positive electrons (positrons)—is the main type of decay observed. In the transuranium elements, alpha-particle decay and spontaneous fission occur, in addition to decay, by emission of negative electrons or by capture of orbital electrons. (Positron emission has not been observed in transuranium elements.) When the beta-particle decay processes are absent in transuranium isotopes, the isotopes are said to be stable to beta decay.

Decay by spontaneous fission. Regularities also are observed for spontaneous fission in the very heavy element region. If the half-life of spontaneous fission is plotted against the ratio of the square of the number of protons in the nucleus (symbolized by Z) divided by the mass of the nucleus (symbolized by A)—*i.e.,* the ratio Z^2/A—then a regular pattern results for nuclei with even numbers of both neutrons and protons (even–even nuclei). Although this uniformity allows very rough predictions of half-lives for undiscovered isotopes, the methods actually employed are considerably more sophisticated. Nuclei with odd numbers of neutrons or protons exhibit longer half-lives for spontaneous fission than those shown in the figure.

Odd–odd and even–even isotopes

The results of study of half-life systematics for alpha-particle, negative beta-particle, and spontaneous-fission decay in the near region of undiscovered transuranium elements can be plotted in graphs for even–even nuclei, and for nuclei with an odd number of protons or neutrons, and for odd–odd nuclei (those with odd numbers for both protons and neutrons). These predicted values are in the general range of experimentally determined half-lives and correctly indicate trends, but individual points may differ appreciably from known experimental data. Such graphs show that isotopes with odd numbers of neutrons or protons have longer half-lives for alpha-particle decay than do neighbouring even–even isotopes.

Nuclear structure and shape. *Liquid-drop models.* From the theoretical point of view, spontaneous-fission half-lives are generally treated by assuming that the nucleus has the properties of a liquid drop whose interior is inhomogeneous. The inhomogeneity arises from the fact that the neutrons and protons within the nucleus are more likely to be found inside rather than outside certain regions of the nucleus, called shells. This circumstance requires that a shell correction be applied to the ordinary homogeneous liquid-drop model of the nucleus. Nuclei with the exact number (or close to the exact number) of neutrons and protons dictated by closed shells (magic numbers, see above) have spherical shapes.

Since many transuranium nuclei have numbers of neutrons and protons different from the magic numbers and thus are nonspherical, considerable theoretical work has been done to describe the motions of the nucleons in their orbitals outside the spherical closed shells. These orbitals are important in explaining and predicting some of the nuclear properties of the transuranium and superheavy elements.

Two stable states for each nucleus

Nuclear-shape isomers. The mutual interaction of fission theory and experiment brought about the discovery and interpretation of fission isomers. At Dubna, U.S.S.R., in 1962, americium-242 was produced in a new form that decayed with a spontaneous-fission half-life of 14 milliseconds, or about 10^{21} times shorter than the half-life of the ordinary form of that isotope. Subsequently, more than 50 other examples of this type of behaviour were found in the transuranium region. The nature of these new forms of spontaneously fissioning nuclei was believed to be explainable, in general terms at least, by the idea that the nuclei possess greatly distorted but quasi-stable nuclear shapes. The greatly distorted shapes are called isomeric states, and these new forms of nuclear matter are consequently called shape isomers. As mentioned earlier, calculations relating to spontaneous fission involve treating the nucleus as though it were an inhomogeneous liquid drop, and in practice this is done by incorporating a correction for shells in the homogeneous liquid-drop model. The theorist found an apparently reasonable way to amalgamate the shell and liquid-drop energies. The remarkable result obtained through the use of this method reveals that nuclei in the region of thorium through curium possess two energetically stable states with two different nuclear shapes. This theoretical result furnished a most natural explanation for the new form of fission, first discovered in americium-242.

This interpretation of a new nuclear structure is of great importance, but it has significance far beyond itself because the theoretical method and other novel approaches to calculation of nuclear stability have been used to predict islands of stability beyond the point at which the peninsula of Figure 17 disappears into the sea of instability.

EXTENSION OF THE PERIODIC TABLE: THE SUPERHEAVY ELEMENTS

Possible existence of superheavy elements. According to these calculations, islands of stability will occur over the region of atomic numbers from approximately 110 to 126 and also at around 164. The so-called superheavy elements that exist at these islands of stability are predicted to have neutron numbers ranging from about 184 to 318. The nucleus most stable against all forms of decay is thought by many to be element 110, of mass 298, although the assignment of a specific atomic number and mass number is speculative. This particular nuclide (isotopic species) may have an overall half-life (although unlikely) of 10^8 years. Other hypothetical nuclides that are predicted to have exceptional stability are those with atomic numbers 114 and 124; when the neutron number of 184 is added to these numbers of protons, mass numbers of 298 and 308, respectively, are obtained. If these projections are correct, it is considered possible that superheavy elements exist in nature, and many scientific groups are looking for such elements.

The possibility of natural occurrence depends not only on the length of the half-life, but also on whether they were created in the first place. The discussion of the possible manufacture of these elements is as difficult and speculative as the discussion of their half-lives. At any rate, in the late 1960s, astronomers first observed a new kind of celestial object called a pulsar. It was thought that the most reasonable model for a pulsar was a rapidly rotating neutron star. The rapidly rotating electromagnetic and electrostatic fields associated with such a star should be able to accelerate charged particles to the velocities found in cosmic rays. If cosmic rays should originate in neutron stars, their composition might include superheavy elements. Unconfirmed evidence suggesting that elements in the atomic number range of 105 to 110 exist in cosmic rays was reported in 1968.

The existence of superheavy elements in meteorites or in terrestrial minerals depends on the probability of their having been formed by the same fundamental processes that created the other elements. Consequently, it is worthwhile to look for superheavy elements in meteorites and terrestrial minerals, since their presence or absence may tell something about the origin of the universe. Since the early 1970s, searches have uncovered certain anomalies that might be attributed to superheavy elements, but the results cannot be said to furnish proof of their existence.

Electronic structure of atoms

Superheavy elements and their predicted properties. The postulated nuclear islands of stability are important to chemistry. The periodic table of the elements classifies a wealth of physical and chemical properties, and study of the chemical properties of the superheavy elements would show how far the classification scheme of the table could be extended on the basis of nuclear islands of stability. Such studies would shed new light on the underlying properties of electrons orbiting the nucleus because it is these properties that produce the periodic system. The positions of superheavy elements in the periodic table ultimately would be determined by the characteristic energies of the electrons of their atoms, especially the valence electrons. Complex calculations have predicted meaningful distribution of electrons in orbitals for a number of superheavy elements. Results for elements 104–121 are given in Table 29, the configurations being those that the atoms have when they are at their lowest energy level, called the ground state.

Table 29: Calculated Electronic Ground States for Some Superheavy Elements

atomic number	electronic structure of two outermost shells*	atomic number	electronic structure of outermost shells†
104	$6d^27s^2$	113	$7s^27p^1$

†Added to the structure of radon, element 86, plus orbitals $5f^{14}6d^{10}$.

Elements 113 and 114. These calculations of electronic structure permit predictions of detailed physical and chemical properties of some superheavy elements. If, for example, the structure of the periodic system (Figure 18) remains predictable to higher atomic numbers, then element 113 will be in the same group of elements as boron, aluminum, gallium, indium, and thallium; and element 114 will be in the group with carbon, silicon, germanium, tin, and lead. Element 113 usually is called ekathallium, and element 114 is called ekalead. If they ever are discovered, of course, these elements will be given proper names of their own. Computer calculations of the character and energy levels of possible valence electrons in the atoms of these two superheavy elements have substantiated the placement of the elements in their expected positions. Extrapolations of properties from elements with

Table 30: Some Predicted Properties of Elements 113 and 114

	element 113 (ekathallium)	element 114 (ekalead)
Chemical group	III	IV
Atomic weight	297	298
Most stable oxidation state	+1	+2
Oxidation potential, V	−0.6 $M \rightarrow M^+ + e^-$	−0.8 $M \rightarrow M^{2+} + 2e^-$
Metallic radius, Å	1.75	1.85
Ionic radius, Å	1.48	1.31
First ionization potential, eV	7.4	8.5
Second ionization potential, eV	. . .	16.8
Density, g/cm³	16	14
Atomic volume, cm²/mole	18	21
Boiling point, °C	1,100	150
Melting point, °C	430	70
Heat of sublimation, kcal/mole	34	10
Heat of vaporization, kcal/mole	31	9
Debye temperature, °K	70	46
Entropy, eu/mole (25°C)	17	20

From G. Seaborg, *Proceedings of The Robert A. Welch Foundation Conference XIII: Transuranium Elements* (November 17, 1969)

lower numbers to elements 113 and 114 can then be made within the usual limitations of the periodic table. In Table 30, the results of such extrapolations are given. Although, in many cases, theoretical calculations are combined with extrapolation, the fundamental method involved is to plot the value of a given property of each member of the group against the appropriate row of the periodic table. The property is then extrapolated to the seventh row, the row containing elements 113 and 114. The method is illustrated in Figure 19 for estimating the melting point of element 113.

Bonding properties

As explained above, the bonding property of an element can be expressed by the energy required to shift a bonding, or valence, electron. This energy can be expressed in various ways, one of which is a relative value called the oxidation potential. The relative stabilities of possible oxidation states of an element represent what is probably that element's most important chemical property. The oxidation number of the atom of an element indicates the number of its orbiting electrons available for chemical bonds or actually involved in bonds with other atoms, as in a molecule or in a crystal. When an atom is capable of several kinds of bonding arrangement, using a different number of electrons for each kind, it has that many oxidation numbers, or oxidation states. The prediction of oxidation states can be illustrated with element 114, ekalead, which occurs in Group IVa of the periodic table. The outstanding periodic characteristic of the Group IVa elements is their tendency to go from a +4, or tetrapositive, oxidation state to a +2, or dipositive, state as the atomic number increases. Thus, carbon and silicon are very stable in the tetrapositive state, whereas germanium shows a weak dipositive state in addition to its strong tetrapositive state. Tin chemistry is characterized by about equal stability in the tetrapositive and dipositive states, and lead chemistry is dominated by the dipositive state—the element showing only weak tetrapositive properties. Extrapolation in the periodic table to the seventh row, then, results in a predicted most stable dipositive oxidation state for element 114. This result is supported by valence bond theory and by extrapolations of thermodynamic data.

Other superheavy elements. Less detailed predictions have been made for other superheavy elements. Element 117, for example, is expected to be a member of the halogen series, which is the group composed of fluorine, chlorine, bromine, iodine, and astatine. Solid element 117 should be metallic in appearance, as is astatine, but it is expected that, instead of the minus one (−1) oxidation-state characteristic of the natural halogens, it will show +3, +5, and +7 oxidation states. It should also form stable interhalogen compounds with fluorine, chlorine, and bromine.

Computer calculations of element 118

Computer calculations suggest that element 118 should have the closed-shell electronic configuration of the noble gas elements helium, neon, argon, krypton, xenon, and radon. The element should be the most electropositive of the noble gases, and, therefore, the existence of a (partially ionized) difluoride of the element 118 is predicted. A tetrafluoride and an oxide of the type formed by xenon (XeO_4) are also expected.

Although detailed predictions of the chemistry of element 119 have not as yet been completed, it is expected to be a typical alkali metal with a plus one (+1) oxidation state. The energetic properties of its valence electron, the 8*s* electron, suggest that its first ionization potential will be higher than the oxidation potential predicted by simple extrapolation, so that the element may be more like potassium than cesium in its chemistry. This higher energy will cause the metallic and ionic radii to be smaller than simple extrapolation would indicate.

Element 120 would be expected to be a typical alkaline-earth element. As with element 119, the ionization potentials should be raised to higher levels than the normal family trend would indicate and should also make the metallic and ionic radii smaller. These changes should make the chemistry of element 120 similar to that of calcium and strontium.

Element 121 should be similar in its chemical properties

From O. Keller Jr. et al., *Journal of Physical Chemistry*, vol. 74 (1970); American Chemical Society

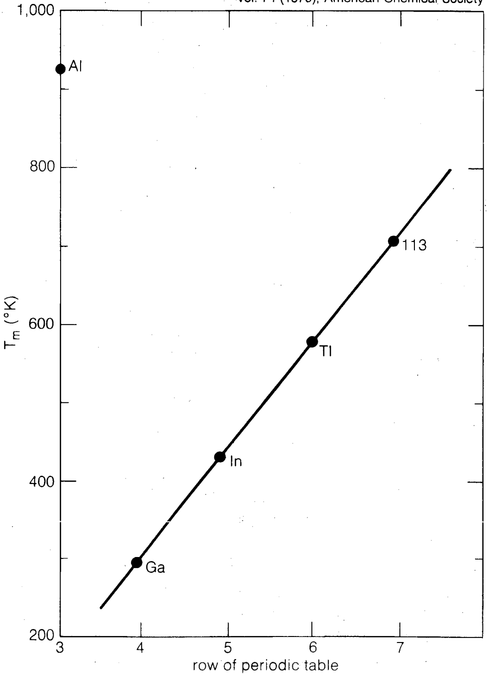

Figure 19: Melting points (Tm) in degrees kelvin (K) of Group III elements extrapolated to element 113 (see text).

to lanthanum and actinium, but detailed properties have not been predicted.

Superactinide series. It is probable, in a formal sense at least, that element 122 will begin another series of elements in which each successive electron is added to a deep inner orbital, in a manner similar (see Figure 18) to that found in the lanthanide and actinide series (see above *Rare-earth elements* and *Actinide elements*). Such a series, which would be listed under the actinide series in the periodic table, should consist of 32 elements, ending in the neighbourhood of element 153 and resulting primarily from the filling of the 5*g* and 6*f* inner electron shells.

Not every element of this new series would correspond to an actinide (or lanthanide) element on a 1:1 basis, and prediction of the chemistry of the members of the series is a very complex problem. The difficulty arises partly because of uncertainty of the exact point at which the energetically similar 5*g* and 6*f* orbitals begin to fill, and partly because calculations indicate that the 8*p* and 7*d* orbitals may be very close in energy to the 5*g* and 6*f* orbitals. (The number 8 shell is outermost from the nucleus and in each shell the *s* orbital is the innermost.) These orbitals may all be filled, then, in a commingling fashion, resulting in a series of elements that show multiple, barely distinguishable oxidation states. The electronic basis for the periodicity shown in Figure 18 will then no longer be present.

As shown, element 153 will be the last member of the superactinide series, at least in a formal sense. The prediction of properties on the basis of an orderly extrapolation appears to be of doubtful validity, however, in this heavy-element region of the periodic table. In still higher elements, the closely spaced energy levels are expected to make multiple oxidation states the rule. The placement of the elements in the heaviest portion of the periodic table as shown in Figure 18 is, therefore, probably also of only formal significance.

Maximum atomic number

End of the periodic table. At some point the stability of the orbital electrons in the ordinary sense must be destroyed as more and more protons are added to the nucleus. There is, therefore, in the ordinary chemical sense, a critical atomic number, or range of atomic numbers, which represents the end of the periodic table. This end, it should be noted, is separate, at least philosophically, from the question of stability of the nucleus itself; *i.e.,* nuclear stability is not the same as stability of the electron shells. The maximum atomic number, according to current theories, lies somewhere between elements 170 and 210, as indicated above.

CHARACTERIZATION AND IDENTIFICATION

Two important factors provided the key to the discovery and identification of many of the transuranium elements: one was knowledge of the lanthanide series coupled with the concept that it could be paralleled in the actinide series, and the other was the technique of separating elements with similar properties from a mixture by using the principle of ion exchange (see CHEMICAL REACTIONS). Ion-exchange reactions depend on the fact that some complex molecules have a charge that will attract ions of the opposite charge, hold them, and then exchange them for other ions of the same charge when brought in contact with them. The actinide concept, proposed in 1944, stated that the transuranium elements were part of a series of elements that started at thorium and that the chemistry of the series would be similar to that of an earlier transition-element series, the lanthanides. By the use of ion-exchange reactions that are highly specific, many of the transuranium elements have been separated and identified. The tripositive ions of the lanthanides and actinides are eluted (washed) from a cation-exchange resin (a resin that has a negative charge and will hold positive ions or cations) using a particular organic ion, alpha-hydroxyisobutyrate. The striking similarity between elution patterns of the two groups constitutes strong support for the actinide concept. A certain measure of stability of the dipositive state for nobelium was predicted by the actinide concept. A position was predicted for lawrencium, but for this element the yields have been so small and the half-lives so short that its positive identification by ion exchange has not been achieved. The tripositive state of lawrencium has been confirmed by a very rapid solvent-exchange experiment in which the lawrencium displayed the behaviour of the tripositive actinides and not that of the dipositive nobelium or radium, again in accord with the predictions of the actinide concept.

Non-chemical identification and separation

When the yields of a new element are small and its half-life is short, chemical identification and characterization are frequently not possible. In such cases the atomic number is deduced from the method of production through nuclear reactions, from the parent-daughter relationship of the new element to known elements of lower atomic number resulting from its nuclear decay, and from its nuclear-decay systematics that cannot be attributed to any known nuclides. Additionally, the variation in the yield of the new element is noted when the bombarding energy is changed or when the target or projectile or both are changed.

Separation of the product nuclide from the target has been accomplished in the discoveries of elements 101 through 106 by a recoil collection method. When the target nucleus is struck by a heavy ion projectile, the product nucleus recoils out of the very thin target and is either attracted to a substrate by an electrostatic potential or is swept onto a substrate by a jet of helium gas. The new element is then in a position to be observed and characterized by suitable detection techniques, essentially free of the parent isotope.

It is desirable, though not essential, that the mass number of the new element be established by evidence related to its mode of production, or to its parent-daughter relationship through radioactive decay to a radioactive isotope of known mass number. When weighable quantities of a transuranium element are available, more extensive characterization experiments can be performed. The most important of these experiments is the preparation of the metal, frequently done by high-temperature reduction of the fluoride of the transuranium element with an alkali or alkaline-earth metal. Another method used for preparation of larger (gram) quantities of high purity is electrolytic reduction of the chloride of the transuranium element. Physical characterization of these metal samples includes determination of the density, melting point, vapour pressure, boiling point, hardness, and other properties. X-ray diffraction measurements permit the determination of the crystal structure and calculation of the metallic radius and metallic valence. Chemical characterization includes a determination of the reactivity of the metal with other substances and the chemical stability of the compounds formed. Also of importance are the oxidation states and chemical-bonding properties of the elements in its compounds.

PRACTICAL APPLICATIONS OF TRANSURANIUM ISOTOPES

Three transuranium isotopes, of plutonium, americium, and californium (plutonium-238, americium-241, and californium-252), have demonstrated substantial practical applications. One gram of plutonium-238 produces approximately 0.56 watt of thermal power, primarily from alpha-particle decay, and this property has been used in space exploration to provide energy for small thermoelectric-power units (see above *Actinide elements*).

Americium-241 has a predominant gamma-ray energy (60 keV) and a long half-life (433 years) for decay by the emission of alpha particles, which make it particularly useful for a wide range of industrial gauging applications and the diagnosis of thyroid disorders. When mixed with beryllium it generates neutrons at the rate of 1.0×10^7 neutrons per second per gram of americium-241. The mixture is designated ^{241}Am–Be and a large number of such sources are in worldwide daily use in oil-well logging operations; *i.e.,* to find how much oil a well is producing in a given time span, as a day. Californium-252 is an intense neutron source: one gram emits 2.4×10^{12} neutrons per second. This isotope has been tested for applications in neutron activation analysis, neutron radiography, and portable sources for field use in mineral prospecting and oil-well logging. (G.T.S./Ed.)

(T.Mo.)

Nitrogen group elements: A short concise summary of nitrogen chemistry is contained in W.L. JOLLY, *The Inorganic Chemistry of Nitrogen* (1964). More detailed is the comprehensive compendium edited by C.A. STREULI and P.R. AVERELL, *Analytical Chemistry of Nitrogen and Its Compounds,* 2 vol. (1970), which includes especially useful tables. For a popularized, readable, introductory account, see ISAAC ASIMOV, *The World of Nitrogen,* rev. ed. (1962). Information about nitrogen and its compounds, as well as about the other elements of the nitrogen group and their compounds, is found in standard textbooks and treatises of inorganic chemistry. Among these are: R.T. SANDERSON, *Inorganic Chemistry* (1967), a modern textbook emphasizing the periodicity of the chemical elements by surveying their binary compounds with each of principal nonmetals; and *Chemical Bonds and Bond Energy* (1970), a brief book giving new insights into the nature of chemical bonds; HEINRICH REMY, *Grundriss der anorganischen Chemie,* 5th ed. (1955; Eng. trans., *Treatise on Inorganic Chemistry,* 2 vol., 1956), a thorough exposition; and E.G. ROCHOW, *The Metalloids* (1966), a brief, very readable survey of the elements that border between metallic and nonmetallic. For detailed discussions on fixation see W.J. BROUGHTON (ed.), *Nitrogen Fixation* (1981).

(R.T.S.)

Oxygen group elements: Among texts written at the general chemistry and secondary level covering the Group VIa elements, C.W. KEENAN and J.H. WOOD, *General College Chemistry,* 4th ed. (1971); and J.A. CAMPBELL *et al., Chemical Systems* (1970), are representative of sources of basic information; at a higher level are W.L. JOLLY, *The Synthesis and Characterization of Inorganic Compounds* (1970); R.T. SANDERSON, *Inorganic Chemistry* (1967); C.S.G. PHILLIPS and R.J.P. WILLIAMS, *Inorganic Chemistry* (1965); and B.E. DOUGLAS and D.H. MCDANIEL, *Concepts and Models of Inorganic Chemistry* (1965). The biosphere and ecosystems related to sulfur and selenium are discussed in A.B. ROY and P.A. TRUDINGER, *The Biochemistry of Inorganic Compounds of Sulphur* (1970); and in W.W. KELLOGG, "The Sulphur Cycle," *Science,* 175:587–596 (1972); allotropy and structure are presented in L.B. Chemical Reactions

The phenomenon of change, noted by everyone almost continuously and said by some to be the only unchanging aspect of the material universe, is the context in which all of the sciences find their place, including the study of chemical reactions. A chemical reaction is a process of change during which either two or more substances both change or one substance changes into at least two other substances. Thus, when wood burns, the substances present initially, wood and oxygen in the atmosphere, are converted in a chemical reaction to water vapour, carbon dioxide, and ash. All combustions are chemical reactions. Other types of familiar chemical reactions include decay, fermentation, the hardening of cement, the development of a latent image in an exposed photographic film, the tarnishing of silver, the corrosion of steel, the evolution of gas when vinegar and soda are mixed, the synthesis of nylon, and the digestion of food.

In a general sense, material substances can undergo change in three ways: a change of position, called movement; a change of form, such as the freezing of liquid water; and a change of substance, a chemical reaction. Some classify changes of form as chemical reactions, but, historically, the term chemical reaction has been applied only to changes of substance. The application to change of form is discussed below. Using the historical definition, each different chemical reaction displays the same unique characteristics.

Transformation. Thus, in a chemical reaction the substances originally present disappear, and substances that were not initially present appear. Factually, however, it is more descriptive to say that properties that were initially observable are no longer observed, and properties not originally observable are now noted. In combustion, a substance called wood, with its unique properties (fibrous, less dense than water, generally light- or dark-brown in colour), and oxygen, with its unique properties, all of which were capable of detection before combustion occurred, cannot be detected after combustion. Instead, after combustion, only the properties of water vapour, carbon dioxide, and ash can be detected.

Conservation of mass. Chemical reactions display another essential quality. Although substances change in a chemical reaction, within limits that can be measured the total mass does not change. That is, the mass of wood and oxygen that disappears in a combustion is equal to the mass of water vapour, carbon dioxide, smoke, and ash that appears. In ordinary chemical reactions, this loss of mass as the reactants vanish is equal to the gain of mass as the new substances form. Because this effect is universal, it has been presumed to be fundamental, an indication that there is some common, universally applicable reason that applies to all material substances.

Fixed composition. Further, substances formed in chemical reactions display another universal but more specific characteristic. For example, water is formed as one of the products in hundreds of quite different chemical reactions, but, without exception, it contains only the elements hydrogen and oxygen and always in the same proportion: the mass of oxygen is eight times as great as the mass of hydrogen. That is, the composition of water is independent of the particular chemical reaction by which it might have been formed. Parallel phenomena are observed with other substances: whenever carbon dioxide is formed as a product, the mass ratio of carbon to oxygen is always 3 to 8; for ammonia (a gas, not the aqueous solution called household), the ratio of its constituent elements, nitrogen and hydrogen, is always 14 to 3. (Precise measurements reveal minor variations in the mass ratio that are understood in terms related not to chemical reaction but to nuclear composition; see ATOMS: *Isotopes.*)

Energy effects. Finally, in all but a very few chemical reactions, energy is either absorbed or evolved. It is often evolved as heat, as in combustion, but also in other forms, such as electrical energy during the chemical reaction in a battery when it is switched on to operate a flashlight or portable radio. The amount of energy evolved depends on the mass of the products formed. For twice the mass of product formed, in two otherwise identical chemical reactions, exactly twice as much energy is evolved. The same relationship applies to reactions during which energy is absorbed rather than evolved.

A chemical reaction can now be defined more explicitly as a process of change in which the substances originally present, called reagents, are changed into substances with other properties, called products, in such a way that, first, there is no observable change in the total mass; second, whenever the same product is formed by a different process of change, that product exhibits the same mass ratio of components; and, third, almost always, energy is either absorbed or evolved in an amount that is directly related to the mass of the products formed.

These facts have two important consequences. First, they can be used to infer universally applicable, theoretical principles to account for the reasons that chemical reactions occur and for some of the details of the process, thereby increasing understanding of the material universe. Second, these facts and the related uncertain but usable theories can be used to alter man's environment for either his benefit or his detriment. Examples abound. The chemical industry manufactures beneficial substances, such as polymeric fibres (*e.g.,* nylon) and elastomers (synthetic rubber), dyes, other polymers (plastics), metallic alloys, fertilizers, paints, insecticides, drugs, ceramics, and fuels; but these manufactures also cause undesired effects upon man's ecological system, creating problems that demand further application of chemistry as well as other branches of knowledge.

This article is divided into the following sections:

Introductory survey

GROWTH OF MAJOR THEORIES CONCERNING CHEMICAL REACTIONS

Phlogiston theory

Chemical reactions were known to prehistoric man, and it is possible to conjecture that he speculated upon their cause. In ancient Greek civilization this speculation led to a qualitative supposition that matter is perhaps composed of individual particles. Not until late in the 17th century, however, did theory and philosophical speculation become conjoined in the first of many far-reaching attempts to explain chemical reactions. The German chemist and physician Georg Ernst Stahl, basing his ideas upon earlier and less specific suggestions, postulated that during combustion a substance, which he named phlogiston, escaped from the burning fuel into the air. Thus if a drinking glass is inverted over a burning candle, the flame dies out in a short time, because, it was postulated, the air within the glass becomes saturated with phlogiston. According to these ideas, because ash remains after combustion, wood is composed of phlogiston and ash. Because no ash is left when a candle burns, candle wax is obviously pure phlogiston. Therefore it should be possible to prepare wood in a chemical reaction between wood ash and candle wax. This prediction of the phlogiston theory failed. It failed in more startling ways, as well. When metals burn, for example, their ash is greater in mass than the original metal. To explain this, it was suggested that phlogiston possessed the quality of negative mass, which is a direct contradiction of its other postulated properties.

Additional evidence that led to the downfall of the phlogiston theory was accumulated by several workers, among whom Carl Wilhelm Scheele, in Sweden, and Joseph Priestley, first in England and later in North America, can be mentioned particularly. Independently, each discovered a gas (actually oxygen), but both failed to recognize the significance of their discovery. Priestley in particular maintained his belief in phlogiston until his death. At about the same time, however, near the end of the third quarter of the 18th century, Antoine-Laurent Lavoisier, in France, independently discovered the same gas, and he recognized its significance. He postulated that combustion was a chemical reaction involving two substances, one, a component of the air, which he named *oxigine* (oxygen), and the other a combustible substance, such as candle wax, wood, or metal.

Dalton's atomic theory

Shortly after the beginning of the 19th century, John Dalton in England postulated that matter is composed of small, indivisible, and unalterable particles called atoms and that in a typical chemical reaction groups of atoms initially conjoined in some way became disassociated and then rejoined in new arrangements. The observed disappearance of properties and the appearance of new properties were thus explained by the theory that the properties of a substance depend upon its atomic composition. Centuries earlier, others had expressed ideas that were very similar, but Dalton was able to convince his contemporaries of the probable validity of his postulate.

Of equal importance was Dalton's concept that each atom of any single element was identical in every respect to every other atom of that same element. As a consequence, the masses of the atoms are quantitatively revealed in the ratio of the masses of the components of a substance. Thus, because the mass of oxygen in water is eight times that of the mass of hydrogen, it can be said that one atom of oxygen is eight times as massive as one atom of hydrogen, on condition that one particle (today denoted by the word molecule) of water is composed of one atom each of hydrogen and oxygen. As Dalton recognized, however, one particle of water might be composed of some other number of hydrogen and oxygen atoms—for example, two atoms of hydrogen and one atom of oxygen—then the relative masses of oxygen and hydrogen atoms would be 8 to $^1/_2$ or, in whole numbers, 16 to 1.

During this same period, other facts obtained in laboratory studies, particularly those of Joseph-Louis Gay-Lussac, in France, suggested that, although the masses of gases that reacted with each other showed no simple consistency, the volumes of those reacting gases did demonstrate a certain simplicity. For example, eight grams of oxygen reacted with one gram of hydrogen, and 14 grams of nitrogen reacted with three grams of hydrogen; but, when measured at equal temperatures and pressures, the volume of hydrogen was found to be exactly twice that of the volume of oxygen in the reaction to form water, and the volume of hydrogen was found to be exactly three times that of nitrogen in the reaction to form the gas ammonia. Apparently, this small integer volume relationship hinted at an as yet unknown fundamental property of matter. Amedeo Avogadro in Italy suggested that this property could be explained by the assertion: All gases at the same temperature, pressure, and volume will contain the same number of particles, which may or may not be single atoms. His suggestion was not well received, but Avogadro's pupil, Stanislao Cannizzaro, carried out further studies, in the light of which it became reasonable to state that water molecules contain two atoms of hydrogen, ammonia molecules three atoms of hydrogen, hydrogen chloride molecules one atom of hydrogen, and, for each, some number of atoms of other elements. These compositions are symbolized today by formulas in which the symbols for the elements represent single atoms. Thus, water is H_2O, the subscript 2 indicating two atoms of hydrogen and a subscript of 1 being understood for one atom of oxygen. For ammonia, the formula is NH_3: one atom of nitrogen and three atoms of hydrogen in each molecule. For hydrogen chloride (Cl being the symbol for chlorine), HCl: one atom of each. Approximately 50 years after the initial publication of Avogadro's ideas and largely through the efforts of Cannizzaro, Avogadro's hypothesis, or theory, as it is more commonly called today, was accepted by most scientists. (Modern methods of analysis have established that the actual number of molecules in a quantity of any substance equal in mass in grams to the molecular weight of the substance—*e.g.,* 18 grams of water—is 6.02×10^{23}, called Avogadro's number.)

Avogadro's number

Facts revealed by intensive laboratory examination of other properties of matter (*e.g.,* magnetism, electricity, radiations) led to theoretical conclusions that atoms are not indivisible but are themselves composed of still smaller parts, or particles. One of these parts is a negatively charged particle named the electron (the meaning of "negative charge" is still unknown except for broad generalities), and another is a positively charged particle called the nucleus. The interaction of electrons from different atoms, often conjointly as electron pairs, with the positively charged nuclei of each of the atoms, constrains them to group together in fixed ways as molecules. Not all substances, however, are molecular. For example, salt, a compound of sodium and chlorine, consists of an aggregation of charged particles called ions. In particular, salt is an aggregation of any number of sodium ions and of an equal number of chloride ions. A sodium ion is derived from a sodium atom by the loss of one electron; a chloride ion is derived from a chlorine atom by the gain of one electron. Still other nonmolecular aggregations are believed possible. Diamond is an aggregation of any large number of carbon atoms arranged in a unique three-dimensional configuration in a repetitive manner, much as the design of wallpaper is repetitive in two dimensions. In this respect, salt is like diamond; its ions are arranged in any single crystal of salt as a repetitive pattern not unlike a three-dimensional chessboard might be imagined, in which black and white squares represent sodium and chloride ions, respectively.

With this information, a more recently developed definition of a chemical reaction can be stated. Thus, if atoms are held together, or bonded, in molecules or in other types of aggregations by electron interactions, then in a chemical reaction these bonds are broken (by the absorption of energy) and, either simultaneously or subsequently, new electronic interactions develop as other bonds are formed (with the release of energy). Hence, distinct from the historically developed ideas, a chemical reaction can now be defined as a process of change in which some bonds are broken and different bonds are formed. This definition includes all processes that involve a change of substance as well as many of the processes that involve a change of form, such as the freezing of water.

ENERGY CONSIDERATIONS

If the energy absorbed in bond rupture exceeds the energy released by the formation of new bonds, then overall the chemical reaction is observed to be energy absorbing. The converse is true for cases in which the energy absorbed is less than the energy released. In a very few instances the overall absorbed and released energies are equal in magnitude.

Types of reaction. Chemical reactions can be classified into three types: exoergic (or exothermic) if, overall, energy is evolved; endoergic (or endothermic) in the converse cases; and aergic (or athermic; *i.e.,* without energy change) for rarer cases.

In every case, however, energy must be supplied to the reactants in order to initiate the breaking of bonds before other bonds can be formed because a stable bond will not of itself degenerate. In general, therefore, all chemical reactions, even exoergic or aergic, require the introduction of energy in some form from an external source in order to begin. The initiating energy, called activation energy, is sometimes supplied as heat from another, already initiated exoergic chemical reaction. Thus, to set fire to paper the activation energy can be supplied by a burning match, for which the activation energy was generated by a chemical reaction of the materials in the match head, for which activation energy was supplied as heat generated from frictional effects when the match head was rubbed upon a suitable surface.

Use of electrical energy

The required energy may be furnished, instead, as electrical energy, as for the endoergic decomposition of water into hydrogen and oxygen, the electrical energy being obtained from generators driven by turbines, which are in turn powered by falling water. In still other instances the requisite energy is supplied in the form of light, which can be thought of as consisting of discrete particles of electromagnetic energy, called photons. Photons that give rise to the sensation of red have less energy than photons that give rise to the sensation of orange, and these have less energy than photons that produce the sensation of yellow, and so on. Photons of lesser energy and photons of greater energy than those that comprise the range of visible colours are known and are called infrared and ultraviolet photons, respectively. If a photon of the particular quantity of energy needed to break a particular chemical bond passes near enough to that bond, it is probable that that photon will cease to exist and its energy will be absorbed by that bond as it breaks. Reactions that can be initiated in this manner are called, appropriately, photochemical reactions. The best known photochemical reaction is actually a series of consecutive reactions that takes place in the green leaves of plants through the influence of sunlight. These reactions, called photosynthesis, involve the consumption of carbon dioxide from the atmosphere and of water present in the plant, with the production of oxygen, released to the atmosphere, and of cellulose and starch (or sugar), which remain within the plant structure.

Catalytic reactions. For reasons not yet well understood, many chemical reactions can be initiated with a lesser activation energy than normally required when they are conducted in the presence of special foreign substances called catalysts; such a reaction is said to be catalyzed. Chlorophyll is a catalyst in the photochemical reaction of plants. Enzymes are involved as catalysts in the metabolic processes (chemical reactions) that occur in living tissue; the enzyme pepsin, present in the stomach, catalyzes the breakup of large protein molecules into smaller molecules.

A sugar cube will sputter but not burn when a match flame is applied to its surface, but very small amounts of substances called rare-earth oxides act as catalysts for this particular combustion; the oxides are present in trace amounts in tobacco ash, and a cube lightly coated with tobacco ash will burn if heated with the flame of a match.

At one time it was thought that the driving force, the cause of the spontaneity of chemical reactions, the reason, so to speak, that wood burns or cement hardens or an egg congeals when it is cooked, could be attributed to energy relationships such as those discussed above.

Entropy. It is now known that these energy relationships are indeed related to the rapidity or slowness of any particular chemical reaction, but the reason a chemical reaction occurs, at any speed, is attributed to changes in what is called the entropy both of the substances involved in the reaction and of the surroundings not otherwise involved in the chemical reaction itself. Entropy is the measure of that energy that is associated with disorder in any system; it is a concept developed in thermodynamics to take into consideration the fact that not all types of energy can be manipulated to do work. Thus, in any isolated system, entropy tends to increase; *i.e.,* the portion of energy that is not available for work is transformed into the energy of disorder. Consider, for example, the reaction in which wood combines with oxygen: water vapour, carbon dioxide, and ash are formed, and heat is evolved. The entropy of the wood and oxygen is relatively small, while the entropy of the products is larger; that is, for the substances themselves, entropy has increased. The evolved heat also causes an increase in the entropy of the surroundings that absorb that heat. Hence, overall, for the substances and for the surroundings, entropy has increased. Unless overall there is an increase in entropy, a chemical reaction cannot occur. In the synthesis of water from hydrogen and oxygen, to be described more fully below, the entropy of the product, water, is less than the entropy of the reagents, hydrogen and oxygen. The heat evolved in this reaction, however, is sufficient to increase the entropy of the surroundings more than the decrease of entropy suffered by the substances themselves; overall, that is, entropy increases. For this reason the reaction is spontaneous.

MODERN VIEWS AND CLASSIFICATION SYSTEMS

When the science of chemistry began, only the masses of the reagents and products could be measured. This early emphasis upon mass and, practically speaking, the weighing of samples influenced the theories of chemical reaction. As understanding developed, measuring instruments more sophisticated than balances and volumetric glassware were designed, particularly as a consequence of developments in physics. Today, it is possible to measure with precision and reliability a variety of subtle effects, ranging from the absorption and emission of energy as heat, as photons, or as electrical energy to detection of almost unimaginably small amounts of reagents. In general, modern chemical theoretical research is concerned with either the mechanism of a chemical reaction (called kinetics, or kinetics and mechanisms, or the dynamics of chemical reactions) or with the construction of mental or physical models of the structure of matter (called structural chemistry). In addition, applications of both new and old theory are made with the consequent introduction of new or improved substances useful in commerce. There is perhaps no single case today for which all of the theoretical details can be completely described, and only a vague distinction can be made between theoretical and applied chemistry.

Concerns of modern theoretical research

Various other classifications and types of chemical reactions exist, derived largely from a theoretical viewpoint. They are not, however, all-inclusive, as are the classifications of chemical reactions as exoergic, endoergic, and aergic. Thus, a synthesis reaction may also be an oxidation–reduction reaction. Some acid–base reactions may also be ionic reactions, or precipitation reactions.

Synthesis. A synthesis reaction, in the simplest sense, involves elements as reagents and the formation of a compound (a substance composed of more than one element) as the product, often as the only product. Iron, symbolized as Fe, reacts with sulfur, S, to form iron sulfide, FeS, as shown by this chemical equation: $Fe + S \rightarrow FeS$. Thus, the plus sign on the left symbolizes "reacts with"; the arrow signifies "forms," "produces," or "yields."

In addition to symbolizing the substances, iron, sulfur, and iron sulfide, the symbols used in a chemical equation also specify the amounts of substances that react and are produced. Thus, Fe represents 55.85 grams of iron, S represents 32.06 grams of sulfur, and FeS represents 87.91 grams of iron sulfide. That is, the chemical equation given above summarizes laboratory-measured fact: 55.85 grams of iron will react with exactly 32.06 grams of sulfur to form exactly 87.91 grams of iron sulfide. If other amounts are used, say one-fifth as much iron, 11.17 grams, no matter how much sulfur was present in excess, only one-fifth of 32.06 grams would be consumed and one-fifth as much product formed. The converse is true (in round numbers): if half as much sulfur is available, then half as much iron would react, and about 44 grams of iron sulfide would be formed. The calculation of the amounts of reagents consumed and of products formed constitutes the branch of chemistry called stoichiometry.

As a second example of synthesis, the following equation describes the synthesis of water from its elements: $2H_2 + O_2 \rightarrow 2H_2O$. Here, a new feature of a chemical equation appears, the stoichiometric factor, 2, preceding the formula for hydrogen molecules, H_2 (two atoms in each molecule), and water molecules. That is, in the laboratory it has been observed that four grams of hydrogen react with 32 grams of oxygen to produce 36 grams of water. The symbol for one gram of hydrogen in the form of atoms is H; the expression for two grams of hydrogen in molecular form is H_2. In the reaction described by the equation, then, the expression $2H_2$ represents four grams of hydrogen in the form of molecules. Analogously, the formula H_2O represents 18 grams of water molecules.

The mole unit

These quantities—H, or one gram of hydrogen atoms; H_2, or two grams of hydrogen molecules; H_2O, or 18 grams of water molecules; Fe, or 56 (approximately) grams of iron atoms; S, or 32 grams of sulfur atoms—are called moles of these substances. Thus, one mole of hydrogen atoms weighs one gram; one mole of water molecules weighs 18 grams; one mole of iron sulfide molecules weighs 87.91 grams. In each of these instances and in all others that could also have been mentioned as additional examples, the same number of particles is understood to be specified. Thus, one mole of hydrogen molecules contains 6.02×10^{23} (602,000,000,000,000,000,000,000) molecules (Avogadro's number, see above); one mole of iron atoms is 6.02×10^{23} atoms; one mole of water molecules is 6.02×10^{23} molecules; and so on. With this kind of stoichiometric emphasis, the equation describing the synthesis of water can be read as: two moles of hydrogen molecules react with one mole of oxygen molecules to form two moles of water molecules. The same stoichiometric emphasis is usually applied to the equations for other types of chemical reactions, described below.

Decomposition. Decomposition reactions are chemical reactions in which chemical species break up into simpler parts. The decomposition of the gas ammonia is represented by the equation $2NH_3 \rightarrow N_2 + 3H_2$; or, in terms of a single mole of ammonia, $NH_3 \rightarrow {}^1\!/_2N_2 + {}^3\!/_2H_2$, read as: one mole of ammonia molecules decomposes to form one-half mole of nitrogen molecules and three-halves of a mole of hydrogen molecules.

Compounds need not break down into elements in a decomposition reaction. For example, ammonium carbonate, $(NH_4)_2CO_3$, decomposes into ammonia, carbon dioxide (CO_2), and water, according to the equation $(NH_4)_2CO_3(s) \rightarrow 2NH_3(g) + CO_2(g) + H_2O(g)$.

The letters in parentheses indicate the physical states of the substances, s for solid, g for gaseous, l for liquid.

Polymerization. Polymerization reactions are not unlike synthesis reactions in that simpler substances combine to form more complex substances. The term polymerization, however, is restricted to chemical reactions in which the product is composed of many, hundreds or thousands, of the simpler reagent species. The polymerization of terephthalic acid, $HO_2C(C_6H_4)CO_2H$, with ethylene glycol, $HOCH_2CH_2OH$, to form the polymer called Dacron in fibre form or Mylar in sheet form, is represented by the equation:

$$n\,HO_2C(C_6H_4)CO_2H + n\,HOCH_2CH_2OH \rightarrow [\ldots OC(C_6H_4)CO_2CH_2CH_2O\ldots]_n + 2n\,H_2O$$

in which n signifies a large number of moles (and $2n$ twice that number of moles): the dotted extensions at either end of the repetitious polymeric molecule symbol signify further extensions of the same pattern. The polymer ends eventually with an $HO_2C(C\ldots)$ at the left and a $\ldots CH_2OH$ at the right end.

Chain reactions. A chain reaction is a series of reactions in which the product of each step is a reagent for the next. Many polymerization reactions are chain reactions. A simpler example, however, is found in the synthesis of hydrogen bromide. The overall synthesis equation is $H_2 + Br_2 \rightarrow 2HBr$. The details by which this synthesis occurs are believed to involve a series of reactions beginning with $Br_2 \rightarrow 2Br$, which is endoergic. Some of the bromine atoms will recombine, however, in the reverse exoergic reaction, $Br + Br \rightarrow Br_2$, but not all do so. If a bromine atom instead moves in such a way as to meet and interact with a hydrogen molecule, another reaction will occur: $Br + H_2 \rightarrow HBr + H$. This hydrogen atom then can react either with a bromine molecule: $H + Br_2 \rightarrow HBr + Br$; or with an HBr molecule, already formed: $H + HBr \rightarrow H_2 + Br$.

Note that HBr is formed and the chain is propagated by the two reactions $Br + H_2 \rightarrow HBr + H$ and $H + Br_2 \rightarrow HBr + Br$; each recurrence of this sequence converts one molecule of hydrogen and one of bromine to two molecules of hydrogen bromide and generates other atoms that reinitiate the sequence, thus continuing the chain. Finally, after most of the hydrogen and bromine molecules present have reacted, the chain-termination reaction, $Br + Br \rightarrow Br_2$, predominates, with the formation of trace amounts of bromine molecules. Here, the symbols used in the equations represent atoms and molecules rather than moles of atoms and molecules. Stoichiometric application is not as appropriate for these details as it is for the overall synthesis equation.

Substitution, elimination, addition. Substitution reactions are reactions in which a molecule is changed by the loss of one or more atoms and the gain of one or more other atoms that in a sense substitute for those that are lost. For example, chloroform, $CHCl_3$, reacts with antimony trifluoride, SbF_3, to form the useful compound monochlorodifluoromethane, $CHClF_2$. The incomplete, nonstoichiometric equation, emphasizing only the substitution, is $CHCl_3 + SbF_3 \rightarrow CHClF_2$. Two fluorine atoms are substituted for two chlorine atoms in this equation. The product substance undergoes a further reaction when heated strongly: $2CHClF_2 \rightarrow C_2F_4 + 2HCl$.

This reaction is an example of an elimination reaction; in this case, a hydrogen atom and a chlorine atom are eliminated as molecular hydrogen chloride, HCl. In the presence of hydrogen peroxide or other catalysts, this compound, tetrafluoroethylene, C_2F_4, polymerizes to form the well-known substance Teflon, $(CF_2)_n$, or $\ldots CF_2CF_2CF_2CF_2CF_2CF_2CF_2CF_2 \ldots$.

Hydrogenation reaction

Addition reactions, as the name implies, are reactions in which atoms are added to a molecule. If the added atoms are hydrogen atoms, the addition reaction is called a hydrogenation reaction. For example, many different vegetable oils can be hydrogenated. The product is a solid that can be used as shortening in the preparation of food. Oleic acid, $C_{18}H_{34}O_2$, serves as an example: $C_{18}H_{34}O_2 + H_2 \rightarrow C_{18}H_{36}O_2$. This reaction and the hydrogenation of other vegetable oils are usually carried out in the presence of a specific catalyst, finely divided porous nickel; for this process to be economically effective, the hydrogen must be under high pressure.

Oxidation–reduction reactions. Oxidation–reduction reactions form another class of important chemical reactions. For example, the generation of electric current by the use of a so-called dry cell or by a storage battery can occur only by means of an oxidation–reduction reaction that takes place within the battery. (The chemical reactions that take place inside any typical battery remain unknown in detail.) In the more recently developed mercury cell, constructed out of zinc (Zn) metal, usually in the form of a cuplike container, in which mercury monoxide, HgO, water, and other substances are enclosed, in the region near the electrode marked with a plus sign, a reduction reaction occurs (the electron itself is represented by the symbol e^-, which can be taken to indicate [stoichiometrically] a mole of electrons): $2e^- + HgO + H_2O \rightarrow Hg + 2OH^-$.

This equation is called a reduction half-equation because it symbolizes the gain of electrons by the reagents, mercury monoxide and water, to form the products, mercury metal, Hg, and hydroxide ion, OH^-. At the corresponding negative electrode, an oxidation reaction occurs, electrons being lost during the formation of product from the reagent. The reaction is symbolized in the oxidation half-equation $Zn + 2OH^- \rightarrow ZnO + H_2O + 2e^-$.

In addition to the disappearance of hydroxide (OH^-) ion, zinc is also consumed. Hence, the cell will certainly cease to function when the enclosing cup, made of zinc, has disappeared. Further, the reduction half-equation states that, as this cell is discharged, metallic mercury is produced within the cell.

Acid–base reaction. Although the classes of chemical reaction have by no means been exhausted, the final class to be mentioned here is acid–base reaction. One definition of an acid is that it is a substance that gives up a proton; *i.e.,* a hydrogen ion, H^+ (a hydrogen atom with its single electron removed). Vinegar is largely composed of water and acetic acid, CH_3COOH. The hydrogen atom on the right end, as depicted here, can be lost as an ion with the electron remaining behind on the acetate residue, now to be identified as an acetate ion $(CH_3COO)^-$. $CH_3COOH \rightarrow (CH_3COOO)^- + H^+$.

The ionization of acetic acid, however, will not occur unless a base is present. A base is defined as a substance that tends to take protons from acids. Water is a suitable base, taking the proton to become a hydronium ion, H_3O^+: $CH_3COOH + H_2O \rightarrow (CH_3COO)^- + H_3O)^+$.

In water solution, sodium bicarbonate, $NaHCO_3$ (common baking soda), forms dispersed sodium ions, Na^+, and bicarbonate ions $(HCO_3)^-$, for the most part. Bicarbonate ions are bases, and they tend to take hydrogen ions from hydronium ions, which act as an acid, to form carbonic acid, H_2CO_3: $(H_3O)^+ + (HCO_3)^- \rightarrow H_2O + H_2CO_3$. The carbonic acid is unstable at ordinary temperatures; most of it decomposes into water and gaseous carbon dioxide: $H_2CO_3 \rightarrow H_2O + CO_2$.

SEPARATION AND ANALYSIS

Broadly, the techniques used to investigate chemical reactions often require that the products of the reaction first be separated, because they are usually formed together within the same enclosure, such as a test tube. Separation techniques often involve the precipitation of one of the products; *i.e.,* by means of a second chemical reaction, a product of the first is altered by addition of or elimination of one or more atoms, so that this new substance can be separated, perhaps by the addition of a liquid in which only it is soluble or in other ways.

Identification of products

Following separation, the product is identified by its properties. For example, water can be identified by its freezing point or its refractive index (a measure of the ratio of the velocities of light when it passes through one medium compared to another) or its elemental composition of 8 to 1 oxygen to hydrogen mass ratio or by the energy of particular photons that it absorbs when exposed to photons of different energies.

An example of a simple case indicates in a general sense a procedure that might be followed. If the amount of acetic acid present in a particular brand of vinegar is to be measured, one first prepares a solution of a base of known concentration, such as baking soda. Then, a measured volume of vinegar is put into a suitable reaction vessel, and, drop by counted drop, the solution of base is added. The volume of base solution added, including the last drop that caused the evolution of gas (carbon dioxide), would serve as a measure (in an approximate way) of the amount of acetic acid in the measured volume of vinegar originally put into the reaction vessel. For more precise work, a solution of hydroxide ion base, made by dissolving sodium hydroxide, NaOH, in water at a known concentration, would be used. In this instance, a few drops of coloured indicator solution, such as the red-coloured liquid made by steeping red cabbage in hot water, would be added to the vinegar before adding the solution of base. The chemical reaction is complete when the indicator, which is dispersed throughout the liquid, changes colour upon the addition of one drop more of base solution. Of course, the procedures currently used to elucidate the details of chemical reactions are considerably more sophisticated, but the principle is the same.

(J.A.Y.)

Mechanisms and kinetics

The mechanisms of chemical reactions are the detailed processes by which chemical substances are transformed into other substances. The reactions themselves may involve the interactions of atoms, molecules, ions, electrons, and free radicals, and they may take place in gases, liquids, or solids—or at interfaces between any of these.

Reasons for study

The study of the detailed processes of reaction mechanisms is important for many reasons, including the help it gives in understanding and controlling chemical reactions. Many reactions of great commercial importance can proceed by more than one reaction path; knowledge of the reaction mechanisms involved may make it possible to choose reaction conditions favouring one path over another, thereby giving maximum amounts of desired products and minimum amounts of undesired products. Furthermore, on the basis of reaction mechanisms, it is sometimes possible to find correlations among systems not otherwise obviously related. The ability to draw such analogies frequently makes it possible to predict the course of untried reactions. Finally, detailed information about reaction mechanisms permits unification and understanding of large bodies of otherwise unrelated phenomena, a matter of great importance in the theory and practice of chemistry.

Generally, the chemical reactions whose mechanisms are of interest to chemists are those that occur in solution and involve the breaking and reforming of covalent bonds between atoms—covalent bonds being those in which electrons are shared between atoms. Interest in these reactions is especially great because they are the reactions by which such materials as plastics, dyes, synthetic fibres, and medicinal agents are prepared, and because most of the biochemical reactions of living systems are of this type. In addition, reactions of this kind generally occur in time scales convenient for study, neither too fast nor too slow, and under conditions that are easily manipulated for experimental purposes. Lastly, there are a number of techniques by which the mechanisms of such reactions can be investigated.

Chemical reactions involve changes in bonding patterns of molecules—that is, changes in the relative positions of atoms in and among molecules, as well as shifts in the electrons that hold the atoms together in chemical bonds. Reaction mechanisms, therefore, must include descriptions of these movements with regard to spatial change and also with regard to time. The overall route of change is called the course of the reaction, and the detailed process by which the change occurs is referred to as the reaction path or pathway.

Also important to the study of reaction mechanisms are the energy requirements of the reactions. Most reactions of mechanistic interest are activated processes—that is, processes that must have a supply of energy before they can occur. The energy is consumed in carrying the starting material of the reaction over an energy barrier. This process occurs when the starting material absorbs energy and is converted to an activated complex or transition state. The activated complex then proceeds to furnish the product of the reaction without further input of energy—often, in fact, with a release of energy. Such considerations are important to an understanding of reaction mechanisms because the actual course that any reaction follows is the one that requires the least energy of activation. This reaction course is not always the one that would seem simplest to the chemist without detailed study of the different possible mechanisms.

Difficulties in studying reactions

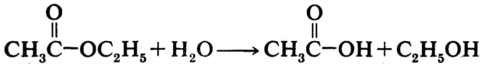
The study of reaction mechanisms is complicated by the reversibility of most reactions (the tendency of the reaction products to revert to the starting materials) and by the existence of competing reactions (reactions that convert the starting material to other than the desired products). Another complicating factor is the fact that many reactions occur in stages in which intermediate products (intermediates) are formed and then converted by further reactions to the final products. In examining chemical reactions it is useful to consider several general subjects: (1) factors that influence the course of chemical reactions, (2) energy changes involved in the course of a typical reaction, (3) factors that reveal the mechanism of a reaction, and (4) the classification of reaction mechanisms. With this information in mind it is then possible to look briefly at some of the more important classes of reaction mechanisms. (The sections *Acid–base reactions and equilibria, Oxidation–reduction reactions,* and *Electrochemical reactions* below deal with the mechanisms of reactions not described in this section.)

GENERAL CONSIDERATIONS

Identification of constituents

Determinants of the course of reaction. *The reactants.* In analyzing the mechanism of a reaction, account must be taken of all the factors that influence its course. After the bulk chemical constituents have been identified by ordinary methods of structure-determination and analysis, any prereaction changes involving the reactants, either individually or together, must be investigated. Thus, in the cleavage of the substance ethyl acetate by water (hydrolysis), the actual reagent that attacks the ethyl acetate molecule may be the water molecule itself, or it may be the hydroxide ion (OH^-) produced from it (see below).

The hydrolysis of ethyl acetate can be represented by the following equation:



$$CH_3\overset{\overset{\displaystyle O}{\|}}{C}{-}OC_2H_5 + H_2O \longrightarrow CH_3\overset{\overset{\displaystyle O}{\|}}{C}{-}OH + C_2H_5OH$$

ethyl acetate water acetic acid ethyl alcohol

in which the structures of the molecules are represented schematically by their structural formulas. An arrow is used to indicate the reaction, with the formulas for the starting materials on the left and those of the products on the right. In the structural formulas,the atoms of the elements are represented by their chemical symbols (C for carbon, H for hydrogen, O for oxygen), and the numbers of the atoms in particular groups are designated by numeral subscripts. The chemical bonds of greatest interest are represented by short lines between the symbols of the atoms connected by the bonds.

Important to this reaction is an equilibrium involving the cleavage of the water molecules into positively and negatively charged particles (ions), as follows:

$$2H_2O \rightleftharpoons H_3O^+ + OH^-$$

water hydronium ion hydroxide ion

In this equation, the numeral in front of the symbol for the water molecule indicates the number of molecules involved in the reaction. The composite arrow indicates that the reaction can proceed in either direction, starting material being converted to products and vice versa. In practice, both reactions occur together and a balance, or equilibrium, of starting materials and products is set up. The significance of this equilibrium for the hydrolysis of ethyl acetate is that any of the three entities (water molecules, hydronium, or hydroxide ions) may be involved in the reaction, and the mechanism is not known until it is established which of these is the actual participant. This often can be established if it is possible to determine the relative amounts of the three in the reaction medium and if it can be shown that the rate of the reaction depends upon the amount (or concentration) of one of them. Under certain conditions the hydrolysis of ethyl acetate is found to involve water molecules (as shown in the equation above); in other cases, hydroxide ion is involved.

The transition state. The transition state, or activated complex, is the fleeting molecular configuration that exists at the top of the energy barrier that the reactants must surmount to become the products. Strictly it is not a component of the reaction system and it cannot be examined directly in the way that an intermediate (however unstable) can because it lasts no longer than the duration of a molecular collision. The transition state may have properties of its own, not reflected in those of the starting materials or of the products and of the reaction, and so it is of vital importance in determining the course of reaction. Inference concerning the nature of the transition state is the essence of mechanistic study.

The solvent. The solvent, or medium in which the reaction occurs, may perform the mechanical, but often vital, role of allowing otherwise immiscible reactants to come together rapidly. Among the important groups of solvents, each with its own special type of behaviour, are hydroxylic solvents (those the molecules of which contain hydroxyl [-OH] groups, such as water and alcohols), dipolar aprotic solvents (those the molecules of which show a separation of electrical charge but do not easily give up a proton, or positive hydrogen ion; *e.g.,* acetone), and nonpolar solvents (those the molecules of which do not show charge separation; *e.g.,* hexane).

Solvent interactions

In dissolving the reactants, the solvent may interact with any or all of them, and it may be involved in the transition state for any reaction available for the system. If the solvent interacts more powerfully with the transition state than with the reactants, it facilitates the reaction. The solvent itself, of course, may be one of the reactants, and this circumstance introduces special problems because of the difficulty of distinguishing experimentally between its functions as a reagent and as an environment for the reaction.

Catalysts. Catalysts are substances that speed up a reaction by facilitating a particular mechanism—sometimes by influencing an existing prereaction and sometimes by making a new process energetically favourable. Their presence or absence frequently determines the course a reaction may take, simply because one of a number of competing reactions is, or is not, favoured. (Most catalysts are changed chemically while they speed up a reaction: sometimes—but not always—they are consumed; sometimes they are reformed and so appear to be unchanged in concentration during a reaction.)

The products. All reactions are reversible in principle, and the nature of the products of the reaction can affect the reaction course in a number of ways. When the position of equilibrium is unfavourable, for example, the accumulation of products may cause a reversal of the reaction. In such circumstances, the physical removal of the products (either through their volatility or insolubility, for example) facilitates the completion of the forward process. Sometimes, too, one of the products acts as a catalyst or as an inhibitor, behaviour that strongly influences the course of the reaction.

The reaction conditions. The conditions under which some reaction occurs, including such variables as the temperature and concentrations of reactants, also are important in determining the course of the reaction. For reactions that have a high energy barrier between reactants and products, the rate is highly responsive to change in temperature, and such reactions become more likely at increased temperatures, so that the minor products of a reaction often appear in larger proportion at higher temperature.

Similarly, the concentration of reagents can be important to the course of a reaction, especially if two mechanisms are available that involve different numbers of molecules in the transition states. Higher concentrations of a particular reagent favour those mechanisms in which greater numbers of molecules are involved in the transition state.

Importance of concentration of reagents

The pressure applied to the reacting system also may be significant; partly because it has an effect on concentration, and partly because mechanisms involving closely associated transition states become more favourable at high pressures. The latter relationship comes about because associated transition states are those in which several molecules or ions are brought close together (and therefore take up less space), a situation that is encouraged by increased pressures.

Energy changes involved in reactions. Collisions between molecules are rapid; therefore, reactions that occur spontaneously whenever the reagents collide are fast at ordinary concentrations. A reaction may be restricted in rate by its dependence on the occurrence of molecular collisions, however, because, for example, the reagents are present in such small amounts that reactions can only occur when they happen to encounter one another. Such a reaction is said to be diffusion-controlled because it is dependent on the process of diffusion to bring the molecules together. In such cases, the viscosity of the medium is relevant; the more viscous, or "thick," the medium, the more difficult the diffusion and the slower the reaction.

As noted above, however, most reactions involve a rate-limiting energy barrier, and it is the nature of this barrier and of the molecular configuration at its top that determines the mechanism. Diagrams of energy changes during the course of reaction often are used to illustrate the energetic aspects of the reaction. An example of a possible energy diagram for a hypothetical one-stage process, the dissociation in a solution of a covalent molecule designated E–N, into its ions, E^+ and N^-, is shown in Figure 1.

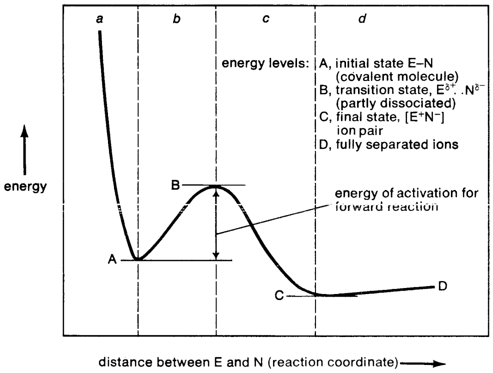


Figure 1: Possible energy diagram for the dissociation of a covalent molecule, E–N, into its ions E^+ and N^- (see text).

In this diagram the energy is plotted against a reaction coordinate—a spatial relationship that varies smoothly during the course of the reaction—in this case the distance between the portions of the molecule designated E and N. At the left-hand energy minimum of Figure 1, the bond between E and N is fully formed; if energy is applied to excite the system in such a way that E and N are brought even closer together (region *a* of Figure 1), the atomic nuclei repel, with the result that energy rises steeply. Alternatively, excitation energy, such as thermal energy from collisions with other molecules, may stretch the bond, and the energy curve then moves into region *b*. The E–N bond is thereby weakened steadily until the transition state is reached. This point, as can be seen in Figure 1, has the maximum energy on the reaction coordinate. At the same time, this point represents the minimum energy required to convert the reactants into the products. The curve shown should be considered as only a planar section of a three-dimensional energy surface relating to the various possible spatial relations among the components of the reaction. The passage of the reactants from the initial state to the products then can be thought of as analogous to the climb from a valley (the initial state) through the lowest mountain pass leading to a second valley (the products). Thus, although the transition state represents a peak on the single curve depicted, it really represents a secondary minimum (or pass) in the energy surface. From the top of this pass (the transition state), the molecule can only descend, losing energy by collision. In doing so it may revert to the starting materials, or it may dissociate to give the products (region *c* in Figure 1). The products in the case of the reaction chosen are the ions E^+ and N^-, which are held together by electrostatic attraction as an ion pair at the right-hand minimum of the graph; beyond this point, further separation of the ions involves the consumption of energy (region *d*). In principle, the products may lie at higher or (as shown) at lower energy than that of the initial state. The mechanism of a reaction such as this may be considered to be completely defined when the structures and energy properties of the starting materials, the products, and the transition state are known.

Computation from atomic structures

Ultimately, it should become possible to compute the properties of the molecules solely from the properties of their constituent atoms and also to deduce the transition states for any of the reactions these molecules may undergo. For a few simple situations, approaches already have been made to definitions of mechanism in this degree of detail. Systems involving several atoms, however, require a many-dimensional representation of the reaction course instead of the two-dimensional description shown in Figure 1. The problems of computation, and of testing theory against experiment, then become enormous. Nonetheless, attempts have been made to deal with some simple reactions of systems involving up to about five atoms.

Multistage. For a reaction involving several distinct stages, a more complicated description of the reaction course also is necessary. Figure 2 gives an example of such a situation. This hypothetical reaction is reversible, with three successive intermediate complexes formed between the reactants. Unlike the case of the simpler situation above, the physical process that best approximates what is happening along the reaction coordinate changes from stage to stage across the diagram.

Principle of microscopic reversibility

The highest point on the energy diagram (Figure 2) corresponds to the energy of the transition state of the rate-limiting step in the reaction—that is, the slowest step in the reaction, the one that governs, or limits, the overall rate. The rate of reaction is independent of the nature and number of the intermediates that lie before this transition state on the reaction coordinate. Progress along the reaction coordinate cannot be identified with the time course of the reaction because any individual pair of reactants may reside for an appreciable time in the partially activated state represented by one of the intermediate complexes before final reaction is achieved. Once the reactants have passed the rate-limiting transition state they must lose energy (usually by collision with other molecules) to reach the final state. In a sense the reaction coordinate in such a reaction may be thought of as representing the chemical course of the reaction (rather than a spatial or a time course). If the diagram represents the only reaction of the system, then it is possible to apply the principle of microscopic reversibility, which states that the course taken by reverse action will be statistically identical with that taken by the forward reaction. This principle is not, however, applicable to a reaction giving several different products not at equilibrium with one another.

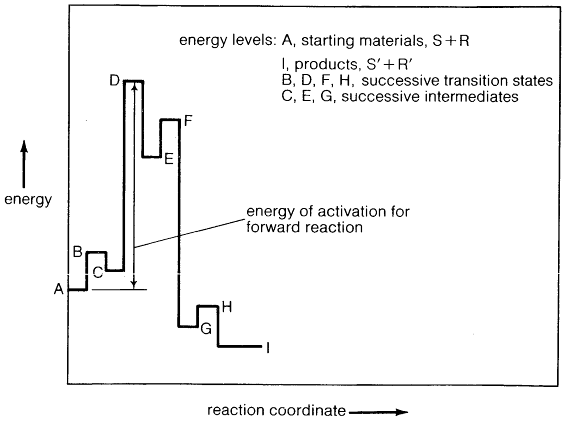

Figure 2: Energy levels in a hypothetical multistage reaction (see text).

Identification of a reaction mechanism. *Chemical and stereochemical nature of reactants, intermediates, and products.* The stoichiometry of a reaction consists of the chemical formulas and relative molecular proportions of starting materials and products. Obviously these have a bearing on the mechanism of the reaction, for the overall reaction course must proceed from starting materials to the products. The stoichiometry of the reaction may be misleading, however, because the participants in the overall reaction may not be involved directly in the rate-limiting step.

The discovery of intermediates in the course of a reaction is important because these point to the existence of distinct stages, the mechanism of each of which must then be determined. The identification of intermediates that persist only briefly or that are present in only small amounts depends on the availability of powerful, sensitive, and rapid experimental techniques. For this purpose, a number of specialized instrumental procedures (including ultraviolet, infrared, magnetic resonance, and mass spectrometry) are widely used to supplement the more usual chemical and physical methods.

The identification of a new chemical substance formed transiently in a reaction mixture, however, does not unambiguously imply that that substance is an intermediate in the reaction. In many cases a newly found material is only a temporary repository of the proportion of the reactants and ultimately produces the products by first reverting to the starting material.

Identification of products

The identification of the products of a reaction also helps to define the reaction course, because the mechanism in question clearly must account for their formation. Mechanistic theory has been greatly facilitated by the development of powerful methods of separation and purification based on chromatography (separation of compounds on the basis of their relative degrees of adsorption to certain solid substances, such as starch or silica) and also by modern methods available for the analysis of small quantities of materials. These spectroscopic procedures are often used, as is another instrumental method, called polarimetry.

An important consideration with regard to the products of the reaction is whether the reaction is under kinetic or thermodynamic control. A reaction is said to be kinetically, rather than thermodynamically, controlled, when the products are formed in proportions different from those that would prevail at equilibrium between the same products under the same conditions. Thermodynamic control leads to the equilibrium ratio of the products. Often, though not invariably, reactions under kinetic control give a greater amount of the thermodynamically less stable of two possible products; if thermodynamic control is then established, the products shift to their equilibrium proportions, which might give a misleading picture of the reaction course. Hence inferences concerning the nature of the transition state can be drawn from the nature of the products only with a good deal of circumspection.

In determining the mechanism of a reaction, one of the major problems is to deduce the spatial or three-dimensional changes that occur to the molecules involved as they proceed from their initial state through the intermediate stages and transition states to the final products. Knowledge about such changes generally can be deduced from knowledge of the stereochemistry (three-dimensional structures) of the starting materials, intermediates, and final products (provided these are obtained under kinetic control). Information of this kind is obtained by determinations of optical activity and analysis of the structures of the compounds by standard means.

In certain instances information about the movement of atoms between molecules during the course of a reaction can be gained by using compounds containing isotopes of certain of the atoms. These isotopes behave much like the ordinary atoms they replace, but they can be identified by their behaviour. For example, in the hydrolysis of ethyl acetate (see above *The reactants*), it is crucial to a determination of the mechanism to be able to establish which of the two reactants (ethyl acetate or water) provides the oxygen atom that ends up in the product ethyl alcohol. In this case, the use of water labelled with oxygen-18 reveals that the oxygen atom in the alcohol comes from the ethyl acetate molecule.

Kinetic order. The possibilities that need to be considered for the transition state having been limited by determination of the chemical structures of the participants, the most powerful method of obtaining further information is the use of the kinetic method; *i.e.,* the study of the effect of reaction conditions on the rate of reaction. Experimental methods that have been used in kinetic studies include most of the known methods of chemical separation and analysis. Techniques that involve removing samples from the reaction mixture at intervals or stopping the reaction and analyzing for starting material or product are common for reactions with half-lives down to about a minute. For faster reactions, methods involving rapid scanning and automatic recording of some characteristic property of the reacting mixture, such as absorption of light at a particular wavelength, recently have become important. Other procedures for following exceptionally fast reactions include the controlled supply of a reagent within extremely small concentration limits, sometimes by electrolytic procedures (the use of an electric current to produce precise amounts of the substance), and sometimes by carrying out the reaction under conditions in which separate flowing streams of the reactants come together to insure rapid mixing. So-called relaxation procedures, in which a system in equilibrium is very rapidly perturbed and its rate of relaxation to the original or to some new equilibrium state is observed, also have been applied to the study of reactions of extremely small half-lives.

Effects on reaction rates

The mechanistic information to be obtained from the observed kinetic behaviour of a system derives from the fact that, for an activated process, the transition state can be considered to be in thermodynamic equilibrium with the starting materials except with respect to its motion along the reaction coordinate. It follows that the rate of reaction is approximately proportional to the product of the concentrations of those substances that comprise the transition state. If the concentrations of all but one reactant are held constant while the concentrations of that reactant are changed, then the variation in rate with the concentration changes will establish how many molecules of that particular reactant are involved in the transition state. This figure is called order of reaction with respect to the reactant in question. A full description of the composition of the transition state then requires identification of the order of reaction with respect to each of the reactants.

Although straightforward in principle, the application of this method involves some difficulties. Sometimes (for example, with ionic solutes in solvents of low polarity), the concentrations of the reagents are not truly representative of their influence on the reaction rate. The kinetic order then does not properly represent the composition of the transition state. The power of the kinetic method is often greatly increased when the rate of reaction can be followed by more than one method. In such instances, it frequently has been found that unexpected differences reveal the intervention of previously unsuspected intermediates.

Environmental effects. Changes in the environment (such as the composition of the solvent) frequently influence the course of the reaction by affecting the relative stabilization of the initial state and the transition state. Large changes in the polar character (charge distribution) of the solvent, for example, may have an effect on the course of the reaction if there is a substantial change in polarity between the reactants and the transition state.

Correlation of rate with structural change

Structure–reactivity relations. An observed correlation of changes in a reaction rate with systematic changes in the structure of one of the reactants often reveals the movements of electrons between atoms as the reactants shift toward the transition state. Systematic changes in structure usually are brought about by selecting a particular molecular system and varying a portion of it (such as, for example, the substituents on a benzene ring). The effects of each variant on the rates of several different reactions are determined experimentally, and the results plotted on graphs, the values resulting from a particular molecular variation in one reaction being measured along one axis and those of the same variation in the other reaction along the other axis. A straight-line relationship indicates that the molecular changes are affecting the rates of the two reactions in related ways. The slope of the line gives a comparison of the relative response of the two systems to the given change in structure; and the sign of the slope tells whether a particular structural change favours both reactions, or favours one while disfavouring the other. The observed effects generally can be correlated with the electronic nature of the molecular variants introduced. For example, if a substituent in the molecule tends to donate electrons toward the reactive centre in the molecule, and this change favours the reaction, it can be concluded that an electron-rich centre is involved in the transition state.

Electronic effects of the above kinds can be complicated by spatial, or steric factors. (A reaction is said to be sterically hindered when the transition state is more congested than the initial state and to be sterically accelerated when the reverse is true.) When suitable allowance is made for the above electronic influences, structural changes can be used to help define the detailed geometry of the transition state. Thus if large or bulky substituents have an inhibiting effect on the course of the reaction, it can be concluded that the transition state differs from the starting material in such a way that the effect of the bulky group is accentuated; in the alternative situation, in which a bulky substituent accelerates the reaction, it may be concluded that the formation of the transition state relieves crowding found in the starting material. Although absolute calculations of reactivity—that is, calculations based on molecular structure alone—have made little progress in the case of polyatomic systems, significant calculations of reactivity differences have been made in favourable instances in which steric and electronic effects can be disentangled.

Carbon–hydrogen and carbon–deuterium bonds

Kinetic isotope effects. Isotopes are atoms that have the same atomic number (and, hence, generally the same chemistry) but different mass. The difference in mass becomes chemically important in certain instances. For example, when a carbon–hydrogen bond is replaced by a carbon–deuterium bond (deuterium being an isotope of hydrogen with about twice the mass), the vibrational frequencies of that bond are changed. The vibrational stretching frequency, for example, of a bond between two atoms gives an approximate measure of the bonding forces holding those two atoms together, the effective masses of the two atoms being allowed for. If the character of the carbon–hydrogen bond is altered between the normal state and the transition state, the change from hydrogen to deuterium may have an effect on the relative stabilities of the normal and the transition states, and also, therefore, an effect on the rate of reaction. Such effects, called kinetic isotope effects, operate when only one bond is concerned in such a way that bonds involving the heavier isotope are broken with more difficulty than those involving the lighter isotope. Isotope effects are large only for the isotopes of hydrogen; but, with heavier elements, even small differences can give important information about the mechanism, provided that sufficiently precise methods are available for their measurement.

Classification of reaction mechanisms. There is no one generally agreed and completely satisfactory method of classifying mechanisms; individual authors have often adopted their own nomenclature and symbolism. There are, however, a number of useful classification principles that should be noted.

Homolysis and heterolysis. When a covalent bond (a nonionic chemical bond formed by shared electrons) is made up of two electrons, each of which is supplied by a different atom, the process is called colligation; the reverse process, in which the electrons of a covalent bond are split between two atoms, is known as homolysis. These reactions are shown schematically by the equation:

$$A\cdot + B\cdot \underset{\text{homolysis}}{\overset{\text{colligation}}{\rightleftarrows}} A:B$$

in which A and B represent the separate atoms (or groups), the single dots represent electrons, and the double dots represent the electron pair that makes up the bond. The products of a homolysis reaction are called free radicals, and all such processes are said to have homolytic or free-radical mechanisms.

Covalent bond breaking

If, on the other hand, a covalent bond is formed by a pair of electrons, both of which come from one of the two reagents, the process may be described as coordination, and its reverse is heterolysis. Coordination and heterolysis are shown schematically by the equation:

$$N\!: + E \underset{\text{heterolysis}}{\overset{\text{coordination}}{\rightleftarrows}} N:E$$

in which the dots indicate the electron pair and the letters N and E represent the atoms (or groups) that, respectively, donate and accept the electrons (see below for special significance of the letters N and E). Reactions of this kind are said to have heterolytic mechanisms.

Nucleophilicity and electrophilicity. In a heterolytic reaction, the unit that carries the electron pair (designated N: above) is nucleophilic; *i.e.,* it seeks an atomic nucleus to combine with. Conversely, the other unit in the reaction (designated E) is electrophilic: it seeks to combine with a pair of electrons. An electrophilic reaction mechanism is one that involves an electrophilic reagent attacking a nucleophilic substrate. Because every such reaction involves both an electrophilic substance and a nucleophilic substance, it must be agreed arbitrarily which unit is the reagent and which the substrate. Often this agreement is made on the basis of molecular size, the larger sized material being classed as the substrate.

In certain reactions, in which movements of electrons are concerted and cyclic, it is not possible to identify any one reagent, or even any one particular atom or set of atoms in the molecule, as electrophilic or nucleophilic. Such processes are classified as electrocyclic.

Molecularity. The mechanism of an individual stage of a reaction can be described as unimolecular, bimolecular, and so on, according to the number of molecules necessarily concerned in covalency change in the transition state. As an extension of this classification, the number of molecules involved in the rate-limiting step of a several-stage reaction also can be used for classification of the overall reaction. Ambiguities and blurred distinctions arise when there are strong interactions between the solvent and the initial or transition state, or when two stages of a reaction are so near in rate that they become jointly rate-determining. Nevertheless, classifications based on molecularity are widely used.

Intermolecularity and intramolecularity. The distinction between intermolecular and intramolecular processes is often useful. In intermolecular reactions, covalency changes take place in two separate molecules; in intramolecular reactions, two or more reaction sites within the same molecule are involved.

Nature of catalysis. Classification also can be made on the basis of the mode of catalytic action. In ester hydrolysis, as the hydrolysis of ethyl acetate (above), for example, distinction can be made between mechanisms in which catalysis is brought about by protons (hydrogen ions), or by acids in general; by hydroxide ion, or by bases in general; or finally by enzymes.

Kinetic order. The kinetic order of a reaction is best considered as an experimental quantity related to (but not identical with) the number of molecules of any reactant involved in the transition state. It may for various reasons reveal only a part of what is happening in the rate-limiting transition state, one reason being that the concentrations of the components of the transition state may not all change with progress of the reaction. Establishing that a reaction is of the first order kinetically (that is, behaves as though only one molecule of the reactant is involved in the transition state) with respect to one of the components, for example, seldom reveals whether or not one or more molecules of solvent also is involved in the transition state. This is so because the solvent is present in such large amounts that its concentration does not change effectively with the course of the reaction. For this reason, the order with respect to an individual component may sometimes be useful for classification, but for the overall reaction molecularity is the more fundamental quantity.

Importance of molecularity

Time sequence of events. The time sequence of events in a chemical reaction also provides a means of classification. In some mechanisms, the bond-making and bond-breaking processes occur together and are said to be concerted; in others, the individual stages are discrete, with recognizable intermediates occurring between them, and it may be necessary to specify not only that the mechanism is stepwise but also the order in which the steps occur.

COMPARISON OF SELECTED REACTION MECHANISMS

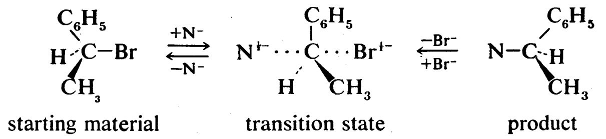
For the following incomplete and abbreviated survey of reaction mechanisms, several mechanisms important in the development of mechanistic study have been chosen.

Nucleophilic substitutions at saturated carbon centres. The term substitution refers in general to the replacement of any group in a molecule by any other group. Saturated carbon centres are carbon atoms at which no multiple bonds occur, and nucleophilic substitutions—those brought about by nucleus-seeking reagents—can occur at such carbon atoms by either of two main mechanisms, bimolecular and unimolecular.

Bimolecular. In bimolecular nucleophilic substitution reactions in which the substrate is attacked at a saturated carbon atom, the starting material has a tetrahedral structure and the transition state has a trigonal bipyramidal structure (both of which are shown below). Each individual act of substitution produces a product of inverted (*i.e.,* mirror-image) stereochemical configuration.

Inversion of structure

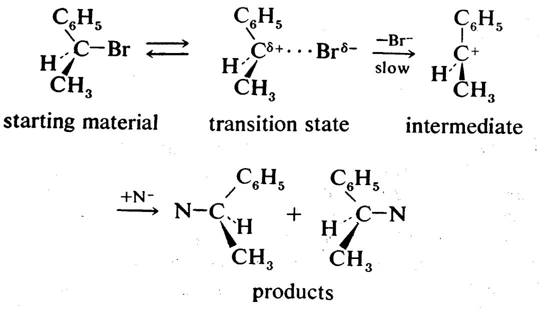
A typical bimolecular substitution reaction is shown by the equation:



in which the chemical symbols represent atoms of the elements as above (with Br the symbol for an atom of bromine and N the symbol for any nucleophilic agent). This equation differs from the earlier ones in that a three-dimensional representation of the structures is intended. The three-dimensional effect is achieved by considering that the bonds represented by ordinary solid lines lie in the plane of the paper, bonds represented by dashed lines project to the rear, and bonds represented by dark triangles project to the front. A further unique feature of this equation is that the representation of the transition state shows half bonds (bonds in the process of being formed or broken), which are indicated by dotted lines. In addition, in the transition state, half negative charges are indicated by the symbols "½–." The mechanism of this reaction is characterized by entry of the nucleophilic reagent from one side of the substrate molecule and departure of the bromide ion from the other side. The resulting change in configuration of the substrate has been likened to the turning inside out of an umbrella, with the transition state representing that precise moment when the ribs are essentially vertical in the course of their passage from one side of the structure to the other. The reaction is synchronized, or synchronous, in that entry of the nucleophile and departure of the leaving group occur simultaneously. It is bimolecular in that one molecule each of substrate and nucleophile are involved in the transition state; and it is stereospecific in that the stereochemical outcome of the reaction is invariably the same.

This bimolecular mechanism occurs with a wide range of structures. It often can be characterized by second-order kinetics, *i.e.,* by reaction rates that are dependent on the concentrations of both the substrate and the nucleophilic reagent. The transition state is highly congested, so that effects of steric hindrance are large. Otherwise, however, structural changes produce a variable response because of the conflicting electronic requirements of the bond-forming and bond-breaking processes. Bimolecular nucleophilic substitutions with rearrangement of the bonding skeleton also are known.

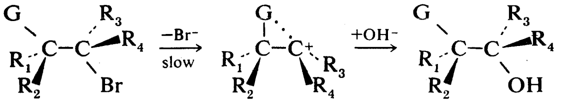
Unimolecular. Unimolecular nucleophilic substitution reactions proceed by a two-stage mechanism, in which heterolysis precedes reaction with the nucleophile. The following equation is a typical example:



in which the symbols are the same as in earlier equations, with the addition of delta plus (δ+) and delta minus (δ–), which indicate partial positive and negative charges respectively. The significant consideration in this reaction mechanism is the initial separation of the bromide ion (by way of a transition state showing partial separation of the ion) to give a free positively charged organic ion (carbonium ion). This step is the rate-determining step of the reaction and, because it involves only a molecule of the substrate, the reaction is unimolecular. The second stage of the reaction is the interaction of the intermediate carbonium ion with the nucleophile to give the products of the reaction.

The unimolecular reaction is characterized experimentally by first-order kinetics; *i.e.,* by a rate that depends only on concentration of the substrate (and not the nucleophile); by the absence of effects of steric hindrance; by powerful facilitation of the reaction by the presence of electron-releasing groups attached to the reaction centre; and by variable, and often diagnostic, stereochemistry. Inversion of stereochemical configuration (change from one configuration to the mirror-image configuration) is frequently encountered, accompanied by racemization (production of both mirror images). The extent of racemization depends upon the life of the intermediate carbonium ion, with longer lived ions leading to more extensive racemization (due to the fact that the symmetrical ion is exposed to attack from either side).

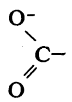
In an important group of structures, a group not formally involved in the overall reaction interacts with a carbonium ion centre to form an intermediate, which then reacts with the nucleophile to give a product of the same stereochemical configuration as the starting material. This behaviour can be represented by the equation:



G=participating or neighbouring group

R_1, R_2, R_3, and R_4=substituents

In the first demonstrations of this behaviour, the participating group (G) was a carboxylate anion group, which can be represented in chemical symbols as:



Neighbouring-group participation

Subsequent investigations have revealed numerous examples involving other substituents, and the phenomenon is now commonly described as neighbouring-group participation.

A frequent consequence of reaction through intermediates having carbonium ionic character is that some of the products have rearranged skeletal structures. In this equation, the symbol Cl represents a chlorine atom.

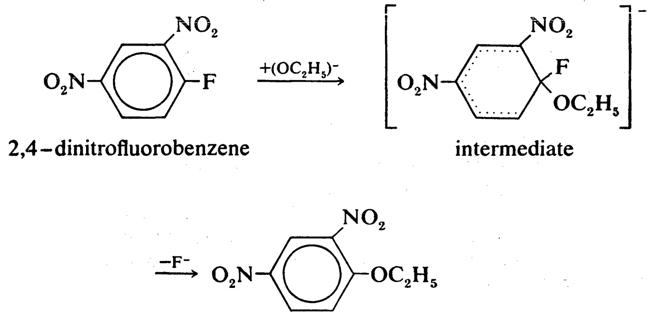
$$\underset{\text{1-chloro-2,2-dimethylpropane}}{(CH_3)_3C{-}CH_2Cl} \xrightarrow{-Cl^-} \underset{\text{intermediate carbonium ion}}{[(CH_3)_3C{-}CH_2^+]}$$

$$\longrightarrow \underset{\text{rearranged carbonium ion}}{[(CH_3)_2C^+{-}CH_2CH_3]} \xrightarrow{+OH^-} \underset{\textit{tert}\text{-amyl alcohol}}{(CH_3)_2C(OH){-}CH_2CH_3}$$

The fundamental difference between the transition states in the bimolecular and unimolecular mechanisms is the degree of covalent bonding between the nucleophile and the substrate in the transition state. In the unimolecular mechanism such bonding is negligible; in the bimolecular case, it has essentially reached the half-bond status. In borderline situations, the matter is difficult to resolve, a number of intermediate cases being known, and there has been much controversy as to the validity of the distinction between the bimolecular and the unimolecular mechanisms. Experimentally, however, clear examples of each class have been established.

Resistance to nucleophilic reagents

Nucleophilic substitution at unsaturated carbon centres. Unsaturated carbon centres—including those involving ordinary carbon–carbon double bonds and those involving the extended cyclic systems of alternate single and double bonds known as aromatic rings—are not easily attacked by nucleophilic reagents unless they have been denuded of electrons by electron-attracting substituents. A two-stage process that includes addition of the nucleophile followed by expulsion of a negatively charged (anionic) group is the course normally taken for substitutions at aromatic centres. The presence of the aromatic ring enforces the geometry of the product, and the reaction is favoured by electron-withdrawing groups, such as the nitro ($-NO_2$) group, which help to accommodate the negative charge on the intermediate. An example of this type of reaction is the displacement of fluoride ion from 2,4-dinitrofluorobenzene by nucleophiles such as ethoxide ion.



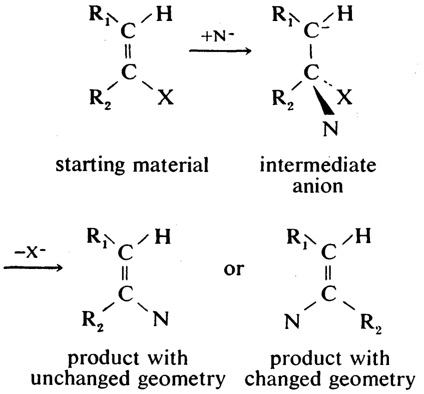
2,4-dinitrofluorobenzene

intermediate

2,4-dinitrophenyl ethyl ether

In this equation fluorine atoms are indicated by the chemical symbol F; nitro groups (consisting of one nitrogen and two oxygen atoms) are indicated by the symbols $-NO_2$; normal benzene rings (of six carbon atoms, each of which carries a single hydrogen atom) are indicated by regular hexagons with circles in them; and benzene rings containing disrupted electronic structures are indicated by hexagons with partial dotted circles.

Substitution reactions at ordinary double bonds (olefinic bonds) also take place by a two-stage process. When the two stages in the reaction occur synchronously or in very quick succession, the product has the same geometrical relationship that existed in the starting material. If, however, the anionic intermediate has sufficient lifetime, rotation about the new carbon–carbon single bond can precede loss of the negatively charged group, resulting in production of two products of differing molecular geometry—that is, products in which the substituents are differently situated with respect to the double bond.



starting material

intermediate anion

product with unchanged geometry

product with changed geometry

X = a halogen atom: fluorine, chlorine, bromine, or iodine

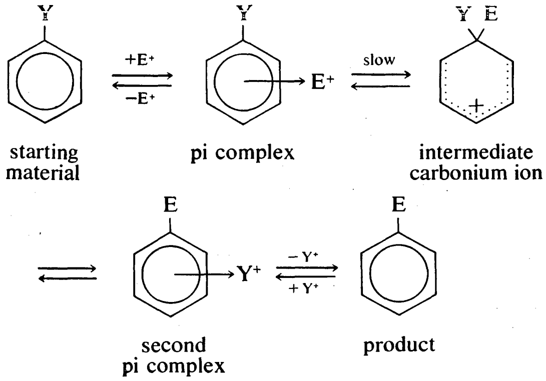
If the intermediate anion takes up a hydrogen ion (proton) and then loses hydrogen and halogen simultaneously (concerted elimination), the reaction then is said to be following an addition–elimination sequence. Examples of such reactions are known, particularly in situations in which the double bond includes an atom other than carbon. In aromatic systems, the reverse situation, in which elimination occurs, followed by addition, also is found. Finally, unimolecular mechanisms of substitution also are known to take place at particularly activated unsaturated centres. For example:

$$Ar-C(Br)=CH_2 \xrightarrow{-Br^-} Ar-C^+=CH_2 \xrightarrow{+OEt^-} Ar-C(OEt)=CH_2$$

in which the symbol Ar represents a benzene ring or other aromatic system.

In aromatic systems

Electrophilic substitution at unsaturated carbon centres. Because of its wide applicability, particularly to aromatic systems, electrophilic substitution is an important reaction. Reaction by any one of several mechanisms is possible. One of the more common is shown here; reactions in this category consist of replacement of a group designated Y (often a hydrogen atom) in an aromatic molecule by an electrophilic agent designated E. Both substituents can be any one of various groups (*e.g.*, hydrogen atoms, or nitro, bromo, or *tert*-alkyl groups).



starting material

pi complex

intermediate carbonium ion

second pi complex

product

Here, Y represents a substituent on the ring; the arrow from the ring centre indicates coordination.

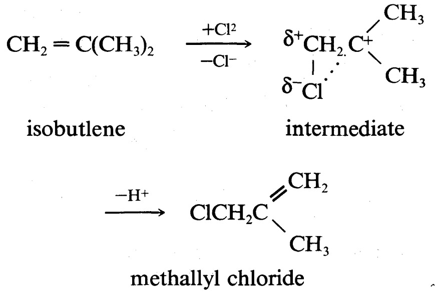
As shown, the reaction begins with formation of a pi complex, in which the electrons associated with the aromatic ring, or other unsaturated centre (pi electrons), coordinate weakly with the electrophile. This complex forms rapidly in an equilibrium preceding the rate-determining step, which itself leads to a carbonium ion intermediate and then by way of a second pi complex to the product. Examples are known in which the removal of the proton from the carbonium ion intermediate (to form the second pi complex) becomes rate-determining.

Reactivity by this mechanism is dominated by the electrophilic character of the reagent (E); it also, however, responds powerfully to changes in structure of the organic substrate. As would be expected, substituents that release electrons toward the reaction site facilitate the reaction, and those that withdraw electrons retard reaction. These effects are very specific with regard to the position at which the modifying group is introduced.

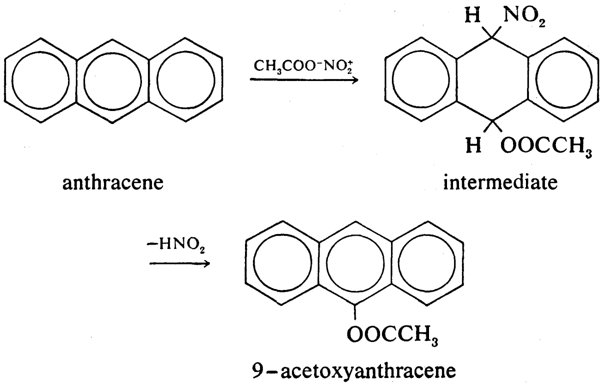
Steric (spatial) effects generally are smaller than electronic effects in determining the characteristics of reaction by this mechanism; but they are not negligible. Direct steric hindrance and steric acceleration both have been found with suitably placed large substituents and reagents, and indirect effects arising because one group interferes with the orienting power of another also are known.

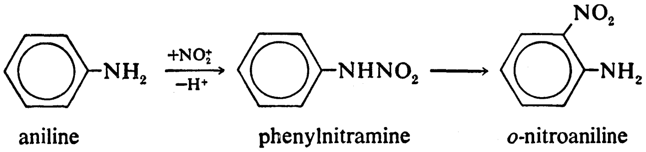
Substitutions with rearrangement

Substitution with accompanying rearrangement of the double-bond system is another established reaction path. An example is shown below in which the positions of chlorine attachment and proton loss were established by isotopic labelling.



Addition–elimination and indirect substitution reactions also can occur and are responsible for a number of unusual products formed in aromatic substitution reactions. Examples of these reaction sequences are shown below:





Addition reactions. Reactions in which a multiple bond between two atoms becomes partly or fully saturated by covalent attachments at both centres are called addition reactions. Many mechanisms are known for such reactions; most of them are variants of four basic mechanisms, which differ chiefly in the sequence of events that occur.

With initial electrophilic attack. Addition reactions beginning with electrophilic attack include many additions to olefins (compounds with double bonds), some additions to acetylenes (compounds with triple bonds), and some additions to compounds with other multiple bonds. There is a close relationship between this mode of addition and the electrophilic substitutions discussed in the preceding section, as shown by this general representation of the reaction:

$$\overrightarrow{CH_3}CH\overset{\frown}{=}CH_2 + H^+ \longrightarrow CH_3\overset{+}{C}HCH_3 + Cl^-$$

propylene proton intermediate carbonium ion chloride ion

(not $CH_3CH_2\overset{+}{C}H_2$)

$\longrightarrow CH_3CHClCH_3$;

2-chloropropane

(not $CH_3CH_2CH_2Cl$

1-chloropropane)

in which the arrows on the olefin structure indicate the flow of electrons toward the terminal carbon, which attracts the electrophilic proton because it becomes an electron-rich centre. Electrophiles, which can be effective either as positive ions (E^+) or in combination with a nucleophile (E–N), include protons (H^+), carbonium ions (R_3C^+), positively charged halogen ions (Cl^+, Br^+, I^+), nitronium ions (NO_2^+), nitrosonium ions (NO^+), and many others. In general, any nucleophile can complete the reaction. When the first stage of the reaction (addition of the electrophile) is rate-determining, the rate responds powerfully to electron-release to the reaction centre, and this factor determines selectively the orientation of initial attack with respect to the double bond. Thus propylene reacts with hydrogen chloride many times faster than ethylene does, and the product is exclusively 2-chloropropane, rather than 1-chloropropane, because the concentration of electrons on the terminal carbon determines that the electrophilic proton finds it easier to attack that carbon rather than the central carbon atom.

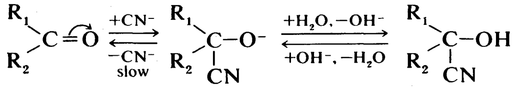
$$CH_2 = CH_2 + H^+ \longrightarrow CH_3\overset{+}{C}H_2 + Cl^- \longrightarrow CH_3CH_2Cl$$

ethylene proton intermediate carbonium ion chloride ion ethyl chloride

Addition by this mechanism can be accompanied by substitution and by rearrangement as alternative reactions of the carbonium ionic intermediate. Characteristically, the ratios of product are kinetically controlled (see above). Reactions by this mechanism can be complicated by the intervention of intermediates that are more complicated structurally. Neighbouring-group interaction can modify the structure of the intermediate toward a bridged structure and thus determine the stereochemistry of addition.

Although it is common to find that the first stage of this sequence is rate-determining, in some cases the rate-limiting transition state lies later along the reaction path. It also is possible for the two stages to be concerted, with the electrophilic and nucleophilic fragments (E and N) of the reagent E–N acting either as still covalently bound or as separate kinetic entities (E^+ and N^-). Especially in acid-catalyzed additions to carbon–oxygen and carbon–nitrogen double bonds, the first stage of the reaction can become rapidly reversible, and the mechanistic characteristics of the reaction are then appropriately modified.

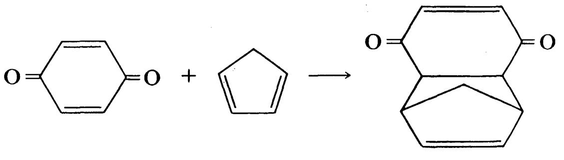
With initial nucleophilic attack. The reverse mode of addition, in which a nucleophile initiates attack on the multiply bonded carbon atom, is less easily realized in simple systems; but it does occur with acetylenes, and it also is the basis of reactions that occur when the centre of attack is denuded of electrons. For example, the formation of substances called cyanohydrins from carbonyl compounds (materials with carbon–oxygen double bonds) occurs as follows:



carbonyl compound intermediate cyanohydrin

in which the curved arrow indicates the movement of electrons in the carbonyl group. Initial attack on carbon by the nucleophilic cyanide ion in this case is facilitated by the electron withdrawal by the oxygen atom (shown by the curved arrow in the formula). Such electron withdrawal also can be transmitted along a series of alternate double and single bonds (a conjugated system), with resultant addition to the ends of the system.

Electrocyclic. In a third class of additions, both portions of the attacking reagent combine simultaneously with the substrate. Reactions of this kind sometimes retain predominantly electrophilic or predominantly nucleophilic character, as can be shown by structural and environmental effects. In a number of important cases, however, quite different behaviour is observed. For example, the addition of cyclopentadiene to 1,4-benzoquinone follows second-order kinetics and proceeds at nearly the same rate in the gas phase and in solvents of widely differing polar character.



1,4-benzoquinone cyclopentadiene adduct

In this equation the polygons represent rings of carbon atoms (one at each corner) with double bonds between certain atoms as shown. There must, therefore, be little development of charge in the transition state, and the formation of the two new single bonds and the accompanying electronic movements must be well synchronized. A large number of such reactions are known; they are characterized by a remarkable stereospecificity (stereochemical specificity), controlled in part by steric effects and in part by the stereo-electronic characteristics of the combining double-bond systems.

Synchronized reactions

Homolytic. Additions by free-radical mechanisms also are well known. They replace the concomitant polar additions most easily when homolytic (decomposition of a compound into two neutral atoms or radicals) fission of the reagent can be readily catalyzed and when the radicals produced as intermediates sustain chain processes. Addition of hydrogen bromide to olefins falls into this class. Equations (1)–(4) describe the main part of the sequence; reactions (2) and (3) are repeated many times before reaction (4) or some other reaction intervenes to break the chain. As a result, one act of initiation results in many molecules of product.

(1) $HBr \longrightarrow H\cdot + Br\cdot$ (chain-initiating step)

(2) $Br\cdot + CH_3CH = CH_2$
$\longrightarrow CH_3\dot{C}HCH_2Br$ (chain-propagating step)

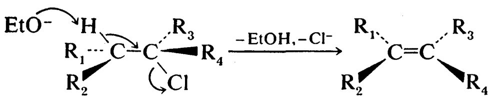
(3) $CH_3\dot{C}HCH_2Br + HBr$
$\longrightarrow CH_3CH_2CH_2Br + Br\cdot$ (chain-propagating step)

(4) $CH_3\dot{C}HCH_2Br + H\cdot$
$\longrightarrow CH_3CH_2CH_2Br$ (chain-terminating step)

The reaction can give an orientation of substituents opposite to that found in electrophilic addition [which in the above example would produce $CH_3CH(Br)CH_3$]; and in suitable cases it can be just as stereospecific.

Elimination reactions. Elimination reactions can be treated formally as the reverse of additions. The simplest examples of this class of reactions arethe olefin-forming 1,2-eliminations—that is, elimination of substituents from adjacent carbon atoms—but eliminations to give other types of double bonds are equally well known. Again, 1,3-eliminations—eliminations of substituents from carbon atoms separated by a third carbon—give compounds with three-membered rings of carbon atoms (cyclopropanes). Furthermore, the so-called conjugate eliminations occur when one or more double bonds are inserted between carbon atoms bearing the substituents that are eliminated; the result of such eliminations is a system of alternating double and single bonds (a conjugated system). Finally, there also are fragmentation reactions, in which two small fragments are lost from the organic molecule. Of these reaction types, only the 1,2-eliminations will be discussed here, it being understood that examples of the mechanisms may be found, as appropriate, in other types of elimination reactions.

Concerted, bimolecular. Concerted bimolecular eliminations are characterized by second-order kinetics; they occur readily with powerful nucleophiles. A favoured stereochemical course (*trans*-elimination) involves a particular geometry, as shown, which requires that in the starting material the eliminated units be situated on opposite sides of the molecule. The olefinic product then must have the particular structure shown, rather than that of its geometric isomer. The relative extent to which the various bonds are formed and broken in the transition state varies considerably with the substrate.



starting material olefin product

Stepwise, bimolecular. If removal of the electrophilic fragment precedes the loss of the nucleophile, the reaction becomes stepwise and involves a carbanionic intermediate.

$$R_2CHCR_2Cl \underset{+BH,-B^-}{\overset{+B^-,-BH}{\rightleftarrows}} R_2C^- - CR_2Cl \xrightarrow{-Cl^-} R_2C = CR_2$$

starting material carbanion intermediate olefin product

Reaction by this path, which sometimes can be characterized by exchange of protons between the solvent and the starting material, is less stereospecific than the reaction by the concerted mechanism. This lessened stereospecificity is caused by the carbanion intermediate's not maintaining the rigid geometry characteristic of the concerted mechanism.

Carbonium ion intermediates

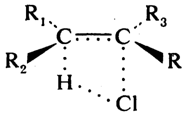
Stepwise, unimolecular. A carbonium ion produced by heterolysis (decomposition of a compound into oppositely charged particles or ions) may lose a proton, thereby effecting a 1,2-elimination reaction:

$$R_2CHCR_2Cl \underset{\substack{+Cl^- \\ slow}}{\overset{-Cl^-}{\rightleftarrows}} R_2CHCR_2{}^+ \xrightarrow{-H^+} R_2C{=}CR_2.$$

starting material carbonium ion olefin product

Such eliminations, which generally accompany nucleophilic substitutions, are promoted by electron-release to the carbonium-ion centre. The loss of the proton usually occurs in such a way as to give predominantly the thermodynamically more stable of the alternative products.

Cyclic. Some cyclic eliminations are fully concerted, but in others the loss of a nucleophilic or of an electrophilic component can be dominant. For example, the gas-phase pyrolysis (destructive heating) of alkyl halides shows the orientation and structure effects characteristic of unimolecular stepwise elimination reactions in solution. In such cases, the transition state (shown below), though still cyclic and preserving the stereochemistry, must involve greater stretching of the carbon–chlorine than of the carbon–hydrogen bond.



transition state

Expanding the valence shell

Nucleophilic replacements in complexes of metals. Stable compounds with more than four groups bonded to a central atom (the situation commonly encountered in compounds of carbon) are formed by elements in the second and higher rows of the periodic table of the elements. Mechanisms of reactions of these compounds therefore become more complex on stereochemical grounds alone. Furthermore, the energy levels of electron paths (orbitals) which can accommodate the bonding electrons of the reacting atom have become closer in these compounds, and reactions involving the formation of new bonds by expansion of the valency shell of this atom often become more readily accessible. For example, nucleophilic attack on carbon tetrachloride is slow, whereas that on silicon tetrachloride is fast, because in the former compound the attacked atom (carbon) has reached its maximum stable coordination number (indicative of the size of the valence shell), whereas in the latter, the central atom (silicon) has not, and its valency shell can be expanded simply by the attachment of a nucleophile. A similar difference in the mechanisms of reactions of metal complexes is found, depending on whether or not the metal atoms are free to engage in valence-shell expansion.

Unimolecular, in octahedral complexes. Octahedral complexes of metals of the first transition series (elements from scandium to copper) have reached their maximum stable coordination number, six. Accordingly, many of their replacement reactions are believed to occur by dissociation to give an intermediate having only five groups bonded to the reaction centre. Several different types of kinetic behaviour have been recognized. The initial stage may be a rate-determining dissociation of the cobalt complex shown below, in which methanol is the solvent, "en" is ethylene diamine ($H_2NCH_2CH_2NH_2$), and N^- can be any of a variety of nucleophiles, including bromide, thiocyanate, and nitrate ion.

$$[Co(en)_2Cl_2]^+ \xrightarrow[\text{slow}]{-Cl^-} [Co(en)_2Cl]^{2+1} \xrightarrow[\text{fast}]{+N^-} [Co(en)_2ClN]^+$$

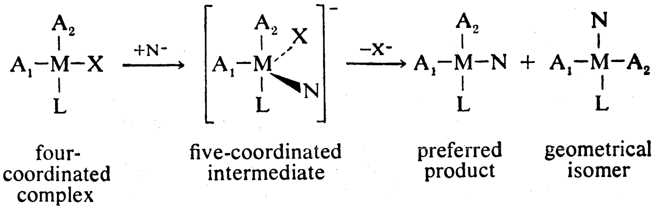
Alternatively the dissociative stage can be a pre-equilibrium, as in many replacements of water, as shown in the reaction below.

$$[Co(NH_3)_5(OH_2)]^{3+} \underset{+H_2O}{\overset{-H_2O}{\rightleftharpoons}} [Co(NH_3)_5]^{3+} \xrightarrow{+N^-} [Co(NH_3)_5N]^{3+}$$

The stereochemistry of these reaction paths is of great mechanistic significance, and varies both with the nature of the central metal atom and the nature of the attached groups (ligands).

Kinetic evidence

Bimolecular, in square planar complexes. Square planar four-coordinated complexes differ from their octahedral six-coordinated analogues in that they generally undergo bimolecular associative, rather than dissociative, nucleophilic displacements. Thus, for many reactions involving replacement of a ligand by a nucleophile in complexes of platinum(II) ions, a kinetic effect proportional to the concentration of the nucleophile can be identified, showing that the nucleophile is involved in the transition state. Furthermore, the stereochemical specificity of such reactions, as shown below, can be accommodated readily in terms of the five-coordinated associated intermediate, whereas a dissociative mechanism would be expected to result in the formation of a mixture of the two geometric isomers.



A ligand across from, or *trans* to, a replaceable group has a much greater influence on the rate of substitution than does the same substituent next to, or *cis* to, the replaceable group, and this *trans* effect helps to define the nature of the bonding in the transition state, because it suggests that only the *trans* substituent is in the same plane as the associated and departing group in the intermediate.

(P.B.D. de la M.)

CHEMICAL KINETICS

Chemical reactions are explained in terms of the atomic structure of matter and of the energy changes that can take place in atoms, bonding them into molecules or breaking up molecules to free or to rebond atoms into different molecules. Chemical reactions may be slow or fast, complicated or relatively simple, and the modes by which they proceed are the subject of chemical kinetics.

Preliminary considerations. In a broader view, molecules have a tendency to react with each other to produce other kinds of molecules on condition that the product molecules have less free energy than the reacting molecules had; *i.e.,* the products lie at a lower level of free energy than the reactants. An analogy is that of water always flowing downhill since, in the Earth's gravitational field, water at a higher level gives up energy as it falls to a lower level. Thus, all reactions for which the free energy, symbolized by ΔG, is negative have a tendency to occur. Accordingly, measurements of energy change suffice to indicate whether there will be a tendency for particular products to form when specific reactants are brought together under variable conditions. How fast a reaction will occur, however, depends on what sort of channels are available for the system to traverse in passing from the higher to the lower free energy state, and a study of the nature and effectiveness of these channels for reaction is best begun with a generalized symbolization of a reaction.

Rates of chemical reactions

In an actual reaction in which molecules of a substance A react with molecules of a substance B to form the molecules of substances C and D, usually the reverse reaction is also possible; that is, molecules of C and D react under suitable conditions to form molecules of A and B. If A, B, C, and D represent single molecules of those substances, a chemical equation may be written for the reaction: $A + B \leftrightharpoons C + D$, the half arrows indicating that the reaction is reversible. Of course, if molecules A and B are to react they must first collide, and certain other conditions must also obtain. The number of collisions will be proportional to the concentrations of A and B molecules; if the amount of A is doubled, twice as many encounters will take place. The same is true if the amount of B is doubled. Thus, a change in the concentrations of the substances will change the number of collisions, and the more numerous these collisions are per second, the faster the reaction will proceed (assuming that other determining factors, such as temperature, remain constant). Thus, the rate of the reaction, or its speed, can be calculated by simply multiplying the concentrations. If concentration is signified by bracketing the symbols for the molecules, $[A]$, $[B]$, $[C]$, and $[D]$, and if v_f symbolizes the forward rate, or the speed of reaction to the right in the equation, then this rate equals the product of the concentrations and of a proportionality factor, k_f, also called the specific reaction-rate constant: $v_f = k_f[A][B]$. Similarly, the backward rate is given by the equation $v_b = k_b[C][D]$. When the two rates are the same—*i.e.,* when $v_f = v_b$—the reaction, or, more correctly, the dynamic system of the two reactions, is said to be in equilibrium and $k_f[A][B] = k_b[C][D]$. Rearranging the equation, a ratio is obtained equal to a constant K, called the equilibrium constant; *i.e.,* the product of the concentrations of the products divided by the product of the concentrations of the reactants is equal to the forward reaction-rate constant divided by the backward reaction-rate constant:

$$\frac{[C][D]}{[A][B]} = \frac{k_f}{k_b} = K.$$

This is known as the reaction-equilibrium equation. The equilibrium constant K, in view of the energy changes necessary for a reaction to proceed, further relates to the free energy, ΔG, which in turn relates to the forward and backward free energy of activation. The energy of activation is a measure of the energy that the reacting molecules must have in order to react, and it is specific for each reaction. Molecules may collide forever without reacting, and all the familiar solids, liquids, and gases consist of molecules in intimate contact but not reacting. Activation energy for the burning of paper, for example, can be provided to the paper molecules by the flame of a match, itself stable until the heat from friction on the head provides enough energy to activate the chemical reaction of the ingredients. The activation energies, therefore, of the forward (ΔG_f) and backward (ΔG_b) reactions are related to the free energy by the equation $\Delta G = \Delta G_f - \Delta G_b$.

Early approaches to kinetics

Natural scientists have been impressed by the growth of crystals and of living things for centuries, but the first recorded, quantitative measurement of the rate of a chemical reaction was made in 1850, when it was noted that the plane of a beam of polarized light, passed through a solution of sucrose, was rotated by the solution and that the amount of rotation changed with time. This indicated that a chemical reaction was changing the sucrose into a new species of molecule (which rotated the polarized light to a different extent). The change in the concentration of sucrose can be measured and related to the passage of time to yield a specific rate constant for the reaction.

It was found that the rate of any reaction depends not simply on the concentration of the reactants but on these concentrations raised to various powers. This principle is known as the law of mass action. It was pointed out by the Norwegian chemists C.M. Guldberg and P. Waage around 1864–67 and precisely stated by a Dutch physical chemist, Jacobus Henricus van't Hoff, in 1877. In 1889 Svante Arrhenius, a Swedish chemist, published his conclusions that molecules must get into an active state before they can become reactive (*i.e.,* their energies must be raised to activation levels before they will react). Van't Hoff had already obtained the result for the equilibrium constant, *K,* by calculations involving the energy of reaction, the absolute temperature, and the gas constant (derived from energy relationships observed in the behaviour of gases). Accordingly, Arrhenius was able to formulate an equation (named after him) for the specific rate constant of a chemical reaction that included the energy of activation.

Arrhenius equation

Factors that affect the rate of reaction. Any change in the relative positions of atoms or molecules, such as the deformation of a solid, that takes place with an activation energy (*i.e.,* only after the energies of the reacting molecules have been increased to specific levels) is governed by the same general reaction-equilibrium equation (see above) as ordinary chemical reactions. Examples of solid reactions are the burning of rocket propellants and explosives by detonation, plastic deformation, phase transformations—such as freezing—and certain kinds of catalytic reactions. Many reactions that take place rapidly in the liquid state are sluggish or fail to take place at all in the gas phase.

Solvent. Conspicuous among these are changes that involve ionization (the breaking up of a substance into positively and negatively charged atoms or groups of atoms, called ions, and into electrons). Such reactions are greatly promoted by a solvent with high dielectric (electrically insulating) constant, such as water or dimethyl sulfoxide. Ions are also formed, however, in gases, such as the effluent gas from a burning rocket and as products of the oxidation of acetylene in the oxyacetylene torch. The temperatures involved are usually in the range from 2,000° to 2,500° C (3,600° to 4,500° F). Thus, certain reactions occurring at high temperatures can build up unstable ions at low concentrations in contrast to the heat-stable dissolved ions formed in high concentrations in ionizing solvents. Polar (*i.e.,* exhibiting positive and negative charges) surfaces, such as that of sodium chloride (common table salt), also promote the ionization of polar substances—such as chloroform, acetone, etc.—on their surface. In fact, many organic reactions occur by the formation of positive (called carbonium) ions in solution. Although the ions are present in very low concentration, careful electrical conductance measurements as well as a study of the products of reaction provide unmistakable evidence of ionization. When a metal is bound to an organic radical (a stable fragment of an organic molecule), there is a marked tendency for the molecule to decompose into a positive metal ion and a negative organic radical (called a carbanion) containing a negatively charged carbon.

Temperature. The effect of temperature on rates of reaction is important. Ordinarily, raising the temperature 10° (Celsius) approximately doubles the rate of most but not all reactions. This is because the chance that molecules are sufficiently energy rich to have achieved activation level and undergo reaction is greatly increased by an increase in temperature.

Pressure. Similarly, increasing the pressure on systems in which a reaction in the liquid or solid state is taking place usually changes the rate of reaction. Thus, if the reacting molecules in the activated state occupy more space than when they are not activated, an increase in the pressure will decrease the relative concentration of the activated state as compared with the nonactivated reactants and so slow down the rate of reaction. When the activated state is less voluminous, the rate of reaction will be increased by pressure. This is in accord with the Le Chatelier principle, which states that any system in equilibrium is shifted by a change in property, such as pressure or temperature, in such a direction as to reduce the stress of that change on the system. High pressure, for example, makes diamonds more stable to heat than graphite (diamond and graphite are the two crystalline forms of carbon) but, in spite of this, the transformation between graphite and diamond is slowed in either direction by pressure because the activated state of a carbon atom is more voluminous than a carbon atom in either diamond or graphite.

Le Chatelier principle

The effect of pressure on gaseous reactions is quite different. Here pressure always increases the concentration of reactants (*i.e.,* the number of molecules of gas per unit volume) and so increases the rate of all resulting reactions that involve more than one gaseous reactant because the frequency of forming the activated state is thereby increased. The pressure effect, which becomes important for condensed (solid and liquid) phases, is related to a difference between the actual volume of tightly packed reactants and the volume of the activated state. This effect is present for gases, too, but it plays an insignificant role in comparison to the role played by increase of concentration.

Catalysts. In catalytic reactions a minute amount of a substance (the catalyst) is added to the mixture of reactants to alter the rate of reaction enormously, usually increasing it, without being itself used up. If the catalyst is not soluble in the reaction mixture, the reaction takes place on the surface of the catalyst at activation levels far lower than are necessary without the catalyst. Thus, surface atoms are involved, and if one or more reactants is gaseous, the pressure effect will act to increase the concentration of reactants, as in a gas, and this will overshadow other pressure effects.

Collisions. Further development of the theory of reaction rates calls for elucidation of the Arrhenius equation. The collision theory, though incomplete, represented a notable advance for such reactions. For example, a hydrogen gas molecule, H_2, reacts with a gaseous iodine molecule, I_2, to give hydrogen iodide molecules, HI, according to the equation $H_2 + I_2 = 2HI$. It can be demonstrated that to exchange atoms in this reaction, the activated state is a four-atom complex in which the hydrogen molecule is sandwiched between two attacking iodine atoms formed by the dissociation of an iodine molecule. The activation energy is equal to the work expended in building the activated complex of atoms and consists of the energy required to dissociate an iodine molecule into atoms plus additional energy expended by the two iodine atoms in the breaking of the hydrogen-molecule bond. Since the activated state consists of the four atoms in collision exactly as it would if it were formed by the direct collision of a hydrogen molecule with an iodine molecule, it necessarily obeys the same collision formula; *i.e.,* a formula that calculates the number of collisions per second (here, between H_2 and I_2) and the chance that such a collision will be energetic enough to be successful. The collision formula is quite accurate for some reactions, but for others the predicted rate exceeds the experimental value by a factor of 10^8. This has led to the rewriting of the formula to include an empirical steric factor; *i.e.,* a factor related to the actual molecular structure.

Activated complexes

Early attempts to understand first-order reactions also ran into difficulties. It was supposed that individual molecules got into the activated state through absorbing radiant energy (called the radiation hypothesis), but this was soon found to be much too slow. It was then (1922) pointed out that activation by collisions alone would explain unimolecular reactions on condition that deactivation of the activated molecules, also by collision, was much faster than the rate at which they were used up in reaction. This point of view was developed (1928) into a useful theory.

In the reaction between hydrogen and chlorine molecules (H_2 and Cl_2) to form hydrogen chloride, HCl, the equation is $H_2 + Cl_2 \rightarrow 2HCl$, and it might be supposed that the same course would be followed as in the reaction between hydrogen and iodine, but this is not so. The preliminary dissociation into chlorine atoms, $Cl_2 \rightarrow 2Cl$, is followed by the reactions $Cl + H_2 \rightarrow HCl + H$ and $H + Cl_2 \rightarrow HCl + Cl$; these two processes constitute a

Chain reactions

chain reaction because a product of each is a starting material for the other. This chain is prevented from becoming infinitely long by chain-breaking reactions involving atom recombinations with another molecule or a surface, symbolized as M, such as $Cl + Cl + M \rightarrow Cl_2 + M$ and $H + H + M \rightarrow H_2 + M$. That the chain of reactions may be very rapid is shown by shining light on a hydrogen–chlorine mixture causing it to explode: the heat evolved as the chain reaction proceeds does not have time to diffuse away through the walls of the vessel before it raises the temperature of the reaction mixture to a point at which the resulting pressure bursts the container.

Factors that affect the order of the reaction. The degree to which the concentration of a reactant enters into the equation for the rate of reaction is called the order, with respect to this reactant. Thus, in the equation $H_2 + I_2 \rightarrow 2HI$, the reaction is of the first order with respect to each of the concentrations $[H_2]$, $[I_2]$.

In this example, the order of the reaction agrees with the stoichiometry. This is frequently not true, however; for example, the stoichiometry of the equations $H_2 + Cl_2 \rightarrow 2HCl$ and $Cl_2 \rightarrow 2Cl$ is the same, yet, because hydrogen and chlorine react by way of a chain of reactions, the reaction order is quite different. Thus, the equation $Cl + H_2 \rightarrow HCl + H$ is half order with respect to Cl_2 and first order with respect to H_2, while the equation $H + Cl_2 \rightarrow HCl + Cl$ is half order with respect to H_2 and first order with respect to Cl_2, so that the order of the overall chain process is complicated and dependent upon the conditions under which it occurs. In general, there is no way of deducing the order of reaction from the stoichiometry of the equation that expresses the overall process. Much of the effort devoted to the study of reaction rates goes into the establishing of the mechanism of the rate-determining step or steps. The overall order of reaction is further complicated if the surfaces catalyze the reaction.

Effects of surfaces

The degree to which the rate of reaction is influenced by a particular catalytic surface is determined by actually varying the ratio of reactant collisions with the surface to collisions with gaseous molecules. This is readily done for glass surfaces by packing the reactant vessel with glass wool; by varying the amount of glass wool it is easy to multiply manyfold the amount of surface with which reactants collide. If the packing produces no noticeable effect when the overall rate is large, it is safe to ignore the effect of the vessel's surface in the absence of packing and to interpret the rate as occurring entirely in the gas phase. Conversely, if the effect of packing is to speed up or slow down the reaction, it is possible to study the surface-catalyzed reaction.

The order of reaction under one set of conditions may be completely altered if the conditions are changed, even though there is no change in mechanism. If one reactant is in great excess over the others, for example, it will not seem to vary and may be left out of the rate equation altogether, even though the other concentrations may change by orders of magnitude. The reaction order is thus not to be confused with what is called the molecularity of the reaction: the molecularity is the number of molecules of each kind in the activated complex. For each elementary rate process the molecularity is fixed, and only a shift to a new mechanism can change it. When the molecularity of a substance in the activated state exceeds its molecularity in the stoichiometric equation for the reaction, that substance is said to be acting as a catalyst. Also, when a process occurs by a chain of reactions, the order with respect to a particular reactant may be fractional or even negative. Only when the effects of wide variations in the concentrations of the reactants and other conditions in a reaction have been studied is it possible to be confident that an observed order of reaction does in fact represent the molecularity of the activated state. As shown below, in more complicated cases, such as in chain reactions, the whole idea of associating a unique integral order with a rate of reaction ceases to be useful.

The equilibrium constant. A fundamental question that must be answered if chemical processes are to be controlled is not only how fast a system reaches equilibrium but under what circumstances equilibrium yields the particular product sought in recoverable amounts. This question is comparatively easy to answer for phase transformations. Thus, to obtain ice, water must be cooled below the freezing point. Even this, however, is not quite as simple as it sounds, since by increasing the pressure, the temperature at which ice melts increases. There are seven kinds of ice; *i.e.,* water freezes into seven different forms. It happens that ordinary ice is readily obtained by cooling, but if one of the other seven kinds is wanted, in general not only must the system be cooled but the pressure must be adjusted so that it falls in the range of stability of the ice that is sought. A similar problem occurs when diamonds are made from graphite. A diamond is unstable at ordinary temperatures and pressures, but the rate at which it changes into graphite is far too slow to cause worry. If the pressure is increased to 15,000 atmospheres (one atmosphere equals about 14.7 pounds per square inch), graphite becomes unstable and tends to change into diamond at room temperature. As before, however, the rate is much too slow to be interesting unless a catalyst is added or the temperature is greatly increased. The work, or the free energy, required to change graphite into diamond can be calculated according to a thermodynamic equation that relates measurements of temperature, pressure, and volume; at pressures and temperatures when the two phases are in equilibrium, the work required to change one phase into the other is zero. Thus, thermodynamics predicts how temperature and pressure can be manipulated to make a desired phase stable.

Thermodynamics and kinetics

A dramatic example of the consequences of studying an equilibrium is the case represented by the equation $3H_2 + N_2 \rightarrow 2NH_3$. Historically, this study has had awesome consequences because, had German scientists not discovered and used this reaction in the Haber process for making ammonia in 1914, Germany would have been dependent on Chile saltpetre for explosives, and a blockade by the Royal Navy might have made World War I impossible.

Using thermodynamics, the equilibrium constant can be calculated from the pressures of hydrogen, nitrogen, and ammonia, and the work required to change three moles of hydrogen and one mole of nitrogen into two moles of ammonia can be obtained as a function of pressure and temperature. Thus, the circumstances required to produce recoverable amounts of ammonia can be determined. In other words, thermodynamics indicates whether a reaction is possible and kinetics, the speed with which it will occur.

Complex reactions. Chemical reactions proceed by all physically possible mechanisms, and the measured rate is the sum of all the possible rates. Often, one mechanism under a given set of conditions is so much faster than all others as to allow the latter to be ignored, without appreciably affecting the accuracy of the calculations. It is in this sense that a preferred mechanism can be defined, and, theoretically, the preferred mechanism can be singled out only by estimating all rates and selecting the highest. If two velocities are equal at some temperature and much faster than all others, the one with the steepest temperature coefficient will be the important one at high temperatures and the other at low temperatures. In a case in which there are only two reactions in a sequence, and they become equal at some temperature, the one with the lowest temperature coefficient will dominate at low temperatures while the other dominates in the high-temperature range. This temperature dependence provides a ready way of distinguishing between two reactions acting sequentially and in parallel.

Competing reactions

Mass spectrography provides a beautiful example of competing reactions. When a molecule is struck by a fast electron or an energetic photon, it is frequently left as a positive ion in an energy-rich state. The mass spectrograph is designed so it records the final product ions about 10^{-6} second after the primary ionization. In the meantime, the parent ion is breaking into all of the various possible products at rates that can be calculated from changes in bond energies, and the percentage of each product ion formed can be calculated.

If a reaction intermediate is formed that can attack more than one species, the relative amounts of products are in proportion to the rates of reaction with the various species.

If a solid is thought of as a giant molecule, its action as a catalyst does not differ in principle from that of a homogeneous catalyst. When the atoms of a solid metal have their electron shells only partly filled, as in the transition elements, the crowded electrons leak into these partly empty shells during the period of intense electron congestion of the activated complex and, in the course of doing so, lower the activation energy speeding up the reaction.

On the other hand, certain ionic substances, such as clays, can act by breaking hydrocarbons into positive and negative ions, which then reassemble into molecules with new properties.

Enzymes are molecules that occur in living systems and that have structural groups that facilitate reactions, as do ordinary catalysts. One view of their behaviour is that they have the additional property of mechanically straining certain bonds lying between two attachments to the enzyme and giving the distorted bond an increased reactivity. This same strain, resulting from changes in the shape of the protein molecules, is promoted by environmental changes and is exhibited in muscles, in the receptors of taste and smell, and in various immune reactions. Study of these conformation changes reveals that they are volume changes because pressure changes slow down or speed up the process in question.

Chain reactions are another interesting aspect of chemical reactions, and it can be shown that there is no single simple order of reaction for a chain of reactions.

Detonations proceed by a quite different mechanism. A simple model will help explain how an energy-rich molecule may be made to yield its energy to reinforce a decaying shock wave, which is the essence of a detonation (see Figure 3).

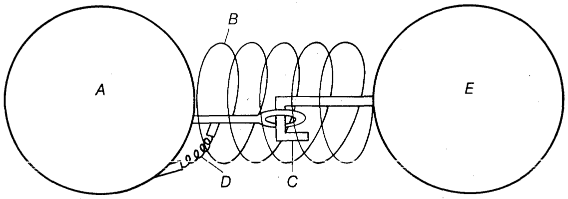


Figure 3: Model of molecular structure that explains detonation (see text).

The two parts of a molecule A and E may be thought of as being separated by a compressed spring B. If the amplitude of vibrations reaches a critical value, corresponding to the activation energy, so that during compression of B the spring D flips the catch C, then A and E will fly apart with the energy stored in the compressed spring B—*i.e.,* the heat of reaction.

Mechanism of detonations

If many such molecules are close packed to form a cylinder and a sharp blow is delivered to one end of the cylinder, a compression wave will pass along the cylinder axis. This shock wave will pass over molecules having random phases and random amplitudes, and some of them will absorb the extra energy that permits them to flip their catch—*i.e.,* to react. If the high pressure and high temperature of the shock wave remain, all of the molecules will react. These reacting molecules release their heat of reaction to enhance the energy in the shock wave. The energy released to the actual movement (called translational degrees of freedom of the molecules) determines the pressure and temperature of the shock wave, and that energy will just balance the energy flowing into the internal degrees of freedom during the period (called the steady state) when the shock wave is advancing at a fixed speed. Since sound is a wave of compression, the detonation will travel through the medium with the velocity of sound of molecules in the shock wave. If the diameter of the detonating cylinder is finite, an appreciable amount of the energy driving the shock wave leaks out through the side, decreasing the shock-wave velocity. The magnitude of this velocity decrease provides a method of measuring the length of the reaction zone.

Experimental study of chemical kinetics. *Measurement of reaction rates.* When reactions proceed at rates that permit making the measurements, many methods of study can be employed. The problem is one of measuring composition by some physical or chemical procedure. If the rate is fast compared with available methods of measurement, it may still be followed by interrupting the reaction by a sudden change—such as lowering the temperature, removal of the catalyst or one of the reactants, or by adding an inhibitor, a substance that drastically slows down a reaction, in effect, a catalyst with a negative effect. Common methods involve measurement of pressure changes, volume changes, and conductivity; more sophisticated methods include polarimetry; circular birefringence; refractometry, colorimetry, and spectrophotometry; potentiometry; polarography; and mass spectrometry. For a method to be useful the property being measured must change (*i.e.,* increase or decrease) with the extent of reaction, preferably in a linear or near-linear fashion—*i.e.,* in direct ratio.

Flowing systems

The study of a continuous flow of reactants through solid catalysts has long been common practice. Since the contact time can be varied, the method provides a way of measuring fast catalytic processes widely applicable in industry. In certain systems, the chemical reaction proceeds to completion within the time required for physical mixing of the reactants. One fruitful method of studying such a system is to displace it from equilibrium by sudden temperature or pressure increases, but some rates are too high or too low to be measured by any method.

Competition methods, used to measure fast reactions, are exactly what the term implies: the reaction is made to compete with a physical process having a known rate, or an equilibrium is displaced by a perturbation (disturbing effect), and the shift in equilibrium (equilibration) measured directly. In polarography, for example, this competition is between the formation of a reducible ion (an ion capable of acquiring electrons, thereby raising its negative charge) and its diffusion to the cathode. Most available information on electron transfer between transition-metal complexes has been found in this way. Proton magnetic resonance is illustrative of a method applicable to various nuclei having magnetic moments (the property comparable to the magnetism of a minute bar magnet). Measuring nuclear magnetic resonance is much like measuring the precession of a spinning top in a gravitational field.

Determining the order of reactions. A general picture of how reactions take place will help in attaching the proper importance to a determination of an order of reaction. The potential energy between any collection or grouping of atoms is a function of the smallest number of distances that fix the configuration of the group complex. If the potential energy is plotted as a function of the distances required to fix the configurations, a potential hypersurface in configuration space is obtained. Although this hypersurface ordinarily involves more than three dimensions, it will be convenient to use the language of three dimensions. Molecules represent valleys or basins on this surface, and a chemical reaction corresponds to passing from one low region to the other over the intermediate barriers. There are, in general, several passes that can be taken between low regions, and the traverse through a particular pass may involve crossing over a succession of passes separated by more or less deep depressions. These depressions are intermediate compounds. If one of these passes along a traverse is enough higher than any other along the traverse, and enough lower than for any other traverse, this particular pass will constitute the point of no return for this reaction, and the molecularity will also be the order of the reaction, provided all reactants are nearly enough at the same concentration so that their concentrations all change measurably during the reaction. If these conditions are not fulfilled, there is no unique activated complex and the order of reaction involves some kind of blend of rates for a variety of activated complexes, which can only accidentally be a measure of the molecularity of a particular activated complex. In chain reactions, the measured rate is a blend of a variety of rates, in general involving elementary processes from different potential surfaces. Accordingly, for such reactions, only by changing conditions drastically can a particular elementary process be made sufficiently prominent in the overall process to allow the corresponding specific rate constant to be de-

Reaction pathways

termined. When the overall rate for a chain reaction is broken into its elementary mechanisms, difficult though this may be, they are all found to involve the concentration of the separate reactants in the activated complex to an integral power.

Only for the simplest of reactions can one expect the measured order to reveal the molecularity of an elementary reaction. Nevertheless, by skillfully arranging conditions the specific rates of many elementary processes have been determined. For an elementary reaction, the reactants are in effective equilibrium with the activated complex. If equivalent amounts of reactants are chosen, the reactants will always remain in fixed proportion with respect to each other.

Bioluminescence

Elucidating reaction mechanisms. Even for very complex living systems, some observable property is controlled by a rate-determining step. It is often possible to gain real insight into what is happening by studying the effect of increasing the temperature and pressure and by changing the composition of the system. This is illustrated by studies made on bioluminescence. Luminescent bacteria give off almost no light at the freezing point; as the temperature is raised the luminescence goes through a maximum near 20° C (68° F), depending on the species, and again sinks to near zero at blood temperature. The luminescence is caused by the oxidation of luciferin by oxygen, in the presence of the enzyme luciferase, a reaction in which oxygen molecules accept electrons from the luciferin. In the process, two protons (hydrogen nuclei, or hydrogen ions with positive charge) from the reduced luciferin go into solution and the remaining two electrons are picked up by oxygen with the help of the enzyme luciferase. Nine times out of ten the oxygen picks off the less tightly bound electrons of the luciferin molecule, but once out of ten times it picks off a lower lying electron (one bonded more tightly into the structure), leaving one in a higher level, which then drops into the hole below, emitting a quantum of light. The intensity of the emitted light measures the overall rate of reaction, which in turn depends principally on the state of the enzyme. Thus, there is a ready means of studying the state of a representative oxidative enzyme *in vivo.*

Luminescence provides penetrating insight into many aspects of biology. The rise in luminescence with temperature is to be expected of a chemical reaction involving an activation energy. The maximum in luminescent intensity followed by a decline in luminescence arises from inactivation of the enzyme, causing a steep drop with temperature that more than overbalances the increase in the rate of the remaining enzyme that is still active. Because the enzyme in the activated complex is more voluminous than the free native enzyme, the increase it causes in hydrostatic pressure decreases the light intensity in the low temperature range lying below the luminescence maximum. Above the maximum, the hydrostatic pressure increases the light intensity because the inactive enzyme is more voluminous than it is in the activated complex.

Chemicals such as the alcohols, the ethers, urethane, and even the noble gas xenon under high pressure introduce hydrophobic (water-repelling) groups into cells and cause the enzymes to unfold and become inactive in a way that is parallel to anesthesia. On the other hand, the substances sulfanilamide and *p*-aminobenzoic acid inhibit luminescence by competing with the reactants for the prosthetic groups, and they are without influence on the unfolding of the enzyme. These results were all deduced from a quantitative fitting of equilibrium theory and activated complex theory to the data and are borne out by work on the purified luciferase and luciferin.

It is convenient to think of solids as giant molecules and of their plastic deformation as a molecular isomerization (*i.e.,* as the same components forced into a spatial rearrangement), to which reaction-rate theory applies just as it does to any other molecule. A stress on a solid, whether an electrical or mechanical one, always acts to lower the energy of activation for deformation. Only when the stresses are small is the relaxation (*i.e.,* the return of the deformed solid to its original structure) proportional to the stress, and two or more stresses then—and only then—obey reciprocal relations as defined by thermodynamics. Reaction-rate theory, however, is applicable for both large and small stresses. In fact, all deformations of matter involving activation energies can be studied and predicted using reaction-rate theory. (H.Ey.)

CHEMICAL RELAXATION PHENOMENA

The term relaxation is used by chemists and physicists to describe the interval or time lag between the application of an external stress to a system—that is, to an aggregation of matter—and its response. The relaxation effect may be caused by a redistribution of energy among the nuclear, electronic, vibrational, and rotational energy states of the atoms and molecules that comprise the system, or it may result from a shift in the ratio of the number of product molecules to the number of reactant molecules (those initially taking part) in a chemical reaction. The measurement of relaxation times can provide many insights into atomic and molecular structures and into the rates and mechanisms of chemical reactions.

Historical survey. The word relaxation was originally applied to a molecular process by the English physicist James Clerk Maxwell. In a paper "On the Dynamical Theory of Gases," which he presented in 1866, Maxwell referred to the time required for the elastic force produced when fluids are distorted to diminish or decay to $1/e$ (e is the base of the natural logarithm system) times its initial value as the "time of relaxation" of the elastic force. The earliest suggestion of a chemical relaxation effect is contained in a dissertation (Berlin, 1910) based on research directed by the German physical chemist Walther Nernst. Measurements of sound propagation through the gas nitrogen tetroxide, which breaks up, or dissociates, into nitrogen dioxide, led Nernst to suggest that experiments at frequencies at which the dissociation reaction could not keep pace with the temperature and pressure variations that occur within a sound wave, would permit evaluation of the dissociation rate. Ten years later, at a meeting of the Prussian Academy of Sciences, Albert Einstein presented a paper in which he described the various theoretical aspects of this relaxation effect.

Dielectric relaxation

The detection of the chemical relaxation effect predicted by Nernst and Einstein did not become technically feasible until the last half of the 20th century. In the first half of the century physicists and chemists in studying relaxation concentrated on physical relaxation processes. Peter Debye referred to the time required for dipolar molecules (ones whose charges are unevenly distributed) to orient themselves in an alternating electric field as dielectric relaxation. Sound absorption by gases was used to investigate energy transfer from translational, or displacement in space, to rotational (spinning and tumbling) and vibrational (oscillations within the molecule) degrees of freedom, the three independent forms of motion for a molecule. The former requires only a few molecular collisions, but the transfer of energy between translational and vibrational modes may require thousands of collisions. Because the processes are not instantaneous but time dependent, relaxation effects are observed. Their measurement provides information about molecular bonding and structure. Chemical relaxation was rediscovered by the German physical chemist Manfred Eigen in 1954. Since then, technological advances have permitted the development of techniques for the measurement of relaxation times covering the entire range of molecular processes and chemical reactivity.

The great variety of relaxation phenomena and of the techniques developed for their study precludes a comprehensive survey. To facilitate a general discussion, the relaxing system, its initial and final states, the nature of the disturbance, and the system's response are considered separately. Examples are cited that emphasize the important features of relaxation phenomena and illustrate the variety of information that can be obtained from their study. A moderately detailed description of one relaxation technique, the temperature-jump method, is used to summarize the discussion.

Relaxation mechanisms. The chemical relaxation of nitrogen tetroxide is easy to visualize, and it illustrates principles common to all relaxation phenomena. Nitrogen tetroxide (formula N_2O_4) actually is a dimer (a molecule

Dimers and monomers

formed from two similar constituents called monomers) that dissociates into two molecules of nitrogen dioxide (formula NO_2). The monomer and dimer are easily distinguishable: the former is a brown gas; the latter is a colourless gas. The product and reactants exist in equilibrium, represented by the reversible reaction,

$$\underset{\text{1 molecule}}{N_2O_4} \rightleftarrows \underset{\text{2 molecules}}{2NO_2}.$$

At ambient (room) temperature and atmospheric pressure, approximately 80 percent of the molecules in the mixture are dimers and the remaining molecules are monomers. The distribution of molecules between the two forms remains unchanged as long as the temperature and pressure are held constant. If the external conditions are altered, then the ratio of monomers to dimers will adjust to a new value. The dependence of the equilibrium on pressure is intuitively understandable as follows: to a good approximation the volume that a gas occupies at a given pressure and temperature depends directly on the number of gas molecules. The dissociation of one molecule of nitrogen tetroxide into two molecules of nitrogen dioxide entails an expansion of the gas, a doubling of molecules, which is opposed by the external pressure. If the external pressure is increased, the system acts to relieve the stress by reducing its volume; *i.e.,* by combining monomers to form dimers and thus reducing the number of molecules. The equilibrium shifts in favour of dimers under increased pressure, and in favour of monomers under reduced pressure. At any steady pressure, the ratio of the two forms eventually becomes constant.

Chemical relaxation results from the inability of systems at equilibria to respond instantaneously to changes in external conditions. The rate of reestablishment of equilibrium, or re-equilibration, is limited by the concentrations of the reactants and their reactivities. At any specified temperature and pressure, there is a definite probability per unit time that a nitrogen tetroxide molecule will dissociate into two nitrogen dioxide molecules and that the latter will recombine to form a dimer. The average lifetime of a nitrogen tetroxide molecule at ambient temperature and atmospheric pressure, for example, is about one-third of a microsecond (one-millionth of a second). The product of the reciprocal of the average lifetime times the concentration of nitrogen tetroxide molecules gives the rate at which they dissociate. At equilibrium there is no net change in the number of nitrogen tetroxide molecules, because their dissociation rate is exactly balanced by the rate at which they are being re-formed through association of nitrogen dioxide molecules. If the external conditions are altered, the reactivities of the monomer and dimer change instantaneously, but their concentrations change at a finite rate until the balance between the association and dissociation rates is reestablished.

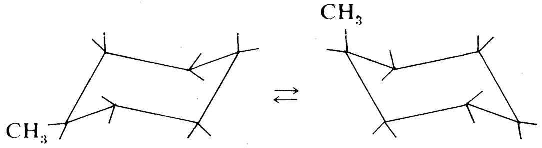
Sound waves in gases

Sound propagating through a gas can be pictured as a pressure wave whose alternating increase and falling off of pressure, called a sinusoidal variation of pressure, with time at any point in the medium is accompanied by a corresponding fluctuation in the temperature. The effect of the varying temperature and pressure of a sound wave moving through nitrogen tetroxide gas on the dissociation of nitrogen tetroxide depends on the frequency of that sound wave. When the pressure oscillates slowly enough, the dissociation reaction will remain at equilibrium with the oscillation; that is, the extremes in the monomer–dimer ratio will coincide with the extremes of pressure and temperature. If, on the other hand, the pressure fluctuates too rapidly for the reaction to follow, the ratio of monomers to dimers will remain constant at the equilibrium value for the ambient temperature and pressure; but at intermediate frequencies, a relaxation effect may be observed, and a readjustment of the chemical equilibrium will lag behind the pressure variation within the gas.

The relaxing chemical equilibrium results both in the absorption of sound by the gas and in dispersion of, or changes in, the sound velocity. Measurement of either of these effects permits evaluation of the relaxation time. The maximum absorption of sound occurs, for example, when the angular frequency (two pi times cycles per second) of the sound wave equals the reciprocal of the relaxation time. The relaxation time can then in turn be related to the mechanism of the chemical reaction and to the reactivities of the reactants.

The relaxing system. Relaxation may occur between any two allowed energy states of nuclei, atoms, or molecules in the solid, liquid, or gas phase. A distinction has already been made between chemical relaxation, which involves a transformation between two chemically distinguishable molecules such as the dissociation of nitrogen tetroxide, and physical processes such as the transfer of energy between translational and vibrational states of a molecule displayed by sound absorption in a homogeneous gas. Although it is useful to classify relaxation processes as chemical or molecular, the distinction between them depends on the height of the energy barrier separating the chemical species, and it becomes blurred when structural isomerizations are considered. Liquid methyl-cyclohexane, for example, absorbs sound of ultrahigh frequency. The relaxation effect is attributed to an isomerization (change in structure) between two forms of the molecule called the axial and equatorial chair forms, as shown below:

Isomerizations



equatorial form of methylcyclohexane

axial form of methylcyclohexane

In the axial form, the methyl group lies perpendicular to the principal axis of the carbon ring, whereas in the equatorial form the methyl group lies in the plane of the ring. Whether or not the interconversion is considered a chemical or a molecular relaxation process is largely a matter of definition.

Atomic nuclei may exhibit relaxation effects. Some nuclei spin mechanically. Because nuclei are charged, there is a magnetic field associated with a spinning nucleus: it behaves like a simple bar magnet with a north and south pole. The nucleus is said to have a magnetic moment that will experience a force when placed in an external magnetic field. A hydrogen nucleus in an external magnetic field, for example, may orient its nuclear magnetic moment either parallel or antiparallel to the external field. The latter is a higher energy orientation, called the upper spin state. The equilibrium distribution of many hydrogen nuclei between the two spin states (parallel and antiparallel) can be perturbed (*i.e.,* changed) by the absorption of electromagnetic radiation of appropriate frequency. The system will then relax to the equilibrium distribution by time-dependent radiationless transitions of the hydrogen nuclei from the upper to the lower spin state. This process of returning to the equilibrium distribution is called spin-lattice relaxation, because the excess energy of the upper spin state is transferred to molecules surrounding the relaxing hydrogen nuclei as increased translational, rotational, or vibrational energy.

As with nuclei, atoms and molecules can be excited to higher energy states by the absorption of electromagnetic radiation. A nonequilibrium distribution of atoms or molecules in excited states is frequently accomplished by a technique, called flash photolysis, in which the system of atoms or molecules is subjected to an intense flash of visible or ultraviolet light. The excited species may undergo many fates, but if they decay to the equilibrium distribution between the ground, or lowest, states and the excited states of the original atoms or molecules, the system is said to have relaxed.

The word relaxation is sometimes used to describe the radiation of energy by individual molecules, atoms, or nuclei, rather than by a large number. A hydrogen nucleus, for example, may decay from the upper to the lower spin state by transferring radiant energy to a nearby hydrogen nucleus in the lower spin state. This exchange of spins is called spin-spin relaxation. It shortens the lifetime of an individual excited nucleus, but it does not restore the equilibrium distribution of parallel and antiparallel spins. Although it is convenient to think of an individual excited nucleus as relaxing, only the response of an excited population of many nuclei can be measured. This usage of the term relaxation obscures the most useful experimental feature of relaxation processes.

Initial and final states. In virtually all relaxation experiments a thermodynamic equilibrium state is disturbed, and the time required for re-equilibration is measured. The practical advantage of starting with a system at equilibrium is most apparent in the study of chemical reactions in solution. Nearly all of the elementary steps in chemical reactions, such as transfers of protons and electrons from one molecule to another, occur in less than a millisecond, and yet as late as the 1960s solution reactions with half-times (time in which the reaction is half completed) shorter than a millisecond could not be studied. This limit was imposed by the hydrodynamic problem of mixing two solutions. Reaction rates had been studied by mixing the reactants and monitoring the rate at which products appeared. The most elaborate mechanical mixing devices that have been built so far require a millisecond to initiate a solution reaction. Manfred Eigen was the first person to clearly perceive that mixing could be avoided by perturbing an equilibrium and watching it relax. His enormous contribution to the study of fast chemical reactions was recognized by the award of a Nobel Prize in 1967.

Perturbation

Instead of disturbing an equilibrium system, a stationary state may be perturbed. Many enzyme-catalyzed reactions, for example, are experimentally irreversible. Nevertheless, for much of the time course of the reaction, the chemical intermediates are present in a stationary state; that is, their concentrations do not change. The stationary state can be disturbed and the rate of its reestablishment may be used to deduce the lifetimes of the chemical intermediates. Combined rapid mixing and relaxation techniques have been used successfully in a study of catalysis by the enzyme ribonuclease.

Creation of the disturbance. Eigen has divided the methods used to disturb systems into indirect, or competition, methods and direct, or perturbation, methods. In the first method, the relaxing system is continuously disturbed. The competition between the disturbance and the relaxation process results in the establishment of a stationary state, from which information about the relaxation process must be inferred. Ultrasonic absorption is an example of a competition method. The competition between the temperature and pressure variations in the sound wave and the dissociation of nitrogen tetroxide sets up a stationary state in which re-equilibration of the chemical reaction lags behind the pressure fluctuations in the sound wave. The reactivities of the monomer and dimer are derived indirectly from measurements of sound absorption. Flash photolysis is an example of the second method, in which the system is momentarily perturbed. The molecules are electronically excited from the ground, or lowest and normal, energy state to higher energy states by the flash. Their return, or decay, to the ground state can be followed directly by monitoring the reemission of the absorbed light.

A chemical equilibrium can be disturbed by changing the pressure or temperature or by applying an electric field. If a volume change accompanies a chemical reaction, the ratio of products to reactants at equilibrium will depend on the pressure. The point at which equilibrium sets in will depend on temperature, if heat is absorbed or released in the reaction. The ratio will also depend on electric field strength, if the polarizabilities (change in orientation or position of electric charges) of the reactants and products are different. Nuclear and electronic states can be excited by the absorption of electromagnetic radiation, and the latter can also be excited thermally. Perturbation forces, when expressed mathematically in terms of strength and time, are called forcing functions. In principle, a forcing function may assume any form, but in practice, it must be easy to generate experimentally and to analyze mathematically. Examples of forcing functions are the sinusoidal temperature and pressure variations in a sound wave (charting the variations produces a curve called a sine curve—which varies from positive to negative values) and sinusoidally alternating electric fields, which are used in dielectric relaxation measurements. Other convenient forcing functions are step, or incremental, perturbations and rectangular pulses (pulses of which the strength rises nearly instantaneously, remains at the higher value for a period of time, and then rapidly returns to its initial value).

Step perturbations of the temperature and pressure can be produced in shock tubes. A gas at high pressure is separated by a membrane from the gas being studied at low pressure. When the membrane is burst, a plane pressure wave caused by the high-pressure driving gas moves through the low-pressure gas under study. Temperature increases of several thousand degrees may accompany moderate pressure shocks. The shock front travels through the gas with a velocity comparable to the mean molecular velocity, so that the width of the shock front is only a few mean free paths (average distances travelled by the molecules between collisions). As the shock passes, the translational energy of the molecules in the shock front is increased. The system relaxes as the excess energy is distributed by collisions to rotational and vibrational degrees of freedom.

Rectangular temperature perturbations (plotted on a graph these show up as a curve that periodically rises suddenly, stays constant for an interval, then drops suddenly to original value) can be produced in aqueous solutions of reacting systems by using microwaves to heat the solution. Water molecules can absorb energy of rotation at 10^{10} hertz (cycles per second). By concentrating the microwave energy in a small volume, an increase of several degrees in temperature can be obtained in one microsecond using pulses of radar. Since the radar generator can be repeatedly pulsed, coupling it with a continuous flow system improves the experimental accuracy by averaging over the period of the experiment.

Detection

Response of the system. Any of the techniques for disturbing an equilibrium can be combined with a variety of detection systems. Depending on the nature of the relaxation effect, it can be monitored by absorption or emission spectroscopy, by fluorometry, or by polarimetry. Conductance changes can be measured. Crystals are used to detect ultrasonic waves and to measure absorption effects.

While a priori there is no restriction on the magnitude of the displacement from equilibrium, in practice small disturbances are used to permit the application of a linear rate equation (terms denoting changes with time are to the first power). The rate of disappearance, for instance, of a small displacement from equilibrium is approximately proportional to the magnitude of the displacement. This relationship is given by the differential equation

$$-\frac{d}{dt}=(\Delta X)=\frac{\Delta X}{\tau}\cdot$$

Here, the displacement (ΔX) is the difference between the instantaneous and the equilibrium values of the relaxing property, which might be the kinetic energy of molecules behind a shock front or the concentration of a chemical reactant. The reciprocal of the constant of proportionality has units of time and is called the relaxation time (τ, *tau*). Since the equilibrium values may be time dependent, the solution of the rate equation depends on the form of the forcing function. Propagation of a sound wave through nitrogen tetroxide gas, for instance, causes a sinusoidal variation of the equilibrium concentrations of monomers and dimers with time. A great advantage of relaxation methods is that the response to small disturbances can be approximated by a first-order differential equation.

The relaxation time for a chemical process can be related to the reactivities of the reactants if the reaction mechanism is known. Conversely, it may be possible to deduce the reaction mechanism from the dependence of the relaxation time on reactant concentrations. If several chemical reactions are coupled, or if more than one vibrational state is excited, a spectrum of relaxation times may be observed. The relaxation times for the individual relaxation processes can be determined from the measured relaxation times, which are the normal modes for the coupled system.

Temperature-jump experiment. To summarize and to clarify this discussion, a temperature-jump relaxation experiment will be described. The name temperature jump is reserved for the relaxation technique in which a stepwise temperature perturbation is achieved by passing a large electric current through the solution under study and thus heating it almost instantaneously. Instrumentally, it is one of the simplest relaxation techniques. It is also the most generally useful method for the study of fast chemical reactions in solution.

Temperature-jump instrument

A typical temperature-jump instrument produces a temperature rise of approximately 8° C within five microseconds. The principles of this instrument are briefly explained as follows. A 0.05-microfarad capacitor is charged to between 30 and 40 kilovolts. The electrical energy stored on the capacitor is proportional to its capacitance and to the voltage squared. It is discharged through the reaction cell at time zero by closing a variable spark gap. The time required for dissipation of roughly 80 percent of the stored energy is given by the product of the capacitance times the cell resistance. The energy is dissipated through collisions between the ions, which conduct the discharge current through the solution and the solvent molecules. The rapid temperature increase causes a shift in the concentrations of reactive molecules in the solution to new equilibrium values. If this shift is accompanied by a colour change, the reaction rate can be monitored spectrophotometrically (*i.e.,* the change in the intensity of light of a selected wavelength with time is measured). The results are recorded on a storage oscilloscope for later display. Provided that the rise time of the temperature pulse is much shorter, and that the thermal re-equilibration time is much longer, than the response time of the chemical reaction being studied, the temperature jump can be approximated as a step perturbation. At times greater than zero, the equilibrium concentrations of the reactants remain constant at the values corresponding to the higher temperature. Consequently, the differential equation for the disappearance of the displacement of reactant X from equilibrium can be integrated to show that this value decays exponentially.

In the introduction to an article on the *Molecular Basis of Visual Excitation* the Nobel laureate George Wald wrote,

> I have often had cause to feel that my hands are cleverer than my head. That is a crude way of characterizing the dialectics of experimentation. When it is going well, it is like a quiet conversation with Nature. One asks a question and gets an answer; then one asks the next question, and gets the next answer. An experiment is a device to make Nature speak intelligibly. After that one has only to listen.

Relaxation phenomena afford a unique method for making nature speak intelligibly about rapid energy transfers and chemical reactions. They have only begun to be exploited, especially to probe the elementary steps in complex biochemical reactions. (L.D.F.)

CATALYSIS

The rates of chemical reactions—that is, the velocities at which they occur—depend upon a number of factors, including the chemical nature of the reacting species and the external conditions to which they are exposed. A particular phenomenon associated with the rates of chemical reactions that is of great theoretical and practical interest is catalysis. As noted earlier, this phenomenon is the acceleration of chemical reactions by substances not consumed in the reactions themselves—substances known as catalysts. The study of catalysis is of interest theoretically because of what it reveals about the fundamental nature of chemical reactions; in practice, the study of catalysis is important because many industrial processes depend upon catalysts for their success. Finally, the peculiar phenomenon of life would hardly be possible without the biological catalysts termed enzymes.

History. The term catalysis (from the Greek *kata-*, "down," and *lyein,* "loosen") was first employed by the great Swedish chemist Jöns Jacob Berzelius in 1835 to correlate a group of observations made by other chemists in the late 18th and early 19th centuries. These included: the enhanced conversion of starch to sugar by acids first observed by Gottlieb Sigismund Constantin Kirchhoff; Sir Humphry Davy's observations that platinum hastens the combustion of a variety of gases; the discovery of the stability of hydrogen peroxide in acid solution but its decomposition in the presence of alkali and such metals as manganese, silver, platinum, and gold; and the observation that the oxidation of alcohol to acetic acid is accomplished in the presence of finely divided platinum. The agents promoting these various reactions were termed catalysts, and Berzelius postulated a special, unknown catalytic force operating in such processes.

In 1834 the English scientist Michael Faraday had examined the power of a platinum plate to accomplish the recombination of gaseous hydrogen and oxygen, the products of electrolysis of water, and the retardation of that recombination by the presence of other gases, such as ethylene and carbon monoxide. Faraday maintained that essential for activity was a perfectly clean metallic surface (at which the retarding gases could compete with the reacting gases and so suppress activity), a concept that would later be shown to be generally important in catalysis.

Early applications of catalysis

Many of the primitive technical arts involved unconscious applications of catalysis. The fermentation of wine to acetic acid, the manufacture of soap from fats and alkalies, and the formation of ether from alcohol and sulfuric acid—all catalytic reactions—were well known in man's early history. Sulfuric acid prepared by firing mixtures of sulfur and nitre (sodium nitrate) was an early forerunner of the lead chamber process of sulfuric acid manufacture, in which sulfur dioxide oxidation was accelerated by the addition of oxides of nitrogen. (A mechanism for the latter process was suggested by Sir Humphry Davy in 1812 on the basis of experiments carried out by others.)

In 1850 the concept of a velocity of reaction was developed during studies of hydrolysis, or inversion, of cane sugar. The term inversion refers to the change in rotation undergone by monochromatic light when it is passed through the reaction system, a parameter that is easily measured, facilitating study of the reaction. It was found that the rate of inversion was, at any moment, proportional to the amount of cane sugar undergoing transformation and that the rate was accelerated by the presence of acids. (Later it was shown that the rate of inversion was directly proportional to the strength of the acid.) This work was, in part, the precursor of later studies of reaction velocity and the accelerating influence of higher temperature on that velocity by J.H. van't Hoff, Svante Arrhenius, and Wilhelm Ostwald, all of whom played leading roles in the developing science of physical chemistry. Ostwald's work on reaction velocities led him in the 1890s to define catalysts as substances that change the velocity of a given chemical reaction without modification of the energy factors of the reaction.

This statement of Ostwald was a memorable advance since it implied that catalysts do not change the position of equilibrium in a reaction. In 1877 Georges Lemoine had shown that the decomposition of hydriodic acid to hydrogen and iodine reached the same equilibrium point at 350° C, 19 percent, whether the reaction was carried out rapidly in the presence of platinum sponge or slowly in the gas phase. This observation has an important consequence: a catalyst for the forward process in a reaction is also a catalyst for the reverse reaction. P-E-M. Berthelot, the distinguished French chemist, had confirmed this observation in 1879 with liquid systems when he found that the reaction of organic acids and alcohols, called esterification, is catalyzed by the presence of small amounts of a strong inorganic acid, just as is the reverse process—the hydrolysis of esters (the reaction between an ester and water).

Industrial applications

The application of catalysts to industrial processes was undertaken deliberately in the 19th century. P. Phillips, an English chemist, patented the use of platinum to oxidize sulfur dioxide to sulfur trioxide with air. His process was employed for a time but was abandoned due to loss of activity by the platinum catalyst. Subsequently poisons in the reactants were found to be responsible, and the process became a technical success at the turn of the

20th century. In 1871 an industrial process was developed for the oxidation of hydrochloric acid to chlorine in the presence of cupric salts impregnated in clay brick. The chlorine obtained was employed in the manufacture of bleaching powder (a dry substance that releases chlorine on treatment with acid) by reaction with lime. Again, in this reaction, it was observed that the same equilibrium was reached in both directions. Furthermore, it was found that the lower the temperature, the greater the equilibrium content of chlorine; a working temperature of 450° C produced the maximum amount of chlorine in a convenient time. Toward the close of the 19th century, the classical studies of the eminent French chemist Paul Sabatier on the interaction of hydrogen with a wide variety of organic compounds were carried out using various metal catalysts; this research led to the development of a German patent for the hydrogenation of liquid unsaturated fats to solid saturated fats with nickel catalysts. The development of three important German catalytic processes had great impact on industry at the end of the 19th century and in the early decades of the 20th. One was the so-called contact process for producing sulfuric acid catalytically from the sulfur dioxide produced by smelting operations. Another was the catalytic method for the synthetic production of the valuable dyestuff indigo. The third was the catalytic combination of nitrogen and hydrogen for the production of ammonia—the Haber process for nitrogen fixation—developed by the chemist Fritz Haber.

Homogeneous catalysis. When the catalyst and the reacting substances are present together in a single state of matter, usually as a gas or a liquid, it is customary to classify these as cases of homogeneous catalysis. Oxides of nitrogen serve as catalysts for the oxidation of sulfur dioxide in the lead-chamber process for producing sulfuric acid, an instance of homogeneous catalysis in which the catalyst and reactants are gases. Traces of water vapour catalyze some gas reactions; for example, the interaction of carbon monoxide and oxygen, which proceeds only slowly in dry conditions. Sulfuric acid used as a catalyst for the formation of diethyl ether from ethyl alcohol is an example of homogeneous catalysis in the liquid phase (when the products, water and ether, are continuously removed by distillation); by this method, considerable quantities of alcohol can be converted to ether with a single charge of sulfuric acid. The inversion of cane sugar and the hydrolysis of esters by acid solutions (see above) also are examples of homogeneous catalysis in the liquid phase.

The oxidation of sodium sulfite solutions by dissolved oxygen is greatly accelerated by minute traces of copper ions in the homogeneous liquid system. This system is of special interest since it has been shown that the process is a chain reaction. In this case many thousands of molecules of sodium sulfite can be oxidized to sulfate if the initial activation process is produced by absorption of a limited number of quanta (discrete energy measures) of light. The best example of a light-initiated chain reaction is the photo-combination of hydrogen (H_2) and chlorine (Cl_2); as many as 1,000,000 molecules of hydrogen chloride can be formed by absorption of a single light quantum (designated $h\nu$). Here the sequence of reaction is

$$Cl_2 + h\nu \rightarrow 2Cl\cdot \tag{1}$$

$$Cl\cdot + H_2 \rightarrow HCl + H\cdot \tag{2}$$

$$H\cdot + Cl_2 \rightarrow HCl + Cl\cdot \tag{3}$$

with reactions (2) and (3) repeated over and over again. It is of interest to note that such chain reactions can be retarded by the presence of negative catalysts, more commonly termed inhibitors. These are materials that slow down the overall reaction by shortening the reaction chains, generally by entering into a non-chain reaction with one of the chemical components that maintain the chain. A wide variety of substances, including alcohols, sugars, and phenols, has been found to act as inhibitors of the oxidation of sulfite solutions.

A generalized treatment of homogeneous catalysis by acids and bases was given by the Danish physical chemist J.N. Brønsted in the mid-1920s on the basis of his concept of acids and bases. According to Brønsted, an acid is a molecule that can furnish a proton, whereas a base is a molecule that takes up a proton. On this assumption, the range of acids includes such varied materials as bisulfate ion, HSO_4^-; acetic acid, CH_3COOH; water, H_2O; hydronium ion, H_3O^+; ammonium ion, NH_4^+; and the corresponding bases are sulfate ion, SO_4^{2-}; acetate ion, CH_3COO^-; hydroxide ion, OH^-; water, H_2O; and ammonia, NH_3 (these substances accept protons to yield the listed acids). Brønsted studied a number of acid- and base-catalyzed reactions, including: (1) the acid-catalyzed hydrolysis of an ester, ethyl orthoacetate; (2) the basic catalysis of nitramide decomposition ($H_2N\text{–}NO_2 \rightarrow H_2O + N_2O$); and (3) the acid-base catalysis of the conversion (mutarotation) of glucose to a closely related form. In each case he observed a direct relationship between the velocity of the catalyzed reaction and the concentration of the catalyzing substance.

Basic mechanisms of homogeneous catalysis

Based in part on the ideas of Brønsted, a general scheme for a change of a substance A to another substance B catalyzed by a material C can be formulated thus:

$$A + C \underset{k_2}{\overset{k_1}{\rightleftharpoons}} Z \tag{1}$$

$$Z \xrightarrow{k_3} B + C \tag{2}$$

The designation Z refers to an intermediate stage, which is formed with a velocity indicated by k_1; Z can disappear either to reform $A + C$, with a velocity k_2, or it can decompose by path (2), with velocity k_3, to give the product B and regenerate the catalyst C. If k_3 is much greater than k_2 the intermediate Z is used up almost as quickly as it is formed. The product will then be formed at a rate governed by the expression $k_1[A][C]$, in which the square brackets indicate concentrations of reactant and catalyst. If k_2 is much larger than k_3, however, the velocity-determining process is the decomposition of Z, the rate of formation of the product being represented by the expression $k_3[Z]$, in which $[Z]$ is the concentration of the intermediate. Examples of both types of change have been studied.

In certain instances two or more catalysts present at the same time produce effects greater than either would produce alone. It is then customary to speak of promoter action. Thus, iron ions in solution fortify the action of copper ions in catalyzing a reaction between hydrogen peroxide and iodine. It is assumed that each catalyst activates only one of the reactants.

Homogeneous catalysis of industrial importance

The most important modern examples of homogeneous catalyses are found in the petrochemical industry. The oxo reaction is one such process; in this process carbon monoxide and hydrogen are added to olefins (unsaturated hydrocarbons) at around 150° C and 200 atmospheres of pressure to form aldehydes and alcohols, oxygen-containing organic compounds. A cobalt carbonyl catalyst $Co_2(CO)_8$ is employed; this hydrocarbon-soluble catalyst is believed to activate hydrogen by formation of $HCo(CO)_4$, which then reacts with the olefin. This reaction has led to a number of studies of organometallic chemistry. Copper, silver, and mercury cations (positively charged ions) and permanganate anions (negative ions) also are known to act as homogeneous catalysts for hydrogen activation. Palladium chloride is employed industrially in the catalytic oxidation of ethylene to acetaldehyde in the presence of cupric chloride. The palladium is presumed to be repeatedly converted from the salt to the free metal, the function of the cupric chloride being to participate in the re-formation of the palladium salt from the metal.

Phosphoric, sulfuric, sulfonic, and hydrobromic acids are important agents in the industrial processes of isomerization, polymerization, hydration, and dehydration, as well as in the classical esterification reactions. Free radicals (molecular fragments bearing unpaired electrons) that are generated by the decomposition of peroxides or metal alkyls also initiate homogeneous catalytic processes.

Heterogeneous catalysis. Many catalytic processes are known in which the catalyst and the reactants are not present in the same phase—that is, state of matter. These are known as heterogeneous catalytic reactions. They include reactions between gases or liquids or both at the surface of a solid catalyst. Since the surface is the place at which the reaction occurs, it generally is prepared in ways that produce large surface areas per unit of catalyst; finely divided metals, metal gauzes, metals incorporated into supporting matrices, and metallic films have all been used in modern heterogeneous catalysis. The metals themselves are used or they are converted to oxides, sulfides, or halides.

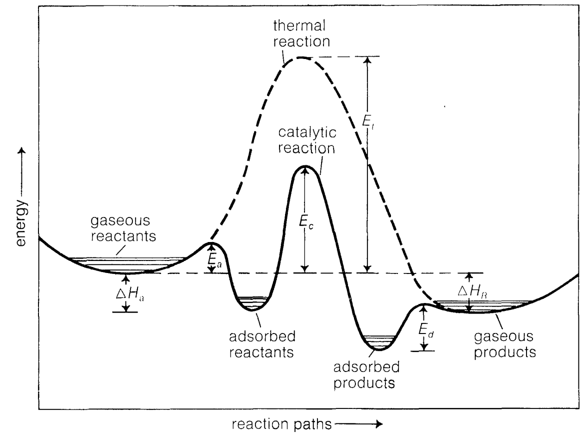


Figure 4: Energy profiles for catalytic and thermal (noncatalytic) reactions in the gaseous phase: E_c is activation energy for catalytic reaction; E_t is activation energy for thermal reaction; E_a is activation energy of adsorption of gaseous reactants; E_d is activation energy of desorption of gaseous products; ΔH_a is heat of chemisorption of reactants; ΔH_R is heat of overall reaction.

With solid catalysts, the reactants are chemisorbed (a portmanteau term for chemically adsorbed) by the catalyst. A catalyst is chosen that releases the products formed as readily as possible; otherwise the products remain on the catalyst surface and act as poisons to the process. Chemisorption can occur over a wide temperature range, the most effective temperature for adsorption depending on the nature of the catalyst. Thus, hydrogen is chemisorbed readily by many metals even at liquid air temperatures (below −180° C). With a series of hydrogenation–dehydrogenation catalysts—*e.g.,* zinc oxide–chromic oxide ($ZnO–Cr_2O_3$)—chemisorption of hydrogen often occurs above room temperature. Nitrogen is chemisorbed on synthetic ammonia-iron catalyst rapidly in the region above 400° C. It has been shown that iron films chemisorb nitrogen even at liquid air temperatures, with additional chemisorption found above room temperatures. It follows from such considerations that whereas physical adsorptions, which parallel the ease of liquefaction of the adsorbed substance, occur spontaneously, chemisorption, which involves the making and breaking of chemical bonds, often requires activation energies (energy needed to initiate reactions) as do uncatalyzed chemical processes. To be efficient catalytically, a process must involve energies of activation for all the steps involved that, at their maxima, are less than those required for the uncatalyzed reaction. This situation is illustrated graphically in Figure 4, for a hypothetical reaction, which can occur by either an uncatalyzed or a catalyzed route. Two competing proposals have been made concerning the mechanism of catalytic reactions at surfaces, and it has not been possible to choose between them. Originally, Irving Langmuir, the American physical chemist, proposed chemisorption of both reacting species at the surface, followed by interaction between adjacent species and evaporation of the products. An alternative proposal involves interaction between an impinging molecule and species already adsorbed on the surface. Subsequent developments have suggested various modes of attachment of the adsorbed and adsorbing species.

Basic mechanisms of heterogeneous catalysis

A major advance in the science of surface catalysis was the development of a method for determining the surface area of catalysts (and other materials) by measuring the multimolecular adsorption of nitrogen at liquid nitrogen temperatures or the adsorption of other gases close to their boiling points. It then became possible to calculate a quantity, designated V_m, which represents the volume of gas necessary to form a monolayer on the accessible surface; furthermore, the area of the surface can be determined from the known dimensions of the adsorbed molecules. It has also been found possible to titrate (measure quantitatively) the area of surfaces by chemisorption of gases.

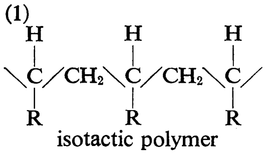
When measurements of surface areas became possible, it was seen at once that many constituents present in minor quantities in the main catalyst material—and known as promoters—could act by extending the effective surface area of the catalyst. It also was shown, however, that a promoter might produce an increase in the quality of the surface for the given reaction. Acting in a reverse direction are minor constituents of the reacting system or unwanted products of the reaction, which by preferential adsorption on the reaction sites and resistance to removal give rise to poisons for the process.

Much can be learned about mechanisms of surface processes by studying the behaviour of isotopic species of the reactants and products on the catalyst. An example of such use concerns the technically important synthesis of ammonia from its elements, the well-known Haber process on promoted-iron catalysts. The synthesis of ammonia involves three types of bonds, hydrogen–hydrogen, nitrogen–hydrogen, and nitrogen–nitrogen, all of which can be studied using isotopes of hydrogen and nitrogen. The first of these can be examined on the reduced-iron catalyst by following the progress of the reaction $H_2 + D_2 \rightarrow 2HD$ (in which D equals the deuterium atom, an isotope of hydrogen) on the surface. The reaction is found to occur rapidly even at liquid air temperatures. Nitrogen–hydrogen bond activation can be studied by following the reaction $NH_3 + ND_3 \rightarrow NH_2D + NHD_2$. This proceeds steadily at room temperatures. The reaction involving only N–N bonds, however, studied by following the process $^{14}N_2 + {}^{15}N_2 \rightarrow 2{}^{14}N–{}^{15}N$ (in which ^{14}N and ^{15}N are stable isotopes of nitrogen), is shown to proceed only at the higher temperatures of ammonia synthesis, around 400° C. From these data one concludes that the activation of the nitrogen molecules is the slow step (the process that limits the overall reaction) in ammonia synthesis. This conclusion is confirmed by measurement of rate of adsorption of nitrogen on the iron catalysts. Other, similar isotopic studies have yielded valuable information on the reactions of hydrocarbons, using deuterium and carbon-14 as the isotopic tracers.

Catalysis in stereoregular polymerization

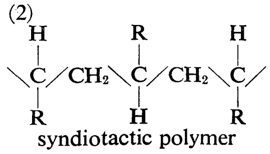
The importance of the concept of adsorption of reactants on the surface of catalysts has been greatly increased by the development of stereoregular polymerization processes—that is, methods that yield polymers whose molecules have definite three-dimensional patterns. Such processes were developed independently by the German chemist Karl Ziegler and the Italian Giulio Natta. An example is the polymerization of propylene with a titanium trichloride–alkyl aluminum catalyst. In the case of a generalized ethylenic compound, $CH_2 = CHR$, stereoregular polymerization may yield three different arrangements of the polymer; an isotactic polymer, a syndiotactic polymer, and an atactic polymer. These have the following arrangements of their molecular chains:

(1)



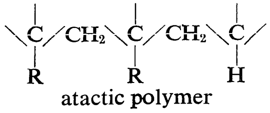
isotactic polymer

(2)



syndiotactic polymer

(3)



atactic polymer

In the isotactic polymer the monomer units have added head-to-tail, to give a series of C–R tertiary bonds with the same configuration in space; in the syndiotactic polymer, the tertiary carbon atoms in the chain have alternate (dextro and levo) spatial configurations; and in the atactic polymer there is no regularity in the distribution of steric configurations of the asymmetric carbon atoms. The various polymeric forms differ in their physical properties. Isotactic polypropylene, for example, has a density of 0.92 g/cm^3 and a melting point of 165° C, whereas an atactic polymer has a somewhat smaller density, 0.85 g/cm^3, and a much lower melting point of −35° C. The more regular isotactic polymer is denser and has a higher melting point than the atactic product because of its greater tendency to crystallize (in spite of the fact that the substituent R may be quite large, hindering crystal formation). Stereoregular polymerization suggests a stereoregulated adsorption at the active centres of the catalyst. In the case of polypropylene, the catalytic centres have been identified by electron micrographs as α-$TiCl_3$ surfaces, which cover only a small fraction of the total surface area, whereas the β-$TiCl_3$ surfaces, which are more abundant, appear to be covered with polymer. The difference between the α- and β-surfaces lies in the random (α) and linear (β) arrangements of Ti^{3+} sites in the two surfaces.

Since the Ziegler–Natta studies, other stereoregulating catalysts have been investigated, notably oxides of chromium, vanadium, molybdenum, and tungsten on silica–alumina or other supports. Other cationic, anionic, and free-radical catalysts are known to produce stereoregulated polymerization. Stereoregular polymerization of dienes has undergone industrial development with the polymerization of isoprene to synthetic natural rubber.

Catalytically active centres

The nature of the active centres in catalytic material is further demonstrated by the enhancement of the catalytic activity of relatively inactive materials when they are subjected to intense radiation. Silica gel bombarded by gamma rays from cobalt-60 turns purplish in colour and becomes capable of inducing the reaction $H_2 + D_2 \rightarrow 2HD$ at liquid nitrogen temperatures. The colour centres, which are positive "holes" (deficiencies) trapped in the vicinity of an oxygen ion next to an aluminum impurity, are bleached *in vacuo* above 200° C and are destroyed by hydrogen even at room temperature.

The properties of dilute concentrations of platinum metals in oxide matrices, such as silica and alumina, as well as on carbon carriers have been studied by Soviet and American scientists. Such catalysts have technical significance in processes for the reforming of gasoline. In such catalysts—containing about 0.5 percent by weight of platinum or palladium—the degree of dispersion of the metal (that is, the ratio of the number of surface metal atoms to the total number present) is close to one. By contrast, on platinum foil the dispersion is only about 4×10^{-3}. The titration and adsorption procedures with hydrogen and oxygen (see above) are employed to evaluate these dispersions.

From these studies it becomes clear that there are two types of behaviour resulting from dispersion. For numerous catalytic processes, ranging from hydrogen–deuterium exchange to the hydrogenation of benzene and the hydrogenolysis of cyclopentane, the reactions are independent of dispersion in the critical region—with catalyst particle size of 50Å or less. Such structure-insensitive processes have been termed facile reactions. On the other hand, there are reactions, such as the isomerization of neopentane to isopentane and simultaneous cracking of the latter to isobutane and methane on platinum–alumina catalysts, where the selectivity for isomerization varies by a factor of 100 for the various catalysts studied (when the hydrogen–neopentane ratio is 10). Thus, the same 1 percent platinum-on-carbon catalyst showed a selectivity ratio of isomerization to hydrogenolysis of 2.5 when the catalyst was reduced in hydrogen at 500° C and a selectivity ratio of 13 when the catalyst was fired *in vacuo* at 900° C (the percentage dispersion remaining at 35 percent in both cases). Such structure-sensitive catalytic reactions have been called demanding reactions. The gain in selectivity appears to be due largely to a reduction in the rate of hydrogenolysis. Since other studies have shown that heating *in vacuo* to 900° tends to develop certain (111) facets of the metal, it is thought that the increase in selectivity is due to a more abundant triadsorption of neopentane on the samples fired at high temperature. It has been shown that a crystallite of platinum about 20Å in size has unusual surfaces not present in a regular octahedral crystallite of similar size. A number of sites where an adsorbed molecule could be surrounded by five platinum nearest neighbours were found on the crystallite with the unusual surface.

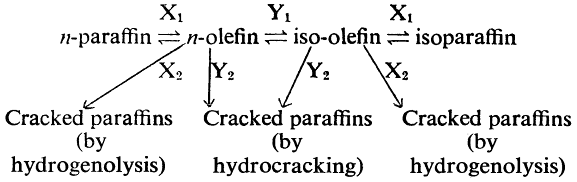
Electronic factors in heterogeneous catalysis

An alternative approach to the problem of surface catalysis involves the consideration of electronic factors in catalyst and reactants. Many catalytic materials are semiconductors. It is thought that these can form a variety of bonds with reactants depending on the free lattice electrons and the "holes" (deficiencies) in the catalyst lattice. Chemisorbed particles react in ways that are dependent on the form of attachment to the surface and that vary with the extent of coverage of the surface as well as with the available supply of electrons and holes. The surface behaves as would free radicals that are introduced directly into the reacting species, dependent on the electrochemical properties of the surface and the bulk of the semiconductor material. Such considerations have led to the determination of the character of the catalyst as a semiconductor and of the adsorbate as an electrochemical species, whether it is composed of positive or negative ions or free atoms or radicals. Catalytic activity also has been explored as a function of the *d*-band character—that is, the number of electrons in *d* orbitals in the atoms of the catalyst materials.

Since 1940 various instrumental techniques have been developed to explore the structure of catalytic materials and the character of the adsorbed species, even during the reaction itself. Among these techniques are electron microscopy, field emission microscopy, electron microprobe methods, magnetic measurements, infrared spectroscopy, Mössbauer spectroscopy, measurements of heats of immersion, flash desorption procedures, low-energy electron diffraction studies, and nuclear magnetic resonance and electron spin resonance techniques.

Polyfunctional heterogeneous catalysis

The term polyfunctional heterogeneous catalysis is applied to a group of catalysts in which more than one component of the surface is active in the processes under study. One example of a bifunctional heterogeneous catalyst is the catalyst of metal (platinum or nickel) deposited on a silica–alumina "acidic" base. Such dual functional catalysts are involved in the interconversions of saturated hydrocarbons (paraffins) and unsaturated hydrocarbons (olefins), and normal (straight-chain) and iso (branched-chain) hydrocarbons, as well as in the splitting (cracking) of the hydrocarbon molecules. The interrelations involved are as follows:



in which X_1 and X_2 are metal-catalyzed processes and Y_1 and Y_2 are acid-catalyzed processes. Operating conditions can be altered to maximize the hydrocracking reactions relative to hydrogenolysis.

A variety of catalysts with "acidic" sites has been found to be active in the dehydration of alcohols and (as above) in the cracking and isomerization of hydrocarbons. Among these are: silica, obtained by calcination (heating) of silica gel; high purity alumina, prepared by the calcining of specially prepared aluminum hydroxide; and silica–alumina mixtures. The catalytic sites have been found to have varying degrees of acidity; their exact nature is still under discussion as well as their characterization in terms of the atomic architecture of the solid catalyst. In the case of silica–alumina, the sites are ascribed to the presence of trivalent aluminum ions Al^{3+}, in a matrix of quadrivalent silicon ions, Si^{4+}, which gives rise to charge differences in the neighbourhood of the aluminum ions. These acidic sites can be poisoned by ammonia and by amines, a finding that confirms their acidic nature. When these catalysts are treated with alkalies their catalytic character is greatly modified. On the other hand, treatment with halogens, especially fluorine or chlorine, enhances the acidic properties of these oxide materials.

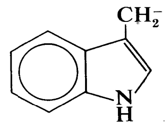
Zeolites

Zeolites are naturally occurring crystalline aluminosilicates having a porous structure and containing cations, generally of the alkali or alkaline earth metals. The cations can be exchanged reversibly with other metal ions without destroying the aluminosilicate structure. Because the zeolites rapidly adsorb certain molecules and exclude others, they have been given the name of molecular sieves. The adsorption characteristics of natural and synthetic zeolites have been studied since the 1930s. Manufactured zeolites, some of which have structures not found in nature, are employed as dehydrating agents but also may be used for the production of catalytic materials by exchange with cationic elements or by impregnation of metal salt solutions into the pores of the zeolite; a large number of zeolitic catalysts have been developed.

Electron donor–acceptor complexes

A class of compounds termed electron donor–acceptor complexes also has been studied for its catalytic activity. The class may be exemplified by a complex between metallic sodium (the donor) and anthracene, $C_{14}H_{10}$, a tricyclic hydrocarbon (the acceptor). The complex can be visualized as an anthracene anion and a sodium cation. Such complexes can exchange the hydrogen of the anion with molecular hydrogen that has been brought into contact with the complex. A complex represented by ZH (in which Z represents all of the molecule except for the exchangeable hydrogen) could undergo exchange with deuterium, as follows: $ZH + D_2 \rightarrow ZD + HD$. It could also take part in corresponding exchanges with hydrocarbons or bring about hydrogenation of hydrocarbons. Among other electron-acceptor catalysts are the metal phthalocyanines (compounds related to certain biological catalysts) and activated charcoal. Some donor–acceptor complexes synthesize ammonia from nitrogen–hydrogen mixtures. This reaction represents a close approach to the activity of biological and bacterial catalysts.

Biological catalysts: the enzymes. Enzymes are substances found in biological systems that are catalysts for specific biochemical processes. Although earlier discoveries of enzymes had been made, a significant confirmation of their importance in living systems was found in 1897 by the German chemist Eduard Buchner, who showed that the filtered cell-free liquor from crushed yeast cells could bring about the conversion of sugar to carbon dioxide. Since that time more than 1,000 enzymes have been recognized, each specific to a particular chemical reaction occurring in living systems. More than 100 of these have been isolated in relatively pure form, including a number of crystallized enzymes. The first enzymes to be crystallized were urease, isolated from the jack bean and crystallized in 1926 by James Batcheller Sumner, and pepsin, crystallized in 1930 by John Howard Northrop, both men being American biochemists. These purified materials were shown to be proteins, chain compounds of about 20 natural amino acids $RCH(NH_2)COOH$, ranging from the simplest, glycine, in which R is hydrogen, to tryptophan, in which R is



Not only have methods been worked out for determining the amino acids, found in an enzyme, but also the sequence of amino acids in an enzyme can be elucidated by a method developed by the English biochemist Frederick Sanger in determining the structure of the protein hormone, insulin. The first enzyme to have its complete amino acid sequence determined in this way was the enzyme bovine pancreatic ribonuclease, which has 124 amino acids in its chain and has a molecular weight of about 14000; the enzyme catalyzes the degradation of ribonucleic acid, a substance active in protein synthesis in living cells. In January 1969, the synthesis of this same enzyme was reported from two different laboratories. The activity of an enzyme depends upon a three-dimensional, or tertiary, structure, but this, in turn, appears to depend solely upon the linear sequence of amino acids. The success of a synthesis of an enzyme can be unequivocally checked by test of its enzymatic activity.

Enzyme reactivity

Enzymes are extremely reactive, as can be shown with a very simple reaction, the splitting of hydrogen peroxide to form water and oxygen, brought about by colloidal metals and by the enzyme catalase. It has been found that one molecule of the latter will cause several million molecules of peroxide to decompose per minute, a rate comparable to that obtained with the best colloidal preparations. This speed of catalase decomposition is probably a maximum for enzymes. Slower acting enzymes normally react at speeds of hundreds of reactions per minute. The rate of reaction is often expressed by an equation developed by L. Michaelis and M.L. Menten of the form:

$$\text{Rate} = \frac{V[S]}{K + [S]}$$

in which V and K are constants for the particular enzymatic process, K being termed the Michaelis constant, and $[S]$ is the concentration of the reactant undergoing change. At low concentrations of S the rate is $V[S]/K$ or proportional to the substrate concentration [S], whereas at high substrate concentrations the $[S]$ terms cancel out and the reaction is essentially independent of the substrate concentration.

A second characteristic of enzymes is their extreme specificity. It has been suggested that each biochemical process has its own specific enzyme. The biochemical processes induced by enzymes fall into broad classifications, such as hydrolysis, decomposition (or "splitting"), synthesis, hydrogenation–dehydrogenation; as with catalysts in general, enzymes are active for both forward and reverse reactions.

Like the laboratory catalysts, enzymes frequently have activators—coenzymes, which may be prosthetic groups (firmly bound to the enzyme itself) and inorganic ions. Adenosine triphosphate, ATP, is an important coenzyme participating in energy-producing processes and passage across cell membranes. Coenzymes often contain vitamins as parts of their structure. Calcium and magnesium ions are important enzyme activators. As with catalysts there are many substances that inhibit, or poison, enzymes. Cyanide ion is a potent inhibitor in many enzymic processes, as are such substances as nerve gases and insecticides. (H.S.Ta.)

Acid–base reactions and equilibria

Acids are chemical compounds that show, in water solution, a sharp taste, a corrosive action on metals, and the ability to turn certain blue vegetable dyes red. Bases are chemical compounds that, in solution, are soapy to the touch and turn red vegetable dyes blue. When mixed, acids and bases neutralize one another and produce salts, substances with a salty taste and none of the characteristic properties of either acids or bases.

Early ideas about acids and bases

The idea that some substances are acids, whereas others are bases, is almost as old as chemistry; and the terms acid, base, and salt occur very early in the writings of the medieval alchemists. Acids were probably the first of these to be recognized, apparently because of their sour taste. The English word acid, the French *acide,* the German *Säure,* and the Russian *kislota* are all derived from words meaning sour (Latin *acidus,* German *sauer,* Old Norse *sūur,* and Russian *kisly*). Other properties associated at an early date with acids were their solvent, or corrosive, action; their effect on vegetable dyes; and the effervescence resulting when they were applied to chalk (production of bubbles of carbon dioxide gas). Bases (or alkalies) were characterized mainly by their ability to neutralize acids and form salts, the latter being typified rather loosely as crystalline substances soluble in water and having a saline taste.

In spite of their imprecise nature, these ideas served to correlate a considerable range of qualitative observations; and many of the commonest chemical materials that early chemists encountered could be classified as acids (hydrochloric, sulfuric, nitric, and carbonic acids), bases (soda, potash, lime, ammonia) or salts (common salt, sal ammoniac, saltpetre, alum, borax). The absence of any apparent physical basis for the phenomena concerned made it difficult to make quantitative progress in understanding acid–base behaviour, but the ability of a fixed quantity of acid to neutralize a fixed quantity of base was one of the earliest examples of chemical equivalence: the idea that a certain measure of one substance is in some chemical sense equal to a different amount of a second substance. In addition, it was found quite early that one acid could be displaced from a salt with another acid, and this made it possible to arrange acids in an approximate order of strength. It also soon became clear that many of these displacements could take place in either direction according to experimental conditions. This phenomenon suggested that acid-base reactions are reversible—that is, that the products of the reaction can interact to regenerate the starting material. It also introduced the concept of equilibrium to acid–base chemistry—this concept states that reversible chemical reactions reach a point of balance, or equilibrium, at which the starting materials and the products are each regenerated by one of the two reactions as rapidly as they are consumed by the other.

Apart from their theoretical interest, acids and bases play a large part in industrial chemistry and in everyday life. Sulfuric acid and sodium hydroxide are among the products of chemical industry manufactured in largest amount, and a large percentage of chemical processes involve acids or bases as reactants or as catalysts. Almost every biological chemical process is closely bound up with acid–base equilibria in the cell, or in the organism as a whole, and the acidity or alkalinity of the soil and water are of great importance for the plants or animals living in them. Both the ideas and the terminology of acid–base chemistry have permeated daily life, and the term salt is especially common.

THEORETICAL DEFINITIONS OF ACIDS AND BASES

The oxygen theory of acids

Hydrogen and hydroxide ions. The first attempt at a theoretical interpretation of acid behaviour was made by Antoine-Laurent Lavoisier at the end of the 18th century. Lavoisier supposed that all acids must contain oxygen, and this idea was incorporated in the names used for this element in the various languages; the English oxygen, from the Greek *oxys* (sour) and *genna* (production); the German *Sauerstoff,* literally acid material; and the Russian *kislorod,* from *kislota* (acid). Following the discovery that hydrochloric acid contained no oxygen, Sir Humphry Davy in about 1815 first recognized that the key element in acids was hydrogen. Not all substances that contain hydrogen, however, are acids, and the first really satisfactory definition of an acid was given by Justus von Liebig of Germany in 1838. According to Liebig, an acid is a compound containing hydrogen in a form in which it can be replaced by a metal. This definition held the field for about 50 years and is still considered essentially correct, though somewhat outmoded. At the time of Liebig's proposal, bases were still regarded solely as substances that neutralized acids with the production of salts, and nothing was known about the constitutional features of bases that enabled them to do this.

The whole subject of acid–base chemistry acquired a new look and a quantitative aspect with the advent of the electrolytic dissociation theory propounded by Wilhelm Ostwald and Svante August Arrhenius (both Nobel laureates) in the 1880s. The principal feature of this theory is that certain compounds, called electrolytes, dissociate in solution to give ions. With the development of this theory it was realized that acids are merely those hydrogen compounds that give rise to hydrogen ions (H^+) in aqueous solution. It was also realized at that time that there is a correspondence between the degree of acidity of a solution (as shown by effects on vegetable dyes and other properties) and the concentration of hydrogen ions in the solution. Correspondingly, basic (or alkaline) properties could then be associated with the presence of hydroxide ions (OH^-) in aqueous solution, and the neutralization of acids by bases could be explained in terms of the reaction of these two ions to give the neutral molecule water ($H^+ + OH^- \rightarrow H_2O$.) This led naturally to the following simple definitions: Acids and bases are substances that give rise, respectively, to hydrogen and hydroxide ions in aqueous solution. This definition was generally accepted for the next 30 or 40 years. In purely qualitative terms, it does not offer many advantages over Liebig's definition of acids, but it does provide a satisfactory definition for bases.

Hydrogen and hydroxide ion definitions of acids and bases

Nevertheless, there is a great advantage in the definition of acids and bases in terms of hydrogen and hydroxide ions and this advantage lies in its quantitative aspects. Because the concentrations of hydrogen and hydroxide ions in solution can be measured, notably by determining the electrical conductivity of the solution (its ability to carry an electrical current), a quantitative measure of the acidity or alkalinity of the solution is provided. Moreover, the equations developed to express the relationships between the various components of reversible reactions can be applied to acid and base dissociations to give definite values, called dissociation constants. These constants can be used to characterize the relative strengths (degrees of dissociation) of acids and bases and, for this reason, supersede earlier semiquantitative estimates of acid or base strength. As a result of this approach, a satisfactory quantitative description was given at an early date of a large mass of experimental observations, a description that remains essentially unaffected by later developments in definitions of acid–base reactions.

The success of these quantitative developments, however, unfortunately helped to conceal some ambiguities and logical inconsistencies in the qualitative definitions of acids and bases in terms of the production of hydrogen and hydroxide ions, respectively. For example, it was not clear whether a substance like anhydrous hydrogen chloride, which would not conduct electricity, should be regarded as an acid, or whether it should be considered an acid only after it had come in contact with water. A modified definition of bases also seemed to be required that would be applicable to nonaqueous solutions, in which the anion (negatively charged ion) produced is not the hydroxide ion, as is the case in water, but varies from solvent to solvent, the methoxide ion (CH_3O^-) acting as the basic anion in methanol (CH_3OH), for example, and the amide ion (NH_2^-) playing the same role in liquid ammonia (NH_3). Even with acids the solvent is involved, since there is much evidence to show that the so-called hydrogen ion in solution does not exist as H^+ but always contains at least one molecule of solvent, as H_3O^+ in water, $CH_3OH_2^+$ in methanol, and NH_4^+ in liquid ammonia. These considerations led to the development of definitions of acids and bases that depended on the solvent (see below). In spite of this change, however, the difficulty still remained that typical acid–base properties, such as neutralization, indicator (vegetable-dye) effects, and catalysis, often took place in solvents such as benzene or chloroform in which free ions could barely be detected at all (by conductivity measurements). Even for aqueous solutions a particular ambiguity arises in the definition of bases, some of which (for example, metallic hydroxides) contain a hydroxyl group, whereas others (such as amines) do not. The latter produce hydroxide ions in solution by reacting with water molecules.

The Brønsted–Lowry definition. In order to resolve the various difficulties in the hydrogen–hydroxide ion definitions of acids and bases, a new, more generalized definition was proposed in 1923 almost simultaneously by J.M. Brønsted and T.M. Lowry. Although the pursuit of exact verbal definitions of qualitative concepts is usually not profitable in physical science, the Brønsted–Lowry definition of acids and bases has had far-reaching consequences in the understanding of a wide range of phenomena and in the stimulation of much experimental work. The definition is as follows: an acid is a species having a tendency to lose a proton, and a base is a species having a tendency to gain a proton. The term proton means the species H^+ (the nucleus of the hydrogen atom) rather than the actual hydrogen ions that occur in various solutions; the definition is thus independent of the solvent. The use of

Proton definition of acids and bases

the word species rather than substance or molecule implies that the terms acid and base are not restricted to uncharged molecules but apply also to positively or negatively charged ions. This extension is one of the important features of the Brønsted–Lowry definition. It can be summarized by the equation $A \rightleftarrows B + H^+$ in which A and B together are a conjugate acid–base pair. In such a pair A must obviously have one more positive charge (or one less negative charge) than B, but there is no other restriction on the sign or magnitude of the charges. Several examples of conjugate acid–base pairs are given in Table 1.

Table 1: Examples of Conjugate Acid-Base Pairs

acid	base
Acetic acid, CH_3CO_2H	acetate ion, $CH_3CO_2^-$
Bisulfate ion, HSO_4^-	sulfate ion, SO_4^{2-}
Ammonium ion, NH_4^+	ammonia, NH_3
Ammonia, NH_3	amide ion, NH_2^-
Water, H_2O	hydroxide ion, OH^-
Hydronium (oxonium) ion, H_3O^+	water, H_2O

A number of points about the Brønsted–Lowry definition should be emphasized:

1. As mentioned above, this definition is independent of the solvent. The ions derived from the solvent (H_3O^+ and OH^- in water, and NH_4^+ and NH_2^- in liquid ammonia) are not accorded any special status but appear as examples of acids or bases in terms of the general definition. On the other hand, of course, they will be particularly important species for reactions in the solvent to which they relate.

2. In addition to the familar molecular acids, two classes of ionic acids emerge from the new definition. The first comprises anions derived from acids containing more than one acidic hydrogen; *e.g.*, the bisulfate ion (HSO_4^-, as in Table 1) and primary and secondary phosphate ions ($H_2PO_4^-$ and HPO_4^{2-}) derived from phosphoric acid (H_3PO_4). The second and more interesting class consists of positively charged ions (cations), such as the ammonium ion (NH_4^+), which can be derived by the addition of a proton to a molecular base, in this case ammonia (NH_3). The hydronium ion (H_3O^+), which is the hydrogen ion in aqueous solution, also belongs to this class. The charge of these ionic acids, of course, always must be balanced by ions of opposite charges, but these oppositely charged ions usually are irrelevant to the acid-base properties of the system. For example, if sodium bisulfate ($Na^+HSO_4^-$) or ammonium chloride ($NH_4^+Cl^-$) is used as an acid, the sodium ion (Na^+) and the chloride ion (Cl^-) contribute nothing to the acidic properties and could equally well be replaced by other ions, such as potassium (K^+) and perchlorate (ClO_4^-), respectively.

3. Molecules such as ammonia and organic amines are bases by virtue of their tendency to accept a proton. With metallic hydroxides such as sodium hydroxide, on the other hand, the basic properties are due to the hydroxide ion itself, the sodium ion serving merely to preserve electrical neutrality. Moreover, not only the hydroxide ion, but also the anions of other weak acids (for example the acetate ion) must be classed as bases because of their tendency to reform the acid by accepting a proton. Formally, the anion of any acid might be regarded as a base, but for the anion of a very strong acid (the chloride ion, for example) the tendency to accept a proton is so weak that its basic properties are insignificant and it is inappropriate to describe it as a base. Similarly, all hydrogen compounds could formally be defined as acids, but in many of them (for example, most hydrocarbons, such as methane, CH_4) the tendency to lose a proton is so small that the term acid would not normally be applied to them.

Amphoteric substance

4. Some species, including molecules as well as ions, possess both acidic and basic properties; such materials are said to be amphoteric. As shown in Table 1, both water and ammonia are amphoteric, a situation that can be represented by the schemes H_3O^+–H_2O–OH^- and NH_4^+–NH_3–NH_2^-. Another example is the secondary phosphate ion, HPO_4^{2-}, which can either lose or accept a proton, according to the following equations: $HPO_4^{2-} \rightleftarrows PO_4^{3-} + H^+$ and $HPO_4^{2-} + H^+ \rightleftarrows H_2PO_4^-$. The amphoteric properties of water are particularly important in determining its properties as a solvent for acid–base reactions.

5. The equation $A \rightleftarrows B + H^+$, used in the Brønsted–Lowry definition, does not represent a reaction that can be observed in practice, since the free proton, H^+, can be observed only in gaseous systems at low pressures. In solution, the proton always is attached to some other species, commonly a solvent molecule. Thus in water the ion H_3O^+ consists of a proton bound to a water molecule. For this reason all observable acid–base reactions in solution are combined in pairs, with the result that they are of the form $A_1 + B_2 \rightleftarrows B_1 + A_2$. The fact that the process $A \rightleftarrows B + H^+$ cannot be observed does not imply any serious inadequacy of the definition. A similar situation exists with the definitions of oxidizing and reducing agents, which are defined respectively as species having a tendency to gain or lose electrons, even though one of these reactions never occurs alone and free electrons are never detected in solution (any more than free protons are).

Alternative definitions. Although the Brønsted–Lowry concept of acids and bases as donors and acceptors of protons is still the most generally accepted one, other definitions are often encountered. Certain of these are adapted for special situations only, but the most important of these other definitions is in some respects more general than the Brønsted–Lowry definition. This definition was first proposed by the U.S. chemist Gilbert N. Lewis in 1923.

The Lewis definition of acids and bases

According to Lewis, an acid is a species that can accept an electron pair from a base with the formation of a chemical bond composed of a shared electron pair (covalent bond). This classification includes as bases the same species covered by the Brønsted–Lowry definition, since a molecule or ion that can accept a proton does so because it has one or more unshared pairs of electrons, and therefore it also can combine with electron acceptors other than the proton. On the other hand, the typical Lewis acids need not (and usually do not) contain protons, being species with outer electron shells that are capable of expansion, such as boron trifluoride (BF_3), sulfur trioxide (SO_3), and silver ion (Ag^+). Lewis originally based his ideas on the experimental fact that these nonprotonic acids often exhibit the properties regarded as typical of acids, such as neutralization of bases, action on indicators, and catalysis. Such substances often are electron acceptors, but this is not always the case; carbon dioxide (CO_2) and nitrogen pentoxide (N_2O_5), for example, contain completed octets of electrons and, according to usual valence theory, cannot accept any more. In addition, hydrogen-containing substances that have always been regarded as acids (acetic acid, for example) are not obviously electron acceptors, being rather adducts of the proton (a true Lewis acid) and a base such as the acetate ion. They can only be brought logically into the Lewis scheme by appealing to the fact that the reaction between a proton acid, which may be designated as XH, and a base, denoted by B, passes through an intermediate hydrogen-bonded state, X-H . . . B (in which the dotted line indicates a hydrogen bond, a relatively weak secondary attractive force).

Numerous lengthy polemical exchanges have taken place regarding the relative merits of the Brønsted–Lowry and Lewis definitions of acids and bases. The difference is essentially one of nomenclature and has little scientific content. In the remainder of this article the term acid will be used to denote a proton donor (following the Brønsted–Lowry terminology) whereas the term Lewis acid will be employed exclusively to refer to electron-pair acceptors. This choice is based partly upon the logical difficulties mentioned in the last paragraph, and partly on the fact (see below) that the quantitative description of acid–base reactions is much simpler when it is confined to proton acids. This terminology also represents the commonest usage of the terms.

The definition of Lewis acids and bases in terms of the gain or loss of electrons should not be confused with the definition of oxidizing and reducing agents in similar terms. In oxidation–reduction reactions one or more electrons is transferred completely from the reducing agent to the oxidizing agent, whereas in a Lewis acid–base reaction an electron pair on the base is used to form a covalent link with the acid.

Generalized solvent definitions

Certain other acid–base definitions have been based upon reactions occurring in specific solvent systems. For proton acids in amphoteric solvents these are equivalent to the Brønsted–Lowry definition. It is sometimes convenient to have general terms for the cation and anion derived from the solvent molecule by the additon and removal of a proton, respectively. The terms lyonium and lyate ions are occasionally used in this way. In water, the lyonium and lyate ions are H_3O^+ and OH^-; in ethanol, they are $C_2H_5OH_2^+$ and $C_2H_5O^-$; and in liquid ammonia, NH_4^+ and NH_2^-. For a given solvent, an acid can then be defined as a substance that increases the lyonium ion concentration (and correspondingly decreases the lyate ion concentration), whereas a base increases the lyate ion concentration (and decreases the lyonium ion concentration). This kind of definition, to be sure, really does not add anything to the concept of acids and bases as proton donors and proton acceptors.

The idea that an acid is a solute that gives rise to cations characteristic of the solvent, and a base is a solute that gives rise to anions characteristic of the solvent, has sometimes been extended to solvents where no protons are involved at all, for example, liquid sulfur dioxide, SO_2. In this example, the solvent is supposed to ionize according to the equation $2SO_2 \rightleftarrows SO^{2+} + SO_3^{2-}$. Thionyl chloride, regarded as $SO^{2+} + 2Cl^-$, then can be considered an acid, and potassium sulfite, $2K^+ + SO_3^{2-}$, a base. The species SO^{2+} and SO_3^{2-} can certainly be regarded as Lewis acids and bases, but it is doubtful that they exist to any appreciable extent in liquid sulfur dioxide, a situation that makes the discussion somewhat artificial. Although this view of acids and bases has been useful in stimulating work in unusual types of solvent (for example in carbonyl chloride, selenium oxychloride, antimony trichloride, and hydrogen cyanide) it has not met with general acceptance.

ACID–BASE REACTIONS

Proton-transfers. As already mentioned, the reaction expressed by the Brønsted–Lowry definition, $A \rightleftarrows B + H^+$, does not actually occur in any solution processes. This is because H^+, the bare proton, has an enormous tendency to add to almost all chemical species and cannot exist in any detectable concentrations except in a high vacuum. Apart from any specific chemical interaction, the very small size of the proton (about 10^{-15} metres) means that it exerts an extremely powerful electric field, which will polarize and therefore attract any molecule or ion it comes into contact with. It has been estimated that the dissociation of 19 grams of the hydronium ion H_3O^+ to give 1 gram of protons and 18 grams of water would require the expenditure of about 1,200,000 joules (290,000 calories) of energy, and thus it is an extremely unlikely process indeed.

Combined pairs of acid–base reactions

Typical acid–base reactions may be thought of as the combination of two reaction schemes $A_1 \rightleftarrows B_1 + H^+$ and $H^+ + B_2 \rightleftarrows A_2$, leading to the combined form: $A_1 + B_2 \rightleftarrows B_1 + A_2$. This represents a proton-transfer reaction from A_1 to B_2, producing B_1 and A_2. A large number of reactions in solution, often referred to under a variety of names, can be represented in this way. This is illustrated by the following examples, in each of which the species are written in the order A_1, B_2, B_1, A_2.

Dissociation of molecular acids in water. In this instance, water acts as a base. The equation for the dissociation of acetic acid, for example, is as follows: $CH_3CO_2H + H_2O \rightleftarrows CH_3CO_2^- + H_3O^+$.

Dissociation of bases in water. In this case, the water molecule acts as an acid and adds a proton to the base. An example, using ammonia as the base, is $H_2O + NH_3 \rightleftarrows OH^- + NH_4^+$. Older formulations would have written the left-hand side of the equation as ammonium hydroxide, NH_4OH, but it is not now believed that this species exists, except as a weak, hydrogen-bonded complex.

Dissociation of acids and bases in nonaqueous solvents. These situations are entirely analogous to the comparable reactions in water. For example, the dissociation of acetic acid in methanol may be written as $CH_3CO_2H + CH_3OH \rightleftarrows CH_3CO_2^- + CH_3OH$, and the dissociation of ammonia in the same solvent as $CH_3OH + NH_3 \rightleftarrows CH_3O^- + NH_4^+$.

Self-dissociation of amphoteric solvents. In this case, one solvent molecule acts as an acid, and another as a base. Self-dissociation of water and liquid ammonia may be given as examples:

$$H_2O + H_2O \rightleftarrows OH^- + H_3O^+$$

$$NH_3 + NH_3 \rightleftarrows NH_2^- + NH_4^+.$$

Neutralization. For a strong acid and a strong base in water, the neutralization reaction is between hydrogen and hydroxide ions; *i.e.,* $H_3O^+ + OH^- \rightleftarrows 2H_2O$. For a weak acid and a weak base neutralization is more appropriately considered to involve direct proton transfer from the acid to the base. For example, the neutralization of acetic acid by ammonia may be written as $CH_3CO_2H + NH_3 \rightarrow CH_3CO_2^- + NH_4^+$. This equation does not involve the solvent; it therefore also represents the process of neutralization in an inert solvent, such as benzene, or in the complete absence of a solvent. (If one of the reactants is present in large excess, the reaction is more appropriately described as the dissociation of acetic acid in liquid ammonia, or of ammonia in glacial acetic acid.)

Acidic and basic salt solutions

Hydrolysis of salts. Many salts give aqueous solutions with acidic or basic properties. This is termed hydrolysis, and the explanation of hydrolysis reactions in classical acid–base terms was somewhat involved. In terms of the Brønsted–Lowry concept, however, hydrolysis appears to be a natural consequence of the acidic properties of cations derived from weak bases and the basic properties of anions derived from weak acids. For example, hydrolysis of aqueous solutions of ammonium chloride and of sodium acetate is represented by the following equations:

$$(Cl^-) + NH_4^+ + H_2O \rightleftarrows (Cl^-) + NH_3 + H_3O^+$$

$$(Na^+) + H_2O + CH_3CO_2^- \rightleftarrows (Na^+) + OH^- + CH_3CO_2H$$

The sodium and chloride ions take no part in the reaction and could equally well be omitted from the equations.

The acidity of the solution represented by the first equation is due to the presence of the hydronium ion (H_3O^+) and the basicity of the second comes from the hydroxide ion (OH^-). The reverse reactions simply represent, respectively, the neutralization of aqueous ammonia by a strong acid and of aqueous acetic acid by a strong base.

A superficially different type of hydrolysis occurs in aqueous solutions of salts of some metals, especially those giving multiply charged cations. For example, aluminum, ferric, and chromic salts all give aqueous solutions that are acidic. This behaviour also can be interpreted in terms of proton-transfer reactions if it is remembered that the ions involved are strongly hydrated in solution. In a solution of an aluminum salt, for instance, a proton is transferred from one of the water molecules in the hydration shell to a molecule of solvent water. The resulting hydronium ion (H_3O^+) accounts for the acidity of the solution:

$$Al(H_2O)_6^{3+} + H_2O \rightleftarrows Al(H_2O)_5OH^{2+} + H_3O^+.$$

Formation of adducts

Reactions of Lewis acids. In the reaction of a Lewis acid with a base the essential process is the formation of an adduct in which the two species are joined by a covalent bond; proton transfers are not normally involved. If both the Lewis acid and base are uncharged, the resulting bond is termed semipolar or coordinate, as in the reaction of boron trifluoride with ammonia.

$$\underset{\text{acid}}{BF_3} + \underset{\text{base}}{NH_3} \rightarrow \underset{\text{adduct.}}{F_3\overset{-}{B}{-}\overset{+}{N}H_3}$$

Frequently, however, either or both species bears a charge (most commonly a positive charge on the acid or a negative charge on the base), and the location of charges within the adduct often depends upon the theoretical interpretation of the valences involved. Examples of such reactions are:

$$\underset{\text{silver ion}}{Ag^+} + \underset{\text{ammonia}}{2NH_3} \rightarrow \underset{\text{adduct}}{[Ag(NH_3)_2]^+}$$

$$\underset{\text{boron trifluoride}}{BF_3} + \underset{\text{hydroxide ion}}{OH^-} \rightarrow \underset{\text{adduct}}{[BF_3(OH)]^-}$$

$$\underset{\text{cadmium ion}}{Cd^{2+}} + \underset{\text{cyanide ion}}{4CN^-} \rightarrow \underset{\text{adduct.}}{[Cd(CN)_4]^{2-}}$$

In another common type of process, one acid, or base, in an adduct is replaced by another:

$$\underset{\text{adduct (1)}}{Cl_4\overset{-}{Sn}{-}\overset{+}{N}H_3} + \underset{\text{acid (2)}}{BF_3} \rightarrow \underset{\text{adduct (2)}}{F_3\overset{-}{B}{-}\overset{+}{N}H_3} + \underset{\text{acid (1)}}{SnCl_4}$$

$$\underset{\text{adduct (1)}}{Al(H_2O)_6^{3+}} + \underset{\text{base (2)}}{6F^-} \rightarrow \underset{\text{adduct (2)}}{AlF_6^{3-}} + \underset{\text{base (1).}}{6H_2O}$$

In fact, reactions such as the simple adduct formations above often are formulated more correctly as replacements. For example, if the reaction of boron trifluoride with ammonia is carried out in ether as a solvent, it becomes a replacement reaction:

$$(C_2H_5)_2\overset{+}{O}{-}\overset{-}{B}F_3 + NH_3 \rightarrow F_3\overset{-}{B}{-}\overset{+}{N}H_3 + (C_2H_5)_2O.$$

Similarly, the reaction of silver ions with ammonia in aqueous solution is better written as a replacement reaction:

$$Ag(H_2O)_2^+ + 2NH_3 \rightarrow Ag(NH_3)_2^+ + 2H_2O.$$

Furthermore, if most covalent molecules are regarded as adducts of (often hypothetical) Lewis acids and bases, an enormous number of reactions can be formulated in the same way. To take a single example, the reaction of methyl chloride with hydroxide ion to give methanol and chloride ion (usually written as $CH_3Cl + OH^- \rightarrow CH_3OH + Cl^-$) can be reformulated as replacement of a base in a Lewis acid–base adduct, as follows: (adduct of CH_3^+ and Cl^-) + OH^- → (adduct of CH_3^+ and OH^-) + Cl^-. Opinions differ as to the usefulness of this extremely generalized extension of the Lewis acid–base-adduct concept.

Reactions of anhydrous oxides

The reactions of anhydrous oxides (usually solid or molten) to give salts may be regarded as examples of Lewis acid–base-adduct formation. For example, in the reaction of calcium oxide with silica to give calcium silicate, the calcium ions play no essential part in the process, which may be considered therefore to be adduct formation between silica as the acid and oxide ion as the base:

$$\underset{\text{acid}}{SiO_2} + \underset{\text{base}}{O^{2-}} \rightarrow \underset{\text{adduct.}}{SiO_3^{2-}}$$

A great deal of the chemistry of molten-oxide systems can be represented in this way, or in terms of the replacement of one acid by another in an adduct.

Acid–base catalysis. Acids (including Lewis acids) and bases act as powerful catalysts for a great variety of chemical reactions, in the laboratory, in industry, and in processes occurring in nature. Historically, catalytic action was regarded as one of the essential characteristics of acids, and the parallel occurrence of catalytic action and electrical conductivity was one of the compelling pieces of evidence in establishing the theory of electrolytic dissociation as the basis of acid–base behaviour at the end of the 19th century.

Acid–base catalysis was originally thought of in terms of a mysterious influence of the acid or base, but it is now generally believed to involve an actual acid–base reaction between the catalyst and the reacting substance, termed the substrate, with the catalyst being regenerated at a later stage of the reaction. Moreover, knowledge of reaction mechanisms is now sufficient to suggest detailed sequences of reactions for many acid- or base-catalysis reactions, most of which sequences are at least plausible and in many instances are well established.

Regeneration of the catalyst

In most acid–base reactions the addition or removal of a proton does not bring about any drastic change in the structure of the molecule, or in its stability or reactivity. It is a characteristic of reactions catalyzed by acids or bases, however, that the addition or removal of a proton either makes the substrate unstable, so that it decomposes or rearranges, or that it causes the substrate to become reactive toward some other species present in the system. In cases of rearrangement, the regeneration of the catalyst often involves the removal or addition of a proton at a site other than that at which the initial addition or removal took place. It is not necessary that the substrate in an acid- or base-catalyzed reaction should itself have marked acid–base properties, since even a very small extent of initial acid–base reaction may be enough to bring about the subsequent change.

Instances of acid–base catalysis are numerous indeed; a few examples are given here, as follows:

Isomerization of olefins, acid-catalyzed. Unsaturated compounds frequently rearrange reversibly under the influence of acids to give products in which the double bond occurs in a new location. The interconversion of 2-butene and 1-butene is shown here:

$$CH_3CH = CHCH_3 + H_3O^+ \rightleftarrows CH_3CH_2\overset{+}{C}HCH_3 + H_2O$$

$$CH_3CH_2\overset{+}{C}HCH_3 + H_2O \rightleftarrows CH_3CH_2CH = CH_2 + H_3O^+.$$

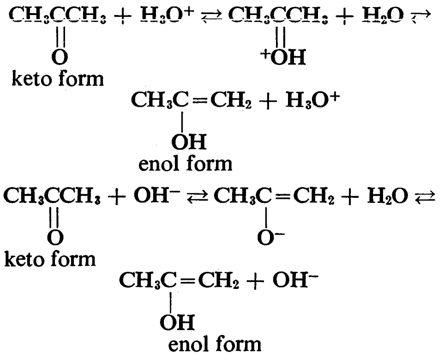
Reversible dehydration of alcohols, acid-catalyzed. Under the influence of acids, alcohols generally undergo loss of water to give olefinic products. The dehydration of ethanol to ethylene occurs as follows:

$$CH_3CH_2OH + H_3O^+ \rightleftarrows CH_3CH_2OH_2^+ + H_2O$$

$$CH_3CH_2OH_2^+ \rightleftarrows CH_3CH_2^+ + H_2O \rightleftarrows$$

$$CH_2 = CH_2 + H_3O^+.$$

Keto–enol tautomerism, acid- and base-catalyzed. Acids and bases both bring about the establishment of an equilibrium between ketones (or aldehydes) and their enol forms, which contain a hydroxyl group directly attached to a doubly bonded carbon atom ($-\underset{\mathrm{OH}}{\underset{|}{C}} = C-$). The interconversion between the two forms is called keto–enol tautomerism. The reaction cannot always be observed directly, since the enol form may not reach measurable concentrations, even at equilibrium, but the highly active enol may be detected by its reaction with various reagents, notably the halogens (bromine, for example). Keto–enol tautomerization of acetone can be brought about by acid or base catalysis, as follows:



$$\underset{\text{keto form}}{CH_3\underset{O}{\underset{\|}{C}}CH_3} + H_3O^+ \rightleftarrows CH_3\underset{^+OH}{\underset{\|}{C}}CH_3 + H_2O \rightleftarrows \underset{\text{enol form}}{CH_3\underset{OH}{\underset{|}{C}}{=}CH_2} + H_3O^+$$

$$\underset{\text{keto form}}{CH_3\underset{O}{\underset{\|}{C}}CH_3} + OH^- \rightleftarrows CH_3\underset{O^-}{\underset{|}{C}}{=}CH_2 + H_2O \rightleftarrows \underset{\text{enol form}}{CH_3\underset{OH}{\underset{|}{C}}{=}CH_2} + OH^-$$

Aldol condensation, base-catalyzed. Self-condensation of aldehydes, the so-called aldol condensation, occurs readily, when catalyzed by bases, to give β-hydroxy aldehydes. The prototype of this reaction is the conversion of acetaldehyde to β-hydroxybutyraldehyde, or aldol. The first step of this reaction is the production of an enolate ion (as in formation of the keto–enol tautomeric mixture), but this anion then reacts with a second molecule of acetaldehyde to give the product as shown below:

$$CH_3CHO + OH^- \rightleftarrows [CH_2CHO]^- + H_2O$$

$$CH_3CHO + [CH_2CHO]^- \rightleftarrows CH_3CH(O^-)CH_2CHO$$

$$CH_3CH(O^-)CH_2CHO + H_2O \rightleftarrows \underset{\text{aldol}}{CH_3CHOHCH_2CHO} + OH^-$$

Importance of acid–base catalysis

These examples illustrate the importance of acid–base catalysis in organic reactions. The equations have been written in terms of H_3O^+ and OH^- as the acid and base catalysts, respectively, and these are certainly the most important catalysts in aqueous solution. For many of these reactions (especially isomerization of olefins and dehydration of alcohols), there is ample evidence that other acids or bases also can act as catalysts. This behaviour is known as general acid–base catalysis. It appears particularly clearly in inert solvents such as benzene, in which catalysis by molecular acids and bases is frequently observed despite the absence of detectable quantities of ions derived from the solvent. Acidic groups, such as sulfonic acid ($-SO_3H$) and carboxylic acid groups ($-CO_2H$), attached to a solid molecular framework (as in some ion exchange resins) also act as heterogeneous catalysts for many chemical reactions.

The above examples show that proton-transfer processes can play a specific part in reaction mechanisms and, in these and similar instances, it is doubtful whether any uncatalyzed or spontaneous reaction of the same type can take place. Apparent evidence to the contrary can usually be explained by catalysis by solvent molecules or by adventitious acidic or basic impurities.

Lewis-acid catalysis

Lewis acids can exert a catalytic effect in two different ways. In the first of these they interact with hydrogen-containing compounds present in the system to assist the release of a proton to the substrate. For example, the polymerization of olefins by Lewis acids, such as boron trifluoride (BF_3), aluminum chloride ($AlCl_3$), and titanium tetrachloride ($TiCl_4$), is believed to be caused by their interaction with proton acids (for example, traces of water) and the olefin to give a carbonium ion, which then reacts further with more olefin:

$$BF_3 + H_2O + CHR = CHR' \rightarrow CH_2R{-}\overset{+}{C}HR' + [BF_3OH]^-$$

$$CH_2R{-}\overset{+}{C}HR' + CHR = CHR' \rightarrow CH_2RCHR'CHR\overset{+}{C}HR', \text{ etc.}$$

In the second mode of action, the Lewis acid acts directly on the substrate, and by withdrawing electrons converts it into a reactive form. A typical example is the action of catalysts like aluminum chloride on alkyl halides to produce carbonium ions: $RCl + AlCl_3 \rightarrow R^+ + [AlCl_4]^-$. The carbonium ion can then react further with other substances, for example, aromatic hydrocarbons. The same type of catalysis probably occurs with many solid oxide catalysts (for example, aluminosilicates), although it is often difficult to decide whether the catalytic action of these materials is due to centres with a deficiency of electrons or to acidic hydroxyl groups.

ACID–BASE EQUILIBRIA

Certain general principles apply to any solvent with both acidic and basic properties, for example, water, alcohols, ammonia, amines, and acetic acid. Denoting the solvent molecule by SH, proton transfer can give rise to the ions SH_2^+ and S^-, sometimes called lyonium and lyate ions, respectively (see above). In the pure solvent these are the only ions present, and they must be present in equal concentrations to preserve electrical neutrality. The equilibrium involved, therefore, is as follows: $2SH \rightleftarrows SH_2^+ + S^-$.

Equilibrium constants

The equilibrium constant (K_s') for this reaction (the mathematical quantity that expresses the relationships between the concentrations of the various species present at equilibrium) would normally be given by the equation $K_s' = [SH_2^+]\ [S^-]/[SH]^2$, in which the square brackets denote the concentrations of the species within the brackets. In a given solvent, however, the concentration of the solvent, [SH], is a large and constant quantity, and it is therefore usual to eliminate this term and express the self-dissociation of the solvent by the equation $K_s = [SH_2^+][S^-]$. In this equation, K_s is termed the ion product or the autoprotolysis constant of the solvent. The concentrations are usually expressed in moles per litre, a mole being the molecular weight of the compound in grams. Since a solvent that is a good proton donor is normally a poor proton acceptor, and vice versa, the degree of ionization is generally low and K_s is usually a small quantity. It is about 10^{-14} for water at ordinary temperatures, and one of the largest K_s values known is 1.7×10^{-4} for 100 percent sulfuric acid. The above equation applies not only to the pure solvent, but also (with the same value of K_s) to any dilute solutions of acids, bases, or salts in the solvent in question. In these solutions $[SH_2^+]$ and $[S^-]$ need not be equal, since the condition of electrical neutrality involves the concentration of other ions as well, and it is obvious from the equation that a high value of $[SH_2^+]$ must imply a low value of $[S^-]$, and vice versa.

If an acid A is added to the solvent SH it will be at least partly converted into the conjugate base B according to the reaction $A + SH \rightleftarrows B + SH_2^+$, which would be characterized formally by an equilibrium constant $[B][SH_2^+]/[A]\ [SH]$. Again, however, it is usual to omit the term for the constant concentration of the solvent, [SH], from this expression, and to define a constant K_a by the equation

$$\frac{[B]\ [SH_2^+]}{[A]} = K_a,$$

Dissociation constants

which is known as the dissociation constant of the acid A in the solvent SH. Any acid–base reaction $A_1 + B_2 \rightleftarrows B_1 + A_2$ will proceed from left to right almost completely if A_1 is a much stronger acid than A_2. It is a natural extension of this idea to use the equilibrium constant as a measure of the strength of A_1 relative to A_2. The dissociation constant is thus (apart from the constant factor [SH], which has been omitted) a measure of the acid strength of A relative to that of the lyonium ion SH_2^+.

In some instances reaction goes so completely from left to right that it is not possible to measure the equilibrium constant. A is said then to be a strong acid in the solvent SH; similarly, acids with readily measurable dissociation constants (in practice less than about 0.1) are known as weak acids.

Similar considerations apply to solutions of bases. The reaction involved in this case is $SH + B \rightleftarrows S^- + A$ and the equilibrium constant K_b defined by

$$\frac{[S^-]\ [A]}{[B]} = K_b$$

is known as the dissociation constant of the base B. Apart from the omitted constant factor [SH], K_b represents the basic strength of B relative to that of the lyate ion S^-. Bases are termed strong and weak in the same way that acids are.

The values of K_a and K_b for a conjugate acid–base pair A–B in a given solvent are not independent, since consideration of the dissociation constants of the solvent, acid, and base show that $K_aK_b = [SH_2^+][S^-] = K_s$ in which K_s is the ion product of the solvent. It is therefore unnecessary to specify both K_a and K_b, and it has become common practice to characterize an acid–base pair by K_a only, which may be termed the acidity constant of A–B in the solvent SH. If the value of K_b is required it is readily obtained from K_a and K_s. Since readily accessible values of K_a are always much less than unity, it is often convenient to introduce a quantity pK_a, sometimes called the acidity exponent, and defined by the relation $pK_a = -\log_{10}K_a$. Values of pK_a are generally of a more convenient magnitude.

Acidity exponent

The above expressions for the various equilibrium constants depend only on the concentrations of the species concerned, which are tacitly assumed to exist in solution independently of one another. This is not always the case, and in exact treatments of these equilibria two modifications are frequently necessary. In the first place, some or all of the reacting species are ions and, because of the electrical forces between them, the law expressing their concentrations at equilibrium is not always valid. Corrections may be applied by multiplying the concentrations by certain factors called activity coefficients, the values of which can be calculated theoretically or derived from other measurements. Furthermore, ions of opposite charge may attract one another so strongly that they no longer exist independently but are partly present as ion pairs, thus altering the forms of the equilibrium equations. For many purposes, however, the simple equations given here are adequate, especially with regard to reactions in aqueous solutions.

Ion product of water

Aqueous solutions. Since aqueous solutions are of particular importance in the laboratory and in the physiology of animals and plants, it is appropriate to consider them separately. The ion product of water, $K_w = [H_3O^+]\ [OH^-]$, has the value 1.0×10^{-14} mole^{2}litre^{-2} at 25° C, but it is strongly temperature dependent, becoming 1.0×10^{-15} at 0° C and 7×10^{-13} at 100° C. In principle the value of K_w can be determined by measuring the electrical conductance of very pure water, in which $[H_3O^+] = [OH^-] = 10^{-7}$ at 25° C, but in practice it is derived from other measurements, for example, measurements of the degree of hydrolysis of salts.

For an uncharged acid, such as acetic, the dissociation constant is given by the following expression:

$$\frac{[CH_3CO_2^-]\,[H_3O^+]}{[CH_3CO_2H]} = K_a.$$

For this example (acetic acid) K_a has the value 1.76×10^{-5} at 25° C. It is often convenient to express the dissociation constant in terms of the degree of dissociation of the acid. This quantity, which is represented in equations by the Greek letter alpha, α, is equal to the fraction of the acid that appears in dissociated form—in this case as the ions $CH_3CO_2^-$ and H_3O^+. If the initial concentration of acid is designated by c, then the concentrations of the ions are each equal to αc, that is $[H_3O^+] = [CH_3CO_2^-] = Ac$, and the concentration of undissociated acid is equal to $c(1 - \alpha)$, or $[CH_3CO_2H] = c(1 - \alpha)$.

Substituting these expressions into the equation giving the value of the dissociation constant gives the following result: $\frac{a^2c}{1-a} = K_a$. From this equation it can be inferred that the degree of dissociation (a) increases with decreasing concentration (c). For small degrees of dissociation ($a < < 1$) the equation becomes $a = \frac{K_a^{\frac{1}{2}}}{c^{\frac{1}{2}}}$ whereas at sufficiently low concentrations ($c < < 1$) a tends to unity ($a \rightarrow 1$).

Discussions exactly analogous to this apply to a number of other acid–base equilibria, for example, (1) the dissociation of ammonia in water, (2) the hydrolysis of ammonium salts, and (3) the hydrolysis of an acetate.

$$(1)\ H_2O + NH_3 \rightleftarrows OH^- + NH_4^+$$

$$(2)\ NH_4^+ + H_2O \rightleftarrows NH_3 + H_3O^+$$

$$(3)\ H_2O + CH_3CO_2^- \rightleftarrows OH^- + CH_3CO_2H$$

Dissociations in water

For reaction (1) α is the degree of dissociation of ammonia, and the dissociation constant is K_b, the basic dissociation constant. In reaction (2), the hydrolysis of an ammonium salt (for example, ammonium chloride), α would be termed the degree of hydrolysis and K the hydrolysis constant. In terms of the general definition of acids and bases, however, K could equally be called the acidity constant for the acid–base pair NH_4^+–NH_3, and this is a more rational way of describing the process. Finally, reaction (3) represents the hydrolysis of an acetate (for example, sodium acetate); the resulting equilibrium constant is termed the hydrolysis constant and can be seen to equal K_w/K_a, where K_w is the ion product of water and K_a the acidity constant for the acid–base pair CH_3CO_2H–$CH_3CO_2^-$; *i.e.*, the dissociation constant of acetic acid. The investigation of equilibria such as this is, in fact, one of the methods for determining the value of K_w (see above).

The equilibria considered so far arise when one component of an acid–base pair is dissolved in water—if necessary, along with an ion, such as Na^+ or Cl^-, having negligible acid-base properties. The direct consequence of this is that the two new species produced (for example, those on the right-hand sides of the equations [1–3] above) have equal concentrations (αc), and hence the previously given equation $K = \frac{a^2c}{1-a}$ is applicable.

Buffered solutions

A solution of a more generally useful type can be obtained by deliberately varying the proportions of acid and base present; such a solution is called a buffered solution or, somewhat more colloquially, a buffer. A buffered solution containing various concentrations of acetic acid and acetate ion, for example, can be prepared by mixing solutions of acetic acid and sodium acetate, by partially neutralizing a solution of acetic acid with sodium hydroxide, or by adding less than one equivalent of a strong acid to a solution of sodium acetate. Similarly, a buffer based on the pair NH_4^+–NH_3 can be prepared by mixing solutions of ammonia and an ammonium salt, by partially neutralizing a solution of ammonia with a strong acid, or by adding less than one equivalent of sodium hydroxide to a solution of an ammonium salt. The hydrogen ion concentration in a buffer solution is, of course, still given by the usual equation, which is conveniently written as

$$[H_3O^+] = K_a\frac{[A]}{[B]}.$$

Hydrogen ion concentration and *p*H

Since hydrogen ion concentrations are usually less than unity, and cover an extremely wide range, it is often convenient to use instead the negative logarithm of the actual concentration, a figure that varies usually only in the range 1–13. This figure is termed the *p*H, and its definition is expressed by the equation $pH = -\log_{10}[H_3O^+]$. For example, in pure water $[H_3O^+] = 1 \times 10^{-7}$, with the result that the $pH = 7.0$. The same term can be applied to alkaline solutions; thus in 0.1 molar sodium hydroxide $[OH^-] = 0.1$, $[H_3O^+] = K_w/[OH^-] = 1 \times 10^{-14}/0.1 = 10^{-13}$, $pH = 13.0$.

Applying the concept of *p*H to buffered solutions gives the following equation: $pH = pK_a - \log_{10}\frac{[A]}{[B]}$ in which $\frac{[A]}{[B]}$, known as the buffer ratio, can be calculated from the way in which the solution is prepared. According to this equation, the *p*H of the buffered solution depends only on the pK_a of the acid and on the buffer ratio. Most particularly it does not depend on the actual concentrations of A and B. Therefore, the *p*H of a buffered solution is little affected by dilution of the solution. It is also insensitive to the addition of acid or alkali, provided that the amounts added are much smaller than both [A] and [B]. This so-called buffering action will be impaired if either [A] or [B] becomes too small; hence, buffer ratios must not deviate too far from unity, and the effective buffering range of a given acid–base system is roughly from $pH = pK_a + 1$ to $pH = pK_a - 1$, corresponding to buffer ratios from 0.1 to 10.

Buffer action

Figure 5 shows the relation between *p*H and composition for a number of commonly used buffer systems. Effective buffer action is confined to the central, steep portion of each curve, where the *p*H is least sensitive to the composition. Figure 5 shows that an acid bearing several acidic hydrogens, such as phosphoric acid, can be used to prepare buffer solutions in several different *p*H ranges. Buffer action plays an important part in controlling the *p*H of many biological fluids; for example, the *p*H of the blood is controlled at about 7.4 by the carbonic acid–bicarbonate system shown in Figure 5. Buffers are widely used to control the *p*H in chemical or biological experiments. For the latter, the system $H_2PO_4^-$–HPO_4^{2-} is particularly useful, being effective in the physiological *p*H range, 6–8.

From N.J. Bjerrum, *Inorganic Chemistry* (1936); Heinemann Educational Books Ltd.

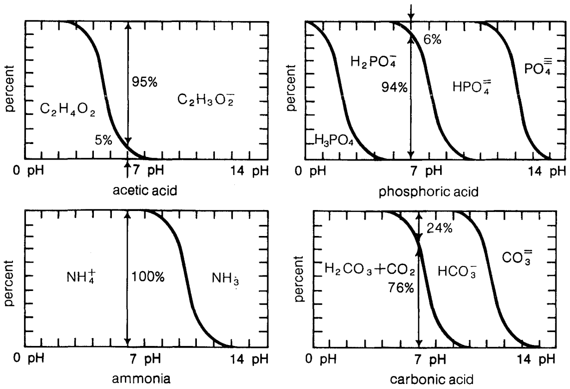


Figure 5: Relation between *p*H and composition for a number of commonly used buffer systems.

The same principles can be applied for the quantitative treatment of systems containing larger numbers of acid–base pairs; for example, in an aqueous solution of ammonium acetate, the following acid–base pairs must be considered: NH_4^+–NH_3, CH_3CO_2H–$CH_3CO_2^-$, H_3O–H_2O, and H_2O–OH^-. The situation is much more complicated in many solutions that are important in industry or in nature, but it is always possible to make a complete prediction of the state of the system in terms of the acidity constants K_a of each acid–base pair (provided, of course, that reactions other than proton transfers do not interfere).

Nonaqueous solvents. Although acid–base properties have been investigated most thoroughly in aqueous solutions, partly because of their practical importance, water is in many respects an abnormal solvent. In particular, it has a higher dielectric constant (a measure of the ability of the medium to reduce the force between two electric charges) than most other liquids, and it is able itself to act either as an acid or as a base. The behaviour of acids and bases in several other solvents will be described briefly here.

Effects of solvent on dissociation

The effect of the solvent on the dissociation of acids or bases depends largely upon the basic or acidic properties of the solvent, respectively. Since many acid–base reactions involve an increase or decrease in the number of ions, they are also influenced by the dielectric constant of the solvent, for a higher dielectric constant favours the formation of ions. Finally, the specific solvation (or close association with the solvent) of particular ions (excluding the solvation of the proton to give SH_2^+, which is already included in the basicity of the solvent) may be important. It is usually not easy to separate these three effects and, in particular, the effects of dielectric constant and solvation merge into one another. These points are illustrated with examples of several of the more important solvents. In this discussion the solvents are classified as amphoteric (both acidic and basic), acidic (in which the acidic properties are much more prominent than the basic), basic (in which the reverse is true), and aprotic (in which both acidic and basic properties are almost entirely absent). Finally, concentrated aqueous acids are mentioned as an example—a particularly important one—of mixed solvents.

Amphoteric solvents. The most important nonaqueous solvents of this class are the lower alcohols methanol and ethanol. They resemble water in their acid–base properties but, because of their lower dielectric constants, facilitate processes producing ions to a much smaller extent. In particular, the ion products of these solvents are much smaller ($K_s = 10^{-17}$ for CH_3OH and 10^{-19} for C_2H_5OH, compared with 10^{-14} for water), and the dissociation constants of molecular acids and bases are uniformly lower than in water by four to five powers of 10. Nitric acid, for example, which is almost completely dissociated in water (K_a about 20), has $K_a = 2.5 \times 10^{-4}$ in methanol. On the other hand, the equilibrium constants of processes such as $NH_4^+ + ROH \rightleftarrows NH_3 + ROH_2^+$ and $CH_3CO_2^- + ROH \rightleftarrows CH_3CO_2H + RO^-$ are similar in all three solvents, since they do not involve any change in the number of ions.

Sulfuric acid as solvent

Acidic solvents. The most important strongly acidic solvent is sulfuric acid, which is able to protonate a wide variety of compounds containing oxygen or nitrogen. Thus, water, alcohols, ethers, ketones, nitro compounds, and sulfones all act as bases in sulfuric acid. This solvent must also possess some basic properties, because its ionic product is high ($[H_3SO_4^+]\,[HSO_4^-] = 1.7 \times 10^{-4}$), but the basicity of the solvent is obscured normally by its very high acidity. For example, carboxylic acids behave as strong bases in sulfuric acid, reacting almost completely according to the equation $RCO_2H + H_2SO_4 \rightarrow RCO_2H_2^+ + HSO_4^-$. Many substances undergo reactions in sulfuric acid that are more complicated than simple proton transfers, often yielding species important because of their chemical reactivity. Thus, some alcohols produce carbonium ions in sulfuric acid; with triphenylcarbinol, for example, the reaction is $(C_6H_5)_3COH + 2H_2SO_4 \rightarrow (C_6H_5)_3\,C^+ + H_3O^+ + 2HSO_4^-$. Nitric acid gives the nitronium ion, NO_2^+, according to the equation $HNO_3 + 2H_2SO_4 \rightarrow NO_2^+ + H_3O^+ + 2HSO_4^-$. This ion frequently is the active agent in the nitration of organic compounds. Hydrogen fluoride has solvent properties resembling those of sulfuric acid, but is less acidic and has negligible basic properties.

Acetic acid is another acidic solvent that has been extensively studied. Because of its low dielectric constant, ions exist in it largely in the form of ion pairs, and more complex associates are frequently formed. For this reason a quantitative interpretation of acid–base equilibria in acetic acid is often difficult, but some general conclusions can be drawn. In particular, it can be seen that all substances more basic in water solution than aniline react completely with acetic acid according to the equation $B + CH_3CO_2H \rightarrow BH^+ + CH_3CO_2^-$. All such bases therefore give solutions with indistinguishable acid–base properties; this is often referred to as a levelling effect of the solvent. The converse is true for acids; for example, the strong mineral acids, nitric, hydrochloric, sulfuric, hydrobromic, and perchloric (HNO_3, HCl, H_2SO_4, HBr, and $HClO_4$) are "levelled" in aqueous solution by complete conversion to the hydronium ion, but in acetic acid they are differentiated as weak acids with strengths in the approximate ratio 1 : 9 : 30 : 160 : 400.

Basic solvents. The only basic solvent that has been investigated in any detail is liquid ammonia, which has the very low ion product $[NH_4^+]\,[NH_2^-] = 10^{-33}$. As might be expected, this solvent has a marked levelling effect upon acids; thus, for example, acetic, benzoic, nitric, and hydrochloric acids all give solutions with identical acidic properties, due to the ion NH_4^+—although, of course, in water they behave very differently.

Aprotic solvents. Strictly aprotic solvents include the hydrocarbons and their halogen derivatives, which undergo no reaction with added acids or bases. Acid–base equilibrium in these solvents can be investigated only when a second acid–base system is added; the usual reaction $A_1 + B_2 \rightleftarrows B_1 + A_2$ then takes place. Most such investigations have employed an indicator as one of the reacting systems, but the results are often difficult to interpret because of association of both ions and molecules in these media of low dielectric constant.

The term aprotic has been extended recently to include solvents that are unable to lose a proton, although they may have weakly basic properties. Some of these aprotic solvents have high dielectric constants (for example, N, N-dimethylformamide, dimethyl sulfoxide, and nitrobenzene) and are good solvents for a variety of substances. They have a powerful differentiating effect on the properties of acids and bases. In particular, basic anions are poorly solvated in these solvents and thus behave as very strong bases; for example, it has been estimated that sodium methoxide dissolved in dimethyl sulfoxide gives a solution 10^9 times as basic as in methanol.

Acidity function

Concentrated aqueous acids. Dilute solutions of strong acids, for example, hydrochloric, sulfuric, and perchloric (HCl, H_2SO_4, $HClO_4$), in water behave essentially as solutions of the ion H_3O^+, and their acidity increases in proportion to their concentration. At concentrations greater than about one molar (that is, containing one mole of acid per litre of solution), however, the acidity, as measured by action on indicators or by catalytic ability, increases much more rapidly than the concentration. For example, a 10 molar solution of any strong acid is about 1,000 times as acidic as a 1 molar solution. This behaviour is undoubtedly largely due to the depletion of water with increasing concentration of acid; the hydronium ion, H_3O^+, is known to have a strong tendency to further hydration, probably mainly to the ion $H_3O^+(H_2O)_3$ (*i.e.*, $H_9O_4^+$), and a decrease in water content increases the proton-donating power of the solution. The acidity of these concentrated solutions is commonly measured by the acidity function, H_0, a quantity measured by the effect of the solvent on a basic indicator I. It is defined by $H_0 + pK_{IH}{}^+ - \log_{10}[IH^+]/[I]$ and becomes equal to the pH in dilute solution. The acidity function H_0 is often found to be independent of the nature of the indicator and to give an approximate measure of the catalytic power of the acid solution. Sulfuric acid–water mixtures ranging from 10 to 100 percent sulfuric acid have H_0 values between −0.3 and −11.1, corresponding to an acidity range of nearly 11 powers of 10.

Lewis acids. Much less information is available about Lewis acid–base equilibria than about ordinary acid–base equilibria, but it is clear that the situation is less simple for the former than for the latter. When a given Lewis acid reacts with a series of similarly constituted bases the equilibrium constants often vary in parallel with the conventional basic strengths. This is the case when a zinc halide, ZnX_2, for example, reacts with a series of amines. In general, however, it is not possible to arrange Lewis acids and bases in a unique order that will predict the extent to which a given pair will react. Thus, although the hydroxide ion (OH^-) is always a much stronger base than ammonia (NH_3) in reactions with proton acids, in reactions with the Lewis acid Ag^+, the complex $Ag(NH_3)_2^+$ is fairly stable, whereas AgOH is completely dissociated. Similarly, for some metal cations complex formation increases in the order fluoride < chloride < bromide < iodide, whereas for other metal cations the order is the reverse of this.

This kind of behaviour has led to a classification of Lewis acids and bases into "hard" and "soft" categories; as a rule, hard acids react preferentially with hard bases and, similarly, soft acids react with soft bases. The terms hard and soft are chosen to suggest that the atomic structures associated with hard acids and bases are rigid and impenetrable, whereas those associated with soft acids and bases are more readily deformable. Hard acids include the proton; sodium, calcium, and aluminum ions; and carbonium ions. The soft acids include cuprous, silver, mercurous, and the halogen cations. Typical soft bases are iodide, thiocyanate, sulfide, and triphenylphosphine; whereas hard bases include hydroxide, fluoride, and many oxyanions. The dividing line between the hard and soft categories is not a sharp one, and its theoretical interpretation is obscure. Nevertheless, a surprising amount of factual information can be coordinated on the basis of preferential reactions of hard acids with hard bases and soft acids with soft bases.

Hard and
soft acids
and bases

The effect of molecular structure. Regularities and trends in the properties of the elements are best understood in terms of the periodic table, an orderly pattern seen when the elements are arranged in order of increasing atomic number. Comparing the hydrides of the various elements in the table reveals appreciable acidity only among those of the elements on the right-hand side of the table, especially the halogen elements—fluorine, chlorine, bromine, and iodine. This generalization is borne out when the elements across the first period of the table are examined in order; as the right-hand side of the table is approached the elements encountered are carbon, nitrogen, oxygen, and fluorine. The hydrides of these elements show increasing acidity. Methane, CH_4, a hydride of carbon, has no detectable acidic properties, and the pK_a decreases sharply in the series ammonia (NH_3), 35; water (H_2O), 16; and hydrogen fluoride (HF), 4. In any given group of the periodic table, the acidity of the hydrides increases as the group is descended. For example, the two groups at the right-hand side of the table include, respectively, and in descending order, the elements oxygen, sulfur, selenium, and tellurium; and fluorine, chlorine, bromine, and iodine. The pK_a's of the hydrides of the first group are as follows: water (H_2O), 16; hydrogen sulfide (H_2S), 7; hydrogen selenide (H_2Se), 4; and hydrogen telluride (H_2Te), 3. Similarly, hydrogen fluoride (HF) is a weak acid, whereas hydrogen chloride (HCl), hydrogen bromide (HBr), and hydrogen iodide (HI) are all completely dissociated (are strong acids) in aqueous solution. These trends are due to variations in bond strength, electronegativity (attractive power of the atomic nucleus for electrons), and ionic solvation energy, of which the first is the most important. When a hydride is able to lose two or more protons, the loss of the second is always more difficult because of the increased negative charge on the base—*e.g.*, $H_2S - HS^-$ (pK 7), $HS^- - S^{2-}$ (pK 15); similarly, $NH_4^+ - NH_3$ (pK 9.5), $NH_3 - NH_2^-$ (pK 35).

A simple rule applies to the strengths of the oxyacids, which can be given the general formula $XO_n(OH)_m$, in which X is any nonmetal. In these compounds, the pK decreases with increasing n, but does not depend significantly upon m. When $n = 0$ (*e.g.*, ClOH, $Si(OH)_4$), pK_a is between 8 and 11; $n = 1$ (*e.g.*, HNO_2, H_2SO_3) gives pK_a 2–4; whereas with $n = 2$ or 3 (*e.g.*, H_2SO_4, $HClO_4$), the acids are completely dissociated in water ($pK_a < 0$).These regularities are probably attributable to the sharing of the negative charge of the anion between $n + 1$ equivalent oxygen atoms; the more extensive the charge spread, the lower is the energy of the anion and hence the stronger the acid.

Strengths
of oxyacids

The most important groups of organic acids are the alcohols (including the phenols) and the carboxylic acids. The simple alcohols are very weak acids (pK 16–19); the phenols are considerably stronger ($pK \sim 10$); and the carboxylic acids stronger still ($pK \sim 5$). The strength of the carboxylic acids is due to the sharing of the negative charge between two equivalent oxygen atoms in the ion RCO_2^-. The most important organic bases are the amines, RNH_2, R_2NH, or R_3N. Most of these are stronger bases than ammonia; *i.e.*, their cations are weaker acids than the ammonium ion.

The effect of substituents on the acid–base properties of organic molecules has been very extensively studied and is one of the main methods of investigating the nature of the electron displacements produced by substitution in these molecules. The simplest classification is into electron-attracting substituents (halogens, carbonyl, nitro, and positively charged groups) and electron-repelling groups (alkyl groups, negatively charged groups). The electron-attracting groups make acids stronger and bases weaker, whereas electron-repelling groups have the opposite effects. There are, however, often more specific electronic effects, especially in aromatic and unsaturated compounds, for which special explanations are needed.

EXPERIMENTAL STUDIES OF ACIDITY AND BASICITY

Dissociation constants in aqueous solution. The classical method for determining the dissociation constant of an acid or a base is to measure the electrical conductivity of solutions of varying concentrations. From these the degree of dissociation (α, see above) can be determined and K_a calculated from the equation:

$$K_a = \frac{\alpha^2 c}{1 - \alpha}.$$

Measurements of
electrical
conductivity

This method is unsuitable for acids with pK less than 2 because α is then close to unity and the value $1 - \alpha$ is therefore subject to error. It also is unsuitable for acids of $pK > 7$, because impurities in the solvent may affect the conductivity or displace the dissociation equilibrium.

It is often preferable to use a more specific method for determining the concentration of one of the species in the scheme $A + H_2O \rightleftarrows B + H_3O^+$. For example, a hydrogen electrode (or more commonly a glass electrode, which responds in the same way) together with a reference electrode, commonly the calomel electrode, serves to measure the actual hydrogen ion concentration, or the pH, of the solution. If E is the electromotive force (in volts) observed by the electrode, the equation giving the pH is as follows:

$$E = E_o + 0.059 \log_{10} [H_3O^+] = E_o - 0.059\, pH.$$

In this equation, the value of E_0 depends on the nature of the reference electrode and is usually obtained by calibration with a solution of known pH. Measurements can be made on aqueous solutions of the acid, in which case $[B] = [H_3O^+]$, but it is better to use a series of buffer solutions with known ratios [A]/[B], since these are less sensitive to the presence of impurities. Such a series is obtained by successive additions of alkali to a solution of the acid (or of a strong acid to a solution of the base) and the procedure is then often termed a pH titration.

If A and B have different optical properties—for example, if they differ in colour or in the absorption of ultraviolet light—this property can be used to measure the ratio [A]/[B], commonly by using an instrument called a spectrophotometer. Since $[H_3O^+]$ must also be known, the commonest procedure is to measure [A]/[B] in a solution made by adding a small quantity of A or B to a standard buffer solution. If A and B do not have convenient optical properties—as is commonly the case—an indicator, that is, an acid–base system that does show a difference in colour in changing from A to B, is used. If a small quantity of indicator A_I–B_I, with acidity constant K_I, is added to a buffer solution A–B, it is easily shown that the following relation holds:

$$K_A = K_I \frac{[B]}{[A]} \cdot \frac{[A_I]}{[B_I]},$$

in which $[A_I]/[B_I]$ is measured spectrophotometrically, and

Table 2: pK_a's of Representative Acids and Bases

	pK_a		pK_a
Inorganic acids		**Carboxylic acids**	
Boric acid	9.1 (20° C)	Formic	3.75 (20° C)
Hypochlorous acid	7.53 (18° C)	Acetic	4.75
Hydrogen sulfide	7.0, 11.9 (18° C)	Chloroacetic	2.85
Carbonic acid	6.4, 10.3	Dichloroacetic	1.48
Phosphoric acid	2.1, 7.2, 12.8	Trichloroacetic	0.70
Sulfurous acid	1.8, 6.9 (18° C)	Oxalic	1.23, 4.19
Nitric acid	−1.6	Malonic	2.83, 5.69
Sulfuric acid	(−3), 1.9	Benzoic	4.19
Hydrogen chloride	(−7)	**Nitrogen bases**	
Perchloric acid	(−8)	Methylamine	10.66
Inorganic bases		Dimethylamine	10.73
Ammonia	9.25	Trimethylamine	9.81
Hydrazine	−0.9, 8.23 (20° C)	Piperidine	11.12
Hydroxylamine	6.03 (20° C)	Aniline	4.63
Alcohols and phenols		Pyridine	5.25
Methanol	15.5	Quinoline	4.90 (20° C)
Trifluoroethanol	12.37	Pyrrole	−0.27
Phenol	9.89		
o-Nitrophenol	7.17		
m-Nitrophenol	8.28		
p-Nitrophenol	7.15		
o-Chlorophenol	8.49		
m-Chlorophenol	8.85		
p-Chlorophenol	9.18		
Picric acid	0.38		

all the other quantities on the right-hand side of the equation are known.

If accurate values of K are required, it is necessary in all the above methods to take into account the effect of interionic forces upon the equation and the quantities measured. This factor can induce a considerable degree of complexity into the problem.

Selected values of acidity constants. Table 2 contains acidity constants for selected substances. These are listed as acids or bases according to the nature of the uncharged species, but in each case the value given is (pK_a) for the acid form (pK_a and pK_b for a conjugate acid–base pair being related by the equation

$$pK_a + pK_b = pK_w = 14.00$$

for aqueous solutions at 25° C). For instances in which several values of pK_a are given, these relate to successive dissociations; *e.g.*, for phosphoric acid they correspond to dissociations of H_3PO_4, $H_2PO_4^-$, and HPO_4^{2-}. All values given refer to aqueous solutions at or near 25° C; parentheses indicate values that have been estimated indirectly, or are uncertain for other reasons. (R.P.B.)

Ion-exchange reactions

As previously noted, ions are atoms, or groups of atoms, that bear a positive or negative electric charge. In pairs or other multiples they make up the substance of many crystalline materials, including table salt. When such an ionic substance is dissolved in water, the ions are freed—to a considerable extent—from the restraints that hold them within the rigid array of the crystal, and they move about in the solution with relative freedom. Certain insoluble materials bearing positive or negative charges on their surfaces react with ionic solutions to remove various ions selectively, replacing them with ions of other kinds. Such processes are called ion-exchange reactions. They are used in a variety of ways to remove ions from solution and to separate ions of various kinds from one another. Such separations are widely utilized in the scientific laboratory to effect purifications and to aid in the analysis of unknown mixtures. Ion-exchange materials such as zeolites are also employed commercially to purify water (among other uses) and medically to serve as artificial kidneys and for other purposes.

EARLY HISTORY

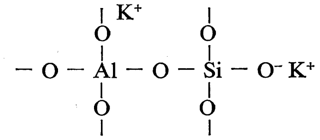
Surprisingly, recognition of ion-exchange processes antedates the great Swedish chemist Svante Arrhenius, who formulated the ionic theory. In 1850, nine years before Arrhenius was born, separate papers appeared in the *Journal of the Royal Agricultural Society of England* by agriculturist Sir H.S.M. Thompson and chemist J.T. Way, describing the phenomenon of ion exchange as it occurs in soils. In his paper, entitled "On the Power of Soils to Absorb Manure," Way addressed himself to the question of how soluble fertilizers like potassium chloride were retained by soils even after heavy rains. Way took a box with a hole in the bottom, filled it with soil, and poured onto the soil a solution of potassium chloride, collecting the liquid that flowed out of the bottom. He then washed the soil with rainwater and analyzed the water he had collected, from both the solution and the rainwater. The water turned out to contain all of the chloride that had been originally added but none of the potassium; the potassium had been replaced by chemically equivalent amounts of magnesium and calcium. Way called the process "base exchange" because of the basic (nonacidic) character of the exchanged elements. That term persisted until after 1940, by which time the process had become universally known as ion exchange.

Base exchange

In modern parlance, the process would be described in the following way: potassium ions enter the soil and displace calcium and magnesium ions. The chloride ions have no part in the operation and pass through unchanged. In terms of a chemical equation, the process is $2K^+ + Ca^{2+}(\text{soil}) \rightleftharpoons Ca^{2+} + 2K^+(\text{soil})$, in which the double arrow indicates that the exchange is reversible. In Way's experiment, the process was pushed to completion (that is, the equilibrium was pushed to the right) because the water trickling through the soil continually came in contact with fresh calcium-loaded soil. As Way also observed, the potassium could be regained by washing the soil with a solution of calcium chloride (which pushed the equilibrium in the opposite direction).

ION-EXCHANGE MATERIALS

Soil is able to bind positive ions (like K^+ and Ca^{2+}) because it contains clay minerals and organic humic acids. Both of those substances are insoluble materials that carry, as a part of their molecular framework, negatively charged ionic groups. In clays, for instance, such groups are the ends of silicon–oxygen chains—either oxygen atoms that carry an extra electron because they are bonded to only one atom instead of the usual two or aluminum atoms bonded to four oxygens instead of the usual three. The following schematic representation shows both kinds of ionic structure as they occur in an almost infinite variety of silicates and aluminosilicates, both natural and artificial.



$$\begin{array}{ccccc} & \mid\ \mathrm{K}^+ & & \mid & \\ & \mathrm{O} & & \mathrm{O} & \\ & \mid & & \mid & \\ -\mathrm{O}- & \mathrm{Al} & -\mathrm{O}- & \mathrm{Si} & -\mathrm{O}^-\mathrm{K}^+ \\ & \mid & & \mid & \\ & \mathrm{O} & & \mathrm{O} & \\ & \mid & & \mid & \end{array}$$

The negative ions are part of the framework; the positive ions, shown here as potassium, are small and can change places with other positive ions if the solid is placed in contact with a solution. The small positive ions must be able to move in and out; they must be located on surfaces or in the interstices of the open lattice structure.

The two requirements for ion exchange—fixed ionic charges on a supporting material and permeability of the material to a solution—are met in a surprisingly large number of materials. The fixed charges may be negative, as in the above example, or they may be positive. The mobile ions must be of opposite charge to the fixed ions. Materials with fixed negative charges (as in Figure 6) exchange positive ions, or cations, and the process is called cation exchange. Those having fixed positive charges correspondingly exchange negative charges, or anions, and are said to undergo anion exchange.

Ion-exchange resins

A big improvement in ion-exchange technology came in 1935, when the first ion-exchange resins were discovered by the English chemists Basil Albert Adams and Eric Leighton Holmes. The resins were chemical relatives of the plastic Bakelite and were made by condensing polyhydric phenols or phenolsulfonic acids with formaldehyde.

In 1944 Gaetano F. D'Alelio patented styrene–divinylbenzene polymers, substances with large, network-like

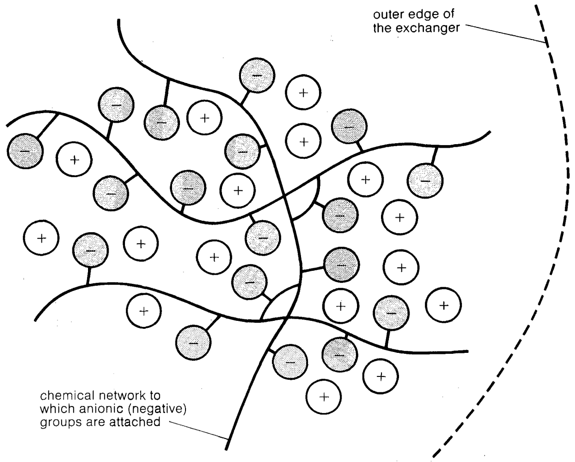


Figure 6: Chemical structure of cation exchanger. The exchangeable ions are marked +. The whole structure is permeated by solvent molecules, usually water (not shown).

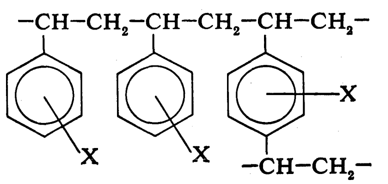
molecules, into which ionic groups were introduced by chemical treatment. The structure of these compounds may be represented thus:

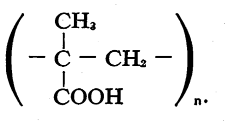


in which X represents the ionic groups, which may occur at various locations on the benzene rings. In the formula as shown, the first two benzene rings come from styrene, whereas the third is from divinylbenzene. Divinylbenzene thus provides cross-linking between the polystyrene chains, joining them into a three-dimensional network that can be tight or loose, depending on the ratio of divinylbenzene to styrene. This ratio can be varied at will; the usual commercial proportion is 8 percent. The ionic groups may be sulfonic acid groups, namely $-SO_3^-H^+$ or quaternary ammonium groups, $-CH_2N^+(CH_3)_3Cl^-$. These two types account for some 90 percent of all ion-exchange resins produced. The hydrogen ions and chloride ions may be replaced by other ions, such as Na^+ (sodium) or OH^- (hydroxide); the hydrogen and hydroxide forms of these resins are very strong acids and bases, respectively.

Styrene and divinylbenzene are liquids and are polymerized as spherical droplets, with the result that the resins have the form of beads that are almost perfect spheres. The beads swell when placed in water, and though they look smooth and impermeable, they are actually very permeable to water and small ions. They may have diameters ranging from a few microns (thousandths of a millimetre) to one to two millimetres. Different sizes are used for different purposes.

Ionic groups other than sulfonic acid and quaternary ammonium salt may be introduced into the resin structure. A useful one is iminodiacetate, $-CH_2N(CH_2COOH)_2$, which forms chelated complexes (structures held together by secondary bonds) with all metals except the alkali metals. The stability of these complexes varies widely from metal to metal. The chelating resins are used in chemical analysis to separate and concentrate trace metals.

Resins carrying the carboxyl group, —COOH—useful in medicine and biochemistry—are based not on polystyrene but on polymethacrylic acid:



$$\left(-\overset{\displaystyle CH_3}{\underset{\displaystyle COOH}{C}}-CH_2-\right)_n.$$

Still another kind of ion exchanger is made from cellulose by introducing various ionic groups into the cellulose molecules. Since the ions are on the surface of the threadlike molecules, instead of being inside molecular frameworks, they are accessible to large ions and molecules. Cellulose-based exchangers are especially useful in biochemistry.

Synthetic inorganic ion exchanges

Synthetic inorganic exchangers have been known since 1903. The first ones were aluminosilicates. About 1955 it was found that phosphates, arsenates, and molybdates of titanium, zirconium, and thorium were good cation exchangers; and many such materials have been prepared, some commercially. They are useful in the nuclear-power industry for they are resistant to radiation and selective to certain radioactive wastes, particularly the long-lived fission product cesium-137. They serve to separate that isotope from other less dangerous fission products.

Another class of inorganic ion exchanger is the molecular sieve. These materials are crystalline aluminosilicates with well-defined structures containing pores of definite sizes that permit only certain ions to enter. When the water is removed from the pores, these substances become selective adsorbents for gas molecules of certain sizes and shapes. They also are powerful catalysts.

The substances termed liquid ion exchangers possibly should be classed as organic solvents, rather than ion exchangers, in spite of their name. The molecules of such substances contain long hydrocarbon chains, which make them insoluble in water, but they also carry ionic groups that attract ions of opposite charge. An example of a liquid ion exchanger is dinonylnaphthalene sulfonic acid, *i.e.,* $(C_9H_{19})_2C_{10}H_5SO_3H$.

ION-EXCHANGE PROCEDURES

Ion-exchange columns

Only rarely are ion exchangers used in stepwise procedures, in which the resin is mixed into a container of solution and then removed for further treatment. Much more frequently the exchanger is packed into a tube or column through which the solution is made to flow. The column arrangement forces the ion-exchange reaction, which is intrinsically reversible, to go to completion in the desired manner. The solution flowing down the column continually meets fresh exchanger, and a reaction that goes half way in the first centimetre of the column may be three-quarters completed in the second centimetre, seven-eighths in the third, and so on. In a short time, the exchangeable ions that entered the column have been adsorbed and become undetectable analytically. When the exchangeable ions do start to emerge from the end of the column, however, the column has become completely saturated with them. It may be restored to its original condition, or regenerated, by passing through it a solution of the ions that it originally contained.

Ion-exchange columns are easy to use, but the theory behind their use is extremely complicated. A column with a solution flowing through it is a nonequilibrium system, and its interpretation must consider not only equilibrium distributions but rates of transfer of material and statistical variations in the paths of liquid flow between the granules that make up the exchanger. There are two chief theories of ion-exchange processes related to the two principal ways in which the columns are employed. In the first procedure, displacement, the column originally contains mobile ions of one kind that are pushed down the column by the steady flow of a solution of ions of a second kind. The theory for this procedure deals with the rate at which the "front" (the boundary between the different classes of ions) advances and its concentration profile (whether the front stays sharp as it moves down the column or whether it becomes progressively more diffuse). In the second process, elution, a thin layer of ions is introduced at the top of a column already saturated with ions of a second kind; it then is washed down the column with the same kind of ions that saturated the column at the start. In elution, the theory must account for the rate of movement of the narrow band of ions and its spread as it proceeds down the column.

When a mixture of two kinds of ions that are held by the exchanger with differing strengths is introduced at the top of a column, the mixture of ions separates as it moves down the column, with the result that the original single band of ions is resolved into two separate bands. This process is called ion-exchange chromatography. Ion-exchange chromatography is an important tool in chemical analysis because it permits separation of materials that are very difficult to separate by other means. It can be applied to organic and inorganic ions and even to substances that are not ionic. It is often used to separate mixtures of many components.

Ion-exchange columns are made in all sizes, from the large tanks used to soften the water supply of great cities to the tiny columns holding less than a cubic centimetre of resin that are used for recovering short-lived radioactive elements in the laboratory. (The element mendelevium was discovered by the isolation of a few atoms on an ion-exchange column.) Care is needed in preparing columns for the laboratory. Dry resin must be stirred with water to let it swell before it is poured into the column. Air bubbles must not be allowed to form in the resin bed for they interfere with the liquid flow. It is desirable to backwash the column—that is, to pass liquid upward to expand the resin bed—in order to release air bubbles and to segregate the resin particles according to size before the column is used. The aim of the preparation procedure is to assure even packing and even flow. For difficult chromatographic separations, resins having uniform, very small particles are used to facilitate mass transfer and give sharper bands. As fine particles offer much resistance to flow, solutions must be forced through under pressure. One procedure is to use long, narrow columns of stainless steel (like those used in a related process called gas chromatography) and to hasten mass transfer by using, instead of resin beads, glass spheres coated with ion-exchange resin.

Preparation of columns

Ion exchangers, especially inorganic and cellulose-based exchangers, are used in thin-layer chromatograpy. Chromatographic paper for this purpose is manufactured from finely ground resins and cellulose fibres. One use for this procedure is to filter small traces of metal ions from large volumes of solution.

Ion-exchange resins also may be fabricated into thin sheets, although it is not easy to make a sheet of ion exchanger that is strong and flexible and at the same time permeable; development of ion-exchange membranes has been slow for this reason. Ion-exchange membranes are used, however, to separate the electrodes of fuel cells and to remove salts from water by the physical processes termed reverse osmosis and electrodialysis. The former is a kind of filtration process—water is squeezed through the membrane under pressure while the dissolved salts are left behind. The reaction can be carried out, for example, by placing a membrane of cation-exchange resin loaded with sodium ions in contact with a dilute solution of sodium chloride. Because of the characteristics of the ion-exchange process, neither the sodium nor the chloride ions can enter the membrane. Water molecules can penetrate the membrane, however; and because of the pressure exerted on the system, they do so, crossing to the other side. The result is the removal of salt from the water without distillation (the usual desalting process).

Ion-exchange membranes

Electrodialysis is a process somewhat similar to reverse osmosis. Ions are able to enter an ion-exchange membrane if they are simultaneously removed from it at the other side; the effect is the same as passing an electric current through the membrane. In practice electrodialysis is carried out by placing a cation-exchange membrane on one side of the solution to be desalted and an anion-exchange membrane on the other and then passing an electric current through the system. The result is that positive ions pass through the membrane on one side and negative ions pass through the membrane on the other. Pure water is left eventually in the area between the membranes.

APPLICATIONS OF ION EXCHANGE

In the laboratory. Ion exchange is used for both analytical and preparative purposes in the laboratory, the analytical uses being the more common. An important use of ion-exchange chromatography is in the routine analysis of amino-acid mixtures. Columns of cation-exchange resin are used, and the solutions are maintained sufficiently acid that the amino acids are at least partly in their cationic forms. The 20 principal amino acids from blood serum or from the hydrolysis of proteins are separated in a few hours, and their concentrations are determined automatically by light-absorption methods. Such analysis is used in clinical diagnosis.

In a less routine and highly important application of ion-exchange chromatography, the products of hydrolysis of nucleic acids are analyzed. In this way, information is gained about the structure of these molecules and how it relates to their biological function as carriers of hereditary information. Cation-exchange resins are used for this purpose as well. Because of their use in analyzing the structures of complex biological materials, ion-exchange chromatographic procedures have been of great importance in the development of modern molecular biology—the explanation of biological processes in terms of the interactions of molecules.

Inorganic ions also can be separated by ion-exchange chromatography. The lanthanides, or rare-earth elements, are separated on columns of cation-exchange resin. Solutions of citrates, lactates, or other salts whose anions form negatively charged complexes with the lanthanide ions are used to wash the ions from the column. The metal ions themselves are held by the resin; the complexes are not. Those ions that form more stable complexes do not adhere to the resin and therefore move off the column more quickly than the ions that do not form complexes (or complex only weakly). Cation exchange in general is not a selective process, but the above process, termed differential complex formation, renders it more so. In lanthanide separations the exchanger is like an undiscriminating sponge that simply holds the metal ions, whereas the real separation of the various metals is accomplished by the weakness or strength of the complexes formed.

Separation of inorganic ions

Anion exchange in hydrochloric acid is an effective way to separate metal ions. Most metals form negatively charged chloride complexes that can be held by anion-exchange resins carrying quaternary ammonium groups (NR_4^+). These complexes differ greatly in their stabilities in solution and in their affinities for the resin. The distribution of metal ions between the solution and the resin depends on the hydrochloric acid concentration and the identity of the metal ion. Impressive separations of metal ions can be achieved by manipulating the hydrochloric acid concentration.

Ion-exchange separations of this kind are widely used; they can be modified by using mixed solvents, like acetone–water, and great selectivity is possible. In the process called "activation analysis," an unknown sample to be analyzed is bombarded with neutrons, and the radioactive elements thus formed are separated by anion-exchange procedures. Such analysis is especially valuable in separating minor metallic constituents from samples containing large amounts of other substances. The technique has been used to analyze lunar rocks.

Chelating resins are used to collect trace metals from seawater. Further, a copper-loaded chelating resin also adsorbs, by coordination, traces of amino acids from seawater. Miscellaneous analytical uses of ion exchange include the dissolving of sparingly soluble salts like calcium sulfate, the determination of total dissolved salts in natural waters (by passing them through hydrogen-loaded, cation-exchange resins and titrating the acid formed), and the identification of minute traces of ions (by absorbing them onto a single resin bead along with a colour-producing reagent).

Preparative uses of ion exchange in the laboratory are not many, but on occasion unusual acids, such as hydroferrocyanic acid, or unusual bases, like cesium hydroxide, are prepared from their salts by passing solutions of the salts through the appropriate resins. Resins also are used to purify acids or bases that contain nonionic contaminants, and to remove ionic contaminants from solvents.

In industry and medicine. Ion exchange finds its major industrial application in the treatment of water. Hard water—caused by the presence of calcium and magnesium ions, which form insoluble precipitates with soaps—is softened by exchanging its calcium and magnesium ions with sodium ions. To accomplish this, the hard water is

Water softening by ion exchange

passed through a column of cation exchanger containing sodium ions. After the column has been in use for some time, calcium and magnesium begin to appear in the water leaving the column. Then the column must be regenerated by passing a concentrated solution of common salt slowly through the column; the excess sodium ions displace the ions that produce the hardness so that, after flushing with water, the bed of exchanger is ready to be used again. At first, the exchangers used for this purpose were natural aluminosilicates; but later, synthetic resins came to be used instead.

For special purposes, such as use in the laboratory, water is deionized—that is, freed entirely from dissolved ions of all kinds. This is accomplished by passing the water through two resin beds in separate columns. The first bed contains a cation-exchange resin bearing hydrogen ions and converts the dissolved salts to their free acids. The second contains an anion-exchange resin loaded with hydroxyl ions; it neutralizes the acids, holding back their anions, and leaves nothing in the water but nonionic impurities. The beds are regenerated by strong acid and strong alkali, respectively. An alternative procedure, "mixed-bed" deionization, uses only one column containing the two resins mixed. Since the resins must be separated for regeneration, however, mixed beds are used chiefly in disposable cartridges for small laboratory units.

Resins used for water treatment should last for many years, but their life may be shortened either by accumulation of colloidal matter (prevented by adding activated carbon filters) or by oxidation caused by the dissolved chlorine in the water. Quaternary-base anion-exchange resins carrying hydroxyl ions also deteriorate; they decompose slowly to give tertiary amine polymers and methanol.

In an even older use of ion exchange, salts are removed from sugar juices to raise the yield of crystallized sugar. Deionization also can improve the flavour and storage time of pineapple juice and wine. In these and other beverage applications, ion exchange removes traces of heavy metals, which not only taste bad but also catalyze oxidation.

In hydrometallurgy, the treatment of ores with water solutions, ion exchange helps to recover valuable metals like copper, silver, and gold from waste waters. Uranium can be recovered from low-grade ores by leaching with dilute sulfuric acid—oxidizing if necessary to convert uranium(IV) to uranium(VI)—and then absorbing the negatively charged uranium sulfate complex ions on a quaternary-base anion-exchange resin. This highly selective absorption process thereby separates the uranium from iron and other metals. The uranium is later removed from the resin with dilute nitric acid.

On an industrial scale, cation exchange separates rare-earth elements by means of a displacement technique in which each element displaces elements bound less strongly than it is as it proceeds down the column. The elements emerge (the one with the weakest bond first) one after the other in high purity.

Ion exchangers can function as catalysts. Strong-acid cation-exchange resins loaded with hydrogen ions catalyze certain chemical reactions carried out in the liquid phase, such as hydrolysis and esterification (ester formation). The advantage of the resin over hydrochloric acid as a catalyst in these reactions is that it is present as a separate phase that does not contaminate the product. In addition, the ion-exchange process lends itself to continuous-flow techniques. Gas-phase reactions catalyzed by metal ions, like the cracking of petroleum fractions to produce gasoline, also can be catalyzed by metal-loaded inorganic exchangers, the molecular sieves being particularly suitable for this purpose since their open crystalline structure makes every metal ion accessible.

Ion exchange in medicine

Ion-exchange resins have a limited use in medicine. Carboxylic resins containing hydrogen or ammonium ions, taken by mouth, remove sodium ions from the gastrointestinal tract and control edema; other resins are consumed to lower acidity in the stomach and hence to soothe stomach ulcers. Interest in these treatments has declined, however, because of the resins' undersirable side effects. Resins also are incorporated into artificial kidneys outside the body to remove ammonium and potassium ions from the blood. The most important medical applications of ion exchange, however, have been made in clinical analysis procedures that depend on ion-exchange chromatography.

EQUILIBRIA AND KINETICS

Ion-exchange equilibria. The reversibility of ion-exchange reactions greatly affects the behaviour of ion-exchange systems. Typical ion-exchange reactions can be written as follows:

$$A^+ + B^+Res^- \rightleftharpoons B^+ + A^+Res^-$$
$$C^{2+} + 2B^+Res^- \rightleftharpoons 2B^+ + C^{2+}(Res^-)_2,$$

in which Res^- stands for an ion fixed in the resin or other type of exchanger and A^+ and B^+ are univalent cations (monopositive ions) while C^{2+} is a divalent cation.

As is generally true of reversible reactions, equations can be written describing the relative concentrations (amount of material per unit volume) of the various species in equilibrium—that is, when the rate of the forward reaction is equalled by that of the reverse reaction. For the ion-exchange processes indicated above, the following equations demonstrate the relations of the materials present under the conditions of equilibrium:

$$K_1 = \frac{[B^+]\,[A^+\,Res^-]}{[A^+]\,[B^+\,Res^-]};\; K_2 = \frac{[B^+]^2\,[C^{2+}\,Res_2^-]}{[C^{2+}]\,[B^+\,Res^-]^2}.$$

In these equations, the constant K_1 is a pure number without units (such as feet per second) because the units on the right side of the equation cancel. The numerical value of K_2, however, as well as its units, depends on the units chosen to express the concentrations on the right side of the equation. Since the constant K_1 or K_2 is the most useful simple description of the equilibrium conditions of an ion-exchange reaction (and knowledge of its value permits calculation of the concentrations of the various substances in equilibrium under specified conditions), determinations of K values are fundamental steps in the study of ion-exchange reactions. For concentrations in the resin, the proportions of mobile ions to the resin framework can be used, or one can refer the amounts of mobile ions to the weight of water that the resin contains. More constant values of K_2 can be obtained by reference to the resin rather than to the water, which is fortunate, because the water content of a swollen resin depends on the mobile ions it contains and it is hard to measure. As experimentally determined, however, the values of K_1 and K_2 are not constant but vary with the proportions of exchangeable ions in the resin. This result leads to the unsurprising conclusion that the interior of the resin is not an ideal solution.

The distribution of ions of unequal charge, like B^+ and C^{2+} above, depends on the total concentration of the solution. The more dilute the solution, the greater the tendency for the ions of higher charge to accumulate in the exchanger. One doubly-charged ion entering the exchanger sends two singly-charged ions back into the solution, and the more dilute the solution, the more likely is this replacement to happen. This effect, called "electroselectivity," is used in water softening. Calcium ions are taken up from hard water, which is a dilute solution, whereas they are removed from the resin by regenerating with a solution of sodium chloride that is concentrated.

Cation exchange

Many studies have been made of ion-exchange equilibria and the factors that influence the values of K. Different ions are held by exchangers with different strengths. As yet it is impossible to predict a priori the magnitude of K, but one can make certain generalizations, which are different for cation and anion exchange. For the alkali and alkaline-earth metal ions, the strength of binding varies inversely as the ionic hydration. Thus, lithium ions, the most strongly hydrated of the alkali metal ions, are the most weakly held by resins, followed in order by sodium, potassium, rubidium, and finally cesium, which forms the strongest bond with the resins. In the alkaline earths the increasing order runs from beryllium to magnesium, calcium, strontium, barium, and to radium, which is the most strongly held.

These sequences are characteristic of resins whose functional group is the sulfonate ion. Resins bearing carboxylate ions, or with fully ionized phosphonate ions, exhibit different sequences. The electrostatic field strength of the fixed ion on the resin determines the order of separation. When the charge on the fixed ion is small and spread over a large area, as in the sulfonate ion, $-SO_3^-$ the field strength is weak and the mobile ions keep their primary hydration shell—that is, the water molecules they hold by direct coordination. The more strongly hydrated ions migrate to where there is more water—that is, out of the resin and into the surrounding solution.

When the ionic charge is concentrated, however, as it is around the terminal oxygens of silicate networks, the mobile cations are attracted so strongly that the primary hydration shell may be squeezed out. The fixed and mobile ions then come into direct contact. The smaller the mobile ion the closer it gets to the fixed ion and the greater the force that holds it. When the ionic charge is extremely concentrated, the alkali-metal sequence is completely reversed: lithium is held most strongly and cesium the least strongly. Intermediate sequences are possible. In this way the selectivity orders in glass electrodes and biological membranes, both of which function by competitive surface adsorption of positive ions, can be explained. This theory is of little help, however, in explaining selectivity orders of heavy-metal ions; in this case, other factors, as yet unknown, seem to be at work.

Anion exchange

The selectivity sequence for halide ions in resins with quaternary-ammonium fixed ions is fluoride, chloride, bromide, and iodide, with fluoride being held the most weakly. This resembles the cation selectivity order, in which the smallest ion also is held most weakly. On the other hand, the differences between the various ions in degree of attachment to the resin is much greater in the series of halide anions than in the series of alkali-metal cations. Iodide is held a hundred times as strongly as fluoride in an 8 percent cross-linked quaternary-ammonium resin; whereas in an 8 percent cross-linked sulfonic resin, cesium is held four times as strongly as lithium.

It is significant that anions are larger than cations (in their crystal-lattice radii) and that they interact with water in a different way. Instead of attracting dipolar water molecules around them, anions tend to break up the hydrogen-bonded structure of liquid water, with the result that the bigger they are, the more difficult it is for them to enter the water. Large ions are thus driven out of the water and into the resin—a phenomenon of great practical value in achieving separations. Perchlorate ions, ClO_4^-, are held 10 times as strongly as iodide ions. This effect extends to complex ions such as the chlorides of iron and gold, $FeCl_4^-$ and $AuCl_4^-$, which are held very strongly by quaternary ammonium-type anion-exchange resins. The effect of large size may sometimes be offset by an increased ionic charge, which tends to orient the water molecules and stabilize the dissolved ion. Thus, the higher charged zinc complex $ZnCl_4^{2-}$, with its double negative charge, is more weakly bound by the resin than the iron complex $FeCl_4^-$, with its single negative charge.

Very large ions, of course, cannot enter the resin network. With ions of moderate size, the entry of the ion into the network may become a limiting factor, and it becomes important to distinguish between unfavourable equilibrium, on the one hand, and slow exchange, on the other. The equilibrium absorption may be large, but it may take a long time to reach it because the ion has difficulty entering the resin.

Ion-exchange kinetics. Generally, ion exchange is fast. No electron-pair bonds need be broken, and the rate of the process is limited only by the rate at which ions can diffuse in and out of the exchanger structure. The openness of the resin structure, however, depends on the degree of its swelling and on its water content. When both swelling and water content are small, diffusion rates are correspondingly slow. This is true of carboxylic-acid resins and of chelating resins in their acid (hydrogen-ion) form, for these acids are weakly ionized. It is also true of metal-loaded chelating resins. These types of exchangers require ample time for reaction; thus, it is advisable to use a resin with fine particles. High temperature also hastens diffusion. Nonetheless, the general rapidity and efficiency of their actions have brought widespread acceptance and use of ion exchangers. (H.F.W.)

Oxidation–reduction reactions

In the classification of chemical reactions, the terms oxidation and reduction cover a large and diverse body of processes. Many oxidation–reduction, or redox, reactions are as common and familiar as fire, the rusting and dissolution of metals, the browning of fruit, and respiration and photosynthesis—basic life functions.

GENERAL CONSIDERATIONS

Characteristics of redox processes

Major classifications. Most oxidation–reduction (redox) processes involve the transfer of oxygen atoms, hydrogen atoms, or electrons, with all three processes sharing two important characteristics: (1) they are coupled—*i.e.,* in any oxidation reaction a reciprocal reduction occurs; (2) they involve a characteristic net chemical change—*i.e.,* an atom or electron goes from one unit of matter to another. Both reciprocity and net change are illustrated below in examples of the three most common types of oxidation–reduction reactions.

Oxygen-atom transfer. Carbon reacts with mercury(II) oxide (a compound in which mercury has a bonding capacity expressed as +2; see below *Oxidation-state change*) to produce carbon dioxide and mercury metal. This reaction can be written in equation form:

$$\underset{\text{carbon}}{C} + \underset{\substack{\text{mercury(II)}\\\text{oxide}}}{2HgO} \longrightarrow \underset{\substack{\text{carbon}\\\text{dioxide}}}{CO_2} + \underset{\substack{\text{mercury}\\\text{metal}}}{Hg}.$$

Carbon, receiving oxygen, is oxidized; mercury(II) oxide, losing oxygen, undergoes the complementary reduction; and the net change is the transfer of two oxygen atoms from mercury(II) oxide units to a carbon atom.

Hydrogen-atom transfer. Hydrogen atoms are transferred from hydrazine, a compound of nitrogen and hydrogen, to oxygen in the following reaction:

$$\underset{\text{hydrazine}}{N_2H_4} + \underset{\text{oxygen}}{O_2} \longrightarrow \underset{\text{nitrogen}}{N_2} + \underset{\text{water}}{2H_2O}.$$

Hydrazine, losing hydrogen, is oxidized to molecular nitrogen, while oxygen, gaining hydrogen, is reduced to water.

Electron transfer. Zinc metal and copper(II) ion react in water solution, producing copper metal and an aqueous (denoted by aq) zinc ion according to the equation:

$$\underset{\substack{\text{zinc}\\\text{metal}}}{Zn} + \underset{\substack{\text{aqueous}\\\text{copper(II)}\\\text{ion}}}{Cu^{2+}(aq)} \longrightarrow \underset{\substack{\text{aqueous}\\\text{zinc(II)}\\\text{ion}}}{Zn^{2+}(aq)} + \underset{\substack{\text{copper}\\\text{metal}}}{Cu}.$$

With the transfer of two of its electrons, the zinc metal is oxidized, becoming an aqueous zinc ion, while the copper(II) ion, gaining electrons, is reduced to copper metal. Net change is the transfer of two electrons, lost by zinc and acquired by copper.

Because of their complementary nature, the oxidation and reduction processes together are referred to as redox reactions. The reactant that brings about the oxidation is called the oxidizing agent, and that reagent is itself reduced by the reducing agent. In the examples given, mercury(II) oxide, oxygen, and the copper(II) ion are oxidizing agents, and carbon, hydrazine, and zinc are the reducing agents.

General theory. *Stoichiometric basis.* Describing the redox processes as above conveys no information about the mechanism by which change takes place. A complete description of the net chemical change for a process is known as the stoichiometry of the reaction, which provides the characteristic combining proportions of elements and compounds. Reactions are classified as redox and nonredox on the basis of stoichiometry; oxygen-atom, hydrogen-atom, and electron transfer are stoichiometric categories.

Oxidation-state change. Comprehensive definitions of oxidation and reduction have been made possible by modern molecular structure theory. Every atom consists of a positive nucleus, surrounded by negative electrons, which determine the bonding characteristics of each element. In forming chemical bonds, atoms donate, acquire, or share electrons. This makes it possible to assign every atom an oxidation number, which specifies the number of its electrons that can be involved in forming bonds with other atoms. From the particular atoms in a molecule and their known bonding capacities, the bonding pattern within a molecule is determined, and each atom is regarded as being in a specific oxidation state, expressed by an oxidation number.

Redox processes defined

Redox processes are defined as reactions accompanied by oxidation-state changes: an increase in an atom's oxidation number corresponds to an oxidation; a decrease, to a reduction. In this generalized theory, three examples of ways in which oxidation-state changes can occur are by oxygen-atom (gain, oxidation; loss, reduction), hydrogen-atom (loss, oxidation; gain, reduction), and electron (loss, oxidation; gain, reduction) transfer. The oxidation-state change definition is usually compatible with the above rules for applying the oxygen-atom-transfer and hydrogen-atom-transfer criteria and always compatible with the electron-transfer criterion when it is applicable. The oxidation state of any atom is indicated by a roman numeral following the name or symbol for the element. Thus: iron(III), or Fe(III), means iron in an oxidation state of +3. The uncombined Fe(III) ion is simply Fe^{3+}.

Historical origins of the redox concept. Of the chemical processes now regarded as redox reactions, combustion was the earliest focus of philosophical and scientific attention. The Greek scientific philosopher Empedocles listed fire as one of the four elements of matter. In more modern times the phlogiston theory enjoyed scientific popularity. This theory was first articulated in 1697 by G.E. Stahl of Germany. As noted earlier, it asserted that matter releases an elementary constituent, phlogiston, during combustion. Thus, the burning of charcoal was interpreted as the loss of phlogiston from carbon to the air. The theory was also applied to processes other than combustion; in the recovery of a metal from its oxide by heating with charcoal, for example, phlogiston was regarded as being transferred from carbon to the oxide.

Phlogiston saturation was believed to be responsible for the limited ability of air in a closed container to support combustion. A notable consequence of the phlogiston theory was the notion that an oxide of a metal, such as mercury(II) oxide (HgO), was a chemically simpler substance than the metal itself: the metal could be obtained from the oxide only by the addition of phlogiston. The phlogiston theory, however, could provide no acceptable explanation of the gain in weight when an oxide is formed from a metal.

The work of Priestley and Lavoisier

Combustion and oxide formation. Late in the 18th century, the interrelated work of Joseph Priestley and Antoine-Laurent Lavoisier led to the overthrow of the phlogiston theory. Lavoisier saw Priestley's discovery of oxygen in 1774 as the key to the weight gains known to accompany the burning of sulfur and phosphorus and the calcination of metals (oxide formation). In his *Traité élémentaire de chimie*, he clearly established that combustion consists of a chemical combination between oxygen from the atmosphere and combustible matter (see below *Combustion and flame*). By the end of the century, his ideas were widely accepted and had been successfully applied to the more complex processes of respiration and photosynthesis. Reactions in which oxygen was consumed were classified as oxidations, while those in which oxygen was lost were termed reductions.

Electrochemical reactions. During the 19th century, the evolving field of electrochemistry led to a broadened view of oxidation. It was possible, for instance, to produce the ferric, or iron(III), ion from the ferrous, or iron(II), ion at the anode (positive electrode, where electrons are absorbed from solution) of an electrochemical cell (a device in which chemical energy is converted to electrical energy), according to the equation:

$$\underset{\text{iron(II) ion}}{\mathrm{Fe^{2+}(aq)}} \longrightarrow \underset{\text{iron(III) ion}}{\mathrm{Fe^{3+}(aq)}} + \underset{\text{electron}}{e^-} \;.$$

Molecular oxygen could effect a similar transformation, according to the equation:

$$\underset{\text{iron(II) ion}}{\mathrm{4Fe^{2+}(aq)}} + \underset{\text{oxygen}}{\mathrm{O_2}} + \underset{\text{hydrogen ion}}{\mathrm{4H^+}} \longrightarrow \underset{\text{iron(III) ion}}{\mathrm{4Fe^{3+}}(aq)} + \underset{\text{water}}{\mathrm{2H_2O}} \,.$$

The similarity of the two processes led to a precursor of the electron-transfer explanation for redox reactions. After the discovery of the electron, the conviction that oxidation and reduction are accomplished through electron loss and gain became firmly entrenched. Thus, early in the 20th century chemists tended to attribute all redox reactions to the transfer of electrons. Later work on chemical bonding, however, demonstrated the incorrectness of that description. An electronegativity scale (listing of elements in descending order of their tendency to attract and hold bonding electrons) provided a firm basis for the oxidation-state assignments on which oxidation–reduction definitions have become based.

Examples of oxidation–reduction reactions. Molecular oxygen is a conspicuously important oxidizing agent. It will directly oxidize all but a few of the metals and most of the nonmetals as well. Often these direct oxidations lead to normal oxides such as those of lithium (Li), zinc (Zn), phosphorus (P), and sulfur (S).

$$\mathrm{4Li + O_2 \longrightarrow 2Li_2O}\ \text{(lithium oxide)}$$

$$\mathrm{2Zn + O_2 \longrightarrow 2ZnO}\ \text{(zinc oxide)}$$

$$\mathrm{4P + 5O_2 \longrightarrow P_4O_{10}}\ \text{(phosphorus pentoxide)}$$

$$\mathrm{S + O_2 \longrightarrow SO_2}\ \text{(sulfur dioxide)}$$

Oxidation of organic foodstuffs

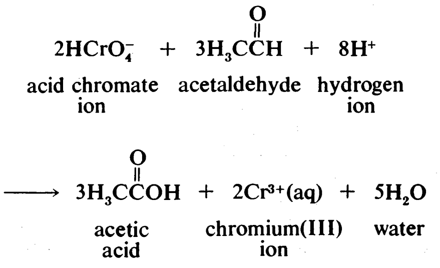
Organic foodstuffs are oxidized to carbon dioxide and water in respiration. The reaction stoichiometry can be illustrated for glucose, a simple sugar:

$$\underset{\text{glucose}}{\mathrm{C_6H_{12}O_6}} + \underset{\text{oxygen}}{\mathrm{6O_2}} \longrightarrow \underset{\text{carbon dioxide}}{\mathrm{6CO_2}} + \underset{\text{water}}{\mathrm{6H_2O}} \,.$$

Although the oxygen–glucose reaction is slow at ambient temperatures outside the living cell, it proceeds quickly under the influence of enzymatic catalysis within the body. Essentially all organic compounds react with oxygen under appropriate conditions, but the reaction rates at ordinary temperatures and pressures vary greatly.

Many other oxidizing agents serve as oxygen-atom sources. Hydrogen peroxide (H_2O_2), acid chromate ion ($HCrO_4^-$), and hypochlorous acid (HClO) are reagents often used in oxygen-atom-transfer reactions, for example in the following reactions:

$$\underset{\text{hydrogen peroxide}}{\mathrm{H_2O_2}} + \underset{\text{chloride ion}}{\mathrm{Cl^-}} \longrightarrow \underset{\text{hypochlorite ion}}{\mathrm{OCl^-}} + \underset{\text{water}}{\mathrm{H_2O}}$$



$$\underset{\text{acid chromate ion}}{\mathrm{2HCrO_4^-}} + \underset{\text{acetaldehyde}}{\mathrm{3H_3C\overset{\overset{\displaystyle O}{\|}}{C}H}} + \underset{\text{hydrogen ion}}{\mathrm{8H^+}}$$

$$\longrightarrow \underset{\text{acetic acid}}{\mathrm{3H_3C\overset{\overset{\displaystyle O}{\|}}{C}OH}} + \underset{\text{chromium(III) ion}}{\mathrm{2Cr^{3+}(aq)}} + \underset{\text{water}}{\mathrm{5H_2O}}$$

$$\underset{\text{hypochlorous acid}}{\mathrm{5HClO}} + \underset{\text{iodine}}{\mathrm{I_2}} + \underset{\text{water}}{\mathrm{H_2O}} \longrightarrow \underset{\text{hydrogen chloride}}{\mathrm{5HCl}} + \underset{\text{iodic acid}}{\mathrm{2HIO_3}} \,.$$

In the simplest hydrogen-atom transfers, molecular hydrogen serves as the hydrogen-atom source. The hydrogenations of ethylene and of molecular nitrogen are illustrative in the following equations:

$$\underset{\text{ethylene}}{H_2C{=}CH_2} + \underset{\text{hydrogen}}{H_2} \longrightarrow \underset{\text{ethane}}{H_3CCH_3}$$

$$\underset{\text{nitrogen}}{N_2} + \underset{\text{hydrogen}}{3H_2} \longrightarrow \underset{\text{ammonia}}{2NH_3}\,.$$

Reactions of molecular hydrogen are characteristically slow at ordinary temperatures. The hydrogenation of molecular nitrogen and of olefins such as ethylene (an olefin is an unsaturated hydrocarbon compound; it has at least two adjacent carbon atoms joined by a double bond to which other atoms or groups of atoms can be joined directly) is a process of extraordinary commercial importance and requires catalysts to occur at useful rates.

Hydrogen-atom transfer in organic oxidation

Hydrogen-atom transfer from an organic molecule to a suitable acceptor is a common mode of organic oxidation. The oxidation of formic acid by permanganate and that of ethanol by acid chromate share stoichiometry that features hydrogen-atom loss by the organic species, as shown in the following equations:

$$\underset{\text{formic acid}}{3H\overset{\overset{\displaystyle O}{\|}}{C}OH} + \underset{\text{permanganate ion}}{2MnO_4^-} + \underset{\text{hydrogen ion}}{2H^+}$$

$$\longrightarrow \underset{\text{carbon dioxide}}{3CO_2} + \underset{\text{manganese dioxide}}{2MnO_2} + \underset{\text{water}}{4H_2O}$$

$$\underset{\text{ethanol}}{3CH_3CH_2OH} + \underset{\text{acid chromate ion}}{2HCrO_4^-} + \underset{\text{hydrogen ion}}{8H^+}$$

$$\longrightarrow \underset{\text{water}}{8H_2O} + \underset{\text{acetaldehyde}}{3CH_3CHO} + \underset{\text{aqueous chromium(III) ion}}{2Cr^{3+}(aq)}$$

The oxidizing agents permanganate and acid chromate, typical of many hydrogen-atom acceptors, undergo complicated changes rather than simple hydrogen-atom addition.

Electron-transfer stoichiometry is usually associated with metal ions in aqueous solution, as shown in the following equations:

$$\underset{\text{iron(II) ion}}{Fe^{2+}(aq)} + \underset{\text{cobalt(III) ion}}{Co^{3+}(aq)} \longrightarrow \underset{\text{iron(III) ion}}{Fe^{3+}(aq)} + \underset{\text{cobalt(II) ion}}{Co^{2+}(aq)}$$

$$\underset{\text{thallium(I) ion}}{Tl^+(aq)} + \underset{\text{cerium(IV) ion}}{2Ce^{4+}(aq)} \longrightarrow \underset{\text{thallium(III) ion}}{Tl^{3+}(aq)} + \underset{\text{cerium(III) ion}}{2Ce^{3+}(aq)}$$

Many positively charged metal ions have been shown to be bonded to water molecules, so that their electron-transfer reaction occurs between rather complex molecular groups. The iron ion formulas above, for example, are more properly written as $[Fe(H_2O)_6]^{2+}$ and $[Fe(H_2O)_6]^{3+}$ to reflect the presence of six water molecules bonded to the metal ion. Simple electron transfer between free ions is known only in the gas phase, as in this argon–sodium reaction:

$$\underset{\text{argon ion}}{Ar^+(g)} + \underset{\text{sodium}}{Na(g)} \longrightarrow \underset{\text{sodium ion}}{Na^+(g)} + \underset{\text{argon}}{Ar(g)}.$$

Several other types of redox reactions do not fall in the oxygen-atom, hydrogen-atom, or electron-transfer categories. Important among these are reactions of fluorine, chlorine, bromine, and iodine. These four elements, known as the halogens, form diatomic molecules, which are versatile oxidizing agents. The following examples are typical:

$$\underset{\text{fluorine}}{3F_2} + \underset{\text{sulfur}}{S} \longrightarrow \underset{\text{sulfur hexafluoride}}{SF_6}$$

$$\underset{\text{chlorine}}{Cl_2} + \underset{\text{iron(II) ion}}{2Fe^{2+}(aq)} \longrightarrow \underset{\text{chloride ion}}{2Cl^-} + \underset{\text{iron(III) ion}}{2Fe^{3+}(aq)}$$

$$\underset{\text{bromine}}{Br_2} + \underset{\text{ethylene}}{H_2C=CH_2} \longrightarrow \underset{\text{ethylene dibromide}}{BrCH_2CH_2Br}$$

$$\underset{\text{iodine}}{I_2} + \underset{\text{thiosulfate ion}}{2S_2O_3^{2-}} \longrightarrow \underset{\text{iodide ion}}{2I^-} + \underset{\text{polythionate ion}}{S_4O_6^{2-}}.$$

Such reactions often qualify as redox processes only in the broad sense that oxidation-state changes occur. The oxidation-state characterization extends oxidation–reduction chemistry to include examples from the reactions of all the chemical elements.

The Earth's surface as a redox boundary

Significance of redox reactions. Oxidation–reduction reactions have vast importance not only in chemistry but in geology and biology as well. The surface of the Earth is a redox boundary between the planet's reduced metallic core and an oxidizing atmosphere. The Earth's crust is largely composed of metal oxides, and the oceans are filled with water, an oxide of hydrogen. The tendency of nearly all surface materials to be oxidized by the atmosphere is reversed by the life process of photosynthesis. Because they are constantly renewed by the photosynthetic reduction of carbon dioxide, life's complex compounds can continue to exist on the Earth's surface.

For similar reasons, much of chemical technology hinges on the reduction of materials to oxidation states lower than those that occur in nature. Such basic chemical products as ammonia, hydrogen, and nearly all the metals are produced by reductive industrial processes. When not used as structural materials, these products are reoxidized in their commercial applications. The weathering of materials, including wood, metals, and plastics, is oxidative, since, as the products of technological or photosynthetic reductions, they are in oxidation states lower than those stable in the atmosphere.

Solar radiation is converted to useful energy by a redox cycle that operates continually on a global scale. Photosynthesis converts radiant energy into chemical potential energy by reducing carbon compounds to low oxidation states, and this chemical energy is recovered either through enzymatic oxidations at ambient temperatures or during combustion at elevated temperatures.

THEORETICAL ASPECTS

Diagramming electron-pair bonding

Oxidation states. The idea of assigning an oxidation state to each of the atoms in a molecule evolved from the electron-pair concept of the chemical bond. Atoms within a molecule are held together by the force of attraction that the nuclei of two or more of them exert on electrons in the space between them. In many cases this sharing of electrons can be regarded as involving electron-pair bonds between adjacent nuclei. Electron-pair bonding is often diagrammed so as to show all the bonding and nonbonding valence electrons; *e.g.,* the structures of atomic hydrogen, atomic chlorine, and hydrogen chloride shown below (each dot represents one valence electron):

$$\underset{\text{hydrogen atom}}{H\cdot} + \underset{\text{chlorine atom}}{:\underset{\cdot\cdot}{\ddot{Cl}}\cdot} \longrightarrow \underset{\text{hydrogen chloride molecule}}{H:\underset{\cdot\cdot}{\ddot{Cl}}:}$$

The hydrogen chloride diagram reflects the presence, in the internuclear region, of two electrons that are under the mutual attractive influence of both the hydrogen and chlorine nuclei. Oxidation states for the hydrogen and chlorine in HCl are assigned according to the net charges that remain on H and Cl when the shared electrons are assigned to the atom that has the greater attraction for them. Through physical measurements on isolated atoms and simple molecules, these relative attractive powers have

Table 3: Pauling Electronegativities of Selected Elements

been determined. Table 3 lists the electronegativity values for some important elements.

In the hydrogen chloride molecule the chlorine is more electronegative than hydrogen and is, therefore, assigned both shared electrons. Chlorine has seven valence electrons in its neutral state. Having acquired an eighth electron in its reaction with hydrogen, chlorine is considered to have an oxidation state of −1. Hydrogen, on the other hand, is assigned +1, having lost the single valence electron that it has in its neutral state. Charges arrived at in this way are the basis for oxidation-state assignments, conventionally represented by roman numerals, such as in H(I) and Cl(−I) for the constituents of HCl. Because determination of oxidation states is simply a method of conceptually distributing shared electrons to individual atoms, the same number of electrons must be accounted for, before and after such assignment. Table 4 includes examples of molecules that have multiple bonds. The oxidation states of the atoms involved are added up algebraically in the table, and their sum must always equal the net charge on the molecule. There is no physical reality to oxidation states; they simply represent the results of calculations based on a formal rule.

Table 4: The Oxidation States of the Atoms in Typical Small Molecules

molecular species	oxidation-state assignments	algebraic sums
	H(I), Cl(−I)	1 − 1 = 0
	H(I), O(−II)	2(1) − 2 = 0
	Cl(I), O(−II)	1 − 2 = −1
	C(IV), O(−II)	4 − 2(2) = 0
	C(−II), O(−II), H(I)	4(1) − 2 − 2 = 0
	N(V), O(−II)	5 − 3(2) = −1
	H(I), N(−III)	4(1) − 3 = +1

Guidelines for assigning oxidation states

Oxidation states can be assigned for most common molecules with the help of a few guidelines. First, electrons shared by two atoms of the same element are divided equally; accordingly, elements are always in oxidation state of 0, regardless of their allotropic form (allotropic refers to the phenomenon of an element's having two or more forms; *e.g.,* carbon can exist as diamond or graphite and in both cases is in the 0 oxidation state). Second, only fluorine is more electronegative than oxygen. Therefore, except in compounds containing oxygen–oxygen or oxygen–fluorine bonds, oxygen can be reliably assigned the oxidation state −2. Similarly, hydrogen is less electronegative than fluorine, oxygen, nitrogen, chlorine, sulfur, and carbon (F, O, N, Cl, S, and C), so it is in the +1 oxidation state in its combinations with those elements. For many common compounds containing only hydrogen, oxygen, and a third element, the third element's oxidation state can be calculated, assuming oxidation numbers of +1 for hydrogen and −2 for oxygen. When bonds are present between two elements that differ little in electronegativity, however, oxidation-state assignments become doubtful, and the distinction between redox and nonredox processes is not evident.

There is a general reluctance, particularly regarding organic systems, to assume oxidation-state changes when the reaction results can be accounted for by the transfer or addition of water (H_2O), ammonia (NH_3), the hydroxide ion (OH^-), or the ions of hydrogen (H^+), chlorine (Cl^-), bromine (Br^-), or iodine (I^-), or combinations of these species; *e.g.,* the ammonium ion (NH_4^+), hydrogen chloride (HCl). The reason is that, in these molecules and ions, the elements are present in their most typical oxidation states: hydrogen(I), chlorine(−I), oxygen(−II), bromine (−I), iodine(−I), and nitrogen(−III).

Example of oxygen-atom-transfer reaction

The oxidation-state concept clarifies the relationship between oxygen-atom, hydrogen-atom, and electron transfer. The oxygen- and hydrogen-transfer criteria apply only when oxygen and hydrogen occur in their typical oxidation states. An example of an appropriate reaction involving oxygen-atom transfer is the reduction of ferrous oxide by carbon monoxide:

$$\begin{array}{ccccccc} \mathrm{FeO} & + & \mathrm{CO} & \longrightarrow & \mathrm{CO_2} & + & \mathrm{Fe.} \\ \text{iron(II) oxide} & & \text{carbon} & & \text{carbon} & & \text{iron} \\ \text{(ferrous oxide)} & & \text{monoxide} & & \text{dioxide} & & \end{array}$$

In terms of oxidation-state changes, this oxygen-atom transfer is equivalent to the two-electron reduction of iron and complementary two-electron oxidation of carbon:

$$\mathrm{Fe(II)} + \mathrm{C(II)} \longrightarrow \mathrm{C(IV)} + \mathrm{Fe(0)}.$$

Oxygen, which occurs in the oxidation state −2 in both reactants and products in the first equation, is not shown in the second. In transferring, the oxygen atom leaves two electrons behind, causing the reduction of iron, and acquires two electrons from the carbon atom, oxidizing the carbon.

In a similar way, the hydrogenation of ethylene corresponds to a two-electron reduction of the two-carbon skeleton:

$$\begin{array}{cccc} \mathrm{H_2} + \mathrm{H_2C{=}CH_2} & \longrightarrow & \mathrm{H_3CCH_3} \\ \text{hydrogen ethylene} & & \text{ethane} \end{array}$$

$$\begin{array}{ccc} \mathrm{2H(0)} & + & \mathrm{2C(-II)} \\ \text{hydrogen in} & & \text{carbon in} \\ \text{oxidation state zero} & & \text{oxidation state} - 2 \end{array}$$

$$\begin{array}{cccc} \longrightarrow & \mathrm{2H(I)} & + & \mathrm{2C(-III).} \\ & \text{hydrogen in} & & \text{carbon in} \\ & \text{oxidation state} + 1 & & \text{oxidation state} - 3 \end{array}$$

In this example also, the second equation includes only the atoms that change oxidation states: the four hydrogen atoms initially present in ethylene are in the +1 oxidation state in both reactants and products and are therefore omitted. Each of the two neutral hydrogen atoms can be regarded as giving up an electron to, and thereby reducing, one of the carbon atoms. This example also demonstrates clearly that the oxidation that complements the reduction of ethylene is that of the two hydrogen atoms in H_2—namely, from the 0 to the +1 oxidation state. General application of the oxidation-state concept leads to a formal viewpoint toward all redox reactions as electron-transfer reactions.

Half reactions. One of the basic reasons that the concept of oxidation–reduction reactions helps to correlate chemical knowledge is that a particular oxidation or reduction can often be carried out by a wide variety of oxidizing or reducing agents. Reduction of the iron(III) ion to the iron(II) ion by four different reducing agents provides an example:

$$\underset{\text{iron(III) ion}}{\mathrm{Fe^{3+}(aq)}} + \underset{\text{vanadium(II) ion}}{\mathrm{V^{2+}(aq)}} \longrightarrow \underset{\text{iron(II) ion}}{\mathrm{Fe^{2+}(aq)}} + \underset{\text{vanadium(III) ion}}{\mathrm{V^{3+}(aq)}}$$

$$\underset{\text{iron(III) ion}}{\mathrm{2Fe^{3+}(aq)}} + \underset{\text{zinc metal}}{\mathrm{Zn(s)}} \longrightarrow \underset{\text{iron(II) ion}}{\mathrm{2Fe^{2+}(aq)}} + \underset{\text{zinc(II) ion}}{\mathrm{Zn^{2+}(aq)}}$$

$$\underset{\text{iron(III) ion}}{\mathrm{2Fe^{3+}(aq)}} + \underset{\text{iodide ion}}{\mathrm{2I^-}} \longrightarrow \underset{\text{iron(II) ion}}{\mathrm{2Fe^{2+}(aq)}} + \underset{\text{iodine}}{\mathrm{I_2}}$$

$$\underset{\text{iron(III) ion}}{\mathrm{2Fe^{3+}(aq)}} + \underset{\text{hydroquinone}}{\mathrm{C_6H_4(OH)_2}} \longrightarrow \underset{\text{iron(II) ion}}{\mathrm{2Fe^{2+}(aq)}} + \underset{\text{quinone}}{\mathrm{C_6H_4O_2}} + \underset{\text{hydrogen ion}}{\mathrm{2H^+}}.$$

Production of the same change in the aqueous iron(III) ion by different reductants emphasizes the fact that the reduction is a characteristic reaction of the iron system itself, and, therefore, the process may be written without specifying the identity of the reducing agent in the following way:

$$\underset{\text{iron(III) ion}}{\mathrm{Fe^{3+}(aq)}} + \underset{\text{electron}}{e^-} \longrightarrow \underset{\text{iron(II) ion}}{\mathrm{Fe^{2+}(aq)}}.$$

Hypothetical equations of this type are known as half reactions. The symbol e^-, which stands for an electron, serves as a reminder that an unspecified reducing agent is required to bring about the change. Half reactions can be written, equally, for the reducing agents in the four reactions with ferric ion:

$$\underset{\text{vanadium(II) ion}}{\mathrm{V^{2+}(aq)}} \longrightarrow \underset{\text{vanadium(III) ion}}{\mathrm{V^{3+}(aq)}} + \underset{\text{electron}}{e^-}$$

$$\underset{\text{zinc(0) metal}}{\mathrm{Zn(s)}} \longrightarrow \underset{\text{zinc(II) ion}}{\mathrm{Zn^{2+}(aq)}} + \underset{\text{electron}}{2e^-}$$

$$\underset{\text{iodide ion}}{\mathrm{2I^-}} \longrightarrow \underset{\text{iodine}}{\mathrm{I_2}} + \underset{\text{electron}}{2e^-}$$

$$\underset{\text{hydroquinone}}{\mathrm{C_6H_4(OH)_2}} \longrightarrow \underset{\text{quinone}}{\mathrm{C_6H_4O_2}} + \underset{\text{electron}}{2e^-} + \underset{\text{hydrogen ion}}{\mathrm{2H^+}}$$

Although hypothetical, half reactions are properly balanced chemical processes. Since $\mathrm{V^{2+}(aq)}$ increases its oxidation number by one, from +2 to +3, in the first half reaction, an electron is shown as a product of the change. Similarly, two electrons are produced when the oxidation number of zinc increases from 0 to +2 in the second half reaction. When half reactions for hypothetical isolated oxidations and reductions are combined, the electrons must cancel if the equation for a possible overall chemical reaction is to result.

The use of half reactions is a natural outgrowth of the application of the electron-transfer concept to redox reactions. Since the oxidation-state principle allows any redox reaction to be analyzed in terms of electron transfer, it follows that all redox reactions can be broken down into a complementary pair of hypothetical half reactions. Electrochemical cells (in which chemical energy can be converted to electrical energy, and vice versa) provide some physical reality to the half-reaction idea. Oxidation and reduction half reactions can be carried out in separate compartments of electrochemical cells, with the electrons flowing through a connecting wire and the circuit completed by some arrangement for ion migration between the two compartments (but the migration need not involve any of the materials of the oxidation–reduction reactions themselves).

Redox potentials for common half reactions. The analysis of the electrical potential, or voltage, developed by pairing various half reactions in electrochemical cells has led to the determination of redox potentials for a substantial number of common half reactions. While a detailed description of redox potentials requires the methods of thermodynamics (the branch of physics concerned with the role played by heat in the transformation of matter or energy), a great deal of useful information can be obtained from redox potentials with minimal recourse to formal theory. Basically, a table of half-cell potentials is a summary of the relative tendencies of different oxidations and reductions to occur. Table 5 lists selected half reactions and their corresponding reduction potentials (which are symbolized by $E°$).

The physical significance of the values is directly linked to several agreements about their use. First, the greater the value of $E°$ (the reduction potential), the greater the tendency of a half reaction to proceed from left to right (as written). The half reactions in Table 5 are listed from top to bottom in order of decreasing $E°$: the higher a reaction's position on the list, the greater the tendency of the reactants to accept electrons. In other words, reagents high on the list, such as fluorine gas ($\mathrm{F_2}$) and permanganate ion ($\mathrm{MnO_4^-}$), are strong oxidizing agents. Second, the reduction of hydrogen ions ($\mathrm{H^+}$) to hydrogen gas ($\mathrm{H_2}$) is arbitrarily assigned the value 0 volts. Half cells with positive reduction potentials involve reactants that are more readily reduced than $\mathrm{H^+}$; conversely, those with negative potentials involve reactants that are more difficult to reduce than hydrogen ions.

Table 5: Selected Values of Standard Reduction Potentials

half reactions*	$E°$ (volts)
$\mathrm{F_2(g)} + 2e^- \rightarrow \mathrm{2F^-}$ fluorine(0) electrons fluoride(−I) ion	2.87
$\mathrm{MnO_4^-} + \mathrm{8H^+} + 5e^- \rightarrow \mathrm{Mn^{2+}(aq)} + \mathrm{4H_2O}$ permanganate ion hydrogen(I) ion electrons manganese(II) ion water	1.51
$\mathrm{Cl_2(g)} + 2e^- \rightarrow \mathrm{2Cl^-}$ chlorine(0) electrons chloride(−I) ions	1.36
$\mathrm{O_2(g)} + \mathrm{4H^+} + 4e^- \rightarrow \mathrm{2H_2O}$ oxygen(0) hydrogen(I) ions electrons water	1.23
$\mathrm{Fe^{3+}(aq)} + e^- \rightarrow \mathrm{Fe^{2+}(aq)}$ iron(III) ion electron iron(II) ion	0.77
$\mathrm{Cu^{2+}(aq)} + 2e^- \rightarrow \mathrm{Cu(s)}$ copper(II) ion electrons copper(0)	0.34
$\mathrm{2H^+} + 2e^- \rightarrow \mathrm{H_2(g)}$ hydrogen(I) ion electrons hydrogen(0)	0.00
$\mathrm{Zn^{2+}(aq)} + 2e^- \rightarrow \mathrm{Zn(s)}$ zinc(II) ion electrons zinc(0)	−0.76
$\mathrm{Na^+} + e^- \rightarrow \mathrm{Na(s)}$ sodium(I) ion electron sodium(0)	−2.71

*The identifications in parentheses refer to the physical state of the substance: (g), gas; (aq), as a hydrated positive ion in water; (s), as the pure solid.

Use of reduction potentials to predict reactions

With the aid of reduction potentials, it is possible to predict whether a particular oxidation–reduction reaction can occur. The predictions require breaking down the overall reaction into two half reactions of known reduction potentials. For example, if a strip of zinc metal is dipped into a solution containing copper(II) ion, the possibility exists for a redox process, which can be regarded as the sum of the half reactions aqueous zinc ion ($\mathrm{Zn^{2+}}$[aq]) to zinc metal (Zn[s]) and aqueous copper ion ($\mathrm{Cu^{2+}}$[aq]) to copper metal (Cu[s]), as follows:

$$\underset{\text{zinc(0) metal}}{\mathrm{Zn(s)}} + \underset{\text{copper(II) ion}}{\mathrm{Cu^{2+}(aq)}} \longrightarrow \underset{\text{zinc(II) ion}}{\mathrm{Zn^{2+}(aq)}} + \underset{\text{copper(0) metal}}{\mathrm{Cu(s)}}.$$

Combining these two half reactions requires writing the zinc ion to zinc metal half reaction the reverse of the way it appears in Table 3. When the direction of a half reaction is reversed, so that it can be added to another half reaction, the sign of its redox potential is also reversed (in this case, from negative to positive), and the two reduction potential values are then added.

$$\begin{array}{rcll}
Cu^{2+}(aq) + 2e^- & \longrightarrow & Cu(s) & +0.34\ \text{volt} \\
Zn(s) & \longrightarrow & Zn^{2+}(aq) + 2e^- & +0.76 \\
\hline
Cu^{2+}(aq) + Zn(s) & \xrightarrow{\text{spontaneous}} & Cu(s) + Zn^{2+}(aq) & +1.10 \\
\begin{array}{cc}\text{copper(II)} & \text{zinc} \\ \text{ion} & \text{metal}\end{array} & & \begin{array}{cc}\text{copper} & \text{zinc(II)} \\ \text{metal} & \text{ion}\end{array} &
\end{array}$$

The resulting $E°$ value for the net reaction, +1.10 volts, measures the tendency of the net reaction to occur. If $E°$ for a particular net reaction is positive, the process may be expected to occur spontaneously when the reactants are mixed at specified concentrations (one mole per litre; see below *Oxidation–reduction equilibria*). Therefore, it is predicted that copper metal should be deposited on a strip of zinc metal when the latter is immersed in a solution of a copper(II) salt. This reaction is, in fact, readily observed in the laboratory. A more specific physical interpretation of the +1.10 volt value is that it represents the voltage that would be produced by an ideal electrochemical cell based on the copper(II) ion to copper metal and zinc(II) ion to zinc metal half reactions with all the reagents at specified concentrations.

When the same two half cells are combined, with both their directions (and therefore the signs of their redox potentials) reversed, it is predicted that the reverse reaction, the depositing of zinc metal from a zinc(II) ion solution onto a copper strip, will not occur spontaneously. As in the case of $E°$ values for half reactions, those for net redox reactions also change sign when the direction of the reaction is reversed.

$$\begin{array}{rcll}
Cu(s) & \longrightarrow & Cu^{2+}(aq) + 2e^- & -0.34\ \text{volt} \\
Zn^{2+}(aq) + 2e^- & \longrightarrow & Zn(s) & -0.76 \\
\hline
Zn^{2+}(aq) + Cu(s) & \xrightarrow{\text{nonspontaneous}} & Cu^{2+}(aq) + Zn(s) & -1.10
\end{array}$$

The results of the copper–zinc system can be applied more generally to the half reactions in Table 3. For example, copper(II) ion in water (Cu^{2+}[aq]) is an oxidant strong enough to force a half reaction lower on the table to proceed spontaneously in the opposite direction of that written. Therefore, not only is copper(II) ion expected to oxidize zinc metal (Zn[s]) to zinc(II) ion (Zn^{2+}[aq]); it is also predicted to oxidize hydrogen gas (H_2[g]) to hydrogen ion (H^+) and sodium metal (Na[s]) to sodium ion (Na^+). Similarly, fluorine gas (F_2[g]), the strongest oxidant listed in Table 3, is predicted to oxidize spontaneously the products of all the other half reactions in the table. In contrast, the strongest reducing agent is solid sodium metal (Na[s]), and it is expected spontaneously to reduce the reactants of all the other half cells.

Oxidation–reduction equilibria. In practice many chemical reactions can be carried out in either direction, depending on the conditions. The spontaneous direction predicted for a particular redox reaction by half-cell potentials is appropriate to a standard set of reaction conditions. Specifically, the temperature is assumed to be 25° C with reagents at specified concentrations. Gases are present at one atmosphere pressure and solutes at one mole per litre (one molecular weight in grams dissolved in one litre of solution) concentration (1M). Solids are assumed to be in contact with the reaction solution in their normal stable forms, and water is always taken to be present as the solvent. Many practical problems can be solved directly with standard reduction potentials.

Role of the Nernst equation

The usefulness of reduction potentials is greatly extended, however, by a thermodynamic relationship known as the Nernst equation, which makes it possible to calculate changes in half-cell potentials that will be produced by deviations from standard concentration conditions. In the reaction between zinc metal and copper(II) ion, standard conditions for zinc and copper metal require simply that both solids be present in contact with the solution; the $E°$ values are not affected by either the total or proportionate amounts of the two metals. The calculation that the overall reaction is spontaneous by +1.10 volts is based on standard one mole per litre (1M) concentrations for aqueous zinc(II) ion (Zn^{2+}[aq]) and aqueous copper(II) ion (Cu^{2+}[aq]). Using the Nernst equation it is found that $E°$ for the overall reaction will be +1.10 volts as long as both ions are present in equal concentrations, regardless of the concentration level.

On the other hand, if the ratio of the zinc(II) to copper(II) ion concentrations is increased, the reduction potential ($E°$) falls until, at a very high preponderance of zinc ion, $E°$ becomes 0 volt. At this point, there is no net tendency for the reaction to proceed spontaneously in either direction. If the zinc(II) to copper(II) ion ratio is increased further, the direction of spontaneity reverses, and zinc ion spontaneously oxidizes copper metal. In practice, such high zinc(II) to copper(II) ion concentration ratios are unattainable, which means that the reaction can only be carried out spontaneously with copper(II) ion oxidizing zinc metal. Many reactions with $E°$ values smaller than +1.10 volts under standard conditions can be carried out in either direction by adjusting the ratio of product and reactant concentrations. The point at which $E° = 0$ volt represents a state of chemical equilibrium. When chemical reactions are at equilibrium, the concentrations of the reagents do not change with time, since net reaction is not spontaneous in either direction. Measurements of half-cell potentials combined with Nernst-equation calculations are a powerful technique for determining the concentration conditions that correspond to chemical equilibrium.

Reaction rates. *Predictability.* There are practical limitations on predictions of the direction of spontaneity for a chemical reaction, the most important arising from the problem of reaction rates. An analogy can be made with the simple physical system of a block on a sloping plane. Because of the favourable energy change, the block tends spontaneously to slide down, rather than up, the slope, and, at mechanical equilibrium, it will be at the bottom of the slope, since that is the position of lowest gravitational energy. How rapidly the block slides down is a more complex question, since it depends on the amount and kind of friction present. The direction of spontaneity for a chemical reaction is analogous to the downhill direction for a sliding block, and chemical equilibrium is analogous to the position at the bottom of the slope; the rate at which equilibrium is approached depends on the efficiency of the available reaction processes. Between zinc metal and aqueous copper(II) ion, the reaction proceeds without observable delay, but various other spontaneous redox processes proceed at imperceptibly slow rates under ordinary conditions.

Biological processes. A particularly significant illustration of the role of mechanisms in determining the rates of redox reactions concerns respiration, the central energy-producing process of life. Foodstuffs that are oxidized by molecular oxygen during respiration are quite unreactive with oxygen before ingestion. Such high-energy foods as grains and sugar can resist the atmosphere indefinitely but are rapidly converted to carbon dioxide and water through combination with oxygen during respiratory metabolism. The situation is exemplified by the behaviour of glucose at ambient temperatures.

The significance of the different rate behaviour of high-energy foods inside and outside the cell has been dramatized by Albert Szent-Györgyi, a Hungarian biochemist resident in the United States, a pioneering researcher into the chemical mechanism of respiration:

> You remember the exciting story of the grave of the Egyptian emperor. At its opening the breakfast of the emperor was found unburned though it had been exposed to the action of oxygen during several thousand years at a temperature that was not very different from 37° C [98.6° F]. Had the king risen and consumed his breakfast, as he had anticipated doing, the food would have been oxidized in no time, that is to say the cells of the emperor would have made reactions take place that would not run spontaneously (from Albert V. Szent-Györgyi, *On Oxidation, Fermentation, Vitamins, Health and Disease;* the Williams and Wilkins Company, 1939).

Living systems are able to use respiratory oxidation as an energy source only because the same reactions are slow outside the cell. In return for providing an efficient mechanism for the oxidation of foods, the cell gains control over the disposition of the liberated chemical energy.

Examples such as the chemistry of respiration make clear the importance of determining the rates and mechanisms of redox reactions. Often questions are difficult to answer even in regard to relatively simple reactions. It has been pointed out that many redox processes can be categorized as oxygen-atom-, hydrogen-atom-, or electron-transfer processes. These categories describe the net changes that are involved but provide no insight into the mechanisms of the reactions.

Mechanisms of redox reactions. Some of the problems associated with formulating descriptions of the mechanisms are illustrated by the reaction between two metal ions that undergo complementary, one-unit changes in oxidation state:

$$M(\mathrm{III}) + N(\mathrm{II}) \longrightarrow M(\mathrm{II}) + N(\mathrm{III}).$$

There are many different metal ions, designated with the letters *M* and *N*, which participate in redox reactions with this basic stoichiometry. To define the possible mechanisms with any precision, it is necessary to identify the groups that are directly bonded to the metals, as well as to specify which particular metals take part in the reactions. One relatively simple example is the chromium(II)–iron(III) reaction. Both chromium and iron aquo ions are surrounded by six water molecules in both the +2 and +3 oxidation states.

$$\mathrm{Fe(H_2O)_6^{3+}} \quad + \quad \mathrm{Cr(H_2O)_6^{2+}}$$

hexaaquoiron(III) ion
hexaaquochromium(II) ion

$$\longrightarrow \quad \mathrm{Fe(H_2O)_6^{2+}} \quad + \quad \mathrm{Cr(H_2O)_6^{3+}}$$

hexaaquoiron(II) ion
hexaaquochromium(III) ion

The reaction appears from its stoichiometry to entail simple electron transfer from Cr(II) to Fe(III). There are, however, other possibilities. Their variety is most evident if it is assumed that the oxidizing agent, hexaaquoiron(III) ($\mathrm{Fe[H_2O]_6{}^{3+}}$), dissociates a hydrogen ion before reacting with hexaaquochromium(II) ($\mathrm{Cr[H_2O]_6{}^{2+}}$). The hexaaquoiron(III) ion is then converted to a hydroxopentaaquoiron(III) ion, known to be an important reactant in the Fe(III)–Cr(II) reaction. Its formation requires no change in the oxidation state of iron and should be regarded as a simple acid–base reaction. With hydroxopentaaquoiron(III) ion, $\mathrm{(H_2O)_5FeOH^{2+}}$, as the oxidizing agent, simple electron transfer does provide one plausible means for the reaction. All the steps in the mechanism must add up to give the overall reaction. Intermediate species such as hydroxopentaaquoiron(III) must cancel out in the addition process by occurring as products in one step and reactants in another:

$$\mathrm{Fe(H_2O)_6^{3+}} \longrightarrow \mathrm{(H_2O)_5FeOH^{2+}} + \mathrm{H^+}$$

hexaaquoiron(III) ion
hydroxopenta-aquoiron(III) ion
hydrogen ion

$$\mathrm{(H_2O)_5FeOH^{2+}} \quad + \quad \mathrm{Cr(H_2O)_6^{2+}}$$

hydroxopenta-aquoiron(III) ion
hexaaquo-chromium(III) ion

$$\xrightarrow[\text{transfer}]{\text{electron}} \mathrm{(H_2O)_5FeOH^{+}} \quad + \quad \mathrm{Cr(H_2O)_6^{3+}}$$

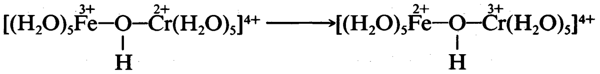
hydroxopenta-aquoiron(II) ion
hexaaquo-chromium(III) ion

$$\mathrm{(H_2O)_5FeOH^{+}} + \mathrm{H^+} \longrightarrow \mathrm{Fe(H_2O)_6^{2+}}$$

hydroxopenta-aquoiron(II) ion
hydrogen ion
hexaaquoiron(II) ion

$$\mathrm{Fe(H_2O)_6^{3+}} + \mathrm{Cr(H_2O)_6^{2+}} \longrightarrow \mathrm{Fe(H_2O)_6^{2+}} + \mathrm{Cr(H_2O)_6^{3+}}$$

An alternative to simple electron transfer is the transfer of a hydrogen atom from a water molecule bound to chromium(II) to the hydroxide ion ($\mathrm{OH^-}$) bound to iron(III). A third important possibility is the transfer of a neutral OH group (called a hydroxyl radical) from iron(III) to chromium(II). Oxygen and hydrogen occur as oxygen(−II) and hydrogen(I) in both reactants and products. These oxidation states correspond to those present in the hydroxide ion $\mathrm{OH^-}$. Therefore, when an OH group transfers, it must leave an electron behind, reducing the iron, and then reaccept an electron from chromium, oxidizing it. Since both the aqueous iron and chromium ions have a strong tendency to remain surrounded by six oxygen molecules, the most likely method of OH transfer would be the sharing of the transferred oxygen between the two metals at an intermediate stage of the reaction. But iron(III) is not a strong enough oxidizing agent to produce a significant concentration of neutral OH groups from $\mathrm{OH^-}$ ions. A more acceptable description of the OH transfer mechanism, therefore, is to regard $\mathrm{OH^-}$ as a bridging group through which electron transfer is accomplished as the two metal ion groups share a bonded oxygen atom.



$$\mathrm{[(H_2O)_5\overset{3+}{Fe}{-}\underset{\substack{|\\ H}}{O}{-}\overset{2+}{Cr}(H_2O)_5]^{4+}} \longrightarrow \mathrm{[(H_2O)_5\overset{2+}{Fe}{-}\underset{\substack{|\\ H}}{O}{-}\overset{3+}{Cr}(H_2O)_5]^{4+}}$$

Experimentally, it is difficult to distinguish between the alternative mechanisms posed above. Classification schemes for reaction mechanisms are of little value unless they offer alternatives that can be experimentally verified. For that reason the most successful system for classifying the mechanisms of redox reactions between metal ions has been the inner sphere–outer sphere dichotomy. Outer-sphere reactions are those that take place without breaking any bonds between a metal and a group such as water or hydroxide ion bound to it. Both the simple electron- and hydrogen-atom-transfer mechanisms are outer-sphere processes. If, on the other hand, the oxidation-state changes take place within an intermediate product in which the two metals are directly bonded to a common bridging group (such as shown in the equation above), the mechanism is inner-sphere. Formation of the intermediate requires loss of a bound water molecule by one of the metals. The inner sphere–outer sphere distinction can be tested experimentally in some redox systems. (M.V.O.)

COMBUSTION AND FLAME

Combustion is a chemical reaction between substances, usually including oxygen and usually accompanied by the generation of heat and light in the form of flame. The rate or speed at which the reactants combine is high, in part because of the nature of the chemical reaction itself and in part because more energy is generated than can escape into the surrounding medium, with the result that the temperature of the reactants is raised to accelerate the reaction even more. A familiar example is a lighted match. When a match is struck, friction heats the head to a temperature at which the chemicals react and generate more heat than can escape into the air, and they burn with a flame. If a wind blows away the heat or the chemicals are moist and friction does not raise the temperature sufficiently, the match goes out; properly ignited, the heat from the flame raises the temperature of a nearby layer of the matchstick and of oxygen in the air adjacent to it, and the wood and oxygen react in a combustion reaction. When equilibrium between the total heat energies of the reactants and the total heat energies of the products (including the actual heat and light emitted) is reached, combustion stops. Flames have a definable composition and a complex structure; they are said to be multiform and are capable of existing at quite low temperatures, as well as at extremely high temperatures. The emission of light in the flame results from the presence of excited particles and, usually, of charged atoms and molecules and of electrons.

General principles. Combustion encompasses a great variety of phenomena with wide application in industry, the sciences, professions, and the home, and the application is based on knowledge of physics, chemistry, and mechanics; their interrelationship becomes particularly evident in treating flame propagation.

In general terms, combustion is one of the most important of chemical reactions and may be considered a culminating step in the oxidation of certain kinds of substances.

Though oxidation was once considered to be simply the combination of oxygen with any compound or element, the meaning of the word has been expanded to include any reaction in which atoms lose electrons, thereby becoming oxidized. As has been pointed out, in any oxidation process the oxidizer takes electrons from the oxidizable substance, thereby itself becoming reduced (gaining electrons). Any substance at all can be an oxidizing agent. But these definitions, clear enough when applied to atomic structure to explain chemical reactions, are not as clearly applicable to combustion, which remains, generally speaking, a type of chemical reaction involving oxygen as the oxidizing agent but complicated by the fact that the process includes other kinds of reactions as well, and by the fact that it proceeds at an unusually fast pace. Furthermore, most flames have a section in their structure in which, instead of oxidations, reduction reactions occur. Nevertheless, the main event in combustion is the combining of combustible material with oxygen.

History. Combustion, fire, and flame have been observed and speculated about from earliest times. Every civilization had its own explanation for them. The Greeks interpreted combustion in terms of philosophical doctrines, one of which was that a certain "inflammable principle" was contained in all combustible bodies and this principle escaped when the body was burned to react with air. A generalization of the concept was provided by the phlogiston theory, formulated in the 17th century (see above). Treated at first as a purely metaphysical quality, phlogiston was conceived later as a material substance having weight, and, sometimes, negative weight. The inadequacy of the phlogiston theory became apparent only in the late 18th century when it proved unable to explain a host of new facts about combustion that were being observed for the first time as the result of increasing accuracy in laboratory experiments.

The English natural philosopher Sir Francis Bacon observed in 1620 that a candle flame has a structure at about the same time that Robert Fludd, an English mystic, described an experiment on combustion in a closed container in which he determined that an amount of air was used up thereby. A German, Otto von Guericke, using an air pump he had invented in 1650, demonstrated that a candle would not burn in a container from which the air had been pumped. Robert Hooke, an English scientist, in 1665 suggested that air had an active component that, upon heating, combined with combustible substances, giving rise to flame. Another idea ascribed the high temperature of flame to the fast motion of active air particles, and it was learned that sulfur mixed with nitre can burn in the absence of air (nitre is a compound of oxygen which releases oxygen to the sulfur).

The first approximation of the true nature of combustion was posited by Lavoisier, who discovered in 1772 that the products of burned sulfur or phosphorus, in effect their ashes, outweighed the initial substances, and postulated that the increased weight was due to their having combined with air. Interestingly, it was already known that metals transformed by heat to metallic ash weighed less than the metallic ash, but the theory was that in certain cases phlogiston in metals had a negative weight, and upon escaping during combustion, left the ash of the metal heavier than it had been with the phlogiston in it. Later, Lavoisier concluded that the "fixed" air that had combined with the sulfur was identical to a gas obtained by Priestley on heating the metallic ash of mercury—that is, the "ashes" obtained when mercury was burned could be made to release the gas with which the metal had combined. This gas was also identical to that described by the Swedish chemist, Carl Wilhelm Scheele, as an active fraction of air that sustained combustion. Lavoisier called the gas "oxygen."

Discovery of oxygen

Lavoisier's theory that combustion was a reaction between the burning substance and the gas oxygen, present only to a limited extent in the atmosphere, was based on scientific principles, the most important of which was the law of the conservation of matter (after Einstein's relativity theory, of matter and energy): the total amount of matter in the universe is constant. Even ancient philosophers had guessed this law and it was substantiated in the 17th century. Lavoisier also clarified the concept of element into a modern generalization, that it was a substance that could not be broken down, and this, too, supported his theory. Soon after, studies of gases by John Dalton, and the first table of atomic weights that Dalton compiled, as well as many new gases discovered by other scientists, were important in supporting not only Lavoisier's theory of combustion but his whole new system of chemistry based on accurate measurement. The discoveries of nitrogen and hydrogen in the latter half of the 18th century, added to the earlier discoveries of carbon dioxide and carbon monoxide, and the discovery that the composition of air is remarkably constant though it is a mixture, all supported Lavoisier's theory. The proper explanation of combustion, perhaps the oldest recognized chemical reaction, is usually said to have been a keystone in the development of modern science.

From 1815 to 1819, Sir Humphry Davy experimented on combustion, including measurements of flame temperatures, investigations of the effect on flames of rarefied gases, and dilution with various gases; he also discovered catalytic combustion—the oxidation of combustibles on a catalytic surface accompanied by the release of heat but without flame.

Despite these discoveries, the materialistic theory of combustion lacked a clear concept of energy and, therefore, of the critical role that energy considerations play in an accurate explanation of combustion. It was Sir Benjamin Thompson's experiments with heat in 1798 that revealed evidence for the concept of heat as a movement of particles. Development of a kinetic theory of gases, based on the premise that heat results from the motion of molecules and atoms, of thermodynamics, and of thermochemistry, all in the 19th century, finally elucidated the energy aspects of combustion.

Investigation of burning velocities, experiments on the order of events in the combustion of gas mixtures, and study of the breaking down of gas molecules by heat (thermal dissociation), in the last half of the 19th century, played a vital part in the refinement of theories concerning combustion mechanism. Studies of light emitted by flames led to its analysis in the spectroscope, a device that separates a mixture of light waves into the component waves, and to spectral analysis generally, including theories of atomic and molecular spectra, which, in turn, contributed to an understanding of the nature of flames. The Bunsen burner was also of importance in the study of flame structure. Progress in industry was a powerful stimulus in the search for clarification of flame phenomena. Explosion hazards in coal mines had drawn attention to flame propagation as far back as 1815, when Davy invented his safety lamp. In 1881 detonation was discovered and led at the beginning of the 20th century to a detonation theory, based on the assumption that a gas behaved as a fluid under certain conditions. Chemical kinetics after the 1930s became an indispensable part of flame propagation theory.

Physical and chemical aspects of combustion. *The chemical reactions.* Combustion, with rare exceptions, is a complex chemical process involving many steps that depend on the properties of the combustible substance. It is initiated by external factors such as heat, light, and sparks. The reaction sets in as the mixture of combustibles attains the ignition temperature, and several aspects of this step can be defined.

Ignition temperature

First, a relationship exists between the ignition temperature and the pressure of the mixture under specific conditions. Figure 7 shows the relationship for a mixture of hydrogen and oxygen. Only one temperature corresponds to a given pressure, whereas one or three pressures, called the explosion limits, may correspond to one temperature. The mechanism of the reaction determines the explosion limits: the reaction can proceed only when the steps in the sequence of reactions occur faster than the terminal steps. Thus, for combustion to be initiated with light, or with a spark, the light intensity or the spark energy must exceed certain minimal values.

The complexity of the combustion reaction mechanism and the rapidly varying temperatures and concentrations

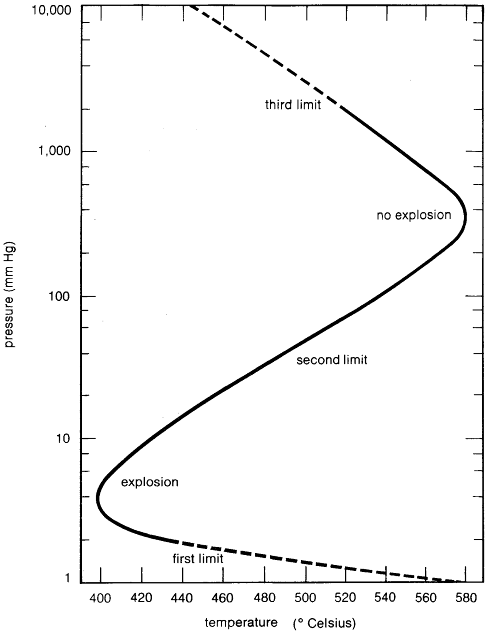


Figure 7: Explosion limits of a hydrogen-oxygen mixture.
From B. Lewis and G. von Elbe, *Combustion, Flames and Explosions of Gases* (1961); Academic Press, Inc.

in the mixture make it difficult and often impossible to derive an equation that would be useful for predicting combustion phenomena over wide temperature and concentration ranges. Instead, use is made of empirical expressions derived for specific reaction conditions.

Most reactions terminate when what is called thermal equilibrium has been attained—*i.e.,* when the energy of the reactants equals the energy of the products.

Special combustion reactions. Reactions of oxygen with hydrogen, with carbon monoxide, and with hydrocarbons are most important from the standpoint of theory and, at the same time, are of great practical value.

Hydrogen combustion proceeds by complicated branched-chain reactions involving the interaction of hydrogen and oxygen atoms with oxygen and hydrogen molecules, respectively, to produce hydroxyl radicals. The final reaction product is water, formed by the combination of hydroxyl with hydrogen molecules. Reactions that terminate the chain, such as recombination of atoms and fragments of molecules, and the adsorption of active particles on solid surfaces, also play an important part in the mechanism of hydrogen combustion. The knowledge of rate constants for these processes derived empirically makes possible a quantitative description of all combustion characteristics, such as explosion limits, delay of ignition, and burning velocity.

Combustion of carbon monoxide is mainly restricted to mixtures containing hydrogen or hydrogen compounds. In this case the reaction mechanism differs from that of hydrogen combustion chiefly in that it involves a step of fast interaction between hydroxyl and carbon monoxide.

Pure mixtures of carbon monoxide and oxygen (or air) can be ignited only with sparks of high energy, or under high pressures and temperatures. The chemical mechanism of their combustion is not yet clear, probably because oxidation of carbon monoxide, a reaction that is part of the combustion of practically all natural fuels, usually occurs in the presence of hydrogen or hydrogen compounds: the breakdown of wood, coal, petroleum, etc., during burning produces carbon monoxide, hydrogen, and compounds of carbon and hydrogen.

The mechanisms of combustion of hydrocarbons and of other organic compounds are known in general outline only. Many elementary steps of hydrocarbon combustion involving oxygen and hydrogen atoms, hydroxyl and organic radicals are similar to those for hydrogen, however, the overall mechanism of hydrocarbon combustion is complicated by the diversity of molecules and radicals involved. Moreover, with oxidation, thermal decomposition, a breakdown of complex organic compounds without oxidation, also takes place.

Cool and
hot flames

Two types of hydrocarbon combustion have been defined; (1) slow combustion at temperatures below 500° C, including cool flames observed at certain pressures, and (2) combustion at higher temperatures, accompanied by hot flames.

Ignition in two stages is characteristic of higher hydrocarbons in which a cool-flame stage yielding readily oxidizable products precedes that of the hot flame.

Physical processes. In addition to chemical reactions, physical processes that transfer mass and energy by diffusion or convection occur in gaseous combustion. In the absence of external forces, the rate of component diffusion depends upon the concentration of the constituents, pressure, and temperature changes, and on diffusion coefficients (a measure of the speed of diffusion). The latter are either measured or calculated in terms of the kinetic theory of gases. The process of diffusion is of great importance in combustion reactions, in flames—that is, in gaseous mixtures, and in solids or liquids. Diffusion heat transfer (by molecular means) follows a law (Fourier law) stating that the heat flux (a measure of the quantity of heat) is proportional to the temperature gradient (the difference in temperature between two limiting temperatures). The coefficient of proportionality, called the thermal conductivity coefficient, is also measured or calculated in terms of the kinetic theory of gases, like the diffusion coefficient.

Convection

Convective transport of mass and energy may be accounted for by buoyant forces, external forces, and turbulent and eddy motions. Convection is in the main responsible for the mixing of gases (*e.g.,* in furnaces).

Sublimation (the direct evaporation of a solid without intermediate liquid stage), evaporation of liquids, and the mechanical destruction of burning samples, all methods of transforming solids and liquids into gases, greatly contribute to their ease of combustion. In general, the combustion of condensed systems—*i.e.,* liquids and solids—is more complex than that of gases, which accounts for the greater development of the gas combustion theory.

Energy transport in combustion may also occur by the emission of light, mostly in the infrared.

Combustion phenomena and classification. All flames can be classified either as premixed flames or as flames that burn without premixing.

Premixed flames. Flame combustion is most prominent with fuels that have been premixed with an oxidant, either oxygen or a compound that provides oxygen, for the reaction. The temperature of flames with this mixture is often several thousand degrees. The chemical reaction in such flames occurs within a narrow zone several microns thick. This combustion zone is usually called the flame front.

Dilution of the burning mixture with an inert gas, such as helium or nitrogen, lowers the temperature and, consequently, the reaction rate. Great amounts of inert gas extinguish the flame, and the same result is achieved when substances that remove any of the active species are added to the flame. Conditions must be such that the flame is fixed at the burner nozzle or in the combustion chamber; this positioning is required in many practical uses of combustion. Various devices, such as pilot flames and recirculation methods, are designed for this purpose.

The principal quantitative characteristic of a flame is its normal, or fundamental, burning velocity, which depends on the chemical and thermodynamic properties of the mixture, and on pressure and temperature, under given conditions of heat loss. The burning velocity value ranges from several centimetres even to tens of metres, per second. The dependence of the burning velocity on molecular structure, which is responsible for fuel reactivity, is known for a great many fuel–air mixtures.

A widely applied thermal theory, one of the first flame propagation theories, implies that combustion proceeds primarily at temperatures close to the maximum the flame can achieve. A set of differential equations developed for thermal conductivity and diffusion is reduced to one equation that yields the burning velocity value. Further development of the theory has been made and computers now make most simplifications unnecessary.

According to thermal theories, flame propagation is accounted for by heat energy transport from the combustion zone to the unburned mixture, to raise the temperature of the mixture. Diffusion theory assumes that thermodynamic equilibrium sets in behind the flame front at a maximum temperature, and that radicals produced in this zone diffuse into the unburned mixture and ignite it. Both heat transport and diffusion of active particles must be considered essential for ignition.

Diffusion flames. Diffusion flames, smoothly flowing (laminar) or turbulent, belong to the class of flames whose ingredients are not mixed prior to entering the burning zone. Molecular or turbulent diffusion is responsible for the mixing of the gases in such flames. The distribution of the combustible material and of oxygen over various flame cross sections is regular in laminar flames but becomes much more complicated in turbulent gas flows. The transition from laminar to turbulent flames occurs at a certain point of the flow and depends upon the actual conditions.

Industrial flames

Industrial flames, including those activated in furnaces, belong to the turbulent diffusion type. The theory of diffusion flames, however, is less advanced than that of premixed flames and, since gas intermixing is mainly responsible for the structure and the features of diffusion flames, the theory operates more in terms of physics and of thermodynamics than chemical reactions. Flames such as those of candles, of liquid droplets, and of many propellants and condensed fuels are diffusion flames.

Diffusion flame

Oxidizing and reducing flame. When a premixed flame burns in open air with an excess of fuel, there appears in addition to the flame zone a zone of diffusion flame; this is accounted for by the diffusion of atmospheric oxygen, as, for example, in the Bunsen flame produced by a burner to which the air intake can be regulated, thereby altering the flow from an intensely hot one—in which most of the fuel gases are oxidized to carbon dioxide and water—to a relatively low temperature flux, in which most of the fuel gas is only partially oxidized. Such flames consist of an inner and outer cone—two zones in which different chemical reactions take place, the reducing and oxidizing zones, respectively. The oxidizing nature of the outer cone is due to excess oxygen (see Figure 8).

From A. Gaydon, *The Spectroscopy of Flames;* Chapman & Hall Ltd.

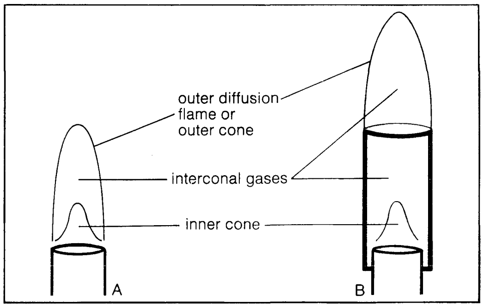

Figure 8: *Cones of burner flames.*
(A) Bunsen burner. (B) Teklu-Smithells burner.

Explosions. The transition from combustion to explosion is caused by an acceleration of the reaction, induced either by a rise in temperature or by increasing lengths of the reaction chain. The first is called thermal explosion, and the second, chain explosion.

Thermal explosions. Thermal explosion theory is based on the idea that progressive heating raises the rate at which heat is released by the reaction until it exceeds the rate of heat loss from the area. At a given composition of the mixture and a given pressure, explosion will occur at a specific ignition temperature that can be determined from the calculations of heat loss and heat gain.

The thermal explosion theory accounts for temperature rise and fuel consumption during the induction period. At sufficiently high rates of consumption the explosion will not occur.

Chain-branch reactions. It follows from the theory of branched-chain reactions that there is a limit to ignition, or to explosion, without a rise of temperature. In this case, what is called a chain explosion will occur when the probabilities of chain branching and of termination are equal. Usually, however, explosions are of a chain-thermal nature (*i.e.,* both heat accumulation and chain autoacceleration contribute to explosion).

Detonation. The progressive acceleration of reaction accounted for by growth of the flame front area and by transition from laminar to turbulent flow gives rise to a shock wave. The increase in temperature due to compression in the shock wave results in self-ignition of the mixture and detonation sets in. The shock wave-combustion zone complex forms the detonation wave. Detonation differs from normal combustion in its ignition mechanism and in the supersonic velocity of 2–5 kilometres per second for gases and 8–9 kilometres per second for solid and liquid explosives.

Detonation is impossible when the energy loss from the reaction zone exceeds a certain limit. The detonation limits observed for high explosives are also eventually dependent on factors responsible for the chemical reaction rate: the charge and diameter of the grain, etc.

Special aspects. Emission of light is a characteristic feature of combustion. Infrared, visible, and ultraviolet bands of molecules, and atomic lines are usually observed in flame spectra. Moreover, continuous spectra from incandescent particles, or from recombination of atoms, radicals, and ions are frequently observed. The sources of flame radiation are the thermal energy of gas (thermoluminescence) and the chemical energy released in exothermic elementary reactions (chemiluminescence). In a Bunsen burner fed with a sufficient amount of air, up to 20 percent of the reaction heat is released as infrared energy and less than one percent as visible and ultraviolet radiation, the infrared being mostly thermoluminescence. Radiation from the inner cone of the Bunsen flame in the visible and ultraviolet regions represents chemiluminescence.

Ionization

Many flames contain electrons and positive and negative ions, a fact evident from the electrical conductivity of flames, and also from the deviation of the flame cone in an electric field (the charges are attracted or repelled, distorting the flame), a phenomenon usually interpreted as a mechanical effect called electric wind. The resulting change of the flame shape can affect the burning velocity. Ionization, like the emission of light, can be the result of equilibrium processes, when it is called thermal ionization, or it can be related to chemical processes and called chemical ionization. Thermal ionization may be expected in very hot flames containing alkali metals or alkaline-earth metals (for example, sodium and calcium) as impurities because of their low-ionization potentials. The high concentrations of ions and electrons in the flames of organic species are undoubtedly due to chemical, rather than to thermal ionization. This is seen in the fact that electroconductivity in the inner cone of the Bunsen flame is several times higher than that of the outer cone. The reactions of ions and electrons may yield atoms and radicals and in this way affect the burning velocity.

Formation of soot is a feature of all hydrocarbon flames. It makes the flame luminous and nontransparent. The mechanism of soot formation is accounted for by simultaneous polymerization, a process whereby molecules or molecular fragments are combined into extremely large groupings, and dehydrogenation, a process that eliminates hydrogen from molecules.

Applications. The uses of combustion and flame phenomena can be categorized under five general heads.

In heating devices. Heating devices for vapour production (steam, etc.), in metallurgy, and in industry generally, utilize the combustion of gases, wood, coal, and liquid fuels. Control of the combustion process to obtain optimal efficiency is ensured by proper ratio and distribution of the fuel and the oxidant in the furnace, stove, kiln, etc., choice of conditions for heat transport from the combustion products to the heated bodies, and by appropriate aerodynamics of gas flows in the furnace. Radiation contributes to a certain extent to heat exchange. Combustion in furnaces being a very complicated process, only general ideas can be given by the combustion theory, so that the optimal conditions and the furnace design are usually decided empirically.

In explosives. The combustion and detonation of explosives are widely used in all sorts of work with mechanical action or explosion as the eventual goals. Practical applications of explosives are based on the theory of their combustion and detonation. The combustion of condensed explosives occurs mostly in the gas phase due to their evaporation, sublimation, or decomposition and can be treated in terms of the theory of gas combustion, which provides for the burning velocity, its dependence on temperature, pressure, and on the parameters determining the combustion regime and the nature of explosives, etc. Control of combustion and detonation in their practical applications is made possible by use of the theory, together with the results of experimental investigations on combustion and detonation.

In internal combustion engines. These comprise various engines, gas turbines, turbojets, and ramjets. The Otto engine operates with a mixture compressed in a cylinder by a piston. Shortly before the piston reaches the top the mixture is ignited with a spark, and the flame propagates at a normal velocity into the unburned mixture, increasing the pressure and moving the piston. There is a maximum of compression for any mixture composition and any engine design. Detonation occurs beyond this maximum because of the appearance of centres where self-ignition takes place before the flame front. Loss of power is one result of detonation; compounds hindering self-ignition are used to prevent it.

The diesel engine operates with a fuel spray injected into the engine cylinder as liquid droplets that mix with air by turbulent diffusion and that evaporate. At normal operations of the engine the temperature of compressed air is sufficiently high for self-ignition of the fuel.

In gas turbines, compressed air enters the combustion chamber where it mixes with the fuel. The expanding combustion products impart their energy to the turbine blades.

Two kinds of jet engines are used in aircraft: the turbojet and the ramjet. The turbine of a turbojet engine is used to operate the compressor. Thrust comes from the repulsion of products flowing out of a nozzle. In a ramjet engine, air is compressed and slowed down in the diffuser without any compressor or turbine device.

In rocket propulsion. The products of combustion of gaseous, liquid, or solid propellants in rockets are ejected from the combustion chamber through the (de Laval) nozzle at a high velocity. Knowledge of the kinetics of chemical processes in the nozzle is essential to determine the thrust required. The thrust decreases with the increasing mean molecular weight of the combustion products. Mixtures of low molecular weight and high heat of combustion, therefore, are used for rockets.

In chemical reactions. Flames are used in various ways to produce chemical reactions. The bead test in analytical chemistry is one example. The reducing power of a flame that has insufficient oxygen is utilized in limited ways. The soot produced by some flames is commercially useful. The manufacture of coke and charcoal is dependent on the judicious control of combustion and flame. (V.N.K.)

Electrochemical reactions

In the most general terms, electrochemical reactions are those chemical changes that are associated with the passage of electrons across interfaces between metal and solution. Under ordinary conditions, the occurrence of a chemical reaction is accompanied by the liberation or absorption of heat and not of any other form of energy; but there are many chemical reactions that—when allowed to proceed in contact with two electronic conductors, separated by conducting wires—liberate what is called electrical energy, and an electric current is generated. Conversely, the energy of an electric current can be used to bring about many chemical reactions that do not occur spontaneously. A process involving the direct conversion of chemical energy when suitably organized constitutes an electrical cell. A process whereby electrical energy is converted directly into chemical energy is one of electrolysis; *i.e.,* an electrolytic process. By virtue of their combined chemical energy, the products of an electrolytic process have a tendency to react spontaneously with one another, reproducing the substances that were reactants and were therefore consumed during the electrolysis. If this reverse reaction is allowed to occur under proper conditions, a large proportion of the electrical energy used in the electrolysis may be regenerated. This possibility is made use of in accumulators or storage cells, sets of which are known as storage batteries. The charging of an accumulator is a process of electrolysis; a chemical change is produced by the electric current passing through it. In the discharge of the cell, the reverse chemical change occurs, the accumulator acting as a cell that produces an electric current.

Finally, the passage of electricity through gases generally causes chemical changes, and this kind of reaction forms a separate branch of electrochemistry that will not be treated here.

GENERAL PRINCIPLES

Electronic and electrolytic conductors

Substances that are reasonably good conductors of electricity may be divided into two groups: the metallic, or electronic, conductors and the electrolytic conductors. The metals and many nonmetallic substances such as graphite, manganese dioxide, and lead sulfide exhibit metallic conductivity; the passage of an electric current through them produces heating and magnetic effects but no chemical changes. Electrolytic conductors, or electrolytes, comprise most acids, bases, and salts, either in the molten condition or in solution in water or other solvents. Plates or rods composed of a suitable metallic conductor dipping into the fluid electrolyte are employed to conduct the current into and out of the liquid; *i.e.,* to act as electrodes. When a current is passed between electrodes through an electrolyte, not only are heating and magnetic effects produced but also definite chemical changes occur. At or in the neighbourhood of the negative electrode, called the cathode, the chemical change may be either the deposition of a metal or the liberation of hydrogen and formation of a basic substance, or some other chemical reduction process; at the positive electrode, or anode, it may be either the dissolution of the anode itself, the liberation of a nonmetal, the production of oxygen and an acidic substance, or some other chemical oxidation process.

An electrolyte, prepared either by the melting of a suitable substance or by the dissolving of it in water or other liquid, owes its characteristic properties to the presence in it of electrically charged atoms or groups of atoms produced by the spontaneous splitting up or dissociation of the molecules of the substance. In solutions of the so-called strong electrolytes, most of the original substance, or in some solutions perhaps all of it, has undergone this process of electrolytic dissociation into charged particles, or ions. When an electrical potential difference (*i.e.,* a difference in degree of electrification) is established between electrodes dipping into an electrolyte, positively charged ions move toward the cathode and ions bearing negative charges move toward the anode. The electric current is carried through the electrolyte by this migration of the ions. When an ion reaches the electrode of opposite polarity, its electrical charge is donated to the metal, or an electric charge is received from the metal. The ion is thereby converted into an ordinary neutral atom or group of atoms. It is this discharge of ions that gives rise to one of the types of chemical changes occurring at electrodes.

HISTORY

The study of electrochemistry began in the 18th century, bloomed until the early 20th century, and then faded, owing to an excessive use of thermodynamic principles in analyzing the processes that take place at points in the system where the various parts form interfaces. Since about 1950 electrochemistry has undergone a change. The study of processes in solutions has been less stressed, but the study of the transfer of electrons between metals and solution has increased explosively. With this new emphasis electrochemistry is becoming a core science. It promises to be an important part of the foundation of the ecology-oriented society of the future, because electricity is not a pollutant. The pollution associated with some methods of generating electricity must, however, be reduced.

The first electrochemical reactions studied, in 1796, were those in the cell of silver and zinc plates with blotting paper wetted by aqueous salt solution between them; these cells were constructed by the Italian scientist Alessandro Volta, for whom the term volt was named. This cell was the first primary battery used for the production of electricity.

Faraday's laws

Michael Faraday formulated the laws of electrochemical stoichiometry, which deals with the application of laws of definite proportions and of the conservation of matter and energy to chemical activity. These state that a coulomb of electricity, a unit of charge, reacts with fixed quantities of a substance (*e.g.,* with 1.11800 milligrams of silver ions) or else that 1 gram equivalent of any substance reacts with 96,489 ± 2 coulombs. This latter number represents a fundamental quantity known as one faraday of electricity. The relationship between the chemical affinity of the reactants in the cell and the voltage of the cell when it is operating was precisely defined by the U.S. chemist Josiah Willard Gibbs in 1875 while the relation of this affinity to the potential of the electrochemical cell was initially formulated by the German physical chemist Walther Hermann Nernst in 1889.

The rise of electrodics

The period 1910 to 1950 was one of decline in electrochemistry, until it became limited mainly to the study of solutions. There was almost no progress in the understanding of electrochemical reactions outside of equilibrium conditions and reversibility, and knowledge of these was applied invalidly to reactions occurring at a net rate; *i.e.,* reactions not in equilibrium and not totally reversible. From about 1950 the study of electrified interfaces, with special reference to the study of the transfer of electrons (called electrodics), gained in importance and became the main aspect of electrochemistry. From about 1960, electrodics began to develop as an interdisciplinary area in the search for solutions to problems such as the source of energy in space flights from fuel cells, the stability of metals in moist environments, the electrochemical aspects of biological functions, extractions from mixtures, and the replacement of fossil fuels such as coal and petroleum and their by-products, by electricity produced or stored electrochemically in transportation.

THE ELECTROCHEMICAL PROCESS

Interactions of matter associated with the passage of an electric current depend upon the characteristics of the negatively charged electron. As the basic particle of electricity, the electron has an affinity for positively charged particles of matter, protons, whether in atoms, groups of atoms, or molecules. This affinity is analogous to the chemical affinity that particles exhibit among themselves. In fact, all chemical reactions result from a shift in the electron structure of atoms, and free electrons can combine with particles of matter (reduction) or be released by them (oxidation). The quantitative relationship between the free electrons of an electric current and the particles of a substance in which they cause a reaction is defined by the laws of Faraday (see above *History*). The substances that take part in electrochemical reactions called electrolytes, or ionic conductors, have been described above.

Electrons are available in large quantities in a relatively free (mobile) state only in substances called electronic conductors, among which metals are the most important. Thus, an electron conductor must be present as a basic component of any system in which electrochemical reactions are to occur. Furthermore, the availability of electrons in a conductor is limited by energy distribution to such an extent that electrochemical reactions take place only in the immediate vicinity of the electronic conductor's surface; *i.e.,* a few angstroms from the conductor into the solution. These reactions are, therefore, normally considered as occurring at the interface, or common boundary, between an electronic conductor, such as an electrode, and an ionic conductor of electricity, such as an electrolytic solution. Electrochemical reaction will take place, however, only to the extent that electricity can flow through such a system as a whole. To achieve this, it is necessary for the system to form a closed loop, electronically speaking. For schematic representation of these details, see Figure 9.

The closed loop of conductors

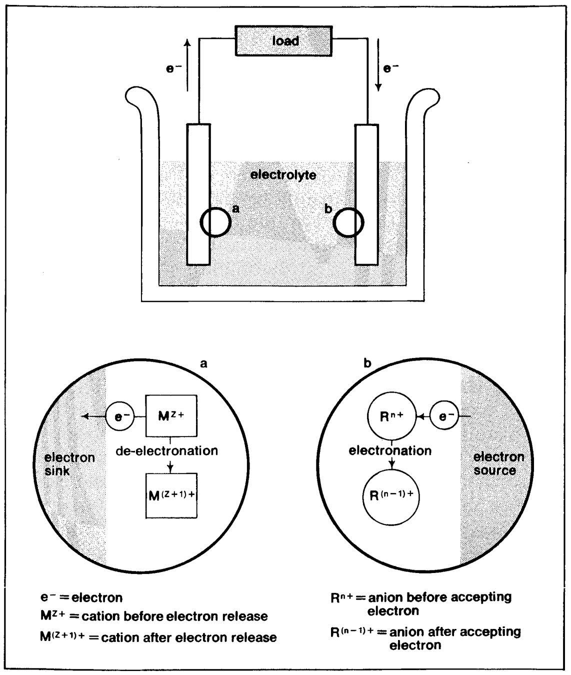

Figure 9: The mechanism of electron movement in an electrochemical cell.

To summarize, if at one metal-solution interface electrons are coming out of the metal, reducing a component of the solution, there must exist a second metal-solution interface where electrons are going into the metal in the process of oxidation.

The two electrodes and the ionic conductor in between (*e.g.,* an aqueous solution of some ionized salt) represent an electrochemical cell. The process occurring in the cell as a whole is a redox process with the reduction of one species spatially separated from the oxidation of another one. As a consequence of Faraday's law, the rates of electrochemical reactions at electrodes (expressed in terms of gram moles per second per square centimetre of electrode surface) are directly proportional to the current density (expressed in amperes per square centimetre); *i.e.,* current flowing through the cell divided by the electrode surface area.

Sites of electrochemical reactions. Electrochemical reactions take place where the electron conductor meets the ionic conductor; *i.e.,* at the electrode–electrolyte interface. Characteristic of this region, considered to be a surface phase, is the existence of a specific structure of particles and the presence of an electric field of considerable intensity (up to 10,000,000 volts per centimetre) across it; the field is caused by the separation of charges that are present between the two bulk phases in contact. For most purposes the surface phase can be considered as a parallel plate condenser, with one plate on the centre of the ions that have been brought to the electrode, at the distance of their closest approach to it, and with the second plate at the metal surface; between the two plates and acting as a dielectric (*i.e.,* a nonconducting material) are oriented water molecules. This structure is termed the electric double layer and is illustrated in Figure 10.

Thermal motion of the positive ions in the solution makes the condenser plate on the electrolyte side of the interface diffuse; *i.e.,* the ions are distributed in a cloudlike way. This condition justifies the division of the potential change between the bulk of metal and the bulk of electrolyte into two parts: first, that between the metal surface and the first ionic layer at the distance of closest approach (called the outer Helmholtz plane, in which the ions are usually surrounded by solvent particles; *i.e.,* are solvated); and second, that between the first ionic layer and the bulk of the solution, the diffuse part of the double layer. The picture is further complicated by the presence of ions in the electrode surface layer in addition to those that are present for electrostatic reasons; *i.e.,* by the force of attrac-

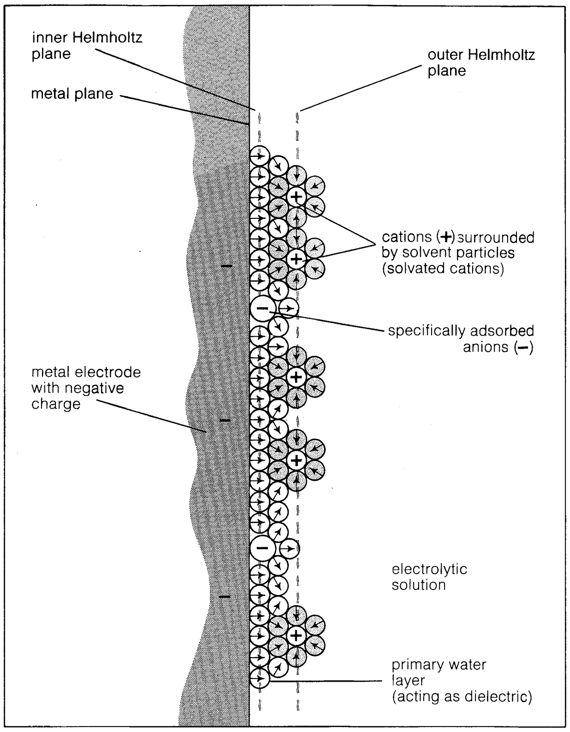

Figure 10: Double-layer structure and change of potential with distance from the electrode surface (see text).

tion or repulsion between electric charges. Such electrode surface layer ions are said to be specifically adsorbed on the electrode surface. Since this species of ions is attracted by the surface to a distance closer than the "distance of the closest approach" of ions, further subdivision of the inner part of the electric double layer is justified. Hence, the inner Helmholtz plane is introduced as the plane formed by the centres of specifically adsorbed ions. Adsorption of neutral molecules on the surface can also change the properties of the electric double layer. This change occurs as a consequence of replacing the water molecules, and thus changes that part of the potential (electrical) difference across the double layer that is caused by the adsorbed dipoles (water molecules that have a polarity—*i.e.,* they behave like minute magnets—because of their hydrogen-oxygen structure, making one end of the molecule positive and the other end negative).

Relative electrode potential

The absolute value of electrical potential difference, symbolized in calculation by the Greek letters delta and psi, $\Delta\psi$, between the bulk of a metal electrode and the bulk of an electrolyte cannot be measured. Instead, the voltage of a special cell, composed of the specific electrode being studied and of an arbitrarily selected reference electrode, is normally measured; the voltage is referred to as the relative electrode potential, E. Of special interest is that state of the electrode at which there is no net charge (in this case, no unbalanced, or extra positive, charge) at the metal side of the double layer. The relative potential at which this state is achieved is characteristic of each metal. This point is termed the potential of zero charge. At that potential, the field across the double layer is due to orientation of water molecules and other dipoles at the surface only.

Most of the knowledge of the detailed structure of the interface between a metal and an electrolyte arises from experimentation with mercury, the only metal that is liquid at ordinary temperatures; the double layer structure turns out to have surface tensions that must be measured, and this measurement is difficult with solid metals. By 1970, however, it had been shown that it is possible to measure surface tension changes at the metal-solution interface. Thus, the way to the determination of the double layer structure involving solids was opened.

Substances that are semiconductors can also be employed as electron carriers in electrochemical reactions. Semiconductors are substances which range between serving as insulators at low temperatures and as metallic-type conductors at high temperatures. In the case of semiconductors, however, the electric double layer has a more complex structure inasmuch as the condenser plate at the electrode side of the double layer also becomes diffuse. Thus, the overall potential difference between bulks of the phases in contact comprises also the potential difference between the bulk of the semiconductor and its surface.

Types of electrochemical reactions. There are several types of electrochemical reactions.

Simple redox reactions. A simple redox reaction is one that involves a change in the electrical charge of a charge carrier, usually a simple or complex ion in the solution, by its taking away, an electron from the electrode (reduction), or its giving an electron to the electrode (oxidation). The same carrier may be present in solution in two states of charge. The higher, more positive charge is called the oxidized state, and the lower, less positive charge is called the reduced state. For example, when ferric and ferrous ions are both present in solution in significant quantity, and when electron exchange with the electrode is sufficiently fast, redox equilibrium is established at the electrode, giving it a well-defined potential, or reversible redox potential.

Reversible hydrogen electrode

Reactions that produce gases. When hydrogen ions in solution react with electrons ejected from a metal, hydrogen atoms are formed at the surface, where they combine among themselves or with other hydrogen ions and electrons to give gaseous hydrogen molecules. If all the reactions are fast enough, an equilibrium is attained between hydrogen ions and gaseous hydrogen. A metal in contact with solution at which such a situation exists is called the reversible hydrogen electrode, and its electrical potential is arbitrarily taken to be zero; every other electrode can thus be compared with it as it represents the basis for constituting the hydrogen scale of relative electrode potentials. Similarly, negative hydroxyl ions in solution (OH^-) can be made to give up electrons to a metal and, in a series of reactions, the final one is the formation of gaseous oxygen. Chlorine is another gaseous product; it evolves upon electrochemical oxidation of chloride ions in concentrated solutions of neutral and acid salts.

Reactions that deposit and dissolve metals. When a metal ion is reduced and discharged as a neutral atom, or species, it tends to build into the metal lattice of the electrode. Thus, metals can be deposited at electrodes. Conversely, if electrons are taken away from the metal electrode by applying positive potentials to it, the metal ions thus formed can cross the double layer of electric charge at the interface, undergo hydration (combination with water), and enter the solution. The metal electrode thus dissolves. Many metals establish well-defined electric potentials when they are in contact with their own ions in solution.

Oxidation and reduction of organic compounds. A reaction of the oxidation and reduction of organic compounds can also be done at electrodes. Such reactions, however, are mostly irreversible in the literal sense that they lead to products that cannot easily be converted back into the original substance. Exceptions are some oxygen- and nitrogen-containing compounds (quinones, amines, and nitrous-compounds), that can give fairly well-defined reversible potentials.

Mechanism of charge transfer. The causes of the thermodynamically irreversible behaviour of electrode reactions are found in the nature of the elementary act of charge transfer. Like any chemical reaction, this act is inhibited by the existence of an energy barrier between the oxidized and the reduced state. This barrier implies that the reaction could take place only in the special circumstances when, during the course of numerous interactions with other species (atoms, ions, molecules, etc.) surrounding it, a molecule attains an excited state in which it has an abnormal energy content. In most chemical reactions, this energy content must be sufficient for the species to come into what is called the transition state; the transition state characterizes the top of the energy barrier just before a reaction begins. If such a model is applied to electron transfer at an interface, calculation shows that electron exchange reactions at electrodes would be prohibitively slow, a conclusion at variance with the observed phenomena; quantum mechanical laws, however, govern the motion of electrons, and their inclusion changes the calculations to fit reality. Quantum mechanics require that for fast electron exchange to take place, electrons in a particle outside the double layer (*e.g.,* a hydrated ion at the outer Helmholtz plane) must attain certain well-defined quantized energy levels equal to those in which free electrons exist in the metal. Since such states can be attained by the particle at a lower energy-content than that needed for its transfer over the top of the energy barrier, according to the classical view, this fast process of electron exchange between the electrode and a particle in solution is termed electron tunnelling through the energy barrier.

Electron tunnelling

Whereas the rate of chemical processes, or what may loosely be termed the speed of reaction, can be influenced only by changing the concentrations of reactants or by changing the temperature or both, the rate of electrochemical processes also can be manipulated by changing the electrode potential. Making the electrode more negative increases the number of electrons in the metal ready to tunnel to ions, and hence the rate of the reduction process increases. Conversely, making the potential more positive decreases this rate and increases the number of particles ready to give away electrons, thus increasing the rate of the oxidation process.

It can be deduced that there must exist a direct proportionality between the rate of reaction and the concentration of the reacting species and at the same time an exponential proportionality between the rate of reaction and the electrode potential.

At any electrode potential, both reduction of one species and oxidation of the product of reduction are taking place but at different rates; the rate of each reaction is determined by the respective concentration and by the corresponding effects of potential. The rate of an electrochemical reaction can best be described as the electric current density; *i.e.,* a measure of the quantity of electrons moving in a certain volume of space during a specified unit of time.

The relationships can be represented quantitatively by an equation in which the net, or resulting, current (the difference of the rate of electron ejection across the interface to particles in solution, diminished by the rate at which particles in solution inject electrons into the metal) is equated to the difference of the rates of reduction and oxidation and the variables and constants that relate to these reactions. See equation (1), and other equations below in *Calculations* at the end of this section. Equation (2), known as the Nernst equation, which can be derived from equation (1), gives the value of the electrode potential when the rate of oxidation exactly equals the rate of reduction. Using this value for the electrode potential, equation (3), called the Butler-Volmer equation, can be derived; it represents the most fundamental relationship in electrodic chemistry.

COMPLEX ELECTROCHEMICAL REACTIONS

Electrochemical processes considered so far involve simple reactions of a particle with a single electron to produce a reduced ion (*e.g.,* the ferrous ion of iron with two positive charges, Fe^{++}), or vice versa. Such are the simple ionic redox processes, where the only difference in structure between a reactant and a reaction product may be due to some rearrangement of the neighbouring solvent molecules. When one or more transfers of electrons between the electrode and a species in solution are accompanied by major structural changes (*e.g.,* when hydroxyl ions, OH^-, transform into a molecule of oxygen, O_2, and a water molecule, H_2O, in the process of oxygen evolution at the anode, or positive electrode), the reaction usually consists of a sequence of events, called elementary acts, or unit steps, constituting the reaction mechanism. Intermediate states between the steps usually involve some unstable intermediate species with higher energy content than those of the reactants or of the reaction products.

Complex reaction mechanisms can consist of a number of electron transfer steps, with some chemical steps preceding or succeeding the electron transfer steps or taking place in between them. Most organic electrochemical reactions are complex, involving large numbers of electrons in the overall reaction. Usually one step in the reaction encounters the largest energy barrier. The rate of occurrence of this step limits the rate of the overall reaction (*i.e.,* all other steps must occur at the same net rate, although they could provide for a much faster overall change). This step is called the rate-determining step and, for most practical purposes, all intermediate steps before and after it can be considered to be in equilibrium. (It is interesting to note that whenever this is the case, the Butler-Volmer equation [equation 3 below] is applicable, but with specific values of the transfer coefficients α_a and α_c characteristic of the mechanism of the reaction.)

Complex reaction mechanism

Experimental studies. Measuring the rates of electrochemical reactions (*i.e.,* current densities) as functions of electrode potential under steady-state conditions represents the normal tool of electrodics. Meaningful results could not be obtained, however, until the sensitivity of electrochemical reactions to impurities was realized and high purity techniques were introduced. Even so, the steady-state method often has shortcomings except for relatively slow electrode reactions. In many cases concentration changes at the electrodes prevent using a sufficiently wide current density range for obtaining meaningful Tafel relationships (see Butler-Volmer equation below under *Calculations*). Hence, so-called transient methods have been developed in which one electrochemical factor in the situation is rationally perturbed and the time dependence of others observed. One such method consists of placing a constant current pulse upon an electrode and measuring the variation of the resulting current through the solution. This is called the galvanostatic method for measuring the rate of an electrochemical reaction. Applying a potential pulse while observing the variation of the rate as a function of time constitutes the potentiostatic method. A third method, called the potentiodynamic, or potential sweep, method involves observations of the current as a function of the potential, while the latter is varied at a constant, known rate.

Galvanostatic, potentiostatic, and potentiodynamic methods

The advantages of transient methods over steady-state ones, in which behaviour before the attainment of the steady-state is not part of the observation, are manifold. If observations are made at sufficiently short times, events can be recorded before the onset of concentration changes, and pure activation values can be found. Hence, Tafel relationships can be obtained over a larger current density range (see below *Calculations*) than if one makes measurements over longer times, as is required in the steady-state methods. The structure of the transient states can reveal important information, such as double layer capacitance and surface coverage of the electrode by intermediate species.

Several so-called kinetic parameters, for example, partial derivatives of current density and potential with respect to concentration of chosen reactants, can be extracted from experimental measurements.

Electrochemical measurements have a limited capacity to reveal the state of an electrode surface. Nonelectrochemical methods of studying electrode surfaces, therefore, have been stressed. Optical methods have considerably gained in importance. Ellipsometry (*i.e.,* measuring changes in basic properties of polarized light as it is reflected from an electrode surface) was the first method that made possible a study of monomolecular layers of oxides and adsorbed oxygen as adsorbed organic molecules. Adaptation of such a method to transient use allows change in the surface to be related to the passivity of metals. Another kind of spectroscopy enables infrared spectra of species adsorbed at electrode surface to be taken. Mössbauer spectra may lead to an identification of thin layers on an electrode surface. A good future is seen for further development of refined techniques for the study of electrochemical processes by various combinations of spectroscopic and electrochemical means.

Types of complex reactions. *Electrocatalysis.* The problems related to the increase of rates of electrochemical reactions, or, to put it another way, the decrease of overpotential, needed to perform reactions at a given rate are the subject of electrocatalysis. Both increase and decrease are of considerable practical importance since they affect the economics of electrochemical processes. Electrocatalysis is concerned with the electrode as a substrate, or base, for electrochemical reaction and with the effect of its bulk and surface properties on the rate of reaction. Contrary to expectation, the rate of the basic step in electrochemical reaction—electron transfer—is independent of the ease with which electrons are released from the metal. Hence, those simple electrode processes in which no other changes but electron transfer take place have heats of activation virtually independent of the metal substrate.

In a reaction involving the formation of a chemical bond between the electrode substrate and one of the radicals (charged particles) formed on the surface, rates of reaction at a given potential may vary for different substrates by many orders of magnitude. The variation is a function of the strength (or energy) of bonds established between the intermediate species and the surface, and when the substrates are transition metals, regular relations between reaction rate and certain characteristics of the metal's electronic structure are observed. If such bonds are too weak, the catalytic effect of the substrate is small. If they are too strong, the intermediate species is too stable to react further, and the surface of the metal becomes virtually blocked for further reaction. Thus, there is an optimum bond strength that can be seen if the rate of a reaction is plotted against a property of the metal substrate, which is proportional to the ability of the surface to form bonds; *e.g.*, its heat of sublimation.

Electrochemical reactions can also be catalyzed or inhibited by foreign species present in the electrolytic solution. In the most general case, ions can change the rates of reactions by changing the properties of the double layer by specific adsorption effects. Organic molecules inhibit electrochemical reaction by blocking the surface. For some organic ions or dipoles, the blocking effect can begin at a certain well-defined potential. Before attaining it, the electrode reaction gives the usual current density-potential relationship, which is then suddenly interrupted by an abnormal fall of the current, corresponding to adsorption.

Electrocrystallization. Deposition of metals and other substances at electrodes as a consequence of an electrode process exhibits a number of specific features. The electrode process is followed by crystal building, and this results in a continuous change of the electrode surface. This change, in turn, affects the electrochemical properties of the system—the double-layer capacity and the rate constants of the charge transfer processes. Hence, if electrochemical properties are to be studied, transient methods should be employed that allow measurements to be made before major changes in surface morphology (structure) take place.

Since the two steps, the discharge of ions at the electrode and the incorporation of the discharged ions into the crystal lattice, are separated in time and space, an intermediate species exists at the surface, that of relatively loosely bound and freely moving atoms, called adatoms. Since the electrons tend to join the rest in the bulk of the metal, adatoms appear to have a partial charge, less than that of the elementary positive charge. The adatoms therefore attract solvent molecules, and the species is partially solvated. This reaction justifies considering an adatom as a kind of adsorbed ion, called an adion, which, however, has already undergone partial discharge.

Because such an intermediate state is possible, ions need not be reduced to the neutral atomic state at the point of incorporation into the crystal lattice. Indeed, energy considerations reveal this reduction to be improbable. Instead, discharge of ions is favoured on crystal planes. Their motion from the location of discharge to a site on the crystal occurs by surface diffusion. When such surface diffusion is inhibited, it can, in some cases, control the rate of reaction.

Problems of the crystal-building step in electrocrystallization are in many respects identical with those of crystal growth from the gas phase. Crystal building can occur in any one of three possible ways.

Kinks, naturally existing at any metal surface, form a suitable half-lattice position at which an atom is surrounded by one-half of the number of atoms that would surround it in the bulk of the metal; there, adatoms can be successively trapped and thus the crystal lattice is extended along a crystal edge and further on across the surface. This step growth mechanism is shown in Figure 11A. The mechanism, however, has a limited capacity for crystal growth. A step can move as far as the edge of a crystal, and step growth would lead to smoothing of the surface to perfection, but then further growth would cease.

Mechanisms associated with screw dislocations, or twinning edges, can provide for a continuous growth of crystals. The screw dislocation mechanism, shown in Figure 11B, is made possible by a specific fault often found in the crystal lattice that may be called a dislocation originating from a shift of one atom in the lattice with respect to a perfect arrangement. This shift may then result in the formation of a monoatomic edge projecting above the electrode surface at which new atoms can be stacked. The stacking produces a turning of the edge around the base atom as a centre, the process producing a spiral growth.

Stacking

If growth sites are rare, or if the substrate at which deposition should take place is foreign to the depositing metal, the charge transfer results in an accumulation of adatoms to a concentration considerably larger than that which can exist there at equilibrium with the crystal lattice. This condition is termed supersaturation. In such a situation, agglomeration of adatoms to form crystal nuclei is favoured. Surface energy requirements show that at any degree of supersaturation, nuclei of certain dimensions are stable and can represent sites for further growth. The process is shown in Figure 11C.

The formation of deposits is controlled by the above mechanism as long as the discharge process supplies ample amounts of adatoms as building material over the entire surface. If the rate of deposition is increased, so as to produce near the surface considerable depletion of ions, uneven deposition will start. This is caused by the protrusions of a normally rough metal surface being closer to the bulk of solution than the recessed parts and, hence, getting

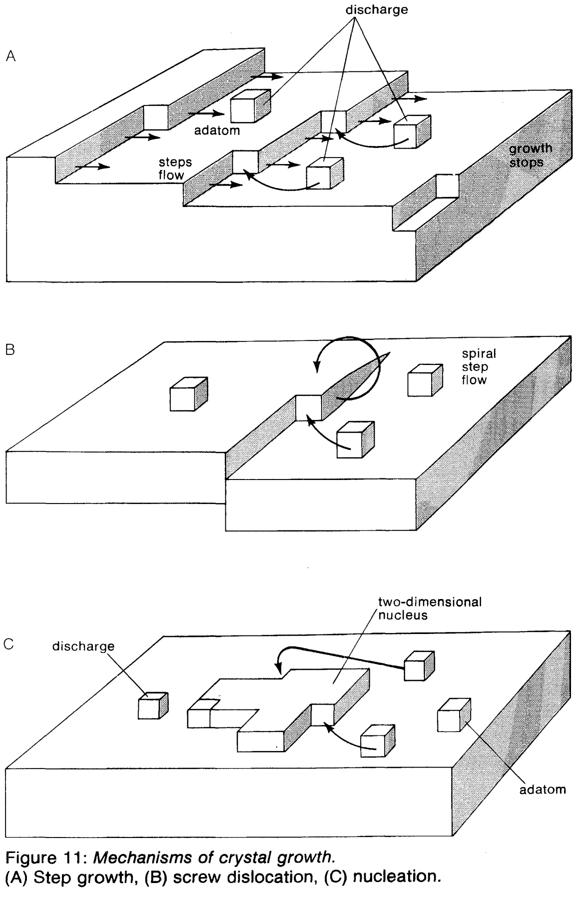

Figure 11: *Mechanisms of crystal growth.*
(A) Step growth, (B) screw dislocation, (C) nucleation.

a somewhat faster supply of the discharging species. Once such a situation is established, it tends to develop further. The faster growing points penetrate into ever richer layers of solution, resulting in ever faster growth. Thus, a natural consequence of deposition under transport-controlled rate is the amplification of the original surface roughness and the appearance of protruding spikes, called dendrites, as deposits.

A converse process is the smoothing of the original surface irregularities, which may occur when some foreign species, called an additive, is present in solution and adsorbs on the surface and inhibits the process of discharge. If those molecules are incorporated into a growing deposit, a situation may arise in which their supply to recessed parts of the surface becomes slower than to elevated parts. As a result, deposition becomes faster at recessed parts than at elevated ones and leveling of the surface occurs. This process has considerable technical application. Metal dissolution can sometimes be governed by a similar, transport-controlled mechanism, in which case a polishing effect is obtained. Electropolishing has found wide application in practice.

Organic electrode reactions. A very large number of electrochemical reactions involving organic molecules are known. An example is the oxidation of ethylene according to the equation:

$$\underset{\text{(ethylene)}}{C_2H_4} \quad + \quad \underset{\text{(water)}}{4H_2O} \quad \rightarrow \quad \underset{\substack{\text{(carbon}\\\text{dioxide)}}}{2CO_3} \quad + \quad \underset{\substack{\text{(hydrogen)}\\\text{ion)}}}{12H^+} \quad + \quad \underset{\text{(electrons)}}{12e^-}.$$

Many chemical organic reactions can be made to function electrochemically, a general advantage being that the rate of the reaction is easily controlled by controlling the potential. A change of potential may change the path of the reaction and hence a certain product may be tuned in. In particular, polymerization reactions at electrodes can be stimulated; such a method is used as a step in the production of nylon.

Ductile and brittle properties

Electromechanical effects. Several properties of solid bulk metals turn out to be dependent upon electrochemical reactions. Thus, if the hydrogen atom concentration on an electrode surface exceeds a certain critical value, the hydrogen molecules (H_2) inside intrinsic voids in the metal's interior may exceed a critical gas pressure and cause the voids to open up and spread, thus causing the metal to lose ductility and become brittle. It is the electrochemical reaction, represented by the equation $H^+ + e^- \rightarrow H$ (hydrogen ion plus electron equals hydrogen atom) at the metal–solution interface that controls the surface hydrogen atom (H) concentration and, hence, the hydrogen molecules (H_2) present inside the metal. A limiting electrode potential which causes hydrogen atom concentration exists, above which a metal loses strength. This concept applies also to moist metal surfaces; *i.e.,* most practical metal surfaces, the electrolyte being in effect a surface moisture layer and the ions being produced from the dissolution of atmospheric carbon dioxide. Friction between solids involving moist or wet surfaces is also dependent on electrochemical factors.

Multielectrode systems. So far, systems have been considered in which a single electrode process takes place. In principle, at any electrode potential all species present in the system fall into two categories: those that are stable, and those that undergo oxidation or reduction. The stable species are those that at the given electrode potential would not decrease their free energy by giving off or accepting electrons.

At any potential there should occur a codischarge of all unstable species. Thus, the system can be considered as a multielectrode system, consisting of as many electrodes as there are redox couples present. The rate at which different processes occur, however, can be so widely different that usually a single process is by far the dominant one. Systems at which two electrode processes occur at comparable rates are of considerable importance. If two kinds of metal ions are discharged simultaneously, an alloy is formed upon crystallization. The properties of the alloy would in most cases be those determined by the phase diagram (a plot of the temperature of melting versus the composition of the mixed system) for the ratio of quantities of discharged metals given by the rates at which the discharges take place. In many cases, nonequilibrium metal phases are formed giving unusual properties to the alloy.

Corrosion

If a process of metal dissolution (an oxidation process) can occur at a rate comparable to that of some reduction process on the same metal, a corrosion couple is established. Thus, zinc immersed in acid solution tends to establish a potential sufficiently positive for the metal to eject metal ions into the solution (oxidation). At the same time, it is also sufficiently negative for the reduction of hydrogen ions, present in any aqueous solution, to hydrogen gas. Hence, a spontaneous process of hydrogen evolution and of dissolution of the metal will take place. The rate at which this corrosion process occurs is governed by rate laws of the type given by equation (3) (see below *Calculations*). The mixed potential, spontaneously established by the corroding metal, is obtained by equating expressions for the anodic and cathodic currents of the two processes in the corrosion couple.

Corrosion can be prevented in two ways. One is by using an external source to make the potential of the metal sufficiently negative to bring it into the potential region in which the metal is stable, called cathodic protection; and the other is by provoking by some means the formation of a film on the surface that would slow the process. Such films could consist of an oxide or a layer of organic molecules that prevents dissolution and hence is called an inhibitor.

APPLICATIONS

Electrochemical processes are used in many ways and their use is likely to increase because they can replace polluting chemical situations with nonpolluting electrochemical ones. In many fields, however, applications have been profitable for some time. Major categories are listed below.

Metallurgy. All technologically important metals, except iron and steel, are either obtained or refined by electrochemical processes; for example, aluminum, titanium, alkaline earth, and alkali metals are obtained by electrodeposition from molten salts, and copper is refined by electrolysis in aqueous copper sulfate solutions.

Electroplating. One of the major ways of both decorating objects and improving their resistance to corrosion is by electroplating them. All major metal-working industries, particularly the automobile industry, have large electroplating plants.

Chemical industry. Electrolysis of brine to obtain chlorine and caustic soda is an electrochemical process that has become one of the largest volume productions in the chemical industry. Modern processes cover a wide field, from the production of a variety of inorganic compounds to the production of such synthetic fibres as nylon. Intensive research in organic electrochemistry promises major developments in application, particularly with the prospect of greatly reduced electricity costs expected eventually to arise from the development of controlled fusion.

Batteries. Electrochemical storage of electricity is effected in batteries. Such devices are electrochemical cells and consist of two electrodes per unit. As the electricity to be stored is accepted on the plates of the cell, it converts substances on the plates to new substances having a higher energy than the old ones. When it is desired to make the electricity available again, the terminals of the battery are connected to the load and the substances on the battery plates retransform themselves to those originally present, giving off electricity as a product of their electrochemical reactions. The steadily rising production of the lead-acid battery is largely the result of its use for starting the internal-combustion engine, which has had an equally steady rise. Other electrochemical systems are also used as storers. The nickel-iron (Edison cell) and nickel-cadmium battery with alkaline electrolyte are both used in applications where longer lives than those of the lead-acid battery are needed; the silver-zinc battery is used to start airplane engines because of its high power per unit of weight. A variety of new systems is being investigated for covering other needs. One of the greatest challenges to electrochemists and electrochemical engineers is that of producing a battery with sufficient power and energy density to run an automobile the way gasoline (petrol) does. Even if the best hypothetical predictions for removal of polluting chemicals from automobile exhausts is realized, the cleanup will not be sufficient because the expected growth of the automobile population will continue to increase the pollutant rate.

Fuel cells. The energy of chemical reactions is converted into electrical energy in fuel cells. In these, the fuel (*e.g.*, hydrogen, hydrazine) is fed continuously to one electrode, while oxygen from the air is reacting at the other one. The efficiency of energy conversion in fuel cells is more than twice that attainable by conventional means, for example, by means of internal combustion.

Analytical chemistry. In analytical chemistry, most modern automated instrumental analysis is based on electrode processes—for example, potentiometry, used to measure ionization constant.

Biological research. In biology the idea that many biological processes, from blood clotting to the transfer of nerve impulses, are electrochemical in nature continues to spread. The biological conversion of the chemical energy of food to mechanical energy takes place at an efficiency so high that it is difficult to explain without electrochemical mechanisms. Intensive research is developing in various directions in bioelectrochemistry.

CALCULATIONS

The three equations referred to above are stated in this section, and other mathematical considerations are also included. The rate of an electrochemical reaction in terms of oxidation and reduction reactions, the concentration of the reacting species, the electrode potentials and the current densities can all be related quantitatively according to equation (1):

$$i = \overrightarrow{i} - \overleftarrow{i} = \overrightarrow{k} C_{\mathrm{red}} \exp\left(\frac{\alpha_a F}{RT} E\right) - \overleftarrow{k} C_{\mathrm{ox}} \exp\left(\frac{\alpha_c F}{RT} E\right)$$

in which i is the net current density, $\overrightarrow{i}$ and $\overleftarrow{i}$ are the partial current densities of the oxidation and reduction respectively, C_{red} and C_{ox} are the concentrations of the reducing and oxidizing agents, respectively, $\overrightarrow{k}$ and $\overleftarrow{k}$ are the corresponding rate constants, while α_a and α_c are the so-called transfer coefficients; *i.e.*, specific constants giving a proper influence factor to the exponential dependence of rate on the potential, E. In the case of a simple one-electron transfer these factors are termed symmetry factors, for they, in a way, reflect the symmetry of the energy barrier. It can be proved that $\alpha_c + \alpha_a = n$, the number of electrons exchanged in a single act of an electrode reaction.

Nernst Equation. For a particular value of E the two partial current densities must become equal. This value of potential is the reversible electrode potential. From equation (1) one can deduce equation (2):

$$E_{\mathrm{rev}} = \frac{RT}{(\alpha_c + \alpha_a)F} \ln \frac{\overrightarrow{k}}{\overleftarrow{k}} + \frac{RT}{(\alpha_c + \alpha_a)F} \ln \frac{C_{\mathrm{ox}}}{C_{\mathrm{red}}}$$

$$= E^\circ + \frac{RT}{nF} \ln \frac{C_{\mathrm{ox}}}{C_{\mathrm{red}}}.$$

This equation is known as the Nernst Equation; E° is the standard electrode potential (at $C_{\mathrm{ox}} = C_{\mathrm{red}} = 1$) characteristic of the given redox couple.

The standard electrode potential on the hydrogen scale is related to the thermodynamics of the electrode process. It reflects the standard free energy change of the redox reaction between the electron and the given redox couple, relative to the free energy change that takes place in the hydrogen electrode process.

Butler-Volmer Equation. The reversible electrode potential can be introduced into equation (1) and the potentials taken relative to its value. When so expressed, they are termed overpotentials and can be stated as $\eta = E - E_{\mathrm{rev}}$; equation (1) then transforms to equation (3):

$$i = i_0 \left\{ \frac{(C_{\mathrm{red}})_i}{(C_{\mathrm{red}})_o} \exp\left(\frac{\alpha_a F \eta}{RT}\right) - \frac{(C_{\mathrm{ox}})_i}{(C_{\mathrm{ox}})_o} \exp\left(-\frac{\alpha_c F \eta}{RT}\right) \right\}$$

in which i_0 represents the value of either of the (equal) electron-emitting and electron-accepting partial current densities at the reversible potential and is termed the exchange current density. Equation (3) is called the Butler-Volmer Equation and represents one of the most fundamental relationships of electrochemistry.

As overpotentials, either positive or negative, become larger than about 5×10^{-2} volts (V), the second or the first term of equation (3) becomes negligible, respectively. Hence, simple exponential relationships between current (*i.e.*, rate) and overpotential are obtained, or the overpotential can be considered as logarithmically dependent on the current density. This theoretical result is in agreement with the experimental findings of the German physical chemist Julius Tafel (1905), and the usual plots of overpotential versus log current density are known as Tafel lines. The slope of a Tafel plot reveals the value of the transfer coefficient α for the given direction of the electrode reaction.

Difficulties in transport of reaction species. The above conclusions about the overpotential-current density relationship are valid as long as the ratios of concentrations at the electrode surface of the species involved at current density i, C_i and in the absence of current C_o stay close to unity. As the current density is increased, the concentration gradient needed to maintain a corresponding diffusion flux of the species concerned must begin to become appreciable. This condition is possible only if the concentration of the species at the surface starts to differ appreciably from the bulk value; *i.e.*, $(C_i)_i/(C_i)_o \neq 1$. The change in concentration of the discharging species at the electrode surface with time can, in principle, be obtained by using a second order partial differential equation (Fick's law), which, however, has explicit solutions only for a limited number of well-defined boundary conditions.

When significant concentration changes set in, no more exponential dependence of current density on potential can be obtained. It can be derived that, instead, a transition toward a limiting value takes place.

The important case is that in which the concentration of the discharging species at the electrode surface becomes equal to zero. The steady-state (*i.e.*, independent of time) current density obtained in such a case is the highest possible for the given set of conditions (diffusion limiting current density). The value of the concentration gradient in this case is directly proportional to the bulk concentration of the species involved and inversely proportional to the thickness of the diffusion layer (*i.e.*, the layer close to the electrode in which the concentration of the species differs from the species concentration in the bulk). This layer most often has a thickness fixed by hydrodynamic conditions in the solution surrounding the electrode. The definition used most often for the diffusion layer thickness is that of the German physical chemist Walther Hermann Nernst (1864–1941), according to whom this quantity is equal to the distance from the electrode at which the concentration would reach the bulk value if the concentration gradient were constant and equal to that at the electrode surface.

If a current larger than the limiting current is forced upon the electrode, the given electrode process will be able to sustain it only in the initial period in which the layer of solution close to the electrode is not completely exhausted of the discharging ions. As the concentration of ions tends toward zero, the electrode potential will change and another electrode process will start. The time at which the abrupt change of potential toward a new process takes place is termed the transition time. The relationship between transition time, current density, and concentration of the discharging species is given by Sand's equation:

$$\tau^{1/2} = \frac{\pi^{1/2} n F C_o D^{1/2}}{2i}.$$

Since τ is a well defined function of the concentration of the discharging species, the observation of the transition time can also be used as an analytical tool (chronopotentiometry). (J.O'M.B./A.De.)

Photochemical reactions

Photochemical reactions are chemical processes initiated by the absorption of energy in the form of visible, infrared, or ultraviolet radiation. The immediate consequence of this absorption is called the primary photochemical process. Subsequent changes, called secondary processes, are part of photochemistry. The process by which a photochemical reaction is carried on is photolysis.

Photochemistry differs from most other aspects of chemistry in one regard. If an atom or molecule absorbs energy from a beam of light, it gains far more energy than it ever could by other methods; *e.g.,* from ordinary heating. Consequently, photochemical processes are sometimes extremely efficient for the conversion of energy from light into chemical energy. The most important single photochemical process for living systems, photosynthesis, is of this type: green plants convert light energy into stored chemical energy by producing carbohydrates from carbon dioxide and water. Many other natural processes are wholly or partly photochemical. Ozone in the upper atmosphere, which shuts out most of the Sun's intense ultraviolet radiation, is produced by the action of light on oxygen molecules: sunlight breaks some of the molecules into atoms, which combine with other oxygen molecules to make ozone.

Natural photochemical processes

Bleaching laundry in sunlight is at least partly a photochemical process, and so is the darkening of white lithopone (zinc sulfide) paint. Photography is based on a photochemical process, the action of light on grains of silver chloride or silver bromide.

GENERAL CONSIDERATIONS

Kinds of photochemical effects. The action of light on a chemical system may take various forms:

1. Light may act as a booster to maintain a reaction that might otherwise proceed at an imperceptibly slow rate, the reacting molecules exchanging little or no net energy with their environment. Some molecular rearrangements (reactions that alter the geometry of individual molecules) fall into this category.

2. Light may act as a trigger, initiating a reaction that, once started, can proceed spontaneously. An example is the initiation of the reaction between hydrogen (formula, H_2) and chlorine (Cl_2) to give hydrochloric acid (HCl). Hydrogen and chlorine can be kept mixed together for an indefinite period at room temperature in a dark container; but if violet or ultraviolet light reaches the mixture, the two substances react explosively, giving off considerable stored chemical energy as heat. The primary photochemical process in this case is the formation of two chlorine atoms from a chlorine molecule, Cl_2.

3. In some photochemical processes, absorbed light converts the reacting molecules to a new state, higher in energy than their initial state; in this case the energy of the absorbed light is converted into chemical potential energy and is stored that way. Most photochemical processes occurring in biological systems are of this type; *e.g.,* ultraviolet irradiation converts ergosterol, found in plant and animal tissues, into biologically active vitamin D.

4. A photochemical system may store light energy from the Sun as chemical energy and then, only incidentally to the photochemical process, release that energy as electrical energy. This reaction occurs in the solar battery, used to supply the power in satellites and space vehicles.

All these processes have one common characteristic: each, at some stage, requires that a large quantity of energy be available to a single reacting atom or molecule. The requirement may be a thermodynamic one; that is, that the products simply contain more stored energy than the reactants. Alternatively, the requirements may be kinetic; in this case the products may store more or less energy than the reactants, but some step along the reaction path requires a large quantity of energy to surmount a barrier, as it were. (The hydrogen–chlorine reaction has as its barrier the requirement that a chlorine–chlorine bond be broken to convert a chlorine molecule into its two constituent atoms.) In more complex molecules, the rearrangement from one shape to another exhibits an energy barrier because, between the initial and final structures, there must be a series of intermediate shapes of higher potential energy than either the initial or final shapes.

The theoretical aspects of photochemistry are derived largely from the principles of atomic and molecular physics and of quantum mechanics, while its analytical methods are mainly those of spectroscopy.

The development of photochemistry. The hydrogen–chlorine reaction cited above, perhaps the first recognized photochemical reaction, was first observed about 1801 and studied in detail some 40 years later. That only the absorbed light can affect a chemical reaction was recognized early, but this qualitative idea could not be stated as a quantitative law until the development of the modern theory by Einstein. Early photochemistry was largely confined to the identification of reaction products, often resulting from the action of sunlight.

Einstein's work in light absorption

The basic process by which light is absorbed by matter was first proposed by Einstein (1905, 1912, 1916). His work was directed particularly toward the photoelectric effect, in which the primary result of the absorption of radiation by a metal is the emission of free electrons; but the interpretation is general and provides the foundation of modern photochemistry: a beam of light is a beam of photons, or quanta (energy packets), of electromagnetic radiation (see below *Photochemical quantities*). The energy of each photon is proportional to the frequency of the light, and the total number of photons is proportional to the intensity of the light. The primary photochemical process then follows directly from the absorption of one photon by one atom or molecule. (If the radiation field is very intense, the concentration of photons may be so high that some molecules absorb two photons.)

After 1910 a German physicist, Emil Warburg, began a detailed study of the formation of ozone (O_3) by the action of ultraviolet light on the normal oxygen molecule (O_2). This work represented the first measurement of the number of product molecules formed for each quantum of energy absorbed: the quantum yield of the reaction. In the next few years most of the foundations of modern photochemistry were completed.

The role of chain reactions in photoprocesses was first elucidated for the hydrogen–chlorine reaction in the period 1913–25, and photochemistry grew steadily in the next three decades. From about 1955 the field expanded rapidly as it came to be used as a tool for the synthesis of organic molecules and was extended to the study of very short wavelengths (including X-rays and gamma rays) and of chemical phenomena produced by the optical amplifier, or laser, the acronym for light amplification by stimulated emission of radiation.

THE PHOTOCHEMICAL PROCESS

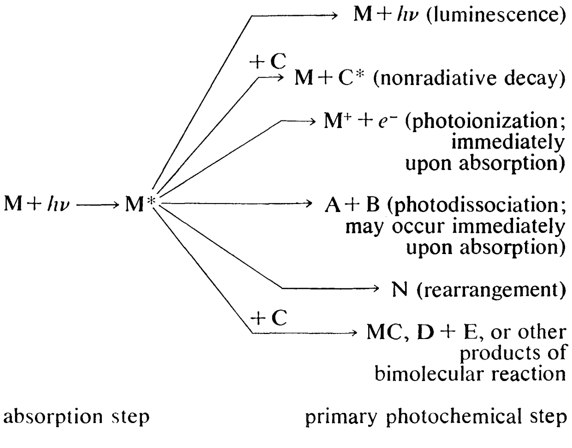
Photochemical quantities. The most fundamental ideas and the basis of all quantitative interpretations in photochemistry are the quantum-mechanical principles that all energy exists in packets, called quanta, and that the quanta of electromagnetic radiation, called photons, act like particles. The energy of each photon is directly proportional to the frequency of light—a relationship that is expressed by the equation $E = h\nu$. In this equation, E is the energy in ergs, and the frequency in cycles per second is symbolized by the Greek letter nu, ν. The constant of proportionality, h, is called, after its discoverer the German physicist Max Planck, Planck's constant; it has the value 6.625×10^{-27} erg-second. (One erg equals the work required to cause a mass of one gram to accelerate at one centimetre per second per second through one centimetre.) Alternatively, since the frequency, ν, and the wavelength, symbolized by the Greek letter lambda, λ, of light are related to c, the velocity of light (3×10^{10} centimetres per second), by the equation $\nu\lambda = c$, the energy of a quantum can be related to the wavelength of the corresponding radiation rather than to its frequency. This relationship is expressed by the equation $E = hc/\lambda$. When E is expressed in ergs and λ in angstrom units, the proportionality becomes $2 \times 10^{-8}/\lambda$; when E is in electron volts per photon, however, it becomes $12{,}400/\lambda$; and when E is in kilocalories (kcal) per mole of photons it is $2.85 \times 10^{5}/\lambda$. The angstrom unit (Å) is 10^{-8} centimetre and is commonly used to designate wavelength. The electron volt (eV), 1.602×10^{-12} erg, is the usual unit for measuring energies of individual particles in atomic physics.

By means of these quantities the relationship between ordinary chemistry and photochemistry can be expressed more precisely in terms of some simple magnitudes. Green light, for example, has a wavelength of about 5000 angstroms. (The entire visible region lies between about 4000 and 7000 angstroms.) A photon of green light, consequently, has an energy of about 2.5 electron volts, or an einstein (one mole of photons) of green-light photons has an energy of 57 kilocalories. Ultraviolet light of wavelength 2500 angstroms has just twice as much energy per photon or per mole. By comparison, a weak chemical bond requires an energy of about one electron volt to be broken, while a very strong bond requires more than 10 electron volts. In contrast, however, two molecules colliding at room temperature strike each other with an energy of only about 0.05 electron volt.

Types of energy in absorbers

Absorption of electromagnetic energy. The history of a photochemical reaction necessarily begins with the absorption of a quantum of electromagnetic energy by an atom or molecule. Initially, the absorbing molecule or atom is in a state in which its energy is relatively low. The energy contained in the absorber is essentially of four types: (1) kinetic energy of motion through space (translational energy); (2) energy of rotational motion about its centre of mass; (3) energy of vibration of the component atoms against each other if the species is a molecule; and (4) energy of the negatively charged electrons moving in the field of force produced by the other electrons and the positively charged nuclei. The energy change initiating a photochemical process virtually always involves excitation of one electron from a state of low energy to a state of higher energy. When the absorber is a molecule, changes in rotational and vibrational energy usually also occur; the translational energy of an atom or molecule, however, is almost completely unaffected when a quantum of radiation is absorbed, except in the case of highly energetic gamma radiation.

Usually, in the initial low-energy state of an absorber, the electrons are in their lowest possible state of energy; that is, their lowest quantum state. The electrons cannot absorb all incident radiation, but only those quanta with energies corresponding to the allowed quantum jumps for that particular absorber. It has been determined that a hydrogen atom in its lowest state can absorb only those quanta having energies that fit the expression $13.7\,(n^2 - 1)/n^2$eV, in which n may equal 2, 3, . . . ; according to this condition, it cannot absorb a six-electron-volt photon, for example. The energies that quanta must have in order to be absorbed by a molecule or atom correspond to the characteristic frequencies of the absorption spectrum of that substance.



Primary photochemical step. The occurrence of a photochemical reaction, then, begins with the absorption of a light quantum of suitable energy. The energy is used mainly or entirely to raise one electron into an excited state, with the result that the molecule or atom itself is in an activated state. The primary photochemical step then occurs; it may take the form of any of a number of different processes, as shown schematically below, in which M is the absorber; A and B indicate products formed by dissociation of M; C is a second substance, which interacts with M; N is a rearrangement product of M; D + E are secondary products that result from the interaction of M and C; e^- is an electron; and the asterisk designates electronically excited substances.

Photo-ionization and photo-dissociation

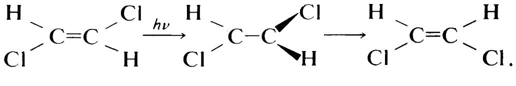
For each kind of molecule, more than one kind of excitation usually is possible. One of the origins of continuous absorption is photo-ionization, in which case the excited state of the electron is one in which it is free to escape from the atom or molecule, leaving behind a charged particle, or ion. It is the one case in which absorption and primary reaction are essentially identical. Photo-ionization can be thought of as a prototype—perhaps the most elementary photochemical process. Continuous absorption is characteristic of a transition in which a new free particle is produced: it may be an electron, as in photo-ionization, or it may be an atom or a molecular fragment. These latter two classes of particle are produced by photodissociation, a second type of photochemical process, which usually occurs when the electron being excited moves away from a locale where it can participate in a chemical bond into some other region where it is unable to use its attraction to pull two nuclei together. In normal photodissociation the excited electron remains bound to one or the other of the products of the photolysis. Photodissociation is sometimes almost as directly linked to the absorption process as photo-ionization is, but it can also be considerably slower.

Absorption in a line or band spectrum leaves all the particles bound together with their geometrical configuration essentially unchanged, at least for a short time (10^{-14} second). The change produced by such an absorption involves the excitation of one electron from a closely held low-energy state to a more loosely bound excited state. In many cases there are two or more possible excited states and several electrons that could undergo a transition; because each spectral line or band corresponds to one specific electronic transition, however, it is frequently possible for an experimenter to study one kind of electron excitation at a time. This condition can be achieved by irradiating the sample with light lying only in the energy range corresponding to the transition that the experimenter is interested in. An experiment of this type can often be done with light of almost a single pure frequency (monochromatic light).

Luminescence and nonradiative decay

As soon as an electron is excited and the molecule is in an activated state, several events can occur. The molecule may return to its initial state, without reacting, in either of two ways: it may radiate, giving up a light quantum by luminescence; or it may lose its excitation energy, without radiating or reacting, by undergoing nonradiative decay, a process that requires effective collision partners to carry off the excitation energy. Nonradiative decay usually goes through two stages. In the first step, little or no energy is lost; the energy of electronic excitation is simply converted into vibrational energy (called intersystem crossing, or internal conversion). In the second stage, the excess energy is given up to the environment gradually through a succession of collisions.

If the excited molecule does react, it may do so in any of several ways. It may undergo photo-ionization or photodissociation, as indicated above. Or it may undergo an intramolecular reaction (an internal rearrangement) or an intermolecular process. An example of intramolecular rearrangement is the conversion of *trans*-1,2-dichloroethylene into its *cis* isomer (a molecule with identical numbers and types of atoms but different arrangement of them). In the equation for this reaction, the lines represent single covalent bonds and the shaded lines provide perspective; *i.e.*, their pointed ends are away from the viewer, their blunt ends toward the viewer:



The product, in this case, has almost the same energy as the starting compound; the excitation energy required to reach the twisted intermediate form must be given off somehow by the product, usually by collision.

Primary intermolecular reactions may involve nothing more than the transfer of a quantum of energy, as with mercury (Hg) and ethylene (C_2H_4):

$$\text{Hg (vapour)} + h\nu \longrightarrow \text{Hg}^*$$

$$\text{Hg}^* + C_2H_4 \longrightarrow \text{Hg} + C_2H_4^*,$$

leaving the excited ethylene to undergo secondary reaction. The intermediate kind of primary nondissociative reaction uses collisions in a way akin to the nonradiative decay process. An excited molecule undergoes a collision that converts it into a new reactive state without removing much of its excitation energy. The collision may change the geometry of the reactive molecule into a form that can rearrange bonds or dissociate readily, or it may change the electronic state of the molecule through internal conversion or intersystem crossing. Changes in electronic state usually involve only the single excited electron, but sometimes the molecular geometry is also involved.

In order for any state, be it the initial excited state or any subsequent one, to play a part in a photochemical reaction, it must endure long enough for the reaction to occur. Each photochemical reaction competes with radiative and nonradiative de-excitation to consume the activated molecules. A few typical numerical examples will illustrate the way this competition goes on. Fast luminescence, called fluorescence, occurs with a half life of about 10^{-8} second; *i.e.*, roughly half of the excited molecules in any sample will radiate their excitation energy away in about 10^{-8} second provided they have an allowed path for fluorescence and provided they are not destroyed faster by some other process. Simple dissociations of excited molecules occur much faster: an excited molecule in an unstable state dissociates in about the time it takes an atom to go through one vibrational period, or about 10^{-13} second. Consequently, a molecule excited to a truly dissociating state has virtually no chance to radiate and will indeed follow the path of dissociation. Other unimolecular processes may occur with characteristic times ranging from 10^{-13} second up to a few seconds, if no other process interferes.

Fluorescence and phosphorescence

Radiative processes can also be slow. Slow luminescence is called phosphorescence and is the result of emission of a quantum from a molecule undergoing a relatively improbable transition. Fluorescence is the result of an "allowed" transition. Phosphorescence frequently is characterized by a lifetime for the excited molecule between 10^{-5} and 10^{-2} second, but many cases outside these bounds are known. Fluorescence, phosphorescence, dissociation, and some rearrangements involve only a single molecule and have specific rates (rate per unit of reactant concentration) or lifetimes for reactant molecules that are independent of the number of molecules present. Processes involving two molecules have specific rates that depend on the concentration of collision partners, because these rates depend on the frequency of collisions. The maximum rate for a bimolecular reaction is just the collision rate; this rate, about 10^{29} per cubic centimetre per second in the normal atmosphere, is attained only if the reaction occurs with every collision.

In solution, the maximum bimolecular rate is governed by the rate at which the reactive species can diffuse together through the liquid or solid medium. Like the collision frequency, the maximum encounter rate represents an upper limit for the rate of reaction. Rates in solution are inversely proportional to the solvent viscosity, with the result that bimolecular processes generally proceed slower in glycerin, for example, than in water. Bimolecular de-excitation processes are usually limited by the rate at which the internal electronic state can change.

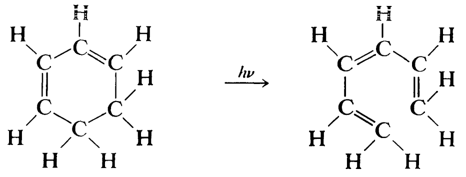
Any molecule that may decay or react in more than one way will follow the fastest of these ways. Comparison of the reaction rates shows that ionization or dissociation usually is fastest, if either can occur; fluorescence is fast in gases but is slow relative to collisions, nonradiative decay, and bimolecular reactions in solutions.

When a molecule changes its electronic state without direct absorption of light, as in nonradiative decay or internal conversion, it may go into a new excited state, which, left alone, would be short-lived (less than about 10^{-6} second); or it may go into a long-lived (metastable) excited state. Both types of reaction are known in photochemistry, but the long-lived states are particularly important in storing energy for chemical processes. The most important of the last named kind of transition is a singlet–triplet transition—singlets and triplets being electronic states that differ in having paired and unpaired electrons, respectively.

Triplet state

Triplets are the most commonly found phosphorescing states. They cannot radiate rapidly and are therefore among the most long-lived excited species. For this reason triplets are frequently the primary products of photochemical reactions. Excited singlets are sometimes found, but they more often decay, often to triplets. Triplets can be identified by their magnetic properties; by contrast with singlets, the individual electron magnets of a triplet do not cancel each other so that triplets exhibit weak magnetism (paramagnetism), which can be detected by suitable techniques.

An interesting case in which the entire photochemical process occurs in the primary reaction is that of valence tautomerization; *i.e.,* the inter-conversion of molecular structures that differ very little in the relative positions of their atoms but have different arrangements of chemical bonds, as in the photoisomerization of 1,3-cyclohexadiene shown in the structural formulas below:



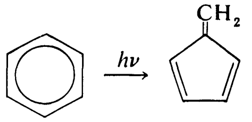
A B

Though structures A and B are nearly identical geometrically, they represent different states of the electrons.

Secondary steps. If an excited molecule does not return by a direct path to its lowest energy state, then it must dissociate, react with neighbours or itself, or revert to a new electronic state, still having some excitation energy. These are the primary steps (above). Any subsequent step is a secondary reaction. An example is the primary dissociation of an oxygen molecule (O_2) into two oxygen atoms; the only secondary reaction of importance in pure oxygen is combination of oxygen atoms with oxygen molecules to produce ozone (O_3). Both ozone and oxygen can then go on to attack hydrocarbons, in typical urban atmospheres.

Rearrangement reactions

Reactions in which atoms move from one site to another within a molecule—that is, rearrangement reactions—may be interpreted as secondary reactions following the photoexcitation process. Benzene irradiated with light between 2000 and 3000 angstroms rearranges (in low quantum yield) to the unstable hydrocarbon fulvene with the movement of a hydrogen atom, as shown in the structural formulas below:



benzene fulvene

in which the circle within the hexagon represents six electrons of benzene; the first step involves only the excitation of one of these six relatively free electrons, which do not participate in carbon–hydrogen bonds to any significant degree. Thus, only in a secondary step following photoexcitation can the atoms rearrange to the molecular structure of the product.

Frequently, the primary photochemical process is used as a tool to permit the secondary reactions to be studied. Photosensitized reactions often fall into this category. Mercury atoms can absorb light from a mercury lamp very efficiently and then, in their excited state, collide with other molecules and transfer their excitation to them. This technique has been used to dissociate nitrous oxide (N_2O) and provide free oxygen atoms. The reaction sequence proceeds as shown below:

$$Hg + h\nu \longrightarrow Hg^*$$

$$Hg^* + N_2O \longrightarrow Hg + N_2 + O.$$

(The alternative mode of decomposition, to give NO + N, has not been found to occur.) Then the oxygen atoms may react with whatever other substances are present. Measuring the amount of nitrogen produced in such a photolysis gives directly the number of oxygen atoms that were available for reaction.

Chain reactions

If a primary step involves dissociation of a molecule into two radicals (molecular fragments with single or unpaired electrons), the secondary steps are often chain reactions. About 1923 it was recognized that there were certain cyclic processes, called chain reactions, in which reaction of an active intermediate with a molecule of starting material to give a product necessarily also produced a new active intermediate. The hydrogen–chlorine reaction is an example. Light dissociates a few chlorine molecules into atoms, which then attack hydrogen molecules to give hydrogen chloride product and hydrogen atoms. The hydrogen atoms react with chlorine molecules to produce more hydrogen chloride and chlorine atoms. The reactions are:

$$h\nu + Cl_2 \longrightarrow 2Cl$$

$$Cl + H_2 \longrightarrow HCl + H$$

$$H + Cl_2 \longrightarrow HCl + Cl.$$

Reactions of this kind require an initiator (light, in this case) and a propagating mechanism and may involve a separate terminating step. Termination actually occurs either when the concentration of at least one reactant becomes very low or when another substance (*e.g.,* oxygen or iodine) is present to react more rapidly with the radicals than can the hydrogen or chlorine molecules. The reaction must also be exothermic (heat-releasing) or nearly thermoneutral (that is, neither releasing nor absorbing heat), otherwise it may cool the system so that it no longer reacts. In the reaction just cited, considerable heat is generated—usually much faster than it is radiated or transferred to the vessel walls—and an explosion is the result. An even more unstable situation—violently explosive—arises if one radical initiator produces more than one new radical.

Chain reactions always produce many product molecules for every quantum of energy absorbed; *i.e.,* the quantum yield may be much greater than one for the reaction. Reactions involving no chain processes necessarily have quantum yields near or below one, while a chain reaction may have a quantum yield of 80,000. Even a rough measurement of quantum yield will generally show whether a reaction proceeds through a chain mechanism.

EXPERIMENTAL METHODS

The methods of studying photochemical reactions have been developed chiefly to deal with problems of three kinds, which are: (1) getting the desired light energy into the system being studied; (2) determining the progress of the reaction—getting immediate pertinent information from the experiment; and (3) determining, from the results of individual experiments, the broader inferences for which the study is carried out. Photochemists commonly try to determine from a series of individual reactions the mechanism of a reaction—*i.e.,* the behaviour of each atom throughout the progress of the reaction.

Illuminating the sample. Providing suitable illumination for photochemical reactions, the experimenter has four controls: (1) The frequency, or energy, of the light can be controlled. (2) The intensity of the light can be varied to control the rate at which photons arrive at the sample and thereby to control the number of excited molecules present at one time. (3) The time of illumination can be varied to control the total number of excited molecules produced. (4) The polarization of the light may be selected.

The Sun as light source

In the earliest photochemical observations the Sun was the source. No control could be exerted, of course, on the frequency of light coming from the source itself, but simple controls of the light reaching the sample were available through the use of sample containers of differing composition; *e.g.,* flint glass transmits very little ultraviolet radiation (of wavelengths less than about 3600 angstroms), borosilicate (Pyrex) glass transmits light of wavelengths above about 3000 angstroms, and some fused silica is transparent to wavelengths shorter than 1700 angstroms. The next simplest way to control the wavelength reaching the sample is to interpose a suitable filter. Filters may transmit broad bands of frequencies or narrow and nearly monochromatic bands. A more complex step is the use of the monochromator, a device (usually a prism or grating) that permits the arbitrary choice of any frequency.

Incandescent sources, such as the Sun and ordinary electric tungsten-filament lamps, emit light of all frequencies, the total intensity and the distribution of intensity depending primarily on the source temperature. For higher intensities it is often possible to use the emission spectrum of an atomic or molecular vapour. Some common sources use mercury, cadmium, sodium, xenon, hydrogen, or deuterium in anelectric-arc discharge to provide intense and steady fluxes of radiant energy. If the lamp pressures are low, the light emitted by mercury, cadmium, or xenon is restricted to a few, intense, well-separated wavelengths, from which it is easy to select one.

Conventional steady arcs, discharge tubes, and incandescent sources are inadequate for very intense illumination. High flux of quanta requires a flash tube, a pulsed X-ray or gamma source, a laser, or the radiation from an electron accelerator such as a synchrotron. The most intense monochromatic source is the pulsed laser, which can deliver as much as 10^9 watts of power for 10^{-11} second over a very narrow range of wavelengths.

Monitoring the reaction. The course of a photochemical reaction may be observed by many physical and chemical methods. Often it is sufficient to know what the final reaction products are; they can be identified by established methods of chemical analysis.

In other cases, the information sought from a photochemical reaction can be derived only by examining the intermediates—the species present during the course of the reaction but not at the end. Sometimes an indirect observation identifies an intermediate; methyl (CH_3), ethyl (C_2H_5), and other radicals react with metal surfaces and can be detected by their ability to remove a metal mirror from the walls of a vessel. More direct methods of studying the intermediates are available in many cases.

Use of flash-kinetic spectroscopy

Transient intermediates can be found and identified in some photochemical reactions proceeding at their natural rapid rates. One method of doing this is flash-kinetic spectroscopy: a rapid photolysis is effected by an intense flash, which is followed by a second flash from a small lamp acting as a light source for absorption spectroscopy (analysis based on absorption of radiation according to the energy content of the sample's molecules and the perturbing effects of surrounding molecules). With ultrafast laser pulses, reactions can be studied at time intervals as short as 10^{-12} second after they are initiated. The method has been particularly successful for identification of spectra of such small transient species as the amino (NH_2), aldehyde (CHO), cyanate (NCO), and methyl (CH_3) radicals and of such more complex species as the phenyl radical (C_6H_5). Gases, liquids, and solids can be examined by flash-kinetic spectroscopy to determine the time dependence of the absorption spectrum. This study can be carried out in a series of photolyses, observing spectra at progressively later times after photolysis and accumulating the data, or one can move a film or an image during the event to obtain a streak photograph of the reacting system.

One can also study the time dependence of the mass spectrum (the array of charged particles sorted according to their masses). The so-called time-of-flight mass spectrometer is capable of scanning the mass spectrum of a gas being sampled as often as once every 10^{-5} second. A particular mass that appears only during the middle stages of a reaction is associated with an intermediate.

Quantum yield

Possibly the most fundamental quantitative measurement of a photochemical process is that of quantum yield, which may be determined from a knowledge of the absolute emission characteristics of the exciting source and of the absolute absorbing ability of the absorbing species; or the measurement may be made as a relative one, by using as a comparison and standard a reaction the absolute quantum yield of which is precisely known. Absolute measurements are usually much more difficult than relative ones, and so the relative method is more common; but the standards must be based upon absolute measurements.

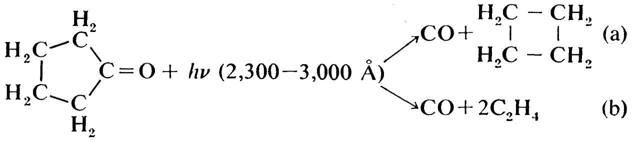
The standard reaction that is most reliable for solutions is the photolytic decomposition of highly purified uranyl oxalate. The quantum yield of this reaction is well established as a function of wavelength, temperature, intensity, and concentration of various ions, particularly hydrogen ions. For gas-phase reactions, other standards are available; *e.g.*, the photolysis of hydrogen iodide, the quantum yield of which is precisely two for a wide range of conditions.

Determining the mechanisms. Determining the actual path of a photochemical reaction frequently requires setting up hypothetical models corresponding to different possible mechanisms; finding from its kinetic equations how each model system depends on concentrations, light intensity, and any other pertinent variables; and then deciding, from experimental variations, which model best describes the system. Using this method, investigators have shown how simple alkyl iodides—*e.g.*, methyl iodide (CH_3I)—decompose on photolysis and how the fragments must react. The methyl iodide system is interesting in that at least part of the energy of the absorbed photon stays in the reactive species long enough to assist in one crucial step. The steps of the mechanism and the evidence used to determine the role of each step are as shown in Table 6.

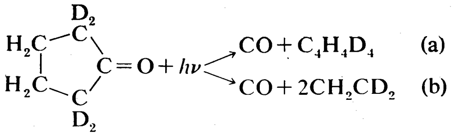
Table 6: Steps in the Photolysis of Methyl Iodide

step	equation	methods of studying individual step
Primary step	$CH_3I \xrightarrow{h\nu} CH_3 + I$	brought about by near-ultraviolet radiation; quantum yield approximately 1, as shown by separate experiments using scavengers for iodine atoms and methyl radicals; presence of radicals shown by kinetic spectroscopy
Normal secondary steps	$2CH_3 + M \rightarrow C_2H_6 + M$ $2I + M \rightarrow I_2 + M$	M is an inert collision partner that carries away energy; ethane (C_2H_6) and iodine (I_2) molecules demonstrated by analysis of products
Inhibiting secondary steps (recombinations)	$CH_3 + I \rightarrow CH_3 + I$	rate determined from low-pressure, low-intensity photolysis to minimize three-body collisions
	$CH_3 + I + M \rightarrow CH_3I + M$	rate determined from high-intensity photolysis to maximize frequency of radical–radical collisions
Other secondary steps	$CH_3 + CH_3I \rightarrow CH_4 + CH_2I$	inferred from presence of methane (CH_4) in products; thermochemistry requires either reactant to have 9 kcal per mole excess energy
	$CH_2I + I + M \rightarrow CH_2I_2 + M$	inferred from presence of methylene iodide (CH_2I_2) in products
	$2CH_2I \rightarrow ICH_2CH_2I$	inferred from presence of 1,2-di-iodoethane (ICH_2CH_2I) in products

Labelling. Other than direct detection of intermediates, the most powerful tool for elucidating mechanisms is probably the use of isotopic labelling. For example, deuterium (the hydrogen isotope that has twice the mass of ordinary hydrogen) can be used in place of hydrogen, or one of the other carbon isotopes in place of carbon-12, at selected sites in the starting material; the tagged atoms then can be located at particular positions in the product molecules. An example of the information isotopic substitution can give in a favourable case is in the photolytic decarbonylation (loss of carbon monoxide) of cyclopentanone. The process has alternative paths (a) and (b):



The use of a specific tetradeuterated species (*i.e.*, containing four deuterium atoms) shows that the paths are mutually exclusive. No ethylene of the formula C_2D_4 is formed, and therefore the ethylene cannot be a product of an intermediate in which all four carbon atoms are equivalent. The reaction is this:



Quenching. A good method, and one of the oldest in photochemistry, for determining both kinetic constants and mechanisms is the study of fluorescence quenching. If a large molecule (*e.g.*, anthracene, pyrene, or acridine) is photoexcited and does not react, in general it will fluoresce. If a species is added that reacts rapidly with the photoexcited substance, fluorescence will no longer occur; *i.e.*, it will be quenched. This method has made possible the determination of the strengths of acids in excited electronic states; of the rate of combination of two anthracene molecules (dimerization; dimer: double molecule formed by the union of two identical simpler molecules—*e.g.*, C_4H_8 is a dimer of C_2H_4); and of rates of long-range transfer of energy.

APPLICATIONS

In synthetic chemistry. Because absorption of a light quantum is frequently a property of a single group of atoms within a molecule, photochemistry sometimes provides the best means for producing a chemical reaction at a specific molecular site. This application becomes especially valuable when thermal excitation would be unselective or would destroy the reactant. Photochemical syntheses include elimination reactions and the formation of isomers and dimers.

Photolytic syntheses are sometimes most effective if the reactants are held rigidly by a solid lattice, so that a reactant molecule absorbing a quantum is fixed in a favourable orientation for reaction. Solid-state photolyses of this kind have been used in the synthesis of the dimers of maleic and fumaric acids.

Products of secondary processes

In radiation chemistry. The photochemistry associated with high-energy radiation (X-rays and gamma rays) is closer to the chemistry of electron-bombarded materials than to the photochemistry of visible-ultraviolet radiation. High-energy electron or photon bombardment produces, in addition to excited neutral molecules, ionized species, which are products of very fast secondary processes, not of the primary quantum absorption process. The basic processes associated with high-energy radiation are simply too fast to lead to any chemistry in the traditional sense of bond formation or breakage. Radiation chemistry is largely concerned with determining what the first-formed new chemical species are and what reactions they undergo:

it assumes a particularly important role in the understanding of how living beings react to radiation and how they can be protected against its damaging effects.

In atmospheric photochemistry. The phenomena of terrestrial and planetary atmospheres—*e.g.,* atmospheric structure, auroras, radiation shielding, and weather—depend on the chemical constituents of the atmosphere and the radiation striking it. The Earth's atmosphere is largely molecular nitrogen and molecular oxygen at the Earth's surface, but it contains quite a different set of atomic and molecular components at high altitudes, largely because of the radiation that these upper layers absorb. The photochemical processes that take place are covered in the article ATMOSPHERE: *Ionosphere.* The very rich chemistry of polluted atmospheres is a comprehensive model that exhibits many aspects of photochemistry. Brown nitrogen dioxide absorbs sunlight and uses this energy to initiate chain reactions of hydrocarbons with oxygen. The nitrogen oxides return to pick up more sunlight, while the partially oxidized hydrocarbon molecules undergo secondary reactions and may even absorb light to start new photochemical processes. (R.S.Be.)

NEWMAN (ed.), *Steric Effects in Organic Chemistry* (1956); F. BASOLO and R.G. PEARSON, *Mechanisms of Inorganic Reactions,* 2nd ed. (1967); R. BRESLOW, *Organic Reaction Mechanism,* 2nd ed. (1969); C.H. LANGFORD and H.B. GRAY, *Ligand Substitution Processes* (1966); A. STREITWIESER, JR., *Molecular Orbital Theory for Organic Chemists* (1961); A.A. FROST and R.G. PEARSON, *Kinetics and Mechanism,* 2nd ed. (1961); S. GLASSTONE, K.J. LAIDLER, and H. EYRING, *The Theory of Rate Processes* (1941); S.W. BENSON, *The Foundation of Chemical Kinetics* (1960); R.P. BELL, *The Proton in Chemistry* (1959); L. MELANDER, *Isotope Effects on Reaction Rates* (1960); J.E. LEFFLER and E. GRUNWALD, *Rates and Equilibria of Organic Reactions* (1963); and R. STEWART, *The Investigation of Organic Reactions* (1966).

Books of specialized interest include: C.A. BUNTON, *Nucleophilic Substitution at a Saturated Carbon Atom* (1963); D. BETHELL and V. GOLD, *Carbonium Ions* (1967); J. MILLER, *Aromatic Nucleophilic Substitution* (1968); R.O.C. NORMAN and R. TAYLOR, *Electrophilic Substitution in Benzenoid Compounds* (1965); P.B.D. DE LA MARE and J.H. RIDD, *Aromatic Substitution, Nitration and Halogenation* (1959); P.B.D. DE LA MARE and R. BOLTON, *Electrophilic Additions to Unsaturated Systems* (1966); and D.V. BANTHORPE, *Elimination Reactions* (1963).

Current information may be found in the following series: *Progress in Physical Organic Chemistry* (1963–); *Advances in Physical Organic Chemistry* (1963–); *Progress in Stereochemistry* (1954–); *Topics in Stereochemistry* (1967–); and in reviews on various topics in *Annual Reports on the Progress of Chemistry,* published by the Chemical Society, London; and *Chemical Reviews* (bimonthly), published by the American Chemical Society. (P.B.D. de la M.)

Chemical kinetics: SAMUEL GLASSTONE, KEITH J. LAIDLER, and HENRY EYRING, *The Theory of Rate Processes* (1941), the earliest comprehensive treatment of the theory of absolute reaction rates; HENRY and EDWARD M. EYRING, *Modern Chemical Kinetics* (1963), a popular presentation of reactive rate theory; ARTHUR A. FROST and RALPH G. PEARSON, *Kinetics and Mechanism,* 2nd ed. (1961), a useful general text covering many aspects of chemical reactions; HENRY EYRING, "The Activated Complex in Chemical Reactions," *J. Chem Phys.,* 3:107–115 (1935), the first general presentation of activated complex or transition state theory. (H.Ey.)

Chemical relaxation phenomena: *Kolloid-Zeitschrift,* vol. 134 (1953), a symposium on the relaxation properties of matter, includes Meixner's theoretical treatment of relaxation phenomena based on irreversible thermodynamics; *Discussions of the Faraday Society,* no. 17 (1954), a colloquium on the study of fast reactions including a discussion of chemical relaxation by Eigen; *Zeitschrift für Elektrochemie,* vol. 64 (1960), an international colloquium on fast reactions in solution; *Molecular Relaxation Processes* (1965), Chemical Society symposium emphasizing the use of relaxation to determine molecular structures; M. EIGEN and L. DEMAEYER, "Relaxation Methods," in S.L. FRIESS *et al.* (eds.), *Technique of Organic Chemistry,* vol. 8, pt. 2, pp. 793–798, 895–1054 (1963), an elegant and comprehensive discussion of chemical relaxation. (L.D.F.)

Catalysis: P. SABATIER, *La Catalyse en chimie organique* (1913; Eng. trans., *Catalysis in Organic Chemistry,* 1922), a classic work written by a Nobel prize winner; E.K. RIDEAL and H.S. TAYLOR, *Catalysis in Theory and Practice,* 2nd ed. (1926), an account of the state of the subject during World War I and the rapid advances in theory that occurred shortly after; P.H. EMMETT (ed.), *Catalysis,* 7 vol. (1954–60), a monumental treatment of the subject, both theory and practice, contributed by a group of international experts in the field; W.G. FRANKENBURG *et al.* (eds.), *Advances in Catalysis and Related Subjects,* 20 vol. (1948–70), a record of the year-to-year advances in the field as reported by international authorities; G.A. MILLS, *Catalysis, Encyclopedia of Chemical Technology,* 2nd ed., vol. 4, pp. 534–586 (1964), a detailed record of the chemistry and chemical technology of catalysis, written by a research scientist associated with the petroleum industry. (H.S.Ta.)

Acids and bases: For a general discussion, see P. WALDEN, *Salts, Acids and Bases* (1929), an account of the early development of concepts in this field; R.P. BELL, *Acids and Bases,* 2nd ed. (1969), an elementary account, *The Proton in Chemistry* (1959); and E.J. KING, *Acid–Base Equilibria* (1965), two books at a somewhat more advanced level. Experimental methods are described in V. GOLD, *pH Measurements* (1956), elementary; R.G. BATES, *Determination of pH; Theory and Practice,* rev. ed. (1964), more advanced; and A. ALBERT and E.P. SERJEANT, *Ionization Constants of Acids and Bases,* 2nd ed. (1970), a laboratory manual containing tables of ionization constants. Special topics covered in this article are discussed in W.F. LUDER and S. ZUFFANTI, *The Electronic Theory of Acids and Bases* (1946); in collected papers reprinted from the *Journal of Chemical Education, Acids and Bases* (1941), and *More Acids and Bases* (1944), three publications dealing mainly with Lewis acids; and in R.G. PEARSON, "Acids and Bases," *Science,* 151:172–177 (1966), an article on hard and soft acids and bases; L.F. AUDRIETH and J. KLEINBERG, *Non-Aqueous Solvents* (1953); J.J. LAGOWSKI (ed.), *The Chemistry of Non-Aqueous Solvents,* 2 vol. (1966–67); and C.H. ROCHESTER, *Acidity Functions* (1970). For tables of dissociation constants, see G.F.A. KORTUEM, W. VOGEL, and K. ANDRUSSOW, *Dissociation Constants of Organic Acids in Aqueous Solution* (1961); and D.D. PERRIN, *Dissociation Constants of Organic Bases in Aqueous Solution* (1965). (R.P.B.)

Ion exchange: F. HELFFERICH, *Ion Exchange* (1962), the standard reference work on the theory of ion exchange; R. KUNIN, *Ion Exchange Resins,* 2nd ed. (1958), a short practical guide to ion-exchange resins and their use; Y. MARCUS and A.S. KERTES, *Ion Exchange and Solvent Extraction of Metal Complexes* (1969), a thorough discussion of extraction and ion-exchange methods; J. KORKISCH, *Modern Methods for the Separation of Rarer Metal Ions* (1969), a practical discussion of ion exchange and solvent extraction; W. RIEMAN and H.F. WALTON, *Ion Exchange in Analytical Chemistry* (1970), a discussion of the theory and types of ion exchangers. (H.F.W.)

Oxidation and reduction: R.E. DICKERSON, H.B. GRAY, and G.P. HAIGHT, *Chemical Principles* (1970), a textbook covering most introductory aspects of oxidation–reduction reactions; F.A. COTTON and G. WILKINSON, *Advanced Inorganic Chemistry,* 2nd ed. rev. (1966), a comprehensive reference work with examples of redox reactions; W.M. LATIMER, *Oxidation Potentials,* 2nd ed. (1952), the definitive survey of the redox behaviour of the elements with an emphasis on half-reaction potentials; W.M. CLARK, *Oxidation–Reduction Potentials of Organic Systems* (1960), emphasizes biologically important reactions; L.

PAULING, *The Nature of the Chemical Bond and the Structure of Molecules and Crystals,* 3rd ed. (1960), contains a detailed treatment of electronegativities; R. STEWART, *Oxidation Mechanisms* (1964), a concise monograph on organic oxidation–reduction mechanisms; H. TAUBE, *Electron Transfer Reactions of Complex Ions in Solution* (1970), a short monograph on the mechanisms of inorganic oxidation–reduction reactions with primary emphasis on the transition metals; J.B. CONANT, *The Overthrow of the Phlogiston Theory* (1950), a short readable account of the phlogiston theory for the nonscientist; E.I. RABINOWITCH and GOVINDJEE, *Photosynthesis* (1969), includes a good overview of the global redox cycle of respiration and photosynthesis. (M.V.O.)

Combustion and flame: J.C. GREGORY, *Combustion from Heracleitos to Lavoisier* (1934), history of combustion science to the 18th century; W.A. BONE and D.T.A. TOWNSEND, *Flame and Combustion in Gases* (1927), a history of combustion science from the late 17th century to the early 20th century; W. JOST, *Explosions- und Verbrennungs vorgänge Gasen* (1939; Eng. trans. *Explosion and Combustion Processes in Gases,* 1946), a review of the main theoretical and experimental research on various problems of combustion and explosions; R.M. FRISTROM and A.A. WESTENBERG, *Flame Structure* (1965), a general review and critical treatment of experimental and theoretical data on flame structure.

More advanced and detailed monographs include: B. LEWIS and G. VON ELBE, *Combustion, Flames and Explosions of Gases,* 2nd ed. (1961); N.N. SEMENOV, *Chemical Kinetics and Chain Reactions* (Eng. trans. 1935), *Some Problems of Chemical Kinetics and Reactivity,* 2 vol. (Eng. trans. 1958–59); and A.G. GAYDON and H.G. WOLFHARD, *Flames: Their Structure, Radiation and Temperature* (1953). (V.N.K.)

Electrochemical reactions: C.L. MANTELL, *Electrochemical Engineering,* 4th ed. (1960), the only text predominantly on the engineering aspects of the field; J.O'M. BOCKRIS and A.K.N. REDDY, *Modern Electrochemistry,* 2 vol. (1970), a textbook slanted toward readers in other fields who want to use electrochemical reactions, but is fairly easy to understand; J.O'M. BOCKRIS and D. DRAZIC, *Electrochemical Science* (1971), a very simple text for freshmen. More advanced works include: K.J. VETTER, *Elektrochemische Kinetik* (1961), the first textbook on the fundamentals and the standard work; P. DELAHAY, *Double Layer and Electrode Kinetics* (1965); and B.E. CONWAY, *Theory and Principles of Electrode Processes* (1965). (J.O'M.B./A.De.)

Photochemical reactions: JACK G. CALVERT and J.N. PITTS, JR., *Photochemistry* (1966), one of the most widely used modern monographs on the subject, covering basic generalities and specific applications; W. ALBERT NOYES, JR., G.S. HAMMOND, and J.N. PITTS, JR. (eds.), *Advances in Photochemistry,* vol. 1–6 (1963–68), a serial publication, complementary to the book by Calvert and Pitts, surveying recent work in specific areas; W. ALBERT NOYES, JR., PHILIP A. LEIGHTON, *The Photochemistry of Gases* (1941, reprinted 1966), a classic, probably an easier introduction to the subject; R.M. NOYES and A. WELLER, "Photostationary Methods," and G. PORTER, "Flash Photolysis," in S.L. FRIESS, E.S. LEWIS, and A. WEISSBERGER (eds.), *Technique of Organic Chemistry,* vol. 8, pt. 2 (1963), two articles that present clear discussions of most of the experimental methods now in use, except lasers; C.B. MOORE, "Lasers in Chemistry," *A. Rev. Phys. Chem.,* 22:387–428 (1971), a brief and descriptive article on laser methods in photochemistry; V. HENRI, *Études de photochimie* (1919), important for the history of the subject. (R.S.Be.)
