Manitobans have a reputation for supporting cultural agencies. Winnipeg is home to major artistic institutions: the internationally famous Royal Winnipeg Ballet, the Winnipeg Symphony Orchestra, Manitoba Theatre Centre, Rainbow Stage, Le Cercle Molière, and the Winnipeg Art Gallery. A major centre in downtown Winnipeg houses a concert hall and planetarium.

The province maintains a strong sense of its past. The Manitoba Historical Society is the leading agency in this regard. The Archives of Manitoba is a major repository for historical documents, including the collection of the Hudson's Bay Company. Museums and historic sites in Manitoba include the Manitoba Museum of Man and Nature in Winnipeg and the reconstruction of Lower Fort Garry, a National Historic Site north of Winnipeg.

Manitobans sponsor and support an exceptional array of community and cultural festivals. Among the more important are the Winnipeg Folk Festival; Folklorama, also in Winnipeg; Gimli Icelandic Festival; National Ukrainian Festival at Dauphin; Festival du Voyageur in St. Boniface; and Northern Manitoba Trappers' Festival at The Pas. Professional teams include the Winnipeg Blue Bombers in the Canadian Football League and the Winnipeg Jets in the National Hockey League. Curling is the premier winter sport. Other sports include hockey, baseball, cross-country skiing, fishing, and hunting. Manitoba has one national park, Riding Mountain, and numerous provincial parks.

HISTORY

The fur-trade era. Native peoples, who had lived in the Manitoba region for thousands of years, first came in contact with Europeans through the fur trade. Explorers searching for the Northwest Passage reached Hudson Bay in 1610, when Henry Hudson navigated the east side of the Bay. He was followed by a number of adventurers, including Thomas Button (1612), Jens Munk (1619), and Luke Fox and Thomas James (1631). At the urging of French Canadian adventurers a trading company, Radisson and Des Grosseilliers, was formed, which in 1670 received a monopoly over the fur trade in an area designated as Rupert's Land. The Hudson's Bay Company established a number of posts along the bay, facing tremendous competition from French traders. It was the French, led by Pierre Gaultier, Lord de La Vérendrye, and his sons, who first extended the trade into the interior; they reached the Red River in the early 1730s and established a series of posts in the area, including Fort Rouge on the present site of Winnipeg. The French trade cut severely into Hudson's Bay Company returns at its post by the bay and forced the company to expand inland. Several decades of intense competition ensued. The Montreal-based North West Company worked closely with the métis and resisted the British company's attempts to establish an agricultural colony at Red River. The bitter, often violent competition culminated in the Seven Oaks Massacre of 1816. Increas-

The Hudson's Bay Company

ing violence and declining profits forced the two firms to merge into the Hudson's Bay Company in 1821.

Settlement boom. The successful settlement of the western United States in the 19th century encouraged expansionists in Central Canada to look to the western regions of British North America. The agricultural potential of the vast prairie lands west of Red River was documented by the Palliser Expedition, commissioned in 1857 by the British government. Negotiations between the Hudson's Bay Company, the British government, and the government of the new Dominion of Canada resulted in an agreement in 1869 to transfer Rupert's Land to Canada. In 1870, under the Manitoba Act, the territory joined the confederation as a province; the remaining lands were designated the Northwest Territories.

The federal government encouraged western settlement, providing land to would-be settlers. There was an initial rush to the new province, but the absence of a rail connection to markets reduced the attractiveness of the region. Construction began on the Canadian Pacific Railway, which, by the early 1880s, had reached Manitoba. Settlement was delayed by a métis uprising in 1885 and was further slowed by the continued availability of homestead lands in the United States. Some settlers did come in this period, Ontario farmers, Mennonite immigrants, and Icelandic peoples among them. At the turn of the century, immigration to Manitoba boomed, fueled by massive government advertising, social conditions in Europe, and the decline in available land in the United States.

Era of prosperity

Manitoba in the 20th century. The immigration boom ushered in an era of prosperity and growth. Winnipeg grew rapidly and became the major urban centre for all of western Canada. Manitoba farmers, aided by reduced freight rates, higher world prices for wheat, and improved strains of grain seed, enjoyed unprecedented prosperity. The economic boom ended just before World War I, ushering in a depression that lasted through the first years of the conflict. Labour unrest over wages and working conditions arose during and peaked after the war.

Manitoba's economy was transformed during the early part of the century. A strong agricultural sector, diversified among wheat and other grains, cattle, and market gardening, provided the province with a measure of stability. Winnipeg's industrial economy, however, grew rapidly. Manitoba also achieved its current form, expanding westward in 1881, eastward in 1884, and northward in 1912. The province was severely affected by the depression of the 1930s, although the problem was more one of prices than of production in the agricultural sector. Nonpartisan or coalition governments ruled the province from 1922 to 1958, when Dufferin Roblin led the Conservatives into office. The return to prosperity during World War II was matched by a resolve to diversify the province's economic base. The provincial government gained control of natural resources in the 1930s and began to encourage northern development, particularly of mining and lumbering. Government involvement in the economy peaked during the administrations of the New Democratic party from 1969 to 1977 and 1981 to 1986, with major investments in infrastructure and some controversial experiments in direct ownership. (P.McL./K.S.C.)

Saskatchewan

Saskatchewan is one of only two Canadian provinces without a saltwater coast, and it is the only one whose boundaries are wholly artificial. It lies between the 49th and 60th parallels of latitude and is bounded on the west by longitude 110° west of Greenwich, and its eastern limit, with minor adjustments, is longitude 102°. Its southern half is largely an extension of the Great Plains of central North America, rarely rising 2,000 feet above sea level, and its northern half, most of which lies in the ancient rock mass of the Canadian Shield, is sparsely populated bush country with many lakes and tundra. Its area is 251,866 square miles (652,330 square kilometres), of which 31,518 square miles are water; and it measures 760 miles (1,223 kilometres) from south to north, tapering from a width of 393 miles (where it abuts Montana and North Dakota in the United States) to 277 (where it meets the Northwest Territories). In area, Saskatchewan is Canada's fifth largest province, and in population, its sixth. Economically, the province has always been heavily dependent on the exportation of its agricultural and mineral products and is thus peculiarly sensitive to fluctuations in world markets beyond its own or even Canada's control.

Dependency on agriculture and mining

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* Although familiarly known as one of the Prairie Provinces, Saskatchewan has little native prairie; a large proportion of its productive acreage (half the province) is rolling ranch and parkland, both of which offer immense vistas from their higher points. There is not a single mountain in the province, although the term is loosely used to identify several landmarks. The Cypress Hills, in the southwestern corner of Saskatchewan, include the provincial summit: 4,816 feet (1,468 metres) above sea level. The hills constitute the only part of the area to escape glaciation and contain unique plant and animal life. Wood Mountain (3,275 feet) and the Vermilion Hills (2,500 feet) are some of the province's other major departures from the rolling plains topography. Cut into the plains are many spectacular river valleys, the most notable being those of North and South Saskatchewan and the Qu'Appelle.

Drainage and soils. Saskatchewan drains from west to east, its great rivers (which provided the first transportation routes) rising in the Rocky Mountains and emptying ultimately into Hudson Bay. The soils through which the rivers flow are predominantly chernozemic (dark-coloured grassland) and podzolic (light-coloured forest) with extensive deposits of poorly drained mineral and peat soils in the north.

Climate. The climate keeps much land out of agricultural production. In the southern half of the province there are as few as 80 to 100 frost-free days annually. Temperature variations are extreme; January temperatures have fallen below −65° F (−53° C) in settled parts, and in July temperatures upward of 105° F (41° C) have often been recorded. The normal mean daily reading for the arable regions ranges from −5° F (−21° C) to 10° F (−12° C) in January and from 55° F (13° C) to 65° F (18° C) in July. Precipitation generally is not high, averaging from 10 to 20 inches (255 to 510 millimetres) each year; snowfall ranges from 30 inches (760 millimetres) in the southwest to more than 60 inches (1,525 millimetres) in the north-central area. Drought years are not uncommon.

Botanical regions

Plant and animal life. Saskatchewan from north to south is marked by six recognizable bands of natural plant life, all running in a southeasterly direction and roughly following the pattern of soil deposits. Farthest north is the subarctic forest tundra, south of which lie the northern coniferous forests and then a strip of mixed forest. The most northerly agricultural belt is aspen parkland, parts of which are still being cleared. The two most southerly bands are composed of midgrass prairie and shortgrass prairie. The three most southerly zones produce a rich profusion of attractive wildflowers, many of which also, paradoxically, qualify as noxious weeds.

The vast unsettled parts of Saskatchewan support a large wildlife population of great variety. Grizzly bears and mountain lions are now rare, but wolves, black bears, moose, deer, caribou, elk, and antelope are common, together with enormous numbers of smaller mammals. Coyotes, foxes, and lynx, together with the gophers, rabbits, and other creatures they prey on, are abundant, and the province supports a considerable amount of trapping. Saskatchewan is on the main western flyway of waterfowl, songbirds, hawks, and owls, many of which nest in the province. The extensive water resources maintain both commercial and game fish in quantity. Northern Saskatchewan, particularly, is a haven for the hunter and angler.

Pollution. The lack of heavy industry and of metropolitan areas keeps Saskatchewan relatively free of the kinds of pollution associated with high population density and manufacturing, but the extensive agricultural development subjects it to those connected with weed killers and insecticides. Significant amounts of mercury have been found in fish and birds, and continuing research suggests that the amount of contamination in wildlife may be larger than had been apparent. The sources of the major rivers also subject Saskatchewan to upstream pollutants from areas over which it has no control; but prevailing winds do not come from heavily polluted regions, and the air is generally clean, though an occasional northern forest fire casts a pall over thousands of square miles to the south. Frequent strong winds produce dust clouds.

Settlement patterns. Saskatchewan's landscape makes its inhabitants conscious of the sky; and the changing patterns of light and shadow on clouds, which commonly offer magnificent sunrises and sunsets, are as much a part of the scenery as any contour of the earth. All of Saskatchewan is farther north than any of the most densely populated parts of Canada, and the province's own north is largely inaccessible except by air, with the result that few citizens are familiar with it. Saskatchewan's best-known regions and sites are its main agricultural and recreational areas: the wheat belt, the ranching country, the Qu'Appelle valley, the Cypress Hills, Lake Diefenbaker, Waskesiu Lake, the old fur-trading routes and trails and their inevitable forts, and the sites of Saskatchewan's few battles.

Saskatchewan is not dominated by any metropolitan centres. Unlike most Canadian provinces, Saskatchewan has in effect two capitals: Regina, the official capital, in the central south, and Saskatoon, 160 miles to the north. Both cities are growing rapidly. Other major cities include Moose Jaw and Prince Albert. Because the four largest cities maintain less than 50 percent of the population, a small-town character is maintained. The most striking man-made feature of the landscape has been for decades the grain elevator, and the typical village is clustered around three or four of these structures. But changing technology has been making the elevators obsolete, and they are being replaced by facilities set farther apart.

Major population regions

The people. The population has changed markedly during the area's history. It was originally exclusively American Indian, to which French and British elements were added early, and a large population of mixed origin, the mêtis, developed. Then other European groups—German, Austrian, Ukrainian, Scandinavian, Russian, and Polish, among others—were attracted, some by generous homestead grants, and some in part by a desire to avoid compulsory military service in their own countries. The period of heaviest immigration was between 1900 and 1920, when the population rose suddenly from less than 100,000 in 1901 to nearly 700,000. The population of British origin was, by the late 20th century, less than 40 percent. Many of these groups, including the British, settled in separate communities where they could use their own language and continue their own religion and customs, and Saskatchewan contains many settlements readily identifiable as Ukrainian, French Canadian, or German. Since the 1960s an appreciable number of migrants from India and the Far East have arrived, settling mainly in the cities. Provincial law permits the use of languages other than English in schools for specific purposes, and widespread advantage has been taken of the law. Ethnic variety is matched by that found in religious affiliation; the largest churches are the United Church of Canada, Roman Catholic, Lutheran, Anglican, Ukrainian Catholic, Greek Orthodox, Mennonite, Presbyterian, and Baptist.

Population growth has been generally slow because of the high emigration rate, which exceeds immigration. This is attributed to increases in the efficiency of Saskatchewan's basic industries, which can steadily produce more with less manpower. Internally, the province, although still one of the least urbanized, has one of the highest rates of urbanization in Canada, the growth coming chiefly from the movement of rural dwellers into urban areas.

The economy. Saskatchewan's economy, since its beginning, has been based on extractive industries: forest products, fish, furs, agricultural products, oil and gas, and potash. In almost all cases the products are consumed outside the province and generally outside Canada, a situation that makes the province one of the most economically vulnerable areas in the world. A grain belt, made up predominantly of wheat but also including large acreages of barley, oats, rapeseed (canola), flax, and rye, lies between the southern border and the 54th parallel of latitude. Potash is found in a narrower band running diagonally across the province from west to east, its northernmost point being west of Saskatoon. Oil and gas lie in the southernmost quarter of the province, while there are rich uranium deposits in the north; there also diamonds of industrial quality were discovered in the 1980s. Other significant minerals include salt, sodium sulfite, lignite, zinc, copper, gold, and a variety of clays. In terms of employment, manufacturing has always played a relatively minor role in the provincial economy and is characterized by several hundred small establishments, most of which have only a few dozen employees.

Minerals

The Saskatchewan economy, always dependent on external markets, has internally required a variety of governmental supports; as a result the province has never had a true free-enterprise system, while public enterprise and mixed public and private ventures have characterized the development of the economy from the beginning. The Canadian protective tariff, long criticized by prairie dwellers because it made them pay more for goods of all kinds, appears to be the mainstay of the developing secondary industries. The first waves of settlers, attracted to Saskatchewan by federal policies, were carried on railways built with federal assistance. Saskatchewan grain moves to federal terminal elevators at controlled freight rates. Within the province, political parties in power, regardless of ideology, have sponsored and maintained publicly owned utilities, a bus company, an insurance company, and public hospitalization and medical care. Nonetheless, in the 1960s and again in the 1980s the people elected governments that stressed private capitalism.

Transportation. Modern Saskatchewan was originally the creation of transcontinental railroads, which carried settlers and supplies in and grain out. Though freight remains an important rail component, passenger carriage has declined, and services have been reduced or abandoned. The province is now crisscrossed with highways. The system of land division in the rural areas provides for "road allowances," strips of territory a mile or two apart that serve as simple, mostly dirt, roads, which when dry are firm and passable and widely used for local travel.

Except for recreation, water transportation is all but obsolete in Saskatchewan; small shallow-draft steamers formerly sailed the main rivers, but, since the rivers are shallow with shifting sandbars, they have not been sig-

nificant transportation routes since before World War I. Airlines, by contrast, have developed dramatically in Saskatchewan, where approximately half the province is accessible only by air. The small plane serves the north for both commerical and recreational purposes, and all major centres are on scheduled airlines.

The provincial constitution

Administration and social conditions. Saskatchewan's constitution, based on custom and the Saskatchewan Act of 1905, provides for a British parliamentary system, in which the life of the executive depends on the support of a majority in the legislature. A general election must be held every five years; short of that period, the premier may advise the holding of an election at any time, and most assemblies last only four years. As in all the provinces, the lieutenant governor is appointed and has become by custom and judicial decision the counterpart of a constitutional monarch, whose position and powers are largely symbolic. Saskatchewan's larger centres have their own local police, but in the province as a whole the law is enforced by the Royal Canadian Mounted Police.

Unlike those of Canada's other Prairie Provinces, the Saskatchewan legislature has a long tradition of strong vocal opposition in the assembly, with the Liberals and the New Democratic Party (NDP; formerly the Cooperative Commonwealth Federation) traditionally providing what was a two-party system ideologically divided into free enterprise versus democratic socialism. Since the 1970s the Progressive Conservatives have gained support at the expense of the Liberals, and they became the governing party in 1982, ousting the NDP. Like the Liberals, the Progressive Conservatives draw their greatest strength from rural areas; the New Democrats have a stronger urban base. Whichever party is in power is vigorously opposed by the others, with the Liberals and Progressive Conservatives generally espousing development of the province by business and corporate means and the NDP strongly urging the use of public and cooperative enterprise.

The province is divided into a multiplicity of local administrations including hospital districts and school districts, all constitutionally under provincial jurisdiction but all having considerable local responsibility. Municipal government in Saskatchewan is based on the U.S. mayor–council model, with a mayor elected separately from the council, and a number of appointed boards and commissions operating largely independently of either.

Federal social aid

For most of its history the province has qualified for the kinds of federal aid available to those whose economy operates below the national average. The province's reliance on federal subsidies as a percentage of total revenues, though it varies with crop conditions, is generally above the national average. Saskatchewan's wage levels for both industry and agriculture are never among the lowest for the provinces but are neither among the highest. The province's "middle" position carries over into its internal affairs: it is socially and economically (except for its poor American Indian and métis peoples) one of the least stratified areas in Canada, having little of great individual or corporate wealth on the one hand, and little general destitution on the other.

Cultural life. Although lacking great metropolitan centres, Saskatchewan has developed creditable art galleries and professional theatre and opera companies; even so, many artists leave for careers elsewhere. Writing in and about the province, always strong, has blossomed since the 1960s, and the same is true of painting and sculpture. Saskatoon and Regina have excellent civic auditoriums, and Saskatoon has an outstanding branch of the Western Development Museum, whose chief exhibits, outmoded farm machinery and automobiles, are annually refurbished in a celebration of pioneer days. The province is well served by the radio and television networks of the Canadian Broadcasting Corporation, augmented by private broadcasting services.

The province's oldest recognizable cultural institution is the University of Saskatchewan, established in 1907 and, with remarkable foresight, given a huge campus at Saskatoon. The university has produced much fundamental research relevant to Saskatchewan (it maintains, for example, an Institute of Space and Atmospheric Studies that has done extensive research on the aurora borealis) and has also a tradition of extension services on and off campus. It has sent forth a steady stream of distinguished workers in a variety of fields, from theatre to nuclear physics. As a result of the limited opportunities available, not many of these have been able to remain in the province. The province is also noted for the number of professional hockey players and curling champions it has produced.

HISTORY

Early exploration

Since Saskatchewan became a full member of the Canadian federation only in 1905, much of the area's historical interest depends on events vastly older than the province. Dinosaur and mammoth finds have been common. The first known human inhabitants were American Indians of several linguistic groups who were present at least 5,000 years ago; they were mainly hunters. With the coming of the Europeans, they became trappers involved in the fur trade. The first European known to see the Saskatchewan River was Henry Kelsey, who in 1691 explored part of the plains for the Hudson's Bay Company, which received its charter in 1670 and is still extant. Fur traders and buffalo hunters, variously American Indian, métis, French, and British, and explorers and missionaries made up the bulk of the area's inhabitants until the second half of the 19th century.

Acquisition by the Dominion of Canada

The area from which Saskatchewan is carved was first granted to the Hudson's Bay Company and then, in 1869, surrendered by the Rupert's Land Act back to the British crown, in order that it could be turned over to the newly formed Dominion of Canada, which was done in 1870. Canada administered its newly acquired western territories almost as if they were colonies and, in 1873, created the North West Mounted Police to maintain law and order. In 1885 the national authorities sent out troops to quell the second Riel Rebellion, an uprising in which a large number of métis, by now deprived of their main sustenance, the buffalo, sought to establish their rights to western lands in the face of growing settlement. Constitutionally, the territories in 1875 were granted an executive council with a promise of an elected assembly, and by 1897 they had won responsible parliamentary government on the British model.

Saskatchewan, created by the Saskatchewan Act in 1905, entered confederation with its present boundaries and the status of a province equal to the others except that, as with its sister province Alberta, the federal government retained control of its natural resources, paying a subsidy in place of the revenues the resources might have yielded. (The resources were assigned to the province in 1930.) The new provincial government, after a good deal of rivalry among the towns, chose Regina, the former territorial capital, as its centre of operations, and the first premier appointed was Walter Scott, a believer in partisan politics, as opposed to those who favoured a continuation of the kind of cooperative effort that had led to the creation of Saskatchewan as a separate province. A member of the party in federal power at the time, the Liberal Scott was the first of several able politicians who kept the party in power in Saskatchewan except in 1929–34 and 1944–64, and after 1971. The 1944–64 period was unique in North American history. During that era the Cooperative Commonwealth Federation (CCF), successively led by T.C. Douglas and Woodrow Lloyd, established the first avowedly socialist government on the continent, and the party won international attention in 1962 when it implemented the continent's first compulsory medical care program, accompanied by a doctors' strike.

Privatization and co-ops

Regardless of which political party has been in power at any given time, the Saskatchewan environment has always demanded much governmental intervention in the economy. The provincial telephone company and the power and gas utility, for example, were publicly owned (although neither was created by a socialist government) down to the 1980s, when privatization began under a Progressive Conservative government. The cooperative movement has been encouraged by all parties and has been influential in a wide range of service, retail, and wholesale activities that include large credit unions and an oil refinery. In the handling of grains, the backbone of the province's economy, the Saskatchewan Wheat Pool, also a cooperative, has been a dominant influence. The co-ops helped many individuals survive the drought and depression of the 1930s, during which Saskatchewan society is considered to have sustained setbacks as severe as any suffered in Canada. After World War II the province attained a major development in mineral exploitation and industrial growth, and its diversified base was combined with new farming techniques to strengthen the economy. (N.W.)

BRITISH COLUMBIA

One of the last regions of the North American continent to be explored and settled, British Columbia emerged in the second half of the 20th century as one of the leading provinces of Canada in population, economic wealth, and overall growth potential. Its 365,947 square miles (947,800 square kilometres) of total area make it the second largest province in physical size. The land has a diversity of climate and scenery unparalleled in the nation, from the island-studded and fjord-indented coast to the great peaks of the western continental cordilleras with their large interior plateaus. The province is bounded on the west by the Pacific Ocean and the panhandle region of Alaska, on the north by the Yukon and Northwest territories, on the east by Alberta, and on the south by the U.S. states of Montana, Idaho, and Washington.

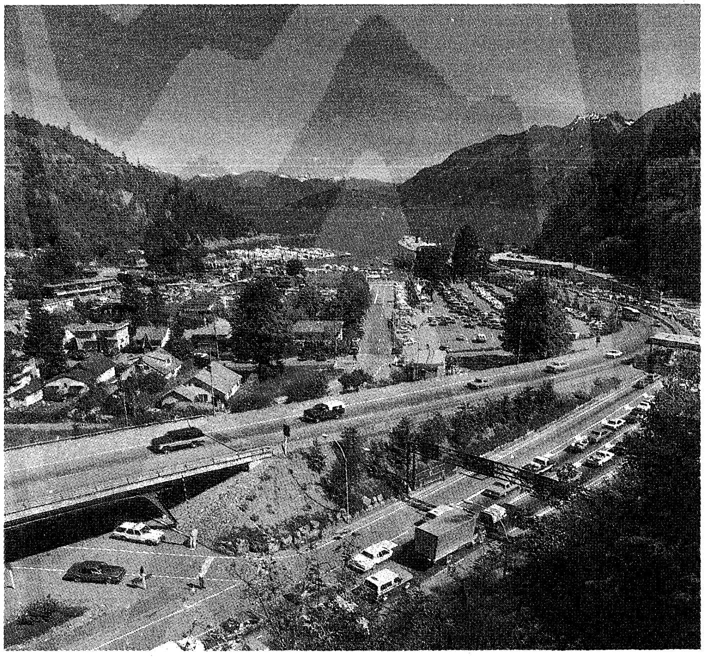
British Columbia's relative prosperity and high growth rate have made it the third most populous province, with a population exceeding three million. Its main cities include Vancouver, the largest port of Canada and of western North America, and Victoria, the provincial capital, located on the southeastern tip of Vancouver Island. British Columbia is one of Canada's more prosperous provinces.

PHYSICAL AND HUMAN GEOGRAPHY

The mountains, the sea, and the islands

The land. *Relief.* The vast territory of British Columbia lies almost entirely within the great mountain system, or cordillèra, that stretches along the western edge of the Americas from above the Arctic Circle to Cape Horn, at the southernmost extremity of South America. These mountains divide the province in ranges aligned in a southeast–northwest direction, creating a series of valleys and a broad central interior plateau where human settlement has concentrated. Hundreds of coast-hugging islands—the largest of which are Vancouver Island and the Queen Charlotte Islands—offer a protected waterway along the coastline, which is indented by narrow fjords that twist inland about the bases of towering mountains. The broad Fraser delta, behind Vancouver to the south, is the largest of the limited coastal lowlands, while in the interior many of the wide plateaus are cut by deep canyons and entirely surrounded by mountain ranges.

Brian Milne/First Light



The Coast Mountains rising over Howe Sound at Horseshoe Bay, West Vancouver, B.C., where (foreground) the Trans-Canada Highway connects with ferries to Vancouver Island and the final stretch of the highway.

Drainage. The province contains three main river systems: the Peace in the far north; the Fraser, which drains nearly all of the interior plateau; and the Columbia in the southeastern and south central regions. Lesser rivers, such as the Skeena, Nass, Iskut, and Stikine, drain the northwestern region into the Pacific, while the Liard system drains the northeastern section into the Arctic Ocean.

The Fraser, the only major river that lies entirely within the province, rises in the Rockies near the Yellowhead Pass, flows north and then southwestward to Prince George, where it turns almost due south for 300 miles (480 kilometres), flowing to Hope, and then westward through the lush farmlands to the sea south of Vancouver. The Columbia follows the Rocky Mountain Trench northward, bends around the northern end of the Selkirk Mountains, and turns south to flow into the Arrow Lakes and then into the states of Washington and Oregon. The Peace also becomes a formidable stream within the Rocky Mountain Trench, but it cuts eastward through the Rockies and into the plains area of Alberta.

Most of the thousands of lakes are small, but they are important for the water they store in an age when hydroelectric power has become a prized resource. The larger lakes are made long and narrow by the north–south mountain ranges that confine them in the deep and narrow valleys in all parts of the province. Atlin and Teslin in the northwest extend into the Yukon. Babine, Stuart, Shuswap, Quesnel, and François, which range from 90 to 200 square miles in area, are important salmon-spawning lakes. The Arrow and Kootenay lakes are important as storage reservoirs for hydroelectric plants.

Precipitation and temperature variation

Climate. Because of the Kuroshio, or Japan Current, which warms the coast, and the adjoining mountain ranges, British Columbia experiences a variety of climates. Some climatologists have claimed that, in its temperature, humidity, and variability, the southwestern corner of the province, tempered by the current, has one of the most favourable climates for people, plants, and animals. The prevailing winds from the Pacific, flowing over succeeding mountain ranges, cause a wide variety of precipitation and temperature ranges across the province, but along the coast such variation is negligible. Summers are comfortably cool, while winters are not severe, and 0° F (−18° C) is seldom recorded. In the Okanagan and Cariboo regions to the east, wider variations are recorded; summers are hot and winters are colder. Still farther east, up against the Rockies, similar temperature ranges prevail but with considerably heavier snowfalls. In the northern interior and Peace River country, very cold winters and very hot summers are normal.

British Columbia receives considerable precipitation, but its distribution is far from ideal. Some coastal towns have average annual rainfalls of 160 inches (4,100 millimetres) or more (perhaps the wettest region on the continent), while Ashcroft and Merritt, only 125 miles from the coast, register only 7 and 9 inches (180 and 230 millimetres), respectively. Victoria, sheltered by Vancouver Island mountains, receives less than 30 inches (760 millimetres), but Vancouver, 72 miles across the Strait of Georgia, receives 60 inches (1,525 millimetres), delivered by the winds crossing that body of water.

Plant life and soils. About 60 percent of the land area is forested, while only 3 percent has soil suitable for agriculture. The most valuable soils of British Columbia are the alluvial soils that developed on sand and silt laid down by streams and rivers. These extremely fertile soils, located mainly in the lower Fraser valley, are of limited extent. Distinctive areas of nonforested open grassland along the Fraser River, south of Williams Lake, and in the Kamloops–Meritt region south of the North Thompson River have rich pedocal soils upon which British Columbia's ranching industry flourishes. Similar prairie grassland soils lie in the Peace River country, the only part of the province suitable for large-scale grain farming. The more extensive but much shallower podzol soils cover the wet areas, especially along the coast, where they sustain a dense forest cover. The mild, wet climate of the coastal region produces large trees, some of the old growth specimens exceeding 200 feet (60 metres) in height. Western hemlock, red cedar, balsam fir, and Sitka spruce predominate, but the Douglas fir, which makes excellent sawn lumber, also grows in slightly drier coastal locations. The trees in Interior forests are smaller. They include Douglas fir and lodgepole and ponderosa pine in the south; balsam fir, spruce, and lodgepole pine in the centre; and white spruce in the far north. One-third of the province consists of barren Alpine tundra, snowfields, and glaciers; more than three-fourths is above 3,000 feet in altitude, beyond the limits of agriculture and often useful only for grazing.

Importance of the valleys

Settlement patterns. Because of the mountains and waters that surround them, British Columbians have become a society of valley dwellers. Valleys have assumed enormous importance for transportation, communications, and settlement, especially in the southern part of the province, where four-fifths of the population lives.

The mountains of Vancouver Island are separated from the Coast Mountains on the mainland by the Strait of Georgia, a saltwater valley along whose rocky slopes, on both sides, are located the province's two largest cities, Vancouver and Victoria. East of that valley is located the valley and canyon of the Fraser, with such service centres as Hope, Boston Bar, Lytton, and Lillooet, while still farther east lie the irrigated fruitlands of the Okanagan valley and the cities of Salmon Arm, Enderby, Vernon, Kelowna, and Penticton. North of the Okanagan, the landscape opens out into broad, gently rolling lands that form a basin surrounded by higher mountain ranges. Rapid expansion of the forest industry after World War II in the Central Interior plateau fostered growth of two regional centres, Kamloops and Prince George. Beyond and pressing against the Rockies are the parallel mining and lumbering valleys of the West and East Kootenays, which include the communities of Rossland, Trail, Nelson, Fernie, and Cranbrook.

For the most part, trails, roads, railroads, oil and gas pipelines, and electric power lines follow the routes of the rivers and often lie within yards of each other.

The people. *Population composition.* British Columbian society is one of the more British of Canada's 10 provinces, but it is also one of its most racially diverse. The English, Scottish, and Northern Irish played the major role in founding the province, and they still form the controlling elite. Scots dominated the fur-trade settlements, and when more than 25,000 miners arrived from California in 1858 the British government dispatched officials and the Royal Engineers to administer the colony. With the return of most American miners to California, British Columbia became essentially British. Immigrants from the British Isles flooded the province in the early years of the 20th century, reinforcing its ethnic character. By contrast, French Canadians are only a small minority scattered throughout the province. The arrival after 1945 of large numbers of Europeans, especially Dutch farmers attracted to Fraser delta lands, Germans to lower mainland cities, and Italians to various construction projects, challenged the province's Anglo-Saxon identity, but not nearly so forcefully as the presence of Asian minorities.

Chinese immigration

Chinese labourers first arrived at the time of the gold rush and suffered official discrimination from the 1870s, when they were disenfranchised. The large number of Chinese men imported in the 1880s to build the Canadian Pacific Railroad were joined later by additional Chinese, East Indian, and Japanese workers. As the Asian population increased to 9 percent of the provincial population in 1881 and 10 percent a decade later, anti-Asian feeling intensified. Discrimination peaked in 1923, when the Canadian government passed the Chinese Immigration Act, virtually ending Chinese immigration for a generation, and in 1942, during World War II, when all people of Japanese origin, whether Canadian citizens or not, were evacuated from the British Columbia coast. Due to more liberal attitudes about race, the declining population of Chinese men, and the forced dispersal of Japanese families, prejudice in British Columbia lessened after the war. Canadian immigration policies changed very slowly, however, and until 1967 continued to discriminate against racial minorities. Thereafter, the Asian population in British Columbia rose quickly through immigration from a low of 1 percent of the provincial total in the 1950s to more than 5 percent in the 1980s. Migration from Hong Kong during this period predominated, a movement fueled by fears of economic change that would accompany the scheduled takeover of the colony by China in 1997. A smaller but important movement of Sikhs from India to British Columbia in the mid-1970s added to the province's ethnic diversity, as did the arrival of Fijian and Vietnamese immigrants.

Among British Columbia's other minority groups, the most significant, for historical reasons, are the native Indians. It has been estimated that native people numbered about 80,000 in the late 1700s, before tuberculosis, diphtheria, smallpox, and other diseases brought by colonists reduced their ranks to 23,600 by 1934. Improved health measures inaugurated since then have permitted their numbers to increase to about the level attained two centuries earlier. Nonetheless, they now constitute less than 3 percent of the provincial population. Scores of reservations dot the province's landscape, chiefly in rural areas. The pressure of an increasing population combined with poverty began to drive Indians into the cities. Lacking education or skills valued by white society, they were relegated largely to underemployment and unemployment. But this relationship of dependence has been changing. Many native men and women now attend provincial colleges and universities and are fighting in the courts to reclaim traditional rights to land and resources taken from them without compensation.

U.S. immigrants

Although persons of U.S. origin constitute a small minority, they are influential in the economic life of the province—in manufacturing, mining, ranching, and forestry. Many have become part of the teaching, administration, and research staffs of the universities and colleges. About 2,500 blacks make up a small minority.

Religion. Religious practice has reflected the province's social character. European immigrants created a predominantly Christian society, and most native people converted to Christianity after the settlers arrived. In addition, the vast majority of British Columbians belong to one of many Protestant denominations, in contrast to the predominance of the Roman Catholic church that is found in other provinces. Religious conflict over whether schools should be denominational or nonsectarian never strongly influenced provincial politics in British Columbia, as it did elsewhere in Canada. The view held by mainstream Protestants that the church should remain separate from the state has been accepted as the norm in public affairs. In the early 1960s the United Church of Canada, formed in 1925 by Methodists, Congregationalists, and some Presbyterians, claimed the affiliation of almost one-third of British Columbians, followed by Anglicans and Roman Catholics. But British Columbia has also been the most secular of Canadian provinces, having the highest proportion of citizens who claim no religious affiliation. The province's Protestant identity is challenged as well by the ethnic diversification of its population. British Columbia is now home to almost one-fourth of Canada's adherents to the Eastern religions.

Demographic trends. British Columbian society has always been relatively fluid, and only recently has the proportion of the population born inside the province come to exceed that born elsewhere. Indeed, British Columbia has attracted immigrants more consistently since confederation than any other Canadian province, and in the

20th century more than any except Ontario. Interprovincial migration, especially from the neighbouring Prairie Provinces, increased noticeably in the 1930s. In the following decades British Columbia's pleasant climate drew retirement-age migrants to Victoria, Vancouver, and the Okanagan, while prosperity and high wages attracted young workers to construction and forest industry jobs in the central and northern part of the province. British Columbia is one of Canada's most urbanized provinces, with more than three-fourths of its residents living in urban places.

The economy. The economy of British Columbia is a mixture of public and private enterprise. Service industries have become the largest sector of the province, followed by manufacturing.

Resources. Natural resources have formed the basis of British Columbia's economy since the arrival of Europeans. Mining and mineral processing account for 3 percent of its labour force but nearly 20 percent of the production value of British Columbia's major industries. Mines are located throughout the province and include open-pit coal mines in the southeastern and northeastern corners of the province and open-pit copper mines southwest of Kamloops. Oil and gas have been drawn from wells in northeastern British Columbia since the 1950s, and new reserves continue to be found. Forestry and fishing are other major resources.

Mining

Agriculture, forestry, and fishing. Agriculture plays an important part in the province's economy, although it is not homogenous and varies widely, from the highly capitalized dairy industry of the lower Fraser valley to the fruit orchards and vineyards of the Okanagan, the mixed farms of the Bulkley valley, and the highly specialized grain farms of the Peace River country. Geography severely limits agricultural production in British Columbia, where cultivated land as a percentage of total provincial area is the second lowest in Canada.

Forestry is the most significant of British Columbia's resource industries. Traditionally centred on the west coast, where the dense rain forest has produced large trees easily accessible by water, logging, sawmilling, and pulp and paper production spread to the central and eastern parts of the province in the postwar years. Since 1972 the total volume of timber cut in the Interior has exceeded that on the coast. British Columbia has 17 percent of Canada's total forested land but 40 percent of its marketable timber, and by the late 1980s British Columbia was producing 70 percent of the country's sawn lumber and 90 percent of its soft plywood. The corporate structure of the industry also changed after World War II, with a few giant multinational corporations, often controlled by American capital, replacing the previously decentralized ownership. Corporate concentration of the forest industry also occurred as a result of provincial government policy.

The five species of Pacific salmon provide the foundation for British Columbia's sport and commercial fishing industry, although halibut, cod, herring, and various shellfish are also much sought after. Fish processing, which was carried on in dozens of small canneries spread along the coast, has since the 1940s become concentrated into a few large plants near Vancouver and Prince Rupert.

Electricity production

Power and manufacturing. The production of hydroelectric power has greatly facilitated British Columbia's economic expansion. Coal from Vancouver Island and, starting in 1898, from the Crowsnest Pass in the province's southeastern corner provided the major energy source for railroads and industry well into the 20th century. But British Columbia's mountainous relief and, in certain areas, high rainfall create vast potential for the production of hydroelectric energy. The quest for cheap electric power, which had been generated in relatively small quantities at several locations starting at the end of the 19th century, led to a privately funded project to produce electric energy for an aluminum smelter at Kitimat on the northwestern coast in the early 1950s and vast construction projects on the Columbia and Peace rivers in the 1960s. On the Peace the province's publicly owned electric utility, the British Columbia Hydro and Power Authority, erected the W.A.C. Bennett Dam, one of the world's largest earth-filled structures, and on the Columbia the Mica, Hugh Keenleyside, Revelstoke, and Duncan dams.

British Columbia's urban areas mainly provide services for, or process the products of, nearby salmon and other types of fishing, farming, mining, and logging industries. For instance, Nanaimo, once a grimy coal-mining town, now prospers as a market centre for fish, lumber, and pulp and paper. Trail specializes in mineral smelting, and Prince George and Kamloops are centres for the large Interior forest products industry. Kelowna, an agricultural service centre, also benefits from logging and mining as well as tourism. Resource industry management for the coastal region gravitated after 1900 to Vancouver, as did sawmilling, fish processing, and secondary manufacturing. Yet greater Vancouver, where 40 percent of the province's population resides, is less tied to the resource economy than other urban places in British Columbia. That area's multifaceted urban economy is increasingly bound by connections of trade and finance to markets around the Pacific Rim. The provincial capital and second largest city, Victoria, has become largely a service community.

Transportation. Although an elementary system of transportation was established in gold-rush days and most of its routes are still followed, no concerted effort was made to tie the isolated areas of the province together by roads, ferries, and railroads until after World War II. Highways are exceedingly important in a province fractured by towering mountains, long coastal inlets, and swift rivers. This crucial fact was recognized and exploited by the infant Social Credit Party, which, upon winning control of the government in 1952, adopted an ambitious and controversial program of road building, tunnel and bridge building, and ferry services as the chief plank of its highly successful political platform.

Vancouver Island, with one-sixth of the province's population, represents a special transportation problem. This has been met by the development of one of the world's largest ferry fleets. Most of the ferries connecting Vancouver with Victoria and Nanaimo carry 1,000 passengers and from 140 to 200 cars each.

Railroads

The province is served by four railroads. The Canadian Pacific Railway (CPR) connects Vancouver with eastern Canada and maintains a network of branches serving the mining, forest, and agricultural industries throughout southern British Columbia. The Canadian National Railway serves the south and the north with terminals at Vancouver and Prince Rupert. The Burlington Northern serves the province from the United States. The British Columbia Railway links Vancouver in the southwest with Prince George and Fort St. John in the north. The vastness of the province combined with difficult terrain has also encouraged the development of air travel, and several small companies now connect the far reaches of British Columbia with its urban centres. Vancouver International Airport is the main air transport centre.

Administration and social conditions. *Government.* Parliamentary government in British Columbia dates from the inauguration of the first legislature of the Colony of Vancouver Island, Aug. 12, 1856, but responsible government was not achieved until confederation.

The lieutenant governor, appointed by the government in Ottawa, ostensibly represents the British crown but in the real sense represents the federal government. The lieutenant governor calls upon the recognized leader of the majority party in the unicameral Legislative Assembly to form a government, with that leader as premier. The premier and the Cabinet, selected from the elected members of the legislature, constitute the Executive Council. The Cabinet is responsible to the Legislative Assembly for the operation of the day-to-day business of the government.

Two political parties dominate provincial politics. One, the Social Credit Party, defends the role of the market in economic affairs, favours freeing economic development from the government, and is socially conservative; the other, the New Democratic Party, emphasizes issues of social and economic justice, sees an active role for government in a mixed economy, and is social democratic. The former, a provincial party, held power for most of the time after 1952. In federal elections the New Democrats compete with two national parties, the middle-of-the-road Progressive Conservatives and Liberals.

Regional division

About four-fifths of the population resides in municipalities governed by elected mayors and councils. These local governments are created, supervised, and, to a considerable extent, funded by the provincial government. British Columbia's unorganized territory is divided into 28 regional government districts that provide services to rural areas and have assumed the responsibility for many municipal services.

By agreement, the Royal Canadian Mounted Police (RCMP) act as the provincial police force under the control of the attorney general. Most cities and district municipalities are responsible for law enforcement within their own boundaries. Most elect to have this function contracted out to the RCMP, but Vancouver, Victoria, Nelson, and New Westminster maintain independent forces.

Education. The provincial government spends about one-third of its budget on the rapidly expanding education industry of the province. Public school education is free and compulsory to the age of 15. Postsecondary education is provided by five degree-granting institutions, among which are the University of Victoria in the capital, Simon Fraser University, the University of British Columbia, and the Open Learning Agency in Greater Vancouver, the last specializing in correspondence courses. Technical and vocational instruction is provided by several schools, the most important of which is the British Columbia Institute of Technology in Burnaby.

Health and welfare. The British Columbia Overall Medical Services Plan is available to all residents of the province on a voluntary subscription basis at low, uniform rates. It provides comprehensive medical care coverage, including specified services of physicians, surgeons, certain dental surgeons, the Red Cross, nurses, chiropractors, osteopathic physicians, and others. Hospital care is also available under the British Columbia Hospital Insurance Service (BCHIS). Medical care for the aged meets the standards of the Medical Care Act of Canada and receives contributions from the federal government.

Cultural life. The majority of cultural activities in British Columbia tend to reflect the pioneer background of the province, the great distances between pockets of population, and the various economic backgrounds of areas still oriented to resource industries and to the outdoors. The Williams Lake Stampede is the great annual event of the white and the Indian populations of the ranching country of the Central Interior. Even the annual Pacific National Exhibition in Vancouver is largely oriented to the agricultural communities of the lower Fraser valley rather than to the urban interest of Vancouver. Other centres hold annual Loggers Day festivals, salmon contests, and pioneer events related to outdoor industry and pursuits.

Urban culture

Cultural activities of the larger cities are in a transitional stage, neither frontier nor unabashedly big city. Vancouver's opera association, both respectable and ambitious, mounts productions featuring artists imported from the world's great opera houses, while its symphony society receives enthusiastic support from a loyal following of citizens. Among the most noteworthy cultural constructions in Vancouver are the Centennial Museum, Maritime Museum, and H.R. MacMillan Planetarium, the Bloedel Conservatory, the Queen Elizabeth Theatre complex, the Vancouver Art Gallery, and the Orpheum Theatre. Prince George boasts a fine library that offers innovative programs to people of the Central Interior, while on the south coast Nanaimo and White Rock present excellent summer theatre. Vancouver's Folk Music Festival, held in mid-July at Jericho Beach, is among the most innovative folk festivals in North America. In Victoria the Royal British Columbia Provincial Museum is outstanding.

Local industrialists have done much to support the recent upsurge in cultural activities through their financial support of such distributing agencies as the Vancouver Foundation and the Koerner Foundation. Private funds are channeled through them into the theatres, orchestras, university libraries, art galleries, and museums, as well as to private artists and scholars.

In a special place is the continuing restoration of Barkerville, once the thriving centre of the Cariboo gold rush of the 1860s. There the provincial government has rebuilt scores of old buildings to re-create the old gold town as it appeared more than a century ago. The restoration of historic buildings of Victoria also reflects the province's cultural heritage. Scores of derelict buildings of historic interest have been restored and rented to merchants. Squares have been opened, and whole streets have been revitalized without recourse to bulldozers or slum clearance.

Commercial, recreational, and athletic activities are concentrated in the southwestern part of the province, as are other cultural activities. Spectator sports gained impetus with the building of Empire Stadium in Vancouver in the 1950s and can also now be presented in that city's 60,000-seat domed stadium, BC Place. Vancouver has professional teams in the National Hockey League and the Canadian Football League.

HISTORY

Indian societies

At the time of initial contact with white explorers, Indians in present-day British Columbia numbered about 80,000. The coast was dominated by Coast Salish, Nootka, Kwakiutl, Bella Coola, Tsimshian, and Haida, whose economy was based on the products of the sea and on the huge coastal cedars. Expert fishermen, they utilized traps, nets, hooks, spears, and even an ingenious toggling harpoon for hunting whales. Their clothing was made of skins and cedar bark covered by beautifully patterned blankets woven from the wool of mountain goats. Indian dwellings were large rectangular buildings of cedar beams and planks, divided into compartments for families. Houses were located in clusters along beaches suitable for canoe landings and just above the high-water mark. These Indians were already enterprising traders in copper, blankets, elk hides, furs, shells, candlefish oil, and slaves along the intertribal routes that ran north–south into California and east–west into the interior. They also enjoyed a rich social life in this land of the potlatch. Rival families competed with each other to distribute blankets, food, jewelry, and other favours to guests, often invited from hundreds of miles away, to mark the birth, adolescence, marriage, or death of an important member of the tribe.

Explorations and trading posts. The area that was to become British Columbia first caught the attention of European nations in the late 18th century. Spanish ships visited the coast in 1774, followed by Captain James Cook, who was searching for the Northwest Passage. The latter's account of the fur wealth of the area stimulated the interest of British and American traders, who soon arrived to trade with the Indians for the highly prized sea otter pelts. The growing interest of Great Britain in the area was indicated by the dispatch of Captain George Vancouver, who circumnavigated Vancouver Island and charted the mainland's intricate coastline.

Simultaneously, other British fur traders penetrated the region from the east. Alexander Mackenzie of the North West Company of Montreal entered the region through its winding waterways; he completed the first overland journey across the entire continent when he arrived at Bella Coola, at the mouth of Dean Channel, in 1793. A fur trade based on fixed posts in the interior followed the establishment, by Simon Fraser in 1805, of the first trading post at McLeod Lake. Three years later he descended the Fraser River to its mouth, the site of present-day Vancouver.

Crown colony status

After the southern boundary was fixed at the 49th parallel, Vancouver Island was recognized as solely British territory, following years of near-conflict with the United States. Fort Victoria became the western headquarters of the Hudson's Bay Company. In 1849 Vancouver Island was made a crown colony by the imperial government, which expected that an orderly settlement in this distant outpost of empire would follow. However, the determination of Governor James Douglas to encourage the fur trade and the lure of the California goldfields impeded settlement so successfully that in 1855 the total population of European origin in the colony was only 774, most of them involved in the pursuit of the fur trade.

Gold rush and permanent settlements. The gold strike of 1858 made Fort Victoria into a city, opened the mainland to settlement, and transformed the frontier into a prosperous and dynamic society that was proclaimed the Colony of British Columbia. Hordes of gold seekers from California, Australia, and other parts of the Pacific community joined with British and Canadian migrants to work the alluvial gold deposits of the lower Fraser and by 1862 the Cariboo gold country on the upper Fraser.

By 1865 the gold days were over, and most of the miners had departed with the larger part of nearly $25 million in gold dust. But the rush had attracted an army of ranchers, farmers, hotel operators, storekeepers, and civil servants who, although diminished in numbers, formed a nucleus for an ongoing, settled society. Left behind also was a fairly well-established transportation and communications network. Steamships linked Victoria and points on the Fraser River, and a 400-mile coach road connected Yale, on the lower Fraser, with Barkerville, in the Cariboo gold country. The two colonies joined Canada in 1871 as the Province of British Columbia.

The arrival of the Canadian Pacific Railway at Port Moody in 1885 opened a new era. Permanent railroad and lumbering settlements sprang up along the railroad route. The extension of the line into Vancouver was completed in 1887, the year after the city was incorporated. The establishment of a steamship line connecting it with the Orient, in 1891, assured Vancouver's future as a port.

The early 20th century. Once the construction of the Panama Canal was assured, British Columbia experienced its first boom since the heady days of the gold rush, a boom based upon the assumption of investors that the province's raw resources would soon be able to compete in the markets of the Atlantic nations. Forest tracts were allotted to eager American, British, German, and Canadian investors by a poorly funded provincial government eager to make an impressive fiscal showing and ensure its perpetual reelection. A similar situation prevailed in the mining industry, with the initial prizes going to British investors. Simultaneous with the opening up of these resource industries, the rapid settlement of the treeless prairies occurred, and the demand for lumber was best filled from British Columbia. As the economy revitalized, the population increased from less than 180,000 to nearly 400,000 between 1901 and 1911, and Vancouver emerged as the leading city, with more than 111,000.

Anti-Asian activity

After 1918, postwar dislocation, strikes, and sporadic unemployment fed the flames of anti-Asian feeling, always strong in Vancouver. Politicians, union leaders, and the *Vancouver Daily World* (now defunct) eagerly laid the blame for lack of prosperity on Asian workers. Exclusionist legislation was passed by an obliging provincial legislature in 1923 and remained in force until the late 1940s, when Asians were enfranchised.

Scarcely recovered from the war years, the province found its newly acquired markets swept away by the economic depression of the 1930s. Recovery was delayed until the economy was stimulated once again, by war in 1939. This time, military demands were extensive enough to ensure the continued prosperity of the province's industry even beyond the war years.

Postwar political consolidation. With postwar economic prosperity came political change. To meet the political threat of the depression-born Cooperative Commonwealth Federation (CCF), a moderate socialist party, the Conservatives and Liberals combined forces to form a coalition government during the war years. Growing disenchantment with the party in power made inevitable the appearance of a new party as an alternative to the CCF. The Social Credit Party, which won the election of 1952, was formed by dissidents of both old-line parties but chiefly by conservatives. The Social Credit government remained in power until 1972, when it lost the provincial election to the New Democratic Party (reformist successor to the CCF). In the election of 1975 the Social Credit Party regained control of the Legislative Assembly, and it remained in power through the 1980s. In that decade the boom- and bust-cycles characteristic of most resource-based economies returned, especially affecting the vast region outside of greater Vancouver. (J.C.L./R.A.J.McD.)

NORTHERN TERRITORIES

Northwest Territories

The Northwest Territories constitute more than a third of Canada, itself the world's second largest nation in area, and they reach almost from the eastern to the western extremities of the country across the roof of the North American continent, occupying an area of 1,322,909 square miles (3,426,320 square kilometres). The territories are among the most sparsely populated but habitable regions of the world. In the north the territory extends far above the Arctic Circle to incorporate thousands of islands, the largest of which are Victoria Island in the west and Baffin Island in the east, as well as the islands within bays and straits of Hudson Bay and Ungava Bay. The land is one of high plateaus separating a virtually Arctic lowland on the east from a western depression of more moderate climate. Thousands of lakes dot its heavily glaciated surface.

Administrative regions

There are five administrative regions in the territories. The Baffin region includes the Arctic islands of the north and Melville, Brodeur, and smaller peninsulas. The District of Keewatin region lies north of the province of Manitoba. The Fort Smith region borders the Yukon Territory to the west and Saskatchewan, Alberta, and British Columbia to the south. The Inuvik region is bordered by the Beaufort Sea in the northwest and the Yukon Territory in the southwest. The Kitikmeot region comprises Victoria Island, part of Prince of Wales Island, and the Boothia Peninsula. The capital and largest town is Yellowknife.

PHYSICAL AND HUMAN GEOGRAPHY

The land. Two main types of landscape blend into one another along the timberline, which runs southeast from near the Mackenzie delta on the Arctic Ocean to near Churchill, Man., on Hudson Bay. Southwest of this line lies the northernmost part of the Canadian boreal forest, extending westward to the mountain ranges that separate the Northwest Territories from Yukon Territory. North and east of the timberline stretch the relatively barren grounds of the Arctic, vast reaches of flat, often poorly drained lowlands and of Precambrian rock more than 570 million years old. Within each of these two main regions, the surface vegetation and the animal life it supports vary with soil and climatic conditions.

The Mackenzie Lowlands. The most favourable conditions are found in the Mackenzie Lowlands in the west, where forests of black and white spruce mixed with deciduous species extend north to the Mackenzie delta. The climate here is relatively mild, with warm and dry summers during which mean July temperatures of 60° F (about 16° C) are recorded at most of the settlements along the Mackenzie River. The winters are long and cold, with an average mean January reading at Yellowknife on the northern shore of Great Slave Lake of −18° F (−28° C). With only about 70 frost-free days, the growing season is short. While it lasts, however, wildflowers and grasses flourish, and root and cereal crops can be cultivated. Many species of valuable fur-bearing animals are found, notably muskrat and beaver. Moose, wolves, black and grizzly bears, and mountain sheep and goats are also native to the area. Pickerel, northern pike, and whitefish inhabit the rivers and lakes.

Mackenzie Lowlands permafrost

The cool climate limits navigation on the Mackenzie River system to about four months a year and causes a permanently frozen subsoil, or permafrost, except in a small area south of Great Slave Lake. Permafrost creates serious construction problems, especially where the subsoil is an unstable mixture of fine silt and water.

The northeast. East of the Mackenzie Lowlands and the tree line the climate is colder, and the terrain changes to that of the ancient and rocky Precambrian mass known as the Canadian Shield, the edge of which is straddled by the two largest lakes, Great Bear Lake, 12,095 square miles, and Great Slave Lake, 11,030 square miles. Tree growth becomes sparse and stunted and eventually disappears, to be replaced by the light but tough vegetation of the Arctic tundra. East of the timberline the Arctic climate prevails, with average winter temperatures similar to those in the subarctic region to the west but with summer temperatures not rising above an average of 50° F (10° C) even in July. In these so-called barren lands, annual precipitation is light, and the soils, where they exist at all on the heavily glaciated surface, are usually sandy and thin. Mosses, lichens, and many small hardy flowering plants survive in these conditions and support a variety of animal life ranging from small burrowing mammals and their predator, the white arctic fox, to the large caribou and musk-ox. Seals, walrus, and polar bears are prevalent along the coasts. Bird life is plentiful in summer, with some species, notably the ptarmigans and ravens, remaining all winter. Mosquitoes and other insects abound during the summers.

Settlement patterns. The native people of the territories once led nomadic lives, surviving by adapting to the harsh natural environment. But this balance was disturbed when Europeans established permanent settlements and introduced firearms. The numbers of barren-ground caribou were drastically reduced, and the musk-ox was almost exterminated before being protected in 1927. Attempts to introduce reindeer and other domesticated animals have not been successful.

Nearly all the population lives in small settlements along the Mackenzie River and along the Arctic coastlines of the mainland and northern islands. In addition to Yellowknife, the main towns are Hay River, Fort Smith, and Inuvik; all are in the Mackenzie area.

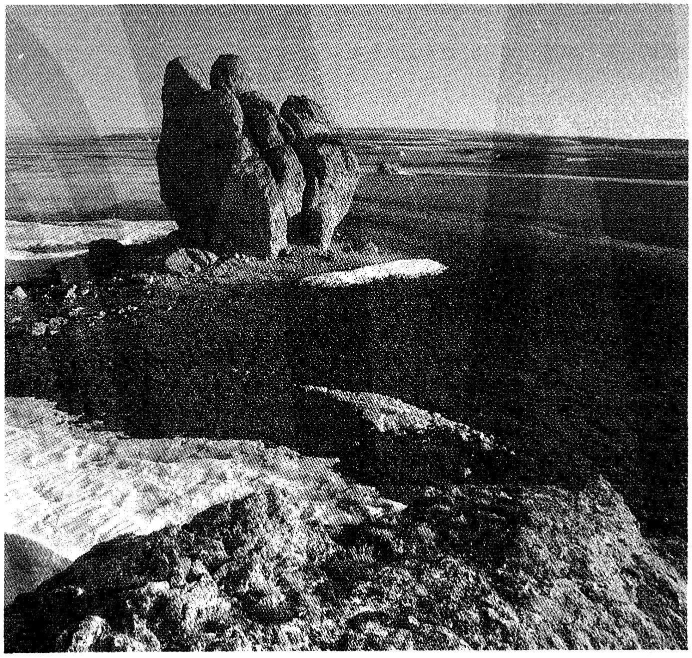
In the eastern Arctic, settlements are very small with the exception of Iqaluit (formerly Frobisher Bay), on Baffin Island between Hudson Bay and the Atlantic, which is the administrative and commercial centre of the region.

The people. The native American Indians and Inuit are two distinct groups, differing in appearance, language, and culture and living apart from one another.

American Indians. The Indians, who make up about one-fifth of the total population, are concentrated in the Mackenzie valley area. These people, who now refer to themselves as the Dene, belong to several tribes, all part of the Athabascan language family. Tribal organization was never strong among the northern Indians, and small bands led by individuals chosen for their skill in the hunt were the effective social unit. This arrangement was easily molded to the needs of the fur trade when it reached the Mackenzie area in the 18th century. Thereafter, the exchange of furs for imported goods became the basis of the Indian economy. Government treaties were made with the groups living south of Great Slave Lake in 1899 and with those living farther north only in 1921. No reservations were established. The decline of the fur trade in the 20th century left many Indians unemployed, and they have had difficulty adapting to wage employment.

The Indian fur-trading economy

Brian Milne/First Light



Rock-strewn tundra of the barren Arctic lands of Polar Bear Pass on Bathurst Island, N.W. Terr.

The Inuit. The origins of the Inuit living in the territories, largely in the coastal areas, are obscure. They constitute about one-third of the territorial population. Although several dialect groups are represented, all apparently have descended from what is known as the Thule culture, a prehistoric maritime society. Early contacts with explorers and whaling crews introduced new diseases and reduced the population during the 19th century. There was also considerable interbreeding. The fur trade was not well established in the Arctic until early in the 20th century; but the Inuit adapted quickly to it, and they, like the Indians, came to depend upon outside sources of supply for most of the necessities of life. Construction activity during World War II and in the postwar years further affected their way of life. Inuit adapted readily to the opportunities for casual employment, and many were quick to abandon the seminomadic trapping and hunting existence for life in the settlements. Canadian government policy in the 1950s and '60s promoted this trend in the interests of upgrading the quality of life.

Europeans. The remaining one-half of the people in the territories are mainly of European and mixed European and native descent. Most live in the more economically advanced Fort Smith region, where they find employment in mining, transportation, and public service. Much of this population has always been transient.

The economy. High production costs and transportation problems inhibit development of many of the territories' mineral resources, including the petroleum and natural gas fields that exist in the western Arctic coastal regions.

Government assistance in the development of major resources has been provided mainly in the form of roads, electric-power facilities, mapping, and geologic services, although the government has participated in the search for oil and natural gas. Government agencies produce and distribute electric power throughout the territories and provide certain transportation services.

Resources. Mining has been the principal nonrenewable resource industry of the territories. Gold has been mined at Yellowknife on the north shore of Great Slave Lake since the late 1930s. Radioactive ores were mined at Port Radium on Great Bear Lake in the 1930s, initially to produce radium; later, during World War II and afterward, uranium was mined. Large-scale lead and zinc mining was carried on at Pine Point from the late 1960s until the 1980s, when the ore deposit became depleted. Smaller metal mining projects have been carried out at widely scattered sites, a few in the high Arctic regions. Silver, copper, tungsten, and cadmium are among the metals that have been produced. Petroleum fuels for use in the territories are obtained from refineries located at the Norman Wells and Pointed Mountain fields. Gasoline and diesel fuel are important both for transportation and for electric power generating purposes. Large-scale hydroelectric power development has not been feasible, but a number of small sites have been developed.

Hunting and fishing. Trapping continues to provide income for some of the native population. Muskrat, beaver, marten, mink, and lynx are the most important furs taken in the Mackenzie area, while the white fox remains the principal fur in the Arctic regions. Fishing and hunting of sea mammals also provides some employment. Whitefish and lake trout are fished commercially on Great Slave and some smaller lakes. Arctic char are fished and exported to southern markets from several communities in the eastern Arctic. Seals and small whales are hunted for food, and some sealskins are marketed commercially. Sport fishing and hunting are major attractions for the small but growing number of tourists who visit each year.

Forestry and agriculture. The Fort Smith region has most of the 200,000 square miles of forested land, but even there, large stands of merchantable timber are not plentiful. The several sawmills process the timber only for local use. Although there are more than one million acres of arable land, farming is not profitable. Some field crops are grown for local use, but most foodstuffs must be imported from the outside, greatly affecting their price.

Airline services

Transportation. Nearly all passenger and much freight traffic is carried by air services. Flights link Yellowknife and other major settlements along the Mackenzie valley to Edmonton, Alta. Settlements on the west coast of Hudson Bay and in Keewatin region are connected to Winnipeg, and those in the eastern Arctic to Montreal.

Surface transportation for heavy freight is mainly by water. Fuel oil for heating, and other bulky supplies, are carried to eastern Arctic settlements by seagoing supply ships organized by the federal Department of Transport. Government departments also supply remote villages and military installations along the eastern coastline. The Northern Transportation Company Limited is the principal carrier on the Mackenzie River waterway. The waterway is supplemented in the southern part of the Fort Smith region by the Mackenzie Highway and a railway connecting Pine Point to the trans-Canada rail systems at Grimshaw, Alta. The southern Mackenzie valley is linked by a highway from Fort Simpson to the Alaska highway system in Yukon, while to the north the Mackenzie delta is connected to Dawson, in Yukon, by the Dempster Highway. Tractor trains and other overland vehicles using temporary winter roadways carry freight into remote areas. Snowmobiles are used for light winter travel.

The commissioner and assembly

Administration and social conditions. *Government.* Ultimate constitutional responsibility for government in the territories rests with the federal government in Ottawa, but most provincial responsibilities have been delegated to a territorial administration sitting at Yellowknife. This consists of a commissioner and a Legislative Assembly comprising 24 members elected by the people to serve a four-year term. The elected council reflects the distinct ethnic mix of the territorial population and has come to be composed of roughly equal numbers of Inuit, Indians, and whites. The council generally convenes during the winter, spring, and fall. During these sessions the council has the authority to enact legislation on most territorial matters. All legislation is subject to the commissioner's assent and may be revoked by the federal government within one year. An executive committee advises the commissioner on policy matters. The commissioner, in turn, proposes legislation to the council, but council members may introduce private bills of a nonfiscal nature. Because royalties and other revenues from natural resource use in the territories are collected by the federal government, the territorial administration relies for most of its revenues on funds transferred to it from the federal authority.

The territories are represented by one elected member of Parliament. Justice is dispensed by a territorial court, a police magistrate, and several justices of the peace. Law enforcement is carried out by the Royal Canadian Mounted Police. The federal government controls all natural resources except game and administers them through its Department of Indian Affairs and Northern Development.

Education and social services. Missionaries provided nearly all the education and health care available in the territories until the 1950s, but since then both have become mainly government responsibilities. The federal Department of Indian Affairs and Northern Development cooperates with the territorial department of education in providing elementary and secondary schooling and in assisting native students to pursue postsecondary education outside the territories. A number of postsecondary programs and courses are offered by a community college system at several centres throughout the territories. Health care is provided through comprehensive territorial hospital and medical-services insurance plans.

Cultural life. Modern forms of transportation and communication have done much to break down the isolation of life in the north, and contemporary North American popular culture is evident in most communities.

Inuit culture

Satellite television has made a wide range of entertainment and educational programs available to viewers in even the most remote settlements. Radio stations relay programs throughout the territories, and most of the larger settlements have their own weekly newspapers. Some even have local television stations that originate programs for distribution in the territories. In the Fort Smith region, little remains of the traditional native culture, although there is growing interest, particularly at the local level, in revitalizing the linguistic and cultural heritage of the Dene. In the eastern regions, elements of the Inuit culture have been preserved. Public policy in recent years has encouraged development of Inuit traditions in arts and crafts, providing an important source of income in some Inuit communities and making Inuit culture familiar to collectors worldwide. Inuit-language broadcasting is well established, and a written language has been introduced to encourage Inuit writing and to facilitate communication among the communities.

HISTORY

Vikings probably visited parts of the Canadian Arctic during the Middle Ages, but there are no records of exploration until the voyage in 1576 of the English mariner Martin Frobisher in search of a northwest passage to the Orient. Other expeditions in the 17th century also failed to find the route, but they added to knowledge of the Arctic regions. Interest in finding the route waned in the 18th century, but whaling ships became commonplace in the Arctic waters. The first recorded exploration of the mainland was by Samuel Hearne, who in 1770–72 journeyed from the west coast of Hudson Bay to the mouth of the Coppermine River on the northern coast. Other inland explorations were mainly the work of Montreal-based fur traders. In 1789 Alexander Mackenzie of the North West Company traveled down the river that bears his name to reach the Arctic Ocean. In the 19th century there was renewed interest in a northwest passage. Sir John Franklin and others explored much of Mackenzie District (now largely the regions of Fort Smith, Kitikmeot, and Inuvik) and mapped parts of the northern coastline during the 1820s, work that Thomas Simpson continued in 1838–39. Searchers for the lost Franklin expedition of 1845–48 explored and mapped other parts of the eastern Arctic in the following decade. Later a series of expeditions attempted to reach the North Pole; such exploits continued into the 20th century but by then were overshadowed by more practical activities directed at identifying the resource potential of the Canadian North.

Early administration

Settlements were first established to serve the whaling fleets and fur traders. Missionaries became active in the Mackenzie valley in 1852 and in the eastern Arctic toward the end of the century. No resident administrative authorities were established within the present limits of the Northwest Territories until the 20th century. Responsibility for the mainland territories that drain into Hudson Bay, known as Rupert's Land, was vested in the Hudson's Bay Company. The remaining part of the mainland, the North-Western Territory, was under nominal British rule until 1870, at which time both it and Rupert's Land were ceded to Canada. In 1880 the Arctic islands claimed by Britain were also placed under Canadian jurisdiction. Separation of the Yukon Territory, creation of new provinces, and enlargement of other provinces reduced the Northwest Territories to its present limits by 1912. The Royal Canadian Mounted Police were made responsible for maintaining law and order and for providing whatever governmental administration was required in the area.

Fur traders, missionaries, and the police directed the life of the Northwest Territories until the 1920s, when discovery of oil near Fort Norman on the Mackenzie River prompted the Canadian government to establish a territorial administration for the area. Mining replaced the fur trade as the most important industry in Mackenzie District in the 1930s. World War II brought much government-financed construction activity to the territories. In the southern Mackenzie area the Canol pipeline, linking the oil field at Norman Wells to a refinery at Whitehorse in the Yukon, and construction of several large airfields in the eastern Arctic did much to open the Canadian North to further exploration and development. After the war, construction of the Mackenzie Highway to Great Slave Lake and the building of the Distant Early Warning radar network, the DEW line, continued this process. A great expansion of government-sponsored health, education, and welfare services transformed living and social conditions throughout the North.

Yukon Territory

A region of rugged mountains and high plateaus, the Yukon Territory comprises 186,661 square miles (483,450 square kilometres) in extreme northwestern Canada. Its mineral wealth has long been known, but the combination of an Arctic climate with remoteness from markets has minimized the economic exploitation of such resources and the development of modern settlement. Instead, the territory remains among the few frontiers on the North American continent, a sparsely populated and largely unspoiled wilderness.

The Yukon Territory lies directly north of the province of British Columbia, with the Northwest Territories to the east and the U.S. state of Alaska to the west. In the north it stretches well above the Arctic Circle to border the Beaufort Sea. The capital is Whitehorse.

PHYSICAL AND HUMAN GEOGRAPHY

The land. The territory lies within the mountainous cordilleran region of western North America. The more settled areas lie in a large central plateau surrounded by mountains and drained by the Yukon River system flowing northwestward into Alaska. Some of the surrounding mountains are spectacular, especially the St. Elias Mountains in the southwest, which have some of the highest peaks in North America, including Mount Logan at 19,524 feet (5,951 metres).

The northern stretches of flat and poorly drained tundra have widespread permafrost, a permanently frozen ground that makes construction of most kinds difficult. Although temperatures vary, sometimes reaching summer highs of 95° F (35° C) and winter lows below −60° F (−51° C), the monthly average readings are not unlike those found in some Canadian cities farther east and south. Summers are short but the days are long, especially in the northern part of the territory lying above the Arctic Circle. Precipitation is light, averaging only 10 inches (250 millimetres) annually at Whitehorse.

Environmental impact of people

Vegetation is sparse in many regions because of the dry, cool climate and poor soils, but some of the southern valleys are heavily forested. Animal life, on the other hand, abounds in the Yukon. Large game animals and smaller fur-bearing mammals are native to the area, as are waterfowl and other common North American birds. Common species of fish include the arctic grayling, lake trout, and northern pike. Much of the territory remains unspoiled wilderness, but the impact of people on the environment is apparent. Near the settlements, reliance on wood for fuel has destroyed timber, and in more remote places forest fires caused by humans have often gone uncontrolled. In addition, surface mining has scarred the landscape near Dawson and Whitehorse.

The city of Dawson and some older Indian villages such as Old Crow, situated well above the Arctic Circle, are set in locations of great natural beauty and retain a picturesque appearance. More modern centres of mining and transportation, such as Whitehorse, Watson Lake, and Mayo, resemble towns of like size elsewhere in western North America. On the fringes of some of these, rude settlements provide shelter for people forced from their more remote habitations by the decline of trapping as an economically viable activity and attracted by the social services available in the more urban areas. Some two-thirds of the total population of the Yukon live in Whitehorse.

The people. About 15 percent of the people are native American Indians; most belong to the Athabascan language family, of which the Kutchin group is the largest. Although registered Indians in the territory are a federal responsibility, there are few occupied Indian reservations. In 1973 the Canadian government recognized the validity of Indian territorial claims based on past treaties, thereby rendering the first official recognition of such rights. The rest of the population comprises people of European descent or of mixed Indian and European stock.

Health and welfare services have been greatly improved in recent decades, contributing to a decline in the total mortality rate. A high infant mortality remains a serious problem, but fertility rates are above the Canadian average, giving the territory a high rate of natural increase in population. The ability of the economy to absorb this increase has become a matter of increasing concern.

Few people continue to make their living by hunting, fishing, or trapping, and, except for some isolated groups, most of the people are now dependent upon wage employment. Wages and salaries are unusually high in most occupations. Since nearly all food, fuel, building materials, and manufactured goods are imported over considerable distances, the cost of living is also high. Marked differences in living standards exist between those who find employment in mining, transportation, and public service and those who lack the education required for such employment.

Value of mining

The economy. Since the late 19th century, mining has been the Yukon's most important industry, although market fluctuations can cause sharp variations in production. The extensive and varied mineral resources include large deposits of combined silver-lead and lead-zinc ores and of copper, coal, iron, and some petroleum and natural gas. Commercial production of silver-lead-zinc and of copper concentrates has been accomplished, but the economic feasibility of developing other known mineral deposits is not established.

Forest resources are limited, but commercial logging is carried out in some southern areas. Small sawmills produce some of the lumber required for local building, for mining timbers, and for fuel, although imported fuel oil is replacing both wood and locally mined coal as the principal fuel. Farming is possible, but climate and soil conditions make it so unprofitable that virtually no settlement is undertaken for agricultural purposes. Trapping is still important despite its decline, and fox, beaver, wolf, and lynx are caught for their pelts.

Tourism is a rapidly expanding industry, however, now ranking second to mining in the value it contributes to the economy. Both federal and territorial governments play an important role in the economy. Since the end of World War II, government has assumed major responsibility for

George Hunter

Dawson, on the bank of the Yukon River in the Yukon Territory.

building roads, airfields, and electric power facilities, as well as for providing incentives to private companies interested in developing resources in the area. Exploration for oil and gas began in the 1950s. Commercially significant gas reserves were discovered in the 1960s, and there was subsequently extensive exploration throughout the territory for petroleum resources.

Modern transportation facilities link the Yukon to the outside world. Scheduled jet air services operate between Whitehorse and Edmonton, Alta., and Vancouver, B.C. Until the White Pass and Yukon railway closed in 1982, it carried freight and passengers between Whitehorse and Skagway, Alaska, from which point ocean services to other west coast ports were available. The Alaska Highway connects the territory to the North American highway system and serves as the backbone for a limited network of roads within the territory. In the late 1970s an important highway link was provided between a point on the Klondike Highway near Dawson to Inuvik in the Mackenzie delta (the Dempster Highway). Helicopters and light aircraft are the normal means of travel to more remote areas. The Whitehorse airport is the most important in the Yukon.

Regional government

Administration and social conditions. With the exception of natural resources, which remain a federal responsibility, most administrative and legislative matters normally under the jurisdiction of Canadian provinces are dealt with by the territorial administration. An appointed resident commissioner oversees the interests of the federal government, but the day-to-day governmental operations are the responsibility of the Executive Council. The council is composed of five members selected from the Legislative Assembly: the elected leader (or the government leader) of the majority party in the Legislative Assembly, and four others nominated by the government leader and appointed by the commissioner. Each member of the Executive Council acts as a Cabinet minister responsible for a specific department of the territorial government. The members of the Legislative Assembly are elected to four-year terms, and the membership of the assembly may be expanded to 25 representatives. Residents of the territory are represented in the federal Parliament by one member of the House of Commons.

Educational, health, and welfare services are administered by the territorial government with financial assistance from the federal government. Primary and secondary education are provided by a territorial school system, and Yukon College, with its main campus at Whitehorse and a network of community branches, provides two years of university-level courses and a number of vocational and adult-education programs. Comprehensive medical and hospital services are provided on the same publicly financed basis as elsewhere in Canada, with the major hospital facilities located in Whitehorse and a system of nursing stations serving more remote centres. Police services are provided by the Royal Canadian Mounted Police.

Reminders of the gold-rush era

Cultural life. Cultural life is dominated by modern media. Satellite communication has made North American television available throughout the territory. Publicly operated radio stations serve the region, and Whitehorse and some communities have local newspapers. There has been a revival of interest in native cultural activities. Promotions keep alive the romanticized image of the Klondike gold-rush era as embodied in the poems of the English-born writer Robert Service, who lived in the Yukon, and more recent writers. Reminders of the gold-rush days are preserved in museums and displays in Whitehorse and Dawson. Some historical sites, notably the Palace Grand Theatre in Dawson, have been restored.

HISTORY

The Yukon was among the last areas of North America to be explored by nonnatives. Two explorers for the Hudson's Bay Company first entered the region around 1840. John Bell came by way of the Peel River from the north, Robert Campbell by the difficult Liard River route from British Columbia. The company subsequently built trading posts in the south, but Indian hostility soon forced them to be abandoned. Farther north, Fort Yukon (in contemporary Alaska) was established in 1847 on the Yukon River in what was then Russian territory. Relocated after the U.S. purchase of Alaska from Russia in 1867, and again in 1890, Fort Yukon remained a centre for a small fur trade. During the early 1870s, gold discoveries on tributaries of the Yukon River attracted prospectors to the area.

Only small amounts of gold had been mined before Aug. 17, 1896, when a pioneer and his two Indian companions found rich deposits in Bonanza Creek, a small tributary of the Klondike River near its confluence with the Yukon. The discovery led to the great gold rush of 1898, at the peak of which the nearby settlement of Dawson grew into a city of some 25,000. Access to the area was quickly improved by construction of a 110-mile (177-kilometre) narrow-gauge railway, the White Pass and Yukon Route, extending from the port of Skagway, Alaska, to Whitehorse on the upper reaches of the Yukon River. In 1898 the Canadian Parliament separated the rapidly growing area from the Northwest Territories and gave it separate territorial status.

The Klondike boom lasted only a few years. By 1900 many of the individual miners had given up and were leaving the Yukon. The gold-mining industry was subsequently reorganized by companies that brought in large-scale mechanical mining techniques. The population fell from 27,219 in 1901 to 8,512 in 1911, and finally to a low of 4,157 in 1921. Although no new gold deposits were located, other minerals were discovered. Copper ore was mined near Whitehorse during World War I, and during the 1920s and 1930s ores containing silver and lead were mined in the Mayo district in the central plateau. Development of these and other resources, however, was hindered by high operating and transportation costs, and in 1941 only 4,914 persons were counted in the census.

Economic expansion during World War II

During World War II such military projects as the Alaska Highway, a part of the Pan-American Highway system, brought a second boom to the territory. Improvements in transportation and communications helped open the territory to greater exploration and development, while increased public interest in the area prompted a great expansion of government services and an increased influx of tourists. Most of this activity centred on Whitehorse, which replaced Dawson as the territorial capital in 1953. Despite such diversification, however, the economy has remained heavily dependent on the mining industry and consequently has been highly unstable. For several years in the mid-1980s, for example, poor market conditions caused every producing mine in the territory to close.

(K.J.R.)

BIBLIOGRAPHY

Physical and human geography. *General works:* Comprehensive, up-to-date general surveys are provided in government publications such as *The Canada Year Book* and its condensed version, *Canada, a Portrait* (biennial). *The Canadian Encyclopaedia,* 2nd ed., 4 vol. (1988), is an invaluable reference work on all aspects of the country. GEOFFREY J. MATTHEWS and ROBERT MORROW, JR., *Canada and the World: An Atlas Resource* (1985), contains maps, graphs, cartograms, tables, and text. *The National Atlas of Canada,* 5th ed. (1985–), is an ongoing publication that consists of singly published maps providing socioeconomic, cultural, and environmental information. Other general sources include JOHN WARKENTIN (ed.), *Canada: A Geographical Interpretation* (1968); L.D. MCCANN (ed.), *Heartland and Hinterland: A Geography of Canada,* 2nd ed. (1987); J. LEWIS ROBINSON, *Concepts and Themes in the Regional Geography of Canada,* rev. ed. (1989); and WILLIAM METCALFE (ed.), *Understanding Canada: A Multidisciplinary Introduction to Canadian Studies* (1982), containing chapters written by various subject specialists.

The land: J. BRIAN BIRD, *The Natural Landscapes of Canada: A Study in Regional Earth Science,* 2nd ed. (1980), is an in-depth treatment of the subject. TIM FITZHARRIS and JOHN LIVINGSTON, *Canada, a Natural History* (1988), describes and interprets the natural environment through photographs and commentary. *Human Activity and the Environment* (1986), prepared by Statistics Canada, is a large volume of statistical information about the relationship of the people and the natural environment. On climate, see F. KENNETH HARE and MORLEY K. THOMAS, *Climate Canada,* 2nd ed. (1979). J.S. ROWE, *Forest Regions of Canada* (1972), is invaluable for the study of natural vegetation; while R.C. HOSIE, *Native Trees of Canada,* 8th ed. (1979), offers a well-illustrated source for the identification of tree species. A.W.F. BANFIELD, *The Mammals of Canada* (1974);

and W. EARL GODFREY, *The Birds of Canada,* rev. ed. (1986), are two well-illustrated volumes.

The people: DIAMOND JENNESS, *The Indians of Canada,* 7th ed. (1977); and E. PALMER PATTERSON, *The Canadian Indian: A History Since 1500* (1971), are authoritative works on the native peoples. BRUCE ALDEN COX (ed.), *Native People, Native Lands: Canadian Indians, Inuit and Metis* (1987), is a later collection of writings. LEO DRIEDGER (ed.), *The Canadian Ethnic Mosaic: A Quest for Identity* (1978), deals with the social and economic problems of minority groups. GERALD L. GOLD and MARC-ADÉLARD TREMBLAY, *Communities and Culture in French Canada* (1973), provides information on basic institutions and cultural dynamics.

The economy: ANTHONY BLACKBOURN and ROBERT G. PUTNAM, *The Industrial Geography of Canada* (1984); and O.F.G. SITWELL and N.R.M. SEIFRIED, *The Regional Structure of the Canadian Economy* (1984), discuss the geophysical basis of the country's economy. RALPH R. KRUEGER and BRUCE MITCHELL (eds.), *Managing Canada's Renewable Resources* (1977); and BRUCE MITCHELL and W.R. DERRICK SEWELL (ed.), *Canadian Resource Policies: Problems and Prospects* (1981), focus on readings on resource management issues. WALLACE CLEMENT and GLEN WILLIAMS (eds.), *The New Canadian Political Economy* (1989), surveys industrialization, resource policies, the role of the state, and other topics.

Administration and social conditions: R. MACGREGOR DAWSON, *Dawson's The Government of Canada,* 6th ed., rev. by NORMAN WARD (1987), is a standard survey. ROBERT BOTHWELL, IAN DRUMMOND, and JOHN ENGLISH, *Canada Since 1945: Power, Politics, and Provincialism,* rev. ed. (1989), offers a witty and sometimes caustic commentary on social, economic, and political issues. MICHAEL A. GOLDBERG and JOHN MERCER, *The Myth of the North American City: Continentalism Challenged* (1986), explores the differences between Canadian and American cities. JOHN PORTER, *The Vertical Mosaic: An Analysis of Social Class and Power in Canada* (1965, reprinted 1971), is a major study of social conditions.

Cultural life: CARL F. KLINCK (ed.), *Literary History of Canada: Canadian Literature in English,* 2nd ed., 3 vol. (1976), is a monumental survey. Among other sources is WILLIAM TOYE (ed.), *The Oxford Companion to Canadian Literature* (1983). For the visual arts, see NANCY-LOU PATTERSON, *Canadian Native Art: Arts and Crafts of Canadian Indians and Eskimos* (1973); and DENNIS REID, *A Concise History of Canadian Painting,* 2nd ed. (1988). For the performing arts, see GEORGE A. PROCTOR, *Canadian Music of the Twentieth Century* (1980); EUGENE BENSON and L.W. CONOLLY, *English-Canadian Theatre* (1987); ÉDOUARD G. RINFRET, *Le Théâtre canadien d'expression française: répertoire analytique des origines à nos jours,* 4 vol. (1975–78); and EUGENE BENSON and L.W. CONOLLY (eds.), *The Oxford Companion to Canadian Theatre* (1989). LEON WHITESON, *Modern Canadian Architecture* (1983), analyzes trends in architectural design.

History. Broad surveys include WILLIAM L. MORTON, *The Kingdom of Canada: A General History from the Earliest Times,* 2nd ed. (1969); KENNETH MCNAUGHT, *The History of Canada* (1970); and GERALD FRIESEN, *The Canadian Prairies: A History* (1984). Specific subjects, still in a broad chronological framework, are explored in MICHAEL BLISS, *Northern Enterprise: Five Centuries of Canadian Business* (1987); J.M.S. CARELESS (ed.), *Colonists & Canadiens, 1760–1867* (1971, reprinted 1980); and J.M.S. CARELESS and R. CRAIG BROWN (eds.), *The Canadians, 1867–1967* (1967, reissued 1980). The historical development of constitutional power is related in J.R. MALLORY, *The Structure of Canadian Government,* rev. ed. (1984). R. COLE HARRIS (ed.), *Historical Atlas of Canada* (1987–), is planned as a multivolume work.

A comprehensive history of the French period is GUSTAVE LANCTÔT, *A History of Canada,* 3 vol. (1963–65; originally published in French, 1960–64). Another study of the preconfederation period is W.J. ECCLES, *The Canadian Frontier, 1534–1760,* rev. ed. (1983). To understand the colonies that became Canada in the British Empire, the following are most useful: HAROLD A. INNIS, *The Fur Trade in Canada: An Introduction to Canadian Economic History,* rev. ed. (1956, reissued 1973); and ARTHUR J. RAY, *Indians in the Fur Trade: Their Role as Trappers, Hunters, and Middlemen in the Lands Southwest of Hudson Bay, 1660–1870* (1974). See also W.S. MACNUTT, *The Atlantic Provinces, the Emergence of Colonial Society, 1712–1857* (1965). HELEN TAFT MANNING, *The Revolt of French Canada, 1800–1835: A Chapter in the History of the British Commonwealth* (1962); CHESTER MARTIN, *Foundations of Canadian Nationhood* (1955); and J.E. HODGETTS, *Pioneer Public Service: An Administrative History of the United Canadas, 1841–1867* (1955), treat the achievement of self-government.

The story of confederation has been told from various perspectives by DONALD CREIGHTON, *The Road to Confederation: The Emergence of Canada, 1863–1867* (1964, reprinted 1976); WILLIAM L. MORTON, *The Critical Years: The Union of British North America, 1857–1873* (1964, reprinted 1977); PETER B. WAITE, *The Life and Times of Confederation, 1864–1867: Politics, Newspapers, and the Union of British North America,* 2nd ed. (1962); and ROBIN W. WINKS, *Canada and the United States: The Civil War Years* (1960, reprinted 1988). On foreign relations, see JOHN BARTLETT BREBNER, *North Atlantic Triangle: The Interplay of Canada, the United States, and Great Britain* (1945, reissued 1970); EDGAR W. MCINNIS, *The Unguarded Frontier: A History of American-Canadian Relations* (1942, reissued 1970); JAMES G. EAYRS, *The Art of the Possible: Government and Foreign Policy in Canada* (1961), and *Northern Approaches: Canada and the Search for Peace* (1961); DONALD CREIGHTON, *Canada's First Century, 1867–1967* (1970); and CHARLES P. STACEY, *Canada and the Age of Conflict: A History of Canadian External Policies,* 2 vol. (1977–81), covering the period between 1867 and 1948. ROBERT CRAIG BROWN and RAMSAY G. COOK, *Canada, 1896–1921: A Nation Transformed* (1974), is a study of the effects upon Canada of the boom that opened the 20th century and of World War I. Economic, political, and social changes in 20th-century Canada are explored in JOHN HERD THOMPSON and ALLEN SEAGER, *Canada, 1922–1939: Decades of Discord* (1985); ROBERT BOTHWELL, IAN DRUMMOND, and JOHN ENGLISH, *Canada, 1900–1945* (1987); IAN MACPHERSON, *Each for All: A History of the Co-operative Movement in English Canada, 1900–1945* (1979); GRANT S. MCCLELLAN (ed.), *Canada in Transition* (1977); and J.L. GRANATSTEIN, *Canada. 1957–1967: The Years of Uncertainty and Innovation* (1986).

New Brunswick. Information on the resources and the economy of New Brunswick is found in government reports, such as NEW BRUNSWICK. OFFICE OF THE ECONOMIC ADVISOR, *New Brunswick Industry Profiles* (irregular), or *New Brunswick Economy* (irregular). For early history, see BONA ARSENAULT, *History of the Acadians* (1966, reprinted 1988; originally published in French, 1965); and L.F.S. UPTON, *Micmacs and Colonists: Indian–White Relations in the Maritimes, 1713–1867* (1979). For later history, see JAMES HANNAY, *History of New Brunswick,* 2 vol. (1909); W.S. MACNUTT, *New Brunswick, a History: 1784–1867* (1963, reprinted 1984); ANN GORMAN CONDON, *The Loyalist Dream for New Brunswick: The Envy of the American States* (1984); GRAEME WYNN, *Timber Colony: A Historical Geography of Early Nineteenth Century New Brunswick* (1981); and P.A. BUCKNER and DAVID FRANK (eds.), *Atlantic Canada Before Confederation,* 2 vol. (1985). For the modern period, see ERNEST R. FORBES, *Challenging the Regional Stereotypes: Essays on the 20th Century Maritimes* (1989).

Newfoundland. A collection of diverse information on the province, planned as a five-volume set, is offered in *Encyclopedia of Newfoundland and Labrador,* ed. by JOSEPH R. SMALLWOOD (1981–); two volumes were published by 1990. ALAN G. MACPHERSON and JOYCE BROWN MACPHERSON (eds.), *The Natural Environment of Newfoundland, Past and Present* (1981), surveys the area's geology, climate, landforms, flora, and fauna. HAROLD A. INNIS, *The Cod Fisheries: The History of an International Economy,* rev. ed. (1954, reprinted 1978), is a mine of information, and not only on the economy. SHANNON RYAN, *Fish Out of Water: The Newfoundland Saltfish Trade, 1814–1914* (1986), is an important economic history. Development of educational services is examined in FREDERICK W. ROWE, *Education and Culture in Newfoundland* (1976). Particular features of cultural life and customs are presented in HERBERT HALPERT and G.M. STORY (eds.), *Christmas Mumming in Newfoundland: Essays in Anthropology, Folklore, and History* (1989); and PATRICK O'FLAHERTY, *The Rock Observed: Studies in the Literature of Newfoundland* (1979).

JAMES A. TUCK, *Newfoundland and Labrador Prehistory* (1976), is both readable and informative. HELGE INGSTAD, *Westward to Vinland: The Discovery of Pre-Columbian Norse House-Sites in North America* (1969, reissued 1972; originally published in Norwegian, 1965), is an account of the only authenticated Viking settlement in North America. A useful general survey is FREDERICK W. ROWE, *A History of Newfoundland and Labrador* (1980). Information on the early political and economic situation is provided in R.I. MCALLISTER (ed.), *Newfoundland and Labrador: The First Fifteen Years of Confederation* (1966); and HAROLD HORWOOD, *Joey: The Life and Political Times of Joey Smallwood* (1989). JAMES HILLER and PETER NEARY (eds.), *Newfoundland in the Nineteenth and Twentieth Centuries* (1980); and S.J.R. NOEL, *Politics in Newfoundland* (1971), provide a sharp perspective on 20th-century history.

Nova Scotia. ROBERT J. MCCALLA, *The Maritime Provinces Atlas* (1988), provides information in a graphic format. GEORGE ROGERS (ed.), *Exploring Nova Scotia* (1984), is a concise guidebook. A look at the economy is provided in STANISLAW CZAMANSKI, *Structure of the Nova Scotia Economy* (1970). On the history of the province, there is a considerable body of literature in the *Collections of the Nova Scotia Historical Society*

(1878–). See also *The Dalhousie Review* (quarterly); and *The Canadian Historical Review* (quarterly). Selected readings include J. MURRAY BECK, *The Government of Nova Scotia* (1957); JOHN BARTLETT BREBNER, *The Neutral Yankees of Nova Scotia* (1937, reissued 1970), and *New England's Outpost: Acadia Before the Conquest of Canada* (1927, reissued 1974); ARTHUR G. DOUGHTY, *The Acadian Exiles: A Chronicle of the Land of Evangeline* (1916, reprinted 1935); and ANDREW H. CLARK, *Acadia: The Geography of Early Nova Scotia to 1760* (1968).

Prince Edward Island. JOSEPH-HENRI BLANCHARD, *The Acadians of Prince Edward Island, 1720–1964* (1964, reprinted 1976; originally published in French, 1956), is a particularly rich source of familial and parochial history; GEORGES ARSENAULT, *The Island Acadians: 1720–1980* (1989; originally published in French, 1987), traces the evolution of the local community. Other historical works include ANDREW H. CLARK, *Three Centuries and the Island: A Historical Geography of Settlement and Agriculture in Prince Edward Island, Canada* (1959); FRANK MACKINNON, *The Government of Prince Edward Island* (1951, reprinted 1974); FRANCIS W.P. BOLGER (ed.), *Canada's Smallest Province: A History of P.E.I.* (1973), and *Prince Edward Island and Confederation, 1863–1873* (1964).

Ontario. *Ontario: A Bicentennial Tribute* (1983), is an illustrated work on the province. GEOFFREY MATTHEWS (ed.), *North of 50°: An Atlas of Far Northern Ontario* (1985), offers informative maps. Other geographic works include L.J. CHAPMAN and D.F. PUTNAM, *The Physiography of Southern Ontario*, 3rd ed. (1984); JACOB SPELT, *The Urban Development in South-Central Ontario* (1955, reissued 1972), on settlement patterns; and K.J. REA, *The Prosperous Years: The Economic History of Ontario, 1939–1975* (1985). F.F. SCHINDELER, *Responsible Government in Ontario* (1969, reprinted 1973), treats the structure of the government. The government's development is analyzed in CHRISTOPHER ARMSTRONG, *The Politics of Federalism: Ontario's Relations with the Federal Government, 1867–1942* (1981). Education is discussed in ROBIN HARRIS, *Quiet Evolution: A Study of the Educational System of Ontario* (1967). For history, see ONTARIO HISTORICAL SOCIETY, *Profiles of a Province* (1967); and GERALD M. CRAIG, *Upper Canada: The Formative Years, 1784–1841* (1963, reissued 1984). Topical histories include JOHN WEBSTER GRANT, *A Profusion of Spires: Religion in Nineteenth-Century Ontario* (1988); and DONALD M. WILSON, *The Ontario & Quebec Railway: A History of the Development of the Canadian Pacific System in Southern Ontario* (1984).

Quebec. Information on current economic and social conditions is found in *Statistical Outlook: Annual Statistical Review of the Régie des Rentes du Québec*. MARCEL RIOUX and YVES MARTIN (eds.), *French-Canadian Society* (1964, reprinted 1978), is a collection of essays on social issues. On history, see J.I. LITTLE, *Nationalism, Capitalism, and Colonization in Nineteenth-Century Quebec* (1989); FERNAND OUELLET, *Economic and Social History of Quebec, 1760–1850* (1980; originally published in French, 1966); PAUL-ANDRÉ LINTEAU, RENÉ DUROCHER, and JEAN-CLAUDE ROBERT, *Histoire du Québec contemporain*, rev. ed., 2 vol. (1989), with the English translation for vol. 1 of the earlier edition available as *Quebec, a History, 1867–1929* (1983). The modern political and social situation, revolving around the autonomy and independence movements, is analyzed in GÉRARD PELLETIER, *The October Crisis* (1971, originally published in French, 1971); RICHARD DALTON BASHAM, *Crisis in Black and White: Urbanization and Ethnic Identity in French Canada* (1977, reprinted 1981); EDWARD MCWHINNEY, *Canada and the Constitution, 1979–1982* (1982); JANE JACOBS, *The Question of Separatism: Quebec and the Struggle Over Sovereignty* (1980); and SHEILA MCLEOD ARNOPOULOS and DOMINIQUE CLIFT, *The English Fact in Quebec*, 2nd ed. (1984; originally published in French, 1979).

Alberta. ROBERT KROETSCH, *Alberta* (1968), is a general description of the province, with a look at its history and economics. Detailed historical maps and charts are provided in *Atlas of Alberta* (1969), an official centennial project of the government of Alberta and the University of Alberta; it is supplemented by TED BYFIELD (ed.), *The Atlas of Alberta* (1984). W.G. HARDY (ed.), *Alberta: A Natural History* (1967, reprinted 1979); DAVID A.E. SPALDING (ed.), *A Nature Guide to Alberta* (1980); and JOY FINLAY and CAM FINLAY, *Parks in Alberta* (1987), are comprehensive surveys. HUGH A. DEMPSEY, *Indian Tribes of Alberta*, rev. ed. (1986), studies the aboriginal inhabitants of the province; and HOWARD PALMER and TAMARA PALMER (eds.), *Peoples of Alberta: Portraits of Cultural Diversity* (1985), examines the significance of various ethnic groups in Alberta's settlement. Current economic information is presented in reports and publications of the Alberta Bureau of Statistics. A historical survey of Alberta's agriculture is provided in GRANT MACEWAN, *Power for Prairie Plows* (1971). A look at the cultural life is offered in SANDRA SHAUL (ed.), *Painting in Alberta: An Historical Survey* (1980); and DAVID LEIGHTON and PEGGY LEIGHTON, *Artists, Builders, and Dreamers: 50 Years at the Banff School* (1982). For the history of the province, see GAIL HELGASON, *The First Albertans: An Archaeological Search* (1987); JAMES G. MACGREGOR, *A History of Alberta*, rev. ed. (1981), a standard general history; DOUGLAS R. OWRAM (ed.), *The Formation of Alberta: A Documentary History* (1979), which collects documents on development before 1905; and ALVIN FINKEL, *The Social Credit Phenomenon in Alberta* (1989), which focuses on the period from the 1930s to the '70s.

Manitoba: W.L. MORTON, *Manitoba, a History*, 2nd ed. (1967), remains the standard historical work. KEN COATES and FRED MCGUINNESS, *Manitoba, the Province & the People* (1987), is useful. Studies of special historical questions include JENNIFER S.H. BROWN, *Strangers in Blood: Fur Trade Company Families in Indian Country* (1980). On early settlement, see C.A. DAWSON and EVA R. YOUNGE, *Pioneering in the Prairie Provinces: The Social Side of the Settlement Process* (1940, reprinted 1974); JOHN LANGTON TYMAN, *By Section, Township, and Range: Studies in Prairie Settlement* (1972); and PIERRE BERTON, *The Promised Land: Settling the West 1896–1914* (1984). The province's economic history is discussed in DAVID JAY BERCUSON, *Confrontation at Winnipeg: Labour, Industrial Relations, and the General Strike* (1974). Political developments are the centre of discussion in such histories as WILLIAM L. MORTON (ed.), *Manitoba: The Birth of a Province* (1965, reprinted 1984); MURRAY S. DONNELLY, *The Government of Manitoba* (1963); and NELSON WISEMAN, *Social Democracy in Manitoba: A History of the CCF-NDP* (1983).

Saskatchewan. The most comprehensive sourcebook on the province is J. HOWARD RICHARDS and K.I. FUNG (eds.), *Atlas of Saskatchewan* (1969); a general description is provided in EDWARD MCCOURT, *Saskatchewan* (1968, reprinted 1977). JOHN H. ARCHER, *Saskatchewan, a History* (1980); D.H. BOCKING (ed.), *Pages from the Past: Essays on Saskatchewan History* (1979); and DEANNA CHRISTENSEN and MENNO FIEGUTH, *Historic Saskatchewan* (1986), offer informative surveys. For current research, see *Saskatchewan History* (three times a year).

British Columbia. A.L. FARLEY, *Atlas of British Columbia: People, Environment, and Resource Use* (1979), provides a comprehensive though brief survey of the province. RODERICK HAIG-BROWN, *The Living Land: An Account of the Natural Resources of British Columbia* (1961); and MARY L. BARKER, *Natural Resources of British Columbia and the Yukon Territory* (1977), are more specialized studies. A historical look at population development pattern in the area is presented in ROBIN FISHER, *Contact and Conflict: Indian-European Relations in British Columbia, 1774–1890* (1977); and H.B. HAWTHORN (ed.), *A Survey of the Contemporary Indians of Canada* (1966). The influence of politics on economic and social conditions is thoroughly studied in DONALD E. BLAKE, *Two Political Worlds: Parties and Voting in British Columbia* (1985). MARGARET A. ORMSBY, *British Columbia, a History* (1958, reissued 1971), offers a comprehensive, if somewhat old, treatment. This history can be supplemented by the more current writings in *BC Studies* (quarterly).

Northwest Territories and Yukon. MORRIS ZASLOW, *The Opening of the Canadian North, 1870–1914* (1971), and *The Northward Expansion of Canada, 1914–1967* (1988), provide a comprehensive general history of the territories; KEN COATES, *Canada's Colonies: A History of the Yukon and Northwest Territories* (1985), includes a critical analysis of government policies. Economic history is treated in K.J. REA, *The Political Economy of the Canadian North: An Interpretation of the Course of Development in the Northern Territories of Canada to the Early 1960s* (1968). KEN COATES and WILLIAM R. MORRISON, *Land of the Midnight Sun: A History of the Yukon* (1988), describes the gold rush. The early whaling industry is treated in W. GILLIES ROSS, *Whaling and Eskimos, Hudson Bay, 1860–1915* (1975). DIAMOND JENNESS, *Eskimo Administration II: Canada* (1964), remains a standard historical account of government policy toward the native population. SHELAGH D. GRANT, *Sovereignty or Security: Government Policy in the Canadian North, 1936–1950* (1988), examines important changes brought about by World War II. The political development of the territories is treated in GURSTON DACKS, *A Choice of Futures: Politics in the Canadian North* (1981); and WILLIAM R. MORRISON, *A Survey of the History and Claims of the Native Peoples of Northern Canada* (1983). Concerns with environmental protection and the impact of economic development is studied in HUGH BRODY, *The People's Land: Eskimos and Whites in the Eastern Arctic* (1975); and THOMAS R. BERGER, *Northern Frontier, Northern Homeland: The Report of the Mackenzie Valley Pipeline Inquiry*, rev. ed. (1988).

Canadian Literature

Reflective of the country's dual origin and linguistic distribution, the literature of Canada falls into two divisions: English and French. This article provides a brief historical account of each of these literatures.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* section 621, and the *Index.* (Ed.)

The article is divided into the following sections:

CANADIAN LITERATURE IN ENGLISH

Prose and poetry. *Beginnings, 1600–1900.* The first writers of English in Canada were visitors—explorers, travelers, British officers and their wives—who recorded their impressions of British North America in charts, diaries, journals, and letters. With these journeys and the resulting documents of discovery, the Canadian tradition of embarking upon the search for both a myth of origins and a definition of "Canada" was initiated.

The earliest such documents were unadorned narratives of travel and exploration. The explorer Samuel Hearne wrote *A Journey from Prince of Wales's Fort in Hudson's Bay, to the Northern Ocean* (1795), and Sir Alexander Mackenzie, an explorer and fur trader, recorded his travels in *Voyages from Montreal . . . Through the Continent of North America, to the Frozen and Pacific Oceans* (1801). These accounts, written in plain language, document heroic journeys to the vast, unknown west and north on behalf of the Hudson's Bay Company and the North West Company, the great fur-trading monopolies.

Frances Brooke, the wife of a visiting British military chaplain in the conquered French garrison of Quebec, wrote the first published novel with a Canadian setting. Her *History of Emily Montague* (1769) is an epistolary romance describing the sparkling winter scenery of Quebec and the life and manners of its residents.

Halifax, in the colony of Nova Scotia, and New Brunswick's Fredericton were the scenes of the earliest literary flowering in Canada. The first literary journal, the *Nova-Scotia Magazine,* was published in Halifax in 1789. The town's literary activity was invigorated by an influx of United Empire Loyalists during the American Revolution and by the energetic Joseph Howe, a journalist, a poet, and the first premier of Nova Scotia. Two of the most potent influences on literary development were in evidence by the end of the 18th century: literary magazines and presses, and a strong sense of regionalism. By satirizing the dialect, habits, and foibles of Nova Scotians, or Bluenoses, Thomas McCulloch, in his serialized *Letters of Mephibosheth Stepsure* (1821–22), and Thomas Chandler Haliburton, in *The Clockmaker* (1835–36), featuring the brash Yankee peddler Sam Slick, adroitly brought their region to life and helped found the genre of folk humour.

Early poetry

Most of the earliest poems were patriotic songs and hymns (*The Loyal Verses of Joseph Stansbury and Doctor Jonathan Odell,* 1860) or topographical narratives, reflecting the first visitors' concern with discovering and naming the new land and its inhabitants. In *The Rising Village* (1825), native-born Oliver Goldsmith used heroic couplets to celebrate pioneer life and the growth of Nova Scotia, which, in his words, promised to be "the wonder of the Western Skies." His optimistic tones were a direct response to the melancholy poem by his Anglo-Irish granduncle, Oliver Goldsmith, whose *Deserted Village* (1770) concludes with the forced emigration of dispossessed villagers.

Immigrants, dreaming of a new Eden but encountering instead the realities of unpredictable Indians, a fierce climate, unfamiliar wildlife, and physical and cultural deprivation, were the subject of prose sketches by the Strickland sisters, Susanna Strickland Moodie and Catherine Parr Strickland Traill. Susanna Moodie's harsh, yet at times comical, *Roughing It in the Bush* (1852) was written to discourage prospective emigrants; but Catherine Parr Traill's *Backwoods of Canada* (1836) presents a more favourable picture of the New World.

The Dominion of Canada, created in 1867 by the confederation of Nova Scotia, New Brunswick, Upper Canada, and Lower Canada (now Ontario and Quebec), precipitated a flurry of patriotic and literary activity. The so-called Confederation poets turned to the landscape in their search for a truly native verse. Unlike their predecessors, they no longer merely described or moralized nature but attempted as well to capture what Archibald Lampman called the "answering harmony between the soul of the poet and the spirit and mystery of nature." The New Brunswick poet Charles (later Sir Charles) G.D. Roberts inspired his cousin, the prolific and vagabond Bliss Carman, and the Ottawa poets Lampman and Duncan Campbell Scott to begin writing verse. Lampman is known for his meditations on the landscape, and Scott is remembered for his sympathetic presentation of Indians trapped by the white man's world. Perhaps the most original poet of this period was Isabella Valancy Crawford, whose colourful mythopoeic verse, with its images drawn from Indian lore, pioneer life, mythology, and a symbolic animated nature, was published as *Old Spookses' Pass, Malcolm's Katie, and Other Poems* in 1884.

During this period, the historical romance was the most popular form of novel. In his Gothic tale *The Golden Dog: A Legend of Quebec* (1877) William Kirby romanticized the seigneurial life of New France, while John Richardson portrayed the uprising led by the Indian chief of the Ottawas, Pontiac, in *Wacousta; or The Prophecy, a Tale of the Canadas* (1832). More original are James De Mille's satiric travel fantasy *A Strange Manuscript Found in a Copper Cylinder* (1888) and Roberts' quasi-documentary animal stories *The Kindred of the Wild* (1902).

20th-century poetry

Modern period, 1900–60. In the early 20th century popular poets responding to the interest in local colour depicted French-Canadian customs and dialect (W.H. Drummond, *The Habitant and Other French-Canadian Poems,* 1897), the Mohawk tribe and rituals (E. Pauline Johnson, *Flint and Feather,* 1912), and the freedom and romance of the north (Robert Service, *Songs of a Sourdough,* 1907). John McRae's account of World War I, "In Flanders Fields" (1915), remains Canada's best known poem. Slowly a reaction against sentimental, patriotic, and derivative Victorian verse set in. E.J. Pratt created a distinctive style both in lyric poems of seabound Newfoundland life (*Newfoundland Verse,* 1923) and in the epic narratives *The Titanic* (1935), *Brébeuf and His Brethren* (1940), and *Towards the Last Spike* (1952), which through their reliance on accurate detail participate in the documentary tradition. Influenced by Pratt was another innovative and experimental poet, Earle Birney, best known for his tragic narrative "David" (1942).

Toronto's *Canadian Forum* (founded in 1920) and Montreal's *McGill Fortnightly Review* (1925–27) provided an outlet for the "new poetry" and the emergence of modernism. Here and in their anthology, *New Provinces* (1936), A.J.M. Smith, F.R. Scott, and A.M. Klein began their long literary careers. Emphasizing concrete images, open language, and free verse, these modernists felt that the poet's task was to identify, name, and take possession of the land. Klein wrote in "Portrait of the Poet as Landscape" (1948) that the poet is "the nth Adam taking a green inventory/in a world but scarcely uttered, naming, praising." The bonds of a colonial frame of mind characterized by fear of the unknown, reliance on convention, a puritan consciousness—what the critic Northrop Frye, in the "Conclusion" written for the first edition of the *Literary History of Canada* (1965), called the "garrison mentality"—were being broken and cast off.

Strong reaction to the Depression, the rise of fascism, and World War II dominated the poems of the 1930s and '40s. Using the documentary mode, Dorothy Livesay condemned the exploitation of workers in *Day and Night* (1944), while her lyric poems spoke frankly of sexual love (*Signpost,* 1932). In opposition to the cosmopolitan and metaphysical verse promoted by Smith and the literary magazine *Preview* (1942–45), Irving Layton, Louis Dudek, and Raymond Souster urged poets to focus on realism and the native or North American context.

The novel of social realism

By 1900 novels of local colour were beginning to overshadow historical romances. Lucy Maud Montgomery's beloved children's book *Anne of Green Gables* (1908) and its sequels were set in Prince Edward Island. Ontario towns and their "garrison mentality" provided the setting for Sara Jeannette Duncan's portrayal of political life in *The Imperialist* (1904), Ralph Connor's *The Man from Glengarry* (1901), Stephen Leacock's satirical stories *Sunshine Sketches of a Little Town* (1912), and Mazo de la Roche's best-selling Jalna series (1927–60). Out of the Prairies emerged the novel of social realism, which documented the small, often narrow-minded farming communities pitted against an implacable nature. Martha Ostenso's *Wild Geese* (1925), a tale of a strong young girl in thrall to a cruel father, and Frederick Philip Grove's *Settlers of the Marsh* (1925) and *Fruits of the Earth* (1933), depicting man's struggle for mastery of himself and his land, are moving testaments to the courage of farmers.

A tentativeness in form and subject matter pervades the novels published during the 1940s and '50s and is reflected in their protagonists, most of whom are sensitive, restless children or artists. In this category fall the Prairie novels *As for Me and My House* (1941) by Sinclair Ross, *Who Has Seen the Wind* (1947) by W.O. Mitchell, and *The Mountain and the Valley* (1952) by Ernest Buckler, set in Nova Scotia's Annapolis Valley. These novels strain the bonds of conventional narrative structures, as they shift from social realism toward lyricism. In the panoramic *Two Solitudes* (1945) and *The Watch That Ends the Night* (1959), Hugh MacLennan attempted to capture moral, social, and religious conflicts that rend individuals, families, and the two aspects of Canada, French and English. Sheila Watson's enigmatic and mythic *The Double Hook* (1959) and Ethel Wilson's *Swamp Angel* (1954), about a housewife's desertion, present quest journeys against the striking backdrop of British Columbia's interior.

1960 and beyond. After the 1950s this tentativeness in fiction either became itself the subject of the novel or dissipated in more confident forms of writing. Robertson Davies' popular Deptford trilogy (*Fifth Business,* 1970; *The Manticore,* 1972; *World of Wonders,* 1975) examines the growth of its protagonists into maturity within a Jungian paradigm. Alice Munro in *Lives of Girls and Women* (1971), set in southwestern Ontario, and Margaret Laurence in her Manawaka novels (*The Stone Angel,* 1964; *A Jest of God,* 1966; *The Diviners,* 1974) explored their heroines' rebellion against a constricting small-town heritage. In an intricately woven style, Mavis Gallant's stories (*Home Truths,* 1981) depict isolated characters whose fragile worlds of illusion are shattered. With trenchant irony, Margaret Atwood dissected contemporary urban life and sexual politics in *The Edible Woman* (1969), *Surfacing* (1972), *Lady Oracle* (1976), *Bodily Harm* (1981), and *The Handmaid's Tale* (1985). Mordecai Richler's Montreal novels, *The Apprenticeship of Duddy Kravitz* (1959) and *St. Urbain's Horseman* (1971), satirize the condition and hypocrisy of modern society through Jewish black humour, while Leonard Cohen's *Beautiful Losers* (1966) explores the relationship between sainthood, eroticism, and creation.

Many writers published in the 1970s and '80s purposely subverted the conventions of fiction, shifting from realist to surrealist, self-reflexive, feminist, or parodic modes. Although historical events and the investigation of place as an imaginative source remained the most common subject matters, the narrative forms were experimental and playful. Jack Hodgins mapped a surreal island world in *The Invention of the World* (1977), while Audrey Thomas revealed the difficulty of women's lives in innovative short stories (*Real Mothers,* 1981) and novels (*Latakia,* 1979, and *Intertidal Life,* 1984). In *The Studhorse Man* (1969) and *Badlands* (1975), Robert Kroetsch transformed the realism of Prairie fiction into postmodern parodies of the quest journey. In *The Temptations of Big Bear* (1973) and *The Scorched-Wood People* (1977), Rudy Wiebe constructed fictional epics based on historical events in the west. Joy Kogawa's *Obasan* (1981) is a skillful "docufiction" describing the internment of Japanese-Canadians during World War II. George Bowering's *Burning Water* (1980), which focuses on the 18th-century explorer George Vancouver, and Michael Ondaatje's *Coming Through Slaughter* (1976), the story of the jazz musician Buddy Bolden, mingle history with autobiography in self-reflexive narratives that enact the process of writing. In *The Wars* (1977) Timothy Findley's narrator, through letters, clippings, and photographs, re-creates the effects of World War I on his hero.

The blossoming of poetry

In the 1960s and '70s poetry also blossomed, fueled by a resurgence of nationalism, as Canadians asserted their difference from Americans, and by the emergence of literary presses and small literary magazines like *Canadian Literature* (founded in 1959) and *Tish* (1961–69). Atwood's *The Circle Game,* a book of ironic, laconic poems, was published in 1966 and was followed later by *Journals of Susanna Moodie* (1970), in which Atwood translated the 19th-century author of *Roughing It in the Bush* into a modern figure of alienation. Ondaatje also turned to historical persona in his collage *The Collected Works of Billy the Kid* (1970), as did Bowering in his long poem "George, Vancouver" (1970). Daphne Marlatt reinvented a town's past in *Steveston* (1974) and Kroetsch his Prairie roots in *Field Notes* (1981). Fascination with place and history also permeates Al Purdy's poems about the country north of Belleville, Ont., and about his travels west and to the Arctic (*Being Alive,* 1978). Margaret Avison (*Winter Sun/The Dumbfounding,* 1982), Anne Wilkinson (*Collected Poems,* 1968), P.K. Page (*Cry Ararat,* 1967), Eli Mandel (*Dreaming Backwards,* 1981), Phyllis Webb (*The Vision Tree,* 1982), and D.G. Jones (*A Throw of Particles,* 1983) grappled with metaphysical concerns and the fragile particles of existence through images drawn from places, travel, and mythology. Regions, particularly the Prairies, grew stronger as centres of imaginative focus, while the desire of women to express their distinctive voices and experiences resulted in stimulating literary journals (*Room of One's Own; Atlantis*) and anthologies (*Writing Right,* 1982; *Stories by Canadian Women,* 1984).

Drama and criticism. Like the poets and novelists, Canadian dramatists in their quest for a myth of origins have often turned to historical incidents. The earliest forms of dramatic writing, Charles Mair's *Tecumseh* (1886) and Sarah Anne Curzon's *Laura Secord, the Heroine of 1812* (1887), both based on the War of 1812, were in verse. In the 1920s and '30s Merrill Denison, Gwen Pharis Ringwood, and Herman Voaden struggled to establish Canadian drama, relying on the amateur little theatres for support. By the 1950s and '60s several professional theatres had opened, producing a more sophisticated milieu for dramatists like John Coulter, whose *Riel* (1962) creates a heroic figure of Louis Riel, the leader of the Métis rebellion. As regional and experimental theatres multiplied, increasingly innovative and daring productions were mounted: examples were John Herbert's *Fortune and Men's Eyes* (1967), on homosexuality in prison; George Ryga's *The Ecstasy of Rita Joe* (1971), about an Indian prostitute; and James Reaney's Donnelly trilogy (1976–77), about the feuds and the massacre of an Irish immigrant family in southern Ontario. Collective creations resulted in *The Farm Show* (1976), *Paper Wheat* (1978), and Rick Salutin's *1837* (1976) and *Les Canadiens* (1977), all flavoured by a strong sense of regionalism. Stark realism shaped David Freeman's *Creeps* (1972), David French's *Leaving Home* (1977), David Fennario's *On the Job* (1976), and Michael Cook's *The Head, Guts and Sound Bone Dance* (1974). Women's lives in the past were the focus of Carol Bolt's *Red Emma* (1974); Sharon Pollock's *Blood Relations* (1981), a powerful drama about the accused murderer Lizzie Borden; and Betty Lambert's *Jennie's Story* (1984). In *Billy Bishop Goes to War* (1981) John Gray created a musical from the story of a well-known World War I fighter pilot.

Literary criticism

Critics have tended to discuss Canadian literature by outlining the stages of its literary evolution from the colonial beginnings through an immigrant and derivative period to the flowering of a national literature. By the 1920s there were several descriptive and evaluative surveys, such as Archibald MacMechan's *Head-waters of Canadian Literature* (1924). During the modern period, criticism dealt primarily with poetry, analyzing its origins, mythmaking tendencies, and degree of sympathy with nature. With the publication of the *Literary History of Canada* in 1965, Canadian literature developed into a field of serious study. Frye's "Conclusion," which describes how the Canadian imagination embarks on a search for identity, influenced Atwood's *Survival* (1972) and D.G. Jones's *Butterfly on Rock* (1970). Frank Davey's article "Surviving the Paraphrase" (*Canadian Literature* 70, 1978) condemns this reductive and thematic approach, which obsessively pinpoints recurring themes—such as the "garrison mentality," the predominance of victim figures, and a vision of Canada as a new Eden complete with a fall and redemption—and neglects structural and formal studies. Subsequent critical works, however, for the most part have continued this approach and have tried to map a tradition (John Moss, *Patterns of Isolation,* 1974; Tom Marshall, *Harsh and Lovely Land,* 1979). More illuminating is the regional orientation of Laurence Ricou's *Vertical Man, Horizontal World; Man and Landscape in Canadian Prairie Fiction* (1973), W.H. News's *Articulating West* (1972), and Patrick O'Flaherty's *The Rock Observed: Studies in the Literature of Newfoundland* (1979). A greater critical range can be found in the collection of essays edited by Eli Mandel, *Contexts of Canadian Criticism* (1971), and in the journals *Canadian Literature* and *Essays on Canadian Writing.* (K.M.)

CANADIAN LITERATURE IN FRENCH

The French language in Canada. The valley of the St. Lawrence River, first explored by Jacques Cartier during his second voyage to North America in 1535, was colonized by France during the 17th and 18th centuries. When New France was ceded to Britain in 1763 the Roman Catholic population of more than 60,000 persons spoke a language that was already a blend of several French dialects, although French was then not yet standardized in France itself.

After the British victory over New France, immigration from France virtually ceased, but the number of French-speaking inhabitants continued to increase. About five-sixths of Canada's Francophones live in the province of Quebec and refer to themselves as Québécois. Their literature, called French-Canadian or *littérature québécoise,* records their common history and expresses their unique identity.

The French régime, 1535–1760. During these two centuries not a page of French was printed in New France; there was no printing press in the colony until after the establishment of British rule. The substantial colonial literature written in and about New France was published in France for a European audience. It included accounts of discovery and exploration, official reports and correspondence, travelers' narratives, annals of missions and religious communities, and histories of the colony. These manuscripts and printed texts were supplemented by an abundant oral literature composed of folk songs, folktales, and legends. Considerable scholarly effort has been expended on the recovery and study of the rich heritage of oral traditions and literary works surviving from the French period.

The importance of newspapers

After the British conquest, 1760–1830. After the devastation of the Seven Years' War, intellectual life was for a time inconceivable. During the first 70 years of British rule, journalism was vitally important to the French-speaking majority. The bilingual *Quebec Gazette* (1764) and, later, French-language newspapers like *Le Canadien* (1806) and *La Minerve* (1826) offered the only medium of mass communication, of contact with Europe and the United States, and of political expression at home. The first scattered indications of literature (anecdotes, poems, essays, and sermons) appeared in their pages, as did the verses and songs of two French immigrants, Joseph Quesnel and Joseph Mermet. Quesnel, French Canada's first significant writer, also composed dramatic texts for amateur actors: his comedy *Colas et Colinette* (1788) was revived as a radio play in 1968.

The literature. *Early literature, 1830–60.* Publication of French-Canadian literature in Canada began in the 1830s. The first collection of verse appeared in 1830; the first novel in 1837; and the first comedy and first tragedy soon afterward. This coincidence of dates reflected in part the gradual organization of primary and secondary education and the increasing availability of French books and periodicals even before the resumption of commercial relations with France in 1855. More important was a growing sense of national identity, apparent in the campaigns for responsible government that preceded and followed the ill-fated rebellion of 1837. The principal publication of the time, François-Xavier Garneau's *Histoire du Canada* (1845–48; *History of Canada*), embodied the new spirit, as did the patriotic poetry of Octave Crémazie, a bookseller in Quebec City.

Movement of 1860

The Quebec Movement, 1860–95. Under the Act of Union (1840), the peripatetic parliament of Upper and Lower Canada moved in 1859 to Quebec City, accompanied by its attendant clerks, public servants, and journalists. The capital, being also the seat of the newly founded Laval University (1852), was an ideal setting for French Canada's first literary grouping, known as the Mouvement Littéraire de Québec or the Movement of 1860. Its dozen members shared patriotic, conservative, and strongly Roman Catholic convictions about the survival of French Canada. Their spokesman, Abbé Henri-Raymond Casgrain, promoted a messianic view of the spiritual mission of French Canadians in North America, now that postrevolutionary France had fallen into what he perceived to be godlessness and materialism. Only a few French Romantic writers were admired and imitated. Philippe Aubert de Gaspé's historical romance of the period of British conquest, *Les Anciens Canadiens* (1863; *The Canadians of Old*); Antoine Gérin-Lajoie's colonization novel, *Jean Rivard* (1862–64); and numerous collections of verse by Pamphile Lemay (*Les Vengeances,* 1875) and Louis Fréchette (*La Légende d'un peuple,* 1887; "The Legend of a People") illustrate the nostalgic and didactic preoccupations of the time. More original works were nevertheless attempted: Eudore Evanturel's *Premières poésies* (1878) broke with conventional imagery, and Quebec's first woman novelist, Laure Conan (the pen name of Marie-Louise-Félicité Angers), published a remarkably sophisticated psychological novel, *Angéline de Montbrun,* in 1881–82 (Eng. trans. 1974).

The Montreal School, 1895–1935. By the end of the century Montreal had become the province's commercial metropolis, and the next literary movement was founded there by Jean Charbonneau and Louvigny de Montigny in 1895 with the École Littéraire de Montréal (Montreal Literary School). The society, with some 60 members, weekly meetings, and elected officers, continued to exist, although intermittently, for nearly 40 years. Its members published extensively, mostly in verse; organized four large public sessions in 1898–99; and issued two collective volumes of their writings, in 1900 and 1925. Their literary doctrine was eclectic, although chiefly influenced by the Parnassian and Symbolist movements in France and Belgium.

The Montreal School included the first French-Canadian poet who can be compared with his French contemporaries. Émile Nelligan, indisputably a genius, composed all his poetry during his teens (1896–99) before lapsing into insanity. His intricate sonnets and rondels were published in 1903 by the critic Louis Dantin (the pen name of Eugène Seers).

Aestheticism versus regionalism

During the first decade of the 20th century two main groups emerged from the Montreal School, the aesthetes (*exotistes*) and the regionalists. The aesthetes, among them René Chopin, Marcel Dugas, Paul Morin, and Robert de Roquebrune, had studied in Paris and were fascinated by contemporary French literature and culture. They founded a short-lived artistic magazine, *Le Nigog* ("The Harpoon"), in 1918, but they remained a tiny minority, often denounced as dilettantes. It was the regionalists (Gonzalve Desaulniers, Albert Ferland, Charles Gill, and later Alfred DesRochers, Claude-Henri Grignon, and Blanche Lamontagne-Beauregard) who became the dominant group over the next 30 years. Their preference for local subject matter and language, as expressed in their magazine *Le Terroir* (1909) and encouraged by the critic Abbé Camille Roy, complemented the French-Canadian nationalism then being promulgated by Henri Bourassa and Abbé Lionel Groulx. Paradoxically, the regionalists were proposing rural and agricultural themes when Quebec society was becoming urban and industrial. The French novel *Maria Chapdelaine* (1914) was grudgingly accepted, but Quebec authors like Rodolphe Girard (*Marie Calumet,* 1904) and Albert Laberge (*La Scouine,* 1918; *Bitter Bread*) who portrayed country life too realistically were censured and ostracized. The one poet who anticipated future trends, Jean-Aubert Loranger (*Les Atmosphères,* 1920), was ignored.

As the educated urban population increased between the two world wars, there was a discernible expansion of intellectual life, modestly supported by the provincial Liberal governments in power from 1905 to 1936.

World War II and the postwar period, 1935–60. By the mid-1930s Canada's economic depression, Quebec's socioeconomic development, and European political events were making Quebec's regionalist literature obsolete.

Urban fiction

In fiction Jean-Charles Harvey attacked bourgeois ideology in *Les Demi-Civilisés* (1934; *Sackcloth for Banner*). Three years later Msgr. Félix-Antoine Savard's *Menaud, maître-draveur* (*Boss of the River*) deplored in lyrical language Anglo-American takeovers of Quebec's natural resources, and in 1938 Ringuet (Philippe Panneton) traced the decline of Quebec's rural economy in *Trente arpents* (*Thirty Acres*). After the interruption of the war years (1939–45), French-Canadian fiction became resolutely urban. Gabrielle Roy's portrait of a Montreal working-class district in *Bonheur d'occasion* (1945; *The Tin Flute*) won the Prix Fémina, and Roger Lemelin's *Les Plouffe* (1948; *The Plouffe Family*) spawned a popular television serial.

Not all novelists were attracted to social realism, however. Some, like Robert Charbonneau, André Giroux, or Robert Élie, wrote first-person introspective fiction influenced by the Roman Catholic novelists of France. Others, like Germaine Guèvremont in *Le Survenant* and *Marie-Didace* (1945 and 1947; translated and published together as *The Outlander,* 1950), continued to examine rural society, though with greater detachment. One of the most prolific novelists, Yves Thériault, found new subjects among Quebec's Eskimo and American Indian peoples (*Agaguk,* 1958; *Ashini,* 1960).

In poetry Hector de Saint-Denys Garneau's unrhymed metaphysical poems (*Regards et jeux dans l'espace,* 1937; "Glances and Games in Space") introduced a new era. Four poets subsequently dominated the 1940s and '50s: Garneau, Alain Grandbois, Anne Hébert, and Rina Lasnier. Although each employed distinctive techniques and images, all expressed their sense of solitude, alienation, frustration, or despair. Each, especially Grandbois, influenced younger writers; for the first time poets of Quebec, rather than poets of France, served as models for the next generation—the Hexagone poets.

A literary association and publishing house, L'Hexagone (1953), became the major force in Quebec poetry for the next 15 years. It published dozens of elegantly printed volumes of verse, launched literary magazines such as *Liberté* (1959; "Liberty"), and organized annual conferences of Quebec and international writers. Its leading figures, Gaston Miron, Roland Giguère, Gilles Hénault, Fernand Ouellette, Jean-Guy Pilon, and Michel Van Schendel, were both theoreticians and practicing poets, writing interpretive essays as well as polished poems.

Theatre in Quebec

Simultaneously, Quebec theatre assumed its modern form. A Montreal company, Les Compagnons de Saint-Laurent (1937–52), created a taste for professional performances of contemporary French plays. Two playwrights, Gratien Gélinas and Marcel Dubé, began writing in colloquial language about the problems of living in a society controlled by the Roman Catholic church and by a paternalistic Union Nationale government. Permanent theatres and professional companies sprang up, their personnel often supported by part-time work with Radio-Canada or with the National Film Board of Canada.

By mid-century Quebec intellectuals knew that their traditional society was out of step with the postwar world. In 1948 the painter Paul-Émile Borduas repudiated the past in a revolutionary manifesto, and in 1950 Pierre Elliott Trudeau and others founded *Cité libre* ("Free City"), a journal of social and political criticism. The "quiet revolution" was not far away.

Separatism's influence on French-Canadian literature

The "Quiet Revolution." During the 1960s Quebec society underwent the greatest upheaval of its history. A new Liberal government set about modernizing the province, revamping the educational system, and creating a powerful Ministry of Cultural Affairs. Campaigns for the independence of Quebec were launched by separatist organizations that coalesced in the Parti Québécois (1968), which became the provincial government in 1976. Writers calling themselves *Parti pris* (Decision Taken) founded a magazine (1963–68) and a publishing house to press their demands for a secular, socialist, and independent Quebec. Intellectuals became vocal and assertive, and literary production more than tripled during the decade.

In poetry the territory of Quebec (referred to as *le pays*) was rediscovered in Paul-Marie Lapointe's *Choix de poèmes: arbres* (1960; "Selection of Poems: Trees") and Gatien Lapointe's *Ode au Saint-Laurent* (1963; "Ode to the St. Lawrence"). Nationalism adopted revolutionary language in Paul Chamberland's *Terre Québec* (1964), and personal rebellion triumphed in the avant-garde magazines *La Barre du jour* (founded 1965) and *Les Herbes rouges* (founded 1968). A preoccupation with freedom of expression (*la parole*) revealed itself in titles like Giguère's *L'Âge de la parole* (1965) and Yves Préfontaine's *Pays sans parole* (1967). Perhaps the most influential collection was Miron's *L'Homme rapaillé* (1970; partial Eng. trans., *The Agonized Life*), a poetic record of the search for a Quebec identity. Michèle Lalonde's ironic "Speak White" (1970) had a similar impact.

During the 1970s poetry was less engaged and more experimental: the concerns of American counterculture were adopted in the works of Raoul Duguay and Claude Gauvreau, and the concerns of French feminist writing were treated by Nicole Brossard and France Théoret, often with marked formalist tendencies.

As published poetry became more esoteric, the general public turned to chansonniers, popular singers, such as Gilles Vigneault or Pauline Julien. The "Quebec song," which in many cases had political overtones, became the poetry of the people.

Fiction became the most widely read genre. Works of fiction reflected the upset of the Quiet Revolution in their radical, often sexual, themes and in their unconventional structures, derived in part from the French *nouveau roman* of the previous decade. The Quebec "new novel" began with Jacques Godbout's *L'Aquarium* (1962) and reached its high point in the brilliantly convoluted novels of Hubert Aquin that followed his *Prochain épisode* (1965; Eng. trans. *Prochain Episode;* "Next Episode"). The same year Marie-Claire Blais's *Une Saison dans la vie d'Emmanuel* (1965; *A Season in the Life of Emmanuel*), which won the Prix Médicis, presented a scathing denunciation of Quebec rural life, and Godbout's *Salut, Galarneau!* (1967; *Hail, Galarneau!*), described the Americanization of Quebec. Constantly renewing himself, Gérard Bessette moved from ironic realism in *Le Libraire* (1960; *Not for Every Eye*) through interior discourse in *L'Incubation* (1965; *Incubation*) to symbolic narrative in *Les Anthropoïdes* (1977). The poet Anne Hébert achieved success with her novel *Kamouraska* (1970; Eng. trans., *Kamouraska*) and won the Prix Fémina for *Les Fous de Bassan* (1982; *In the Shadow of the Wind*). Réjean Ducharme in *L'Avalée des avalés* (1966; *The Swallower Swallowed*) and other novels presented the disenchantment of young people in the nuclear age. Other popular novelists of the 1970s were Jacques Ferron, who poked fun at Quebec institutions; the author and publisher Victor-Lévy Beaulieu, with his continuing saga of the Beauchemin family; Roch Carrier, who mocked biculturalism in *La Guerre, yes sir!* (1968); and Antonine Maillet, creator of the immortal Acadian charwoman (*La Sagouine,* 1971; Eng. trans. *La Sagouine;* "The Slattern") and recipient of the Prix Goncourt for *Pélagie-la-charrette* (1979; *Pélagie: The Return to a Homeland*). The subsequent success of Yves Beauchemin's *Le Matou* (1981; "The Tomcat") and similar books suggested a return to favour of "action fiction."

Innovations in Quebec theatre

The contemporary period has seen an impressive growth in Quebec theatre and dramatic writing, with several dozen original plays being performed each year. This "new Quebec theatre" can be dated from the success of Michel Tremblay's *Les Belles-Soeurs* in 1968 (Eng. trans. *Les Belles-Soeurs;* "The Sisters-in-Law"). It is characterized by experimental approaches, including improvisation and collective creation; by proletarian language (*le joual* in plays by Jean-Claude Germain and Jean Barbeau); by parody (Robert Gurik, *Hamlet, prince du Québec,* 1968; "Hamlet, Prince of Quebec"); and by audience participation (Françoise Loranger, *Double jeu,* 1969; "Double Game"). The leading dramatist of the 1970s was Michel Tremblay, who presented various aspects of alienation, often symbolized by homosexuality. The most significant contemporary development has been the emergence of women's theatre, performed by groups such as the Théâtre Expérimental des Femmes and featuring controversial plays like Denise Boucher's *Les Fées ont soif* (1978; "The Fairies Are Thirsty") or Jovette Marchessault's *La Saga des poules mouillées* (1981; "The Saga of Wet Hens").

With the increase in publication subsidies and publishing activity in Quebec after 1960, production of new literary works eventually exceeded 500 titles per year. Hundreds of anthologies, bibliographies, biographies, and critical studies have appeared, making French-Canadian literature one of the most thoroughly documented and exhaustively analyzed literatures of the Americas. Critics like Jean-Éthier Blais, André Brochu, Gilles Marcotte, and Pierre Nepveu, together with literary historians like John Hare, Laurent Mailhot, and Paul Wyczynski, have studied the traditional literary genres, while new forms of paraliterature (science fiction, detective novels, comic strips) are constantly being recognized as legitimate objects of investigation.

Cancer

Cancer in humans is a complex of diseases characterized by uncontrolled multiplication and disorganized growth of the affected cells; it may arise in any of the body's tissues. Cancer cells infiltrate and destroy adjacent tissues, eventually gain access to the circulatory system, are transported to distant parts of the body, and ultimately destroy the host. Concomitant with their capacity for unrestrained growth, cancer cells and the tissues they constitute lose their normal appearance, as viewed through a microscope, and assume aberrant functions.

Not all abnormal growths are malignant; those that are not are referred to as benign tumours. In contrast to malignant growths, benign tumours consist of an orderly growth of cells that often are identical to or very closely resemble their normal counterparts. They are not aggressive and do not invade surrounding tissues, spread to distant sites, or kill the host. Such tumours are usually surrounded by a capsule of fibrous connective tissue.

Cancer was known in antiquity. Malignant tumours have been found in Egyptian and Pre-Columbian mummies, about 5,000 and 2,400 years old, respectively. They are documented in ancient medical writings, such as the Edwin Smith and Ebers papyruses, both written about 3,500 years ago. Cancer is also seen in other species, such as domestic animals, birds, reptiles, and fishes. Although growths that resemble and behave like cancer occur in invertebrates and plants, their precise equivalence to cancer in higher living forms remains to be unequivocally established.

Statistics of cancer incidence and mortality show striking geographic differences, varying significantly from country to country; and within countries differences of incidence and mortality occur between the sexes, various ethnic groups, and various occupations. Epidemiologic analysis of such statistics continues to provide valuable clues and insights into the myriad factors that appear to be involved in the causation of cancer.

This article examines the main causes of cancer, the spread of cancer, the various types that are known today, and the methods of treatment that are being used.

The article is divided into the following sections:

CAUSES

It is now known that cancer can be caused by a variety of factors acting either singly or in concert. These include a wide variety of chemical substances, various types of ionizing radiation, and various classes of viruses. This knowledge has accrued from a composite of epidemiologic studies of cancer in humans and from experimental studies in the laboratory. Although much is known about how cancer is caused, the precise mechanism or group of mechanisms involved continues to elude researchers.

Chemicals. Chemicals numbering in the hundreds are known to induce cancer in laboratory animals, and some of these have also been shown to be carcinogenic for humans. While it is well established that long exposure to certain chemicals gives rise to cancer in humans, it is most difficult to determine accurately what proportion of human cancer is due to such exposure. The difficulty arises from the fact that the length of time between exposure and the appearance of cancer is usually prolonged, lasting some 20–30 years; that exposure is more often than not to a variety of chemicals, so that identifying the carcinogen may be difficult, if not impossible; and that carcinogenesis, *i.e.,* the induction and development of cancer, is a process that involves many factors and many phases.

Experiments on laboratory animals have established that the majority of carcinogenic chemicals are not capable of inducing cancer in their original form. Chemical carcinogens are toxic compounds that are foreign to the host. Once they gain entrance into the body by ingestion, inhalation, or absorption, they are modified by metabolic processes in the host's tissues to forms that are less toxic and water-soluble. The modification is an attempt by the host to detoxify the foreign chemicals and eliminate them by excretion. This capacity to detoxify such substances is an adaptive property of a wide spectrum of living systems, including humans, which affords them a selective advantage to exist in a hostile environment. As in most cases, however, this protective property is not foolproof, and in the process of detoxification certain forms of the carcinogen may arise that are even more toxic and active than the parent compound. In this instance the host renders a less toxic compound into one that causes injury to its cells and may eventually cause them to become cancerous. Highly reactive forms of such chemicals interact with vital macromolecules in the host's cells, causing them to be chemically altered. It is believed that when deoxyribonucleic acid (DNA), the genetic material of cells, is so altered that its expression is accompanied by uncontrolled growth, the cell undergoes a transformation that eventually leads to the development of cancer.

Alteration of DNA

DNA appears to be the most probable macromolecule whose alteration leads to cancer, because once cells become malignant their transformed behaviour is passed on to subsequent cell generations, indicating that it is a heritable change. There is evidence, however, that alterations of nongenetic macromolecules capable of regulating cell growth may also be involved in the causation of cancer.

The alteration of DNA is one phase of carcinogenesis. The second phase is a prolonged one during which the genetically altered cell loses its ability to grow in a regulated fashion. During this phase the altered cell, not yet expressing its malignant potential, apparently is influenced by other factors, including noncarcinogenic chemicals; dietary components, such as fat; or substances produced by the host, such as hormones. Since this phase is prolonged and subject to manipulation, it is a major focus of contemporary cancer research; it is hoped that persons at high risk of developing cancer (presumably with cells genetically altered by a chemical, but not yet cancerous) may be treated to prevent overt cancer from developing. Certain chemical substances, such as antioxidants and vitamin A, are particularly promising in this regard.

Despite the fact that cancer is a prevalent disease in modern society, quantitative experimental evidence in animals suggests that, following the exposure of cells to a carcinogenic chemical, the ultimate development of cancer is a relatively rare event. This is no doubt due to the fact that some genetic mutations lead to the death of the affected cells, so that no cancer can develop. A second, more important, reason is due to the ability of cells to "repair" altered or damaged DNA. In this process the segments of damaged DNA are excised, and identical single strands of the required segments are synthesized; these are then spliced into the defect, reestablishing its continuity. If the synthesis has accurately copied the DNA segment as it was prior to damage, there will be no adverse effects. If, on the other hand, cell replication occurs before the damage is repaired, the altered DNA is copied and the damage is amplified. When such cells undergo division the genetic defect is passed on to their descendants. It is reassuring to know that repair processes appear to be uniformly present in living cells and are very efficient, rapidly repairing damaged DNA with great fidelity.

Occupational chemicals. The association of "substances" in the environment with the development of cancer was suggested in 1775 by Sir Percivall Pott, who reported the frequent occurrence of cancer of the scrotum in chimney sweeps chronically exposed to flue dusts. Pott suggested that this might be due to the prolonged exposure of scrotal skin to the dust. Since then, there have been numerous instances in which the development of cancer has been associated with specific occupations.

Numerous carcinogenic chemical hazards have been identified in a variety of extraction and processing industries. These include polycyclic hydrocarbons present in coal tar and its derivatives, such as pitch, tar oils, and creosote, and in products of the combustion and distillation of coal, oil, shale, lignite, and petroleum. In the past, skin cancer took the lives of many long-time workers in these industries. Fumes inhaled by workers during coke-oven operations and in refineries have been associated with high incidences of lung cancer. Benzene, a product of coal-tar distillation, may affect blood-forming tissues and is suspected of being a carcinogen capable of inducing leukemia. Various metals have been implicated as carcinogens for the lung and several other body sites among copper-ore miners and smelters of nickel and cobalt ores. Beta-naphthylamine, a chemical once widely used in the manufacture of aniline dyes, has been shown to be a carcinogen for the urinary bladder.

Asbestos and lung cancer

Asbestos has been established as a carcinogen for the lung and for the mesothelium (membrane) that lines body cavities. Workers chronically exposed to dust containing asbestos fibres have an incidence of lung cancer 10 times the normal rate. (It is noteworthy that the risk of cancer is increased 90-fold in asbestos workers if they also smoke. This is an excellent example of two agents acting synergistically to induce cancer at a higher incidence and often in a shorter time than either agent does alone.) Although a serious effort has been made to reduce industrial exposure to asbestos, in some parts of the world occupational pollution remains responsible for a debilitating and progressive form of lung disease (asbestosis), as well as cancer, in asbestos workers.

Environmental chemicals and pollution. The environment, which includes the atmosphere, land, seas, lakes, and rivers, reflects the activities of society. Environmental pollutants include the myriad effluents of daily living, industrial as well as naturally occurring. Among the greatest atmospheric pollutants are the gaseous and particulate emissions that range from the massive outputs of industry and motor transport, measuring millions of tons annually, to individual puffs of cigarette smoke.

Smoking and cancer

Cigarette smoke has been shown to contain numerous compounds that are known to cause cancer in experimental animals and that appear to be strongly linked to human cancer, especially cancer of the lung. In addition, tobacco smoke has been implicated in the causation of cancer of the mouth, and to a lesser extent the esophagus, pancreas, biliary system, and urinary bladder. Cigarette smoke also has been shown to contain a number of cocarcinogens, substances that appear to enhance the effect of carcinogens when they are administered concomitantly.

Increasing evidence has accrued to suggest that the release of polychlorinated hydrocarbons and certain insecticides into the environment may pose a carcinogenic hazard. Some of these compounds have enjoyed such widespread use that significant areas of land and bodies of water have been contaminated. This, coupled with the fact that such compounds, once ingested by humans, are stored in body fat and released and metabolized very slowly, has made their removal from the environment extremely important, even though it is a difficult, prolonged, and expensive undertaking.

The effect of environmental pollution can best be illustrated by describing the phenomenon of bioconcentration and its impact on the food chain. Widely used insecticides, which metabolically degrade very slowly and are highly soluble in fat, are a case in point. After being applied on land for agricultural uses, such compounds are washed by rains into streams, rivers, and lakes, where they are ingested by microscopic life forms, which serve as food for fish that are, in turn, the major food source for larger fish and aquatic birds. Since these compounds are soluble in fat, after being ingested by an animal they are stored and concentrated in the animal's body fat. Repeated feeding eventually leads to high concentrations of the compounds in the animal's body, so that its subsequent ingestion by a larger predator, perhaps by humans, presents the predator with a significant level of the compound. This can pose a health hazard so serious that, for example, fishermen on a contaminated lake are warned not to eat the fish they catch. The magnitude of the problem is illustrated by the insecticide DDT, high levels of which persist in the environment and in the bodies of humans, despite the fact that its use was restricted worldwide by the early 1970s.

Food additives and cancer

Food additives are another source of environmental chemicals that has caused concern. Although these have been the object of dispute and have given rise to the "natural food" fad, there is no evidence that food additives cause human cancer. In fact, some food additives, especially those that protect foods from becoming rancid, have actually been shown to prevent chemically induced cancer in experimental animals. An additive that remains a matter of concern, however, is sodium nitrite, which is widely used to preserve processed meats. It has been shown that nitrite can react in the stomach with amines, which arise from the digestion of meat, to form nitrosamines, a group of compounds that are potent carcinogens for certain laboratory animals. These compounds are formed in such minute amounts in the stomach that some researchers doubt that they pose a significant carcinogenic hazard for humans. Similarly, the demonstration that certain compounds formed by the burning of meat are carcinogenic for animals must be placed in proper perspective. Carcinogenesis experiments in animals usually require continuous exposure to high levels of chemicals to obtain statistically valid results in their relatively short life span of a year or two; extrapolation of these results to the effect on human health should be approached most carefully.

Problems of greater importance are the naturally occurring carcinogens, which constitute an important hazard in certain environments. One of these, aflatoxin, is formed by *Aspergillus flavus,* a mold that is widely distributed and is a frequent contaminant of improperly stored nuts, grains, meals, and certain other foods. In certain areas of Africa the high incidence of liver cancer in humans appears to coincide with their ingestion of foods highly contaminated with aflatoxin. Such correlations must be interpreted conservatively, however, since these populations are also often plagued by viral hepatitis B, which also has been linked to liver cancer. In Japan and parts of China similar correlations exist, but again their interpretation must be tempered because of the presence of viral hepatitis B and other factors.

Radiation. The carcinogenic effects of ionizing radiation first became apparent at the turn of the 20th century with reports of cancer of the skin in physicians who pioneered the application of X-rays and radium to medicine. Since then it has been well established that ionizing radiations of all forms, including ultraviolet light, are carcinogenic.

Occupational radiation. Numerous examples of radiation carcinogenesis have been documented in occupational settings. Well known among these were women who developed bone cancer as a consequence of the chronic ingestion of radium salts that resulted from licking brushes to a fine point while painting luminous watch dials. Following ingestion, radium is deposited in the mineral component of bones; and the deposition of radium in the bones is sufficiently high to make them autoradiographic—that is, their image can be reproduced on X-ray film simply by placing the bones in contact with the film. Another notable example is uranium mine workers, who develop lung cancer to a significantly higher degree than the general population. The cause has been traced to the inhalation of the radioactive gas radon, released from trace amounts of radium in uranium ore.

Environmental radiation. The environment contains three major natural sources of radiation: radioactive elements in mineral deposits, ultraviolet light from the Sun, and cosmic rays. The carcinogenic potential of radioactive elements and ultraviolet light has been established, while that of highly energetic cosmic radiation remains to be documented. Clearly, chronic exposure to intense sunlight is a major cause of skin cancer in humans; incidence is high in farmers, sailors, and habitual sunbathers. Since the most effective natural screen for ultraviolet light is the natural skin pigment, melanin, individuals with large amounts of melanin—blacks, for example—are resistant to the carcinogenic effects of ultraviolet light. Fair-complexioned people, on the other hand, are quite susceptible. It is important to point out that the term skin cancer, as it is generally used, includes not only malignant tumours of the nonpigmented cells of the skin but also tumours of the pigmented cells (melanoma). Under the proper conditions ultraviolet light can cause cancer to develop in the very cells that produce the pigment that affords protection from solar radiation.

Sunlight and cancer

The environment also contains dangerous ionizing radiation from artificial sources. These include X-rays used for medical diagnosis and therapy, radioactive chemicals, radioactive elements used in atomic reactors, and radioactive fallout arising from the testing of nuclear devices. Home appliances have been known to emit potentially harmful X-rays under certain circumstances, as was the case with some colour television sets made during the 1950s. Radiation leaks from improperly constructed or operated microwave ovens can also occur, but the health hazards from such exposures have yet to be established.

Certain medical applications of X-rays, such as those used to establish the size and position of a fetus before birth and to control acne, have been largely abandoned because of the increased risk of cancer. Modern technology has greatly reduced the risk of diagnostic X-rays, however. During therapeutic X-irradiation for the treatment of cancer, great care is taken to focus radiation on the tumour and to shield the adjacent normal body tissues from undue exposure. Laboratory workers who use radioactive chemicals are careful to prevent undue exposure by contamination and to dispose of radioactive wastes properly. The cancer risk from radioactive fallout resulting from the testing of atomic devices is virtually impossible to establish with certainty because of the large geographic areas affected. In general, such exposure is not massive, and immediate effects are probably not of high significance. The absorption by growing crops and farm animals of long-lived radioactive isotopes, such as strontium, from fallout may pose a threat to humans, however, because the crops and animals are a source of food.

Viruses. Numerous viruses have been identified that can induce cancer in every major class of vertebrates, including lower vertebrates such as fish. The evidence for the viral causation of cancer in humans long remained strong but only circumstantial; it is now clear, however, that Burkitt's lymphoma, nasopharyngeal cancer, and T-cell leukemia are almost surely caused by viruses.

Oncogenic (cancer-causing) viruses are classified according to the type of nucleic acid they contain. A common feature of oncogenic viruses is that they induce malignant transformation of target cells, which, upon transplantation into suitable animal hosts, exhibit true autonomous growth, local invasion, and metastases to distant sites. Another common feature is physical integration of virus-specific genetic material in the DNA of the host cells. In the case of DNA tumour viruses, the viral genes are integrated directly, whereas with ribonucleic acid (RNA) viruses the RNA is first transcribed into DNA, which is then integrated. Furthermore, RNA tumour viruses are frequently replicated by the cells they transform, while DNA tumour viruses are not. The complexities of tumour viruses are such that progress to establish cause and effect has been quite difficult. The following viruses are strongly suspected of being oncogenic for humans.

Herpes-type viruses. A herpesvirus has been found to be closely associated with two cancers in humans: Burkitt's lymphoma, a malignant tumour of lymphatic tissue first described in children in East and Central Africa; and nasopharyngeal carcinoma, a squamous-cell carcinoma of the posterior part of the nasal cavity, which occurs in high incidence in Chinese originating from South China. Biopsies from both tumours grown in culture gave rise to cell lines in which a DNA virus of the herpes class was identified; it was named the Epstein-Barr (EB) virus. Patients with either type of cancer have high levels of antibody directed against EB virus, indicating that they have encountered the virus and responded to it. Human blood lymphocytes can be transformed in culture by EB virus, and there is experimental evidence that EB virus is also oncogenic for cottontop marmosets and owl monkeys. In addition, EB virus is considered to be the causal agent for infectious mononucleosis, a distressing but self-limited viral infection well known in North America; yet infectious mononucleosis is not followed by either Burkitt's lymphoma or nasopharyngeal carcinoma. It is not known why EB virus causes a self-limited disease in one instance and a variety of cancers in others. Evidence suggests that genetic factors may be important for development of the malignant tumour.

Burkitt's lymphoma

A second herpesvirus that is becoming increasingly suspect as a human oncogen is the herpes simplex virus type 2 (HSV-2), a close relative of the virus that causes the common fever blister. The epidemiology of squamous-cell cancer of the uterine cervix is entirely consistent with the possibility that it may be caused by an agent that is transmitted during sexual intercourse. A woman who develops a herpes infection of the cervix is likely to develop cervical cancer, and women with cervical cancer often have high levels of HSV-2 antibody. Other viruses that may be involved and are known to be transmitted by sexual contact are cytomegalovirus (CMV) and papillomavirus; both are capable of causing cell transformation in culture. The experimental application of radioactive probes of antibodies to specific viral proteins and to components of the viral genome have localized either the integrated genome or the viral antigens of HSV-2, CMV, and papillomavirus in the cells of cervical cancer in women. Although this cannot be taken as unequivocal evidence that the viruses are indeed the causal agents, it does strengthen the hypothesis that cervical cancer may have a viral basis.

Herpes simplex virus type 2 and cancer

The implication of virus as a cause of human cancer has been largely circumstantial, but in one human cancer, thymus-derived (T-cell) leukemia–lymphoma, the evidence is quite impressive. These tumours, which appear in inhabitants of the southernmost island of Japan and in the West Indian population in the Caribbean, have been shown possibly to have an infectious basis. Furthermore, an RNA virus, human T-cell leukemia virus (HTLV), which bears no apparent relation to any of the known animal oncogenic RNA viruses, appears to be present in patients with T-cell leukemia and can be isolated from their tumour tissue with reasonable reproducibility. Finally, infection of normal blood T lymphocytes in culture by HTLV leads to their uncontrolled growth.

Infection with hepatitis B virus (HBV) is endemic in populations that also have a high incidence of liver cancer. This has led some researchers to conclude that the virus is the cause of liver cancer. As noted earlier, however, cancer is a multifactorial disease, and liver cell cancer is an excellent example. HBV infection invariably leads to the augmented growth of liver cells, which renders them exquisitely sensitive to carcinogens. Since populations plagued by a high incidence of liver cancer are also chronically exposed to numerous toxic substances, some of which are carcinogenic for the liver, it is difficult to dissect the interactions of virus and carcinogen with sufficient precision to either indict or exonerate HBV as a liver oncogen. Thus, HBV must be considered only as a possible carcinogen. HBV may well be considered a cocarcinogen, however; it may so increase the sensitivity of liver cells to carcinogens that it decreases the latent period during which the cells undergo malignant transformation and increases the number of tumours that ultimately develop.

Oncogenes. Progress in tumour genetics and molecular biology may lead to a clearer understanding of how cells undergo malignant transformation. As stated earlier, RNA tumour viruses invariably integrate their DNA into the host's DNA. Cells of numerous vertebrate species, including humans, have such integrated DNA in their genes. The conservation of such genes throughout so many diverse species suggests that they probably serve an important role in cells, perhaps in growth regulation. The fact that such genes are almost ubiquitous in their distribution and apparently are simply not expressed in normal cells led to the enunciation of the oncogene hypothesis, which suggests that silent (unexpressed) oncogenes, or genes capable of inducing cancer, can, upon proper stimulation, become expressed and thus cause a previously normal cell to become malignant. Oncogenes have been found in chromosome 8 in Burkitt's lymphoma cells and in a variety of other human tumours. Introduction of such oncogenes in DNA from human tumours into normal cells in culture causes the normal cells to become transformed and behave like cancer cells. Activation of an oncogene in a human tumour has been shown to be accompanied by a minor change in its chemical structure. This suggests that silent oncogenes may be activated by chemicals, radiation, and viruses, all of which are known to alter DNA and to cause cancer. The oncogene may be the common denominator through which such diverse agents act.

Genetic factors. The common cancers of humans are not generally inherited, although some families show an incidence of a particular cancer beyond expectations. Multiple cases of childhood cancer may occur in a family. When leukemia develops in one of a pair of identical twins, the other twin also develops leukemia in about 15 percent of the cases. Among fraternal twins this happens less than 1 percent of the time. Some familial tendencies have also been observed for cancer of the breast, uterus, prostate, stomach, colon–rectum, and lung, although the hereditary effect is not strong. It is possible that familial tendencies reflect common environmental relationships or an environmental factor superimposed on a genetic one.

Leukemia in twins

In studies of familial tendencies for breast cancer in England, Denmark, and the United States, an incidence two to three times that expected in the general population has been noted for close relatives of persons with the disease.

A rare cancer of the eye called retinoblastoma occurs in childhood as a result of the transmission of a single dominant gene (a dominant gene need be inherited from only one parent for the trait to become manifest).

Pheochromocytoma, a rare cancer of the adrenal gland, and carcinoma of the thyroid medulla (the inner portion of the thyroid) sometimes occur in various members of the same family. Either both tumours or only one may occur. Persons with pheochromocytoma also have an increased risk of parathyroid and other rare tumours.

Xeroderma pigmentosum, an inherited, abnormal sensitivity of the skin to ultraviolet radiation, almost always leads to skin cancers. The sensitivity is due to an inherited defect in the ability of cells to repair DNA that has been damaged by ultraviolet light.

Children with Down's syndrome, or mongolism, a disorder associated with an extra chromosome in each cell, have a much greater likelihood of developing leukemia than do other children. Persons with Fanconi's aplastic anemia (in which all types of blood cells are abnormally few and the bone marrow is not fully developed) and some other rare syndromes characterized by greatly increased chromosome breakages also have an increased risk of leukemia.

In chronic myelocytic leukemia (myelocytes are precursors of certain white blood cells), an abnormally short chromosome called the Philadelphia chromosome is a genetic marker in bone marrow cells and white blood cells of some patients. It is not known whether the cancer and chromosomal abnormality are independent events or whether one is the result of the other.

There is increasing evidence that genetic alterations are involved in the causation of cancer, and that these can be either inherited or induced and involve either a minute point in a strand of DNA or a major rearrangement of a chromosome.

Trauma and infection. Repeated trauma (injury) or irritation has been associated with some cancers. Ill-fitting dentures associated with cancer of the mouth and chronic infection of the uterine cervix associated with cervical cancer are examples. In each instance it must be remembered that injury and infection are invariably followed by healing, which involves increased local growth of host cells in the affected tissues, and such cells are quite sensitive to carcinogenic factors. There is no scientific basis to support the notion that trauma alone is a carcinogenic stimulus.

THE SPREAD OF CANCER

The ability of certain cancers to spread from their sites of origin, rendering their treatment and eradication difficult, is the major reason for the sense of hopelessness that is closely associated with them. If it were not for this ability to spread, most cancer could be successfully treated.

The spread of cancer results from either or both of two processes: cancer cells may spread by direct extension from the primary site as a consequence of growth and tumour cell movement invading the surrounding normal tissues, or they may enter the vascular system by invading lymphatics or blood vessels. In the latter process the cancer cells can be transported to sites distant from the primary site, whereas in the process of direct extension the cancer cells may remain close to the site of origin.

Direct extension. The ability of a localized focus of cancer to spread directly is dependent upon its interaction with adjacent tissue. Research has shown that experimental and some human cancers with a high incidence of spread contain enzymes capable of digesting elements of the surrounding normal connective tissues. This allows cancer cells to migrate through the connective tissues, which normally serve as a barrier. Once invasion by local extension has occurred, the opportunity for successful therapy is diminished. There is considerable evidence that tumour cell populations are heterogeneous and differ markedly in their ability to spread. The ability to digest elements of the connective tissue may be limited to a small number of cells in a given tumour cell population.

Metastasis. Metastasis is the process by which cancer cells are spread to sites distant from the primary tumour. The process requires that the cancer cells enter the vascular system, which includes lymphatics, veins, and arteries. Once they are within the system, the cancer cells are transported passively to distant sites. In lymphatics they are trapped in lymph nodes, which may serve as temporary barriers. They may enter the blood vessels by extension from lymph nodes or, more rarely, by passing directly through the connective tissue sheath surrounding lymph nodes. The cancer cells are eventually entrapped in the smallest branches of blood vessels, the capillaries. Cancer cells thus trapped are the "seeds" from which larger colonies of tumour cells grow into secondary sites, called metastases.

It was once thought that metastasis was a random process. Within certain limits, however, the patterns of metastases now appear to be tumour-specific. For example, cancer of the breast and prostate have a predilection for spreading to bone, in contrast to melanoma and kidney cancer, which lodge preferentially in the lung. It appears that the process of lodgement of cancer cells in a distant organ may be related to specific interactions between the cancer cells and those of the organ in which they ultimately settle and resume their growth. Basic research on the nature and mechanism of such interactions may eventually lead to a better understanding of the metastatic process and may result in the development of therapeutic strategies to either limit or totally prevent the spread of cancer to distant organs. (It should be pointed out that the ultimate success of a metastatic focus to establish itself and thrive may depend on other host factors, such as cell-mediated and humoral immunity.) Since the capacity for distant metastasis appears to be a property of a small subpopulation of cancer cells within the primary tumour, prevention or control of metastases may prove to be both feasible and effective in the future.

Effects of metastasis on survival

Spread of cancer and survival. Clinical experience with the relation of the spread of cancer to patient survival is dramatically emphasized by the statistics of cancer of the colon and rectum and of the female breast. In both the colon and the rectum, cancer begins in the cells that line the inner surface of the thin-walled, sausage-like connective tissue structure of the organ. If the cancer cells are localized to and within the wall, 94 percent of patients survive five years after surgical removal of the cancer; when the cancer has spread through the wall, but has not entered the adjacent lymph nodes, five-year survival is 88 percent. On the other hand, once cancer has involved the lymph nodes, the five-year survival decreases to 55 percent. Similarly, in breast cancer in women the 10-year survival rate in the absence of nodal involvement is 72 percent, and when lymph nodes closest to the tumour are involved, 10-year survival is 66 percent. When the tumour has spread to more distant nodes, however, five-year survival decreases to only 31 percent. It is important, therefore, to diagnose cancer and begin treatment before cancer cells begin to spread.

Implications of metastasis for therapy. Just as subpopulations of cancer cells within primary tumours have varying abilities to spread by metastasis, they may also differ in response to treatment by radiation and chemotherapy. This is supported by the observation that metastases may differ significantly in their response to radiation therapy and chemotherapy, and that tumours often appear to become resistant to therapy. In both instances the different response of the cancer cells may be due to a selection process. In the first instance, the differing responses of metastases suggest a coupling of the tumour cell's sensitivity to its capacity to spread widely. In the second, the tumour's decreasing sensitivity to therapy may be due to a selection of more resistant tumour cells by virtue of therapy, in a process analogous to the appearance of bacteria resistant to a particular antibiotic during a course of treatment.

TYPES OF CANCER

Cancers are classified by the type of tissue in which they arise and the cell type that constitutes the tumour. This system of classification recognizes in humans more than 150 types of cancer with different behaviours.

Types of tissue. The organs of the body consist of a variety of tissues, including those that line their inner surfaces (epithelia) and those that render structural support and contain their blood supply (the connective tissues). Tumours of a given type of tissue differ from those of the normal tissues in that and other organs but may closely resemble tumours of similar tissue in other regions of the body.

Carcinoma and sarcoma

Classification of cancers according to the tissue from which they evolve is by two major types: carcinoma and sarcoma. Carcinoma, the larger category, refers to cancers of epithelial tissues, which cover the external body (the skin) and line the inner cavitary structures of organs such as the breast; the respiratory and gastrointestinal tracts; the endocrine glands, such as the pituitary, thyroid, and adrenals; and the genitourinary system, which includes the prostate, testes, ovaries, fallopian tubes, uterus, kidneys, and urinary bladder. Sarcoma refers to cancers of the various elements that constitute the connective tissues, such as fibrous tissues, muscle, blood vessels, bone, and cartilage. Rarely, a cancer is composed of both epithelial and connective tissue simultaneously and is referred to as carcinosarcoma. Leukemias, lymphomas, and other cancers of the blood-forming tissues are classified separately, although strictly speaking they can be regarded as a subset of cancers of the connective tissues. Tumours of nerve tissues, including the brain, and melanoma, a cancer of the pigmented cells of the skin, are also classified separately.

A carcinoma of the intestine has more in common with a carcinoma of the stomach, lung, or breast than with a sarcoma of lymphoid cells of the intestine. It is on the tissue and cells of origin, not the organ of origin, that the peculiar and characteristic properties of a tumour more usually depend.

Squamous-cell and basal-cell carcinomas

Types of cells. Tumours are also classified according to the type of cell from which they are derived. For example, skin cancer includes tumours composed of the major cellular component, squamous cells, giving rise to squamous-cell carcinoma; of the less frequent basal cells found at the base of the skin, whose tumours are referred to as basal-cell carcinomas; and of the still more rare cells that produce melanin pigment, whose malignant tumours are classified as melanomas. Cancers in different organs and individual carcinomas of the same cell type may have different doubling times (*i.e.,* the time it takes for the tumour mass to double in the number of cells or in size). Doubling times observed for lung cancer, for instance, may vary widely, with ranges from eight days to more than 700 days. The doubling time is a reflection not only of the rate of tumour cell growth but also of the loss of cells through spontaneous death.

Paraneoplastic syndromes

In addition to the obvious problems associated with the local mechanical effects of tumours, as well as their spread to distant vital organs such as the lungs, brain, and liver, where their subsequent growth may interfere with function, tumours may also exert other potent biological effects. These tumour-associated phenomena are referred to collectively as paraneoplastic syndromes and may include a wide and bewildering variety of adverse effects, such as loss of appetite, body wasting, fatigue, stupor, coma, excessive thirst, inappropriate flushing of the skin, anemia, spontaneous bleeding, clotting, loss of motor function, dementia, and paralysis. Some of these effects have been linked to the inappropriate production and release of certain hormones by tumours, while other effects remain unexplained. The fact that some effects appear before cancer is diagnosed and disappear as soon as the tumour is removed suggests that many of the unexplained effects are probably also caused by substances released by the tumours. Such effects can be so severe and debilitating that they present a more acute clinical problem than the underlying cancers.

Death in patients with cancer is more often than not due to a superimposed systemic complication, such as an overwhelming infection or uncontrollable hemorrhage. In certain instances death is the result of tumour invasion of contiguous tissues, leading to kidney obstruction or perforation of the gastrointestinal tract.

Sites of origin. Cancers of organs such as the brain, lung, esophagus, stomach, liver, gallbladder, pancreas, kidney, prostate, ovary, and testis grow to form firm masses and hence are referred to as solid tumours. These are contrasted with those tumours involving cells of the blood-forming organs and lymphatic systems, which are normally free and circulating and remain so when they become malignant. The most common sites in which cancers arise in adults include the skin, large intestine, lung, breast, pancreas, prostate, and uterus. Leukemia is the most common tumour of childhood. Some of the more common forms of cancer are discussed below.

Skin. Cancers of the skin are relatively common; they occur in highest incidence on the exposed skin of the head and neck of persons chronically exposed to sunlight. The most common form, about 82 percent of all cases, is that arising from basal cells in the deepest layer of the skin. The initial lesion is a small pimple-like elevation, which enlarges very slowly and after a few months forms a shiny, somewhat translucent lesion that eventually develops a small central ulcer. When the scablike surface is denuded it tends to bleed and then appears to "heal" by forming another shiny covering. Although basal-cell carcinomas grow slowly and only very rarely metastasize, they do invade locally and cause considerable destruction of adjacent tissues, which can result in disfigurement. Either ample surgical excision or radiation therapy is curative.

Squamous-cell carcinoma arises from the platelike flat cells that constitute the major cellular component of skin. The early lesion is less localized and elevated than that of basal-cell cancer. It is red and scaly and may be confused with eczema or infection. Eventually, the lesion becomes larger, elevated, and ulcerated. The behaviour of squamous-cell carcinoma differs somewhat from that of basal-cell cancer, in that the cells are not only capable of local invasion but also may metastasize to regional lymph nodes and, rarely, to more distant sites. Treatment is identical to that for basal-cell cancer.

Lung. Lung cancers arise in the epithelium lining the bronchi (the branching complex of air passages), by which air passes to the lungs, or in the fine air sacs at the periphery. The most common forms arise in bronchial glandular epithelium that has been altered by long exposure to cigarette smoke to form less specialized squamous cells, which eventually evolve into squamous-cell carcinomas. Structurally, unaltered glandular epithelia of bronchi may also undergo malignant transformation to give rise to adenocarcinomas, but these tumours do not appear to be related to cigarette smoking.

Cancers of the lung tend to metastasize widely to lymph nodes in the neck and chest, to the pleura (membrane) lining the chest and lungs, and to the liver, adrenals, and bone. The average survival of persons with untreated lung cancer is about nine months after diagnosis; spread to regional or distant lymph nodes or other sites has already occurred in the majority of cases. In operable cases removal of the tumour may prolong life for a number of months. Five-year survival of patients affected with squamous-cell carcinoma of the lung is about 25 percent and for adenocarcinoma 12 percent.

Risk factors for breast cancer

Breast. Cancer of the breast is the leading cause of death from cancer in women. (The incidence of cancer of the breast is significantly higher in North America and northern Europe than in Asian and African countries.) Women who begin menstruation at an early age are at greater risk than those who begin later, and women who have their ovaries removed surgically before age 35 appear to be at significantly less risk than women who undergo natural menopause. Women who bear their first child before age 18 have one-third the risk of developing breast cancer of those who have their first full-term pregnancy between ages 18 and 30. Treatment is reasonably successful when it is guided by knowledge of the degree of sensitivity of the tumour cells to the estrogenic hormones.

Esophagus. Cancer may arise at any point along the passage through which food is conveyed to the stomach, although the most frequent site is the middle third. The tumours are bulky, fungus-like growths that rapidly close the esophagus; rarely they may spread superficially without causing obstruction. Esophageal cancers are usually squamous-cell carcinomas that invade locally and metastasize rapidly to organs in the chest as well as to more distant sites. Even with the best therapy available, the cure rate is quite low. Chronic smoking and use of alcohol are considered to be major risk factors; diet and certain environmental factors may also be involved.

Stomach. Cancer of the stomach is a major cause of death worldwide. In some countries, such as the United States, the death rate from stomach cancer has decreased dramatically since the 1930s, for reasons that remain unknown. High increased rates of stomach cancer have been documented in coal miners and asbestos workers, in farmers in Japan, in nickel refinery workers in the Soviet Union, and in rubber and timber workers. The cancers almost exclusively affect the glandular epithelium lining the stomach and are adenocarcinomas. The tumours infiltrate and invade the wall of the stomach or form masses that protrude from the surface and ulcerate. These tumours tend to metastasize early and widely. Surgery is the treatment of choice but is curative only when the tumour is diagnosed and removed early. Rarer tumours include lymphosarcomas and tumours of the smooth muscle cells of the wall. These tend to grow more slowly and as a result are more easily cured by surgical intervention.

Liver. Cancer of the liver is a disease whose incidence varies widely; in African countries such as Nigeria and Benin and among Chinese in Singapore, Taiwan, and Hawaii the incidence is high, while in the continental United States and in western Europe primary cancer of the liver is relatively rare. Environmental factors appear to play an important role; the disease is linked to infectious hepatitis B virus, to malnutrition, and to natural chemical carcinogens such as aflatoxin B_1, toxic alkaloids from plants used to brew certain native teas, and nitrosamines. Chronic alcohol abuse, which leads to cirrhosis (scarring) of the liver, is a significant risk factor, especially in the Western world, since it appears to predispose a person to the development of liver cancer. Primary cancers of the liver are carcinomas arising from liver cells, the major cellular component of liver (hepatocellular carcinomas), or, more rarely, from a minor cellular component of liver, bile duct cells (cholangiocarcinomas). Both types of carcinoma tend to spread extensively within the liver; and the hepatocellular carcinomas also grow into the veins of the liver, from which they may spread to more distant sites, such as the lungs. Cancer of the liver may be successfully treated surgically if the tumour has not spread widely within the liver or beyond it.

Risk factors of pancreatic cancer

Pancreas. Pancreatic cancer arising from the epithelium lining the duct system is the most frequent malignant tumour of this organ. In the United States, England, Israel, and several Scandinavian countries the incidence of the disease is high; in other western and eastern European countries and Japan it is intermediate; and in southern Europe and Southeast Asia it is low. Risk factors include cigarette smoking, diabetes mellitus, and perhaps the typical Western diet, consisting of a high intake of meat and fat. Onset of the disease is insidious, so that by the time symptoms and signs such as loss of appetite and weight, jaundice, and painless enlargement of the gallbladder due to obstruction are apparent, the tumour has often already involved contiguous tissues and organs. The cancers are adenocarcinomas that metastasize early and often widely. These characteristics are responsible for the lethality of this disease, which has less than a 2-percent five-year survival rate. Despite considerable clinical research aimed at the development of new diagnostic techniques, successful results by surgical resection have been obtained only in a relatively small percentage of patients who have an early diagnosis. Cancer of the endocrine tissue in the pancreas, which secretes hormones such as insulin, can induce severe disturbances in blood-sugar levels that lead to dizziness, confusion, weakness, and loss of consciousness. These tumours are generally not aggressive and are often cured by surgery. Cancer of the acinar cells, which produce the enzymes necessary for the digestion of food, though rare, has a very poor prognosis, closely resembling that of ductal cancer.

Colon and rectum. Colorectal cancer is very common in the Western world, with an equal incidence in males and females. By contrast, its incidence in Japan, many South American countries, and sub-Saharan African countries is very low. Epidemiologic studies suggest that a major risk factor may be the low fibre content and high meat protein and fat content of the Western diet. It has been observed that Japanese immigrants to the United States within a generation acquire a much higher incidence of colorectal cancer than their counterparts in Japan. Similarly, their children, and the children of other immigrant ethnic groups from countries with low incidence, have incidences for colon and rectal cancer equal to those of other Americans. This is an excellent example of the role of the environment in the causation of cancer. Numerous studies aimed at identifying the early precursor lesions seem to indicate that the majority of cases arise from certain types of preexisting polyps and that these may remain benign for many months before becoming malignant. The tumours are adenocarcinomas, and some apparently also grow very slowly, taking as long as six to eight years to reach a size of about 2.4 inches (six centimetres). The tumours are round and raised and may be ulcerated. Once the tumour has grown through the wall of the bowel, successful treatment becomes more difficult. The tumours metastasize to the liver, lung, and other distant sites. Surgery is the most favoured treatment, although chemotherapy and radiation therapy may also be used when warranted by the extent of the disease.

Kidney and bladder. Adenocarcinoma of the kidney, which arises in the epithelium lining the renal tubules, is the most common primary malignancy affecting this organ. It is more common in men than in women and appears during the fifth and sixth decades of life. Although its causes remain to be determined, a number of retrospective epidemiologic studies implicate an association with cigarette smoking. An important manifestation is blood in the urine (hematuria), which may be painless or accompanied with flank pain. Tumours are large and bulky and may occupy a large portion of the kidney. Renal adenocarcinoma spreads by direct extension to adjacent tissues, and metastasis occurs to lung and bone by way of the lymphatics and the bloodstream. Some tumours may become quite large, however, without any evidence of metastasis. The mean survival rate following surgical removal is about 35 percent. A special type of kidney cancer that occurs in infancy and early childhood is often first discovered as a mass by a parent while bathing a child. These cancers, called nephroblastoma, or Wilms' tumour, arise from abnormal embryonic tissue and involve both connective tissue and epithelial cells. They can spread both by direct invasion and by the lymphatics and the bloodstream. Early diagnosis and combined surgical removal and radiation therapy give favourable results, with a cure rate of about 80 percent.

Wilms' tumour in children

In the United States bladder tumours account for about 6 percent of all cancers, while in Zimbabwe, Egypt, and Iraq bladder cancer constitutes about 40 percent of all cancers. The disease is three times more frequent in men than in women. Naphthylamine and other chemicals used in the production of dyes are known to cause bladder cancer. A metabolite of the amino acid tryptophan is also carcinogenic and may represent one of the means by which bladder cancer appears in people having no contact with the chemical industry. Chronic conditions of the bladder, such as infestation by the parasite *Schistosoma,* found in the Middle East and Africa, and developmental defects that predispose a person to the formation of bladder stones and infection are also considered high-risk factors. Hematuria is the most important symptom associated with this disease. Tumours often begin as benign lesions (papillomas), which become progressively more aggressive, with a high tendency to recur, and finally assume the behaviour of malignancy. The majority are carcinomas of transitional-cell epithelium, which lines the bladder; a much smaller number are squamous-cell cancers, which arise as a consequence of the modulation of transitional epithelium to squamous epithelium by factors and mechanisms that remain obscure. The tumours can be treated successfully with early diagnosis and vigorous treatment. Once they invade the bladder wall and enter adjoining structures, however, the prognosis is poor.

Prostate. Cancer of the prostate is a common disease, but markedly low incidences are seen in Oriental populations, especially in Japan. As with other tumours, immigration from low-incidence to high-incidence countries is followed by an increased incidence in the migrant population. Although no definite etiologic factors have been established, the isolation of HSV-2 from cells of prostatic cancer and the presence and persistence of CMV virus in cultured human prostatic cells have suggested that these viruses might be involved. The fact that prostatic carcinoma is rare before the age of 50, increases in incidence in subsequent years, is not seen in castrates, and regresses following castration implicates aging and the presence of male hormone as significant factors. Cancer arises in the epithelium lining the prostatic acini and small ducts, and, more rarely, in the main ducts. The majority are adenocarcinomas that tend to infiltrate the organ stroma and break through the capsule to spread to the rectum, the base of the bladder, and eventually to more distant sites by dissemination via lymphatics and blood vessels. Metastases to the bones are quite common and, together with involvement of nerves in the pelvis, are often the cause of considerable pain. Treatments include castration, administration of diethylstilbestrol, and, as the extent of involvement may require, surgical removal, radiation therapy, and chemotherapy.

Uterus. Cancers of the uterus are relatively common and represent about 19 percent of all malignant diseases in women in the United States, as contrasted, for example, to Thailand, countries of the Far East such as Japan, and African countries, where they are relatively rare. The two major types of uterine cancer are adenocarcinoma of the lining of the uterus (endometrium) and squamous-cell carcinoma of the womb or cervix. Endometrial carcinoma has its highest incidence late in the sixth decade. The disease is associated with obesity, diabetes, hypertension, and late menopause. Etiology has not been established; estrogens probably play a significant role. Endometrial cancer spreads both superficially and by invasion of the wall of the uterus. Lymphatic spread occurs late. Inappropriate bleeding from the fifth decade of life onward is an important symptom that must be heeded early if treatment of the disease is to be effective. Treatment of choice is radiation therapy followed by surgical removal, and the cure rate is good. Treatment for disease that spreads beyond the uterus includes hormonal therapy with progesterone and, less frequently, chemotherapy.

Major types of uterine cancer

Squamous-cell carcinoma of the uterine cervix is a somewhat more common disease than endometrial cancer and tends to occur at a younger age, beginning as early as the third decade. A viral etiology is strongly implicated and is supported by a higher incidence of the disease in women who have had an early and active sexual history, including multiple pregnancies. Such cancers are infrequent in women who have not been pregnant and are very rare in celibate women. An early symptom of the disease is abnormal bleeding. The cancers arise in the squamous epithelium of the womb and tend to remain confined to the lining for a number of years in the in situ stage before becoming invasive. Women who have an annual examination, including a Papanicolaou (Pap) test, a painless sampling of cells from the cervix, have an improved chance of early diagnosis. Once the tumour becomes invasive, involving both direct extension and lymphatic metastasis, the prognosis becomes grave. Serious complications, such as infection and eventual failure of the kidneys as a consequence of obstruction and fistula formation, occur in late stages.

Ovary. Cancer of the ovary kills many women of the industrialized countries of the Western world. It is relatively uncommon in Far Eastern countries, especially Japan, and in less developed countries. Immigrants to Western countries show higher incidences about 20 years after their immigration, suggesting the possible role of environmental factors; no firm associations have been established, however. Many different types of ovarian cancer have been identified; they arise either in the epithelium or in connective tissue components, very rarely in both. The most common forms are adenocarcinomas arising in the epithelium. Some of these retain their capacity to produce estrogenic hormones and, more rarely, masculinizing hormones. The tumours may be treated successfully through surgery if they are diagnosed early. Extension of the disease beyond the ovary requires more radical treatment, such as radiation therapy and chemotherapy.

Incidence of cancer of the ovary

Lymphoid tissue. Malignant diseases of lymphoid tissue (lymphomas) are the seventh most common cause of cancer death in the United States, and certain forms are common throughout many countries of the world. In African countries and on New Guinea, Burkitt's lymphoma is common, while in the Western countries it is relatively rare. Certain lymphomas in humans have been closely linked with viruses; other established lymphomas are linked to significant chronic exposure to ionizing radiation and to inherited immunologic deficiency or to such deficiency induced to prevent rejection of organ transplants or resulting from treatment for certain diseases. Malignancies of lymphoid tissue may arise in one or more of the organs rich in such tissue, including the lymph nodes, spleen, bone marrow, and thymus. More rarely they can arise in organs containing small amounts of such tissue, including the stomach, intestines, testis, and breast. Lymphomas are aggressive malignancies that tend to spread to distant organs and become systemic in their distribution. As with other malignant tumours, early diagnosis and aggressive treatment by radiation therapy or chemotherapy, or in many instances the two in combination, have resulted in an increasing number of cures.

Blood-forming tissues. Leukemias are a heterogeneous group of malignancies of the blood-forming (hematopoietic) tissues, which include the bone marrow, lymph nodes, and spleen. The acute form of the disease in adults is rapidly fatal, with infiltration of bone marrow and other hematopoietic tissues by the malignant cells, while the acute form in children has yielded to treatment and a number of cures are documented. The disease has a worldwide distribution, and the best established etiologic factor involves chronic exposure to ionizing radiation. Other factors that have been implicated include congenital disorders associated with increased chromosomal fragility and instability, such as Down's syndrome, Bloom's syndrome, and Fanconi's anemia; viruses; and certain chemicals and drugs. Leukemic cells tend to disseminate through the bloodstream, lodging in blood-forming and other tissues and organs. The cells proliferate to the extent that they often crowd out normal elements of the blood, so that patients afflicted with leukemia are rendered anemic by an interference with red blood cell production or from bleeding because of abnormalities of the blood-clotting mechanisms. They are rendered susceptible to infection by a diminution of the various types of white blood cells, which comprise a major defense system of the body. Treatment involves attempts to correct these complications by transfusion of normal blood and blood products, as well as the use of antibiotics to combat infection and of chemotherapeutic agents to destroy the malignant cells. Chronic, more slow-growing, and less aggressive forms of leukemia may continue for years and may respond favourably to radiation therapy, surgical removal of the spleen, and chemotherapy. In terminal cases leukemia cells either show accelerated growth or are transformed to more primitive cells that tend to disseminate widely and cause death within a few months. (D.G.Sc.)

TREATMENT

Successful treatment of cancer requires the complete removal or destruction of all cancerous tissue. If therapy fails to remove all of the cancer cells, the disease recurs. Surgery and radiation are the most effective forms of treatment. Chemotherapy—treatment with drugs and hormones—has proved helpful in some forms of cancer. The choice of therapy is governed by the type, location, size, and extent of invasion and metastases of the cancer at the time of diagnosis, and by the general condition of the patient.

Surgery. For surgery to be curative, it must be performed before the cancer has spread into organs and tissues that cannot be safely removed. Since the late 19th century increasingly radical operations for cancer have become standard. Despite the increasing extent of these procedures, risk has been reduced by improvements in surgical techniques, anesthesiology, and preoperative and postoperative care, especially in the control of infection. Heart–lung pumps, artificial kidneys, and methods of maintaining electrolyte balance and metabolic equilibrium have permitted patients with impaired cardiovascular and kidney functions or poor general metabolism to survive cancer surgery.

Reconstructive techniques

Major advances have been made in the restoration of structures altered by cancer surgery and in the rehabilitation of people who have undergone radical surgery. Patients undergoing certain surgical procedures for cancer of the colon or rectum, for instance, can be equipped with simple devices for the elimination of solid waste. For patients with cancer of the head and neck, the use of grafting methods and of tissue flaps make it possible to apply reconstructive techniques at the time the cancer is removed.

Rehabilitation of the patient also plays an important role. Women who have extensive surgery for breast cancer are given treatment for restoration of muscle tone needed for movement of the arms. Progress has also been made in teaching new mechanisms of speech to people who have undergone surgical removal of the larynx.

In addition to saving lives by eradicating cancer, surgery also may improve the remaining months or years of life for persons whose cancers cannot be eradicated, restoring comfort and a sense of usefulness. When severe pain accompanies cancer, surgery may bring relief by severing the nerve pathways that carry the painful sensations. In addition, surgery is sometimes necessary to treat abscesses resulting from either the tumour or infection and to relieve intestinal obstructions.

Surgery is also valuable as a preventive measure in controlling cancer. It may be used to eliminate precancerous conditions in the mouth, chronic ulcers (ulcerative colitis) that may lead to cancer of the colon, and certain precancerous polyps in the colon and rectum. It may be used to remove burn scars that may lead to cancer, precancerous nodules in the thyroid gland, and certain precancerous pigmented moles.

Radiation therapy. Radiation therapy makes use of ionizing radiations—X-rays, particles (electrons, neutrons, and pi-mesons), and gamma rays—to destroy cells by impairing their capacity to divide. Although some normal cells are also killed during radiation therapy, this occurrence is minimized by careful shielding of the adjacent areas.

Some cancers do not respond to radiation therapy. The differing sensitivities of various malignant tumours to irradiation are due primarily to the variations in the cells of origin of the tumours. In addition, individual cells within a tumour may have a widely different susceptibility to irradiation. In cancers composed of a variety of cells in different stages of differentiation (*e.g.,* epidermoid carcinoma), even a large dose of radiation may not affect the most differentiated cells. Poor circulation within some tumours decreases their oxygen supply, further diminishing their sensitivity to radiation.

Development of instruments that produce energy in the range of millions of electron volts has permitted extensive use of radiation therapy. Such instruments can deliver a greater radiation dose to deep-seated tumours without the serious skin reactions and discomfort often associated with lower energy X-ray beams. Large areas can be irradiated with more precise definition of the margins and alignment of the beam, less side-scatter, and therefore more protection of adjacent vital structures. The greater versatility of such equipment has made possible the development of treatment techniques involving multiple intersecting radiation beams, rotation of the patient or the radiation source, large fields of radiation shaped to the contours of particular organs, and the pinpointing of beams for cancers of the eye and the larynx. Because of their increased usefulness, instruments (linear accelerators, betatrons, and radioactive cobalt-60 teletherapy apparatus) have become standard instruments for radiation therapy of deep-seated cancers.

Chemotherapy. Chemotherapy can cure certain forms of cancer. Cancers frequently cured by drugs include choriocarcinoma, a rare, highly malignant tumour that originates in the placenta; acute leukemia of childhood; and Burkitt's lymphoma. Treatments with combinations of drugs have produced long-term, disease-free remissions in many children with acute leukemia and in persons with advanced stages of Hodgkin's disease. Some of these patients have been in remission longer than five years and may, in fact, be cured.

Multiple carcinomas of the superficial layers of the skin have been eradicated after the application of certain cancer-drug ointments to the skin. Wilms' tumour, for example, is often curable when cancer drugs are used in combination with surgery and radiation. Many other forms of cancer benefit temporarily or partially by chemotherapy. Some cancers are resistant to drugs, however.

Problems with chemotherapy

Most cancer drugs are limited in their usefulness. One problem is that only a certain proportion of cells is dividing at any one time, and most cancer drugs can destroy only that part of the cell population undergoing division. Another problem is that cancer drugs damage normal, as well as cancer, cells and tissues. In addition, some cancer cells eventually become resistant to drugs. To help overcome these difficulties, combinations of chemotherapeutic agents that act on cells in different ways have been used in various treatment programs simultaneously or in sequence. This allows cancer cells at different stages of division to be killed, causes less damage to normal cells, and diminishes the tendency of malignant cells to become resistant to a single drug.

Special measures have been developed to protect persons undergoing cancer chemotherapy from the combined effects of the drugs and the disease. Refinements in the transfusion of blood platelets permit multiple transfusions in leukemia patients with critical platelet deficiencies caused either by leukemia or drug toxicity. During periods when a patient's white blood cells are depleted, administration of antibiotics offers protection from many infections. Relatively germ-free environments, such as specially designed hospital rooms, provide sterile atmospheres to protect against fatal infection. Transfusion of type-matched white blood cells, and, more recently, transplantation of bone marrow cells from carefully matched donors, have also been of value in protecting persons with nonfunctioning bone marrows against infections. (C.G.B./D.G.Sc.)

Experimental treatments. Since the 1970s considerable effort has been expended toward the development, control, and elimination of cancer by immunotherapy. Methods have involved the use of immunotherapeutic agents such as Bacille Calmette-Guérin (BCG), a vaccine against human tuberculosis; killed suspensions of several types of bacteria; chemical products isolated from certain bacteria; and interferon, a family of proteins that inhibit the growth of viruses. All of these substances appear to stimulate the immunologic defense system. It may someday prove possible to cure cancer by manipulating the complex immunologic mechanisms of the host.

Hyperthermia

A second experimental approach involves the use of hyperthermia (high temperature). Research indicates that cancer cells are more sensitive to the killing effects of high temperature than are their normal counterparts. The success of treatment by hyperthermia appears to depend on the development of new instrumentation that will allow the application of highly localized heat to the site of a tumour.

Two developments in radiation therapy that may add significantly to its effectiveness include the use of chemicals that greatly sensitize tumour cells to the damaging effects of ionizing radiation, while not affecting normal cells, and the application of particle-beam radiation therapy, using beams of protons, helium ions, and heavy ions of such isotopes as carbon-12, neon-20, and argon-40. Such beams have sufficiently high energy to penetrate deeply into tissues; they do more damage to malignant cells than do the less energetic forms of ionizing radiation administered at the same dosages. Such developments may allow treatment of deep-seated tumours without significantly damaging overlying normal tissues. (D.G.Sc.)

Canton

The largest city of South China, Canton lies near the head of the Pearl River Estuary (Chu Chiang K'ou), more than 90 miles (145 kilometres) inland from the South China Sea and the British crown colony of Hong Kong. Although the city is commonly known as Canton to Westerners—a name that derives from that of Kwangtung Province, of which it is the capital—the true Chinese name of the city since the 3rd century AD has been Kuang-chou (Guangzhou in Pinyin). Because of its position at the meeting point of inland rivers and the sea, it has long been one of China's main commercial and trading centres. It has served as a doorway for foreign influence since the 3rd century AD and was the first Chinese port to be regularly visited by European traders. The city is also a historic centre of learning and, as a centre of political activity for the Chinese Nationalist leader Sun Yat-sen, it was the cradle of the Chinese revolution.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

The city site. The city proper of Canton lies within the county (*hsien*) of P'an-yü, although the municipality (*shih*) of Kuang-chou embraces P'an-yü and several additional counties. The main part of the city is situated on the north bank of the Pearl River, which branches off the Hsi Chiang ("West River") and forms the northern border of the immense Pearl River, or Canton, Delta (*san-chiao-chou*) to the south.

Most of Canton lies to the south of Pai-yün Shan (White Cloud Mountain), which rises to 1,253 feet (382 metres) above sea level about four miles from the city centre. At the southern extension of the Pai-yün Shan are the Yüeh-hsiu Shan, on which the earliest known inhabitants of the region lived. Archaeological work has revealed that the site of the city during the Ch'in (221–206 BC) and the Han (206 BC–AD 220) dynasties was slightly north of the modern urban centre. Later, the city expanded southward as river-borne silt and sand were deposited and the Pearl gradually became narrower.

Urban renewal

Old Canton was a crowded city of narrow streets and winding alleys. A vigorous modernization program was carried out in the 1920s and 1930s, during which wide streets were built, modern sewers introduced, arcades constructed for sidewalk shops, and numerous parks created. New dikes built along the Pearl allowed the city to expand southward to its present waterfront. Limited by hills to the north and by numerous waterways to the west, Canton's subsequent expansion has been mainly into the low plains to the east.

Climate. Canton has three seasons. From April through October, the summer season is wet, hot, and humid; south and southwest winds are often accompanied by typhoons, which are seldom destructive. The July mean temperature is 83° F (28° C). Winter lasts from October through early February and is mild and free of snow; the January mean temperature is 56° F (13° C). The third season, from February through mid-April, is a period of transition that is marked by muggy weather. The average annual rainfall is 64 inches (1,625 millimetres), and farmers in the surrounding country enjoy a year-round growing season.

City districts

The city layout. Canton stretches along a waterfront, which runs east and west along the Pearl. Both the Old City (dating to the Ming dynasty and now mostly in the Yüeh-hsiu district) and the districts of Li-wan to the west and Tung-shan to the east are located on the north bank. Since the demolition of the city walls in the 1920s, these sections have become one city. On the south bank are the industrial suburbs of Hai-chu to the south and Hua-ti to the southwest. Another industrial section is located in the northwestern suburb of Hsi-ts'un.

The Yüeh-hsiu district is the commercial centre of Canton as well as the site of provincial and municipal government offices. To the north is Yüeh-hsiu Park, the largest of the city's parks. Within the park are artificial lakes, a five-story red pagoda (built in 1380) that now houses the Canton Municipal Museum, a flower exhibition hall, the Sun Yat-sen Memorial Hall (1931), and sports and recreational facilities. To the west of the park is the Canton Foreign Trade Centre (formerly the Exhibition Centre), from 1956 the site of the Chinese Export Commodities Fair (also called the Canton Trade Fair). The main north–south thoroughfare of the city, Chieh-fang Lu (Liberation Avenue), is intersected in the centre of Canton by the east–west Chung-shan Lu (Sun Yat-sen Avenue). The Peasant Movement Institute, which flourished in the mid-1920s under Mao Zedong's leadership, is located near the city centre. Also in the central part of the district are the Huai-sheng Mosque (built 627), considered to be the oldest mosque in China; the Buddhist Liu-jung Ssu ("Temple of the Six Banyan Trees"), founded in the 5th century, and its nine-story Hua T'a ("Flower Pagoda"); and the Gothic Roman Catholic Cathedral, built in 1860. The district includes the city's major hotels, department stores, and cinemas; traditional Chinese buildings rarely are found except in the hills to the north. Skyscrapers line the banks of the Pearl in the downtown area and ring Hai-chu Square, a huge open space by the river.

Li-wan district, as part of the Old City, has retained traditional-style housing alongside modern buildings. Li-wan Park is located in the southwest part of the district, while to the northeast is Liu-hua Park. To the south, Sha-mien, a tiny island in the Pearl and once an exclusive enclave of the British and French, is noted for its Western-style mansions.

Tung-shan district, east of central Canton, is predominantly residential; many government officials and repatriated Chinese live there. Located in the district are the Martyrs Memorial Park, dedicated to those killed in the uprising in 1927 against the Kuomintang (Nationalists) and a mausoleum for 72 people who lost their lives in an unsuccessful revolt against the Ch'ing dynasty in 1911. Many of the city's institutions of higher learning are located in the district.

South of the Pearl is Hai-chu district. It is characterized by modern residential quarters and industrial centres. The Sun Yat-sen University (founded 1924) is located there.

THE PEOPLE

Canton is one of the most densely inhabited areas in China; most of its residents live in the central district of the city. The people, called Cantonese, speak a dialect of Chinese that is distinctively different from Mandarin. The earliest inhabitants, of Tai or Shan origin, were assimilated by the Chinese (Han) long ago. There are, however, small groups of Manchus and Chinese Muslims (Hui) in the city. A notable demographic feature is the large number of "overseas Chinese" who emigrated to Southeast Asia, the United States, Europe, and other parts of the world. Since the early 1980s, many of them have returned and resettled in and around Canton.

THE ECONOMY

Industry. Since 1950 there has been substantial expansion of such light industries as the manufacture of electronics, textiles, newsprint, processed food, and firecrackers. Heavy industries include the production of machinery, chemicals, iron and steel, and cement, as well as shipbuilding. Smaller plants have also been developed for the manufacture of consumer goods. Canton is celebrated for its many handicraft products, including ivory carvings, jade objects, embroideries, fans, porcelain, and paper umbrellas. Since the late 1970s there has been considerable foreign investment in Canton, and the city has become one of China's principal tourist attractions.

Handicrafts

Trade. Canton is the centre of the trade of Kwangtung and Kwangsi and the adjacent provinces of South China. Products such as sugar, fruits, silk, timber, tea, and herbs are exported, whereas manufactured goods and industrial equipment are transshipped via Canton into the interior. The semiannual Chinese Export Commodities Fair has become an institution of world trade.

Transportation. Buses, bicycles, and automobiles are the principal means of transportation; the city has some of the worst traffic congestion in all of China. The delta is blessed with innumerable canals and creeks; the smaller canals are used by sampans (flat-bottomed boats propelled by oars) and the larger by steamers or motor launches. Canton is a terminus of inland navigation and is also the focal point of coastal and ocean navigation. The port facilities at Canton and at Huang-pu, 12 miles downstream and now a district of the city, have been expanded to accommodate larger vessels.

Canton is served by railroads linking it to Peking, Kowloon, and San-shui (at the confluence of the Hsi Chiang and the Pearl). Kwangtung is the nation's most advanced province in highway development. Major arterial roads link Canton with other large cities in Kwangtung and with Macau. The city's international airport, north of the city, is the largest in southern China.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Canton's municipal government is part of the hierarchical structure of the Chinese government—and the parallel structure of the Chinese Communist Party—that extends from the national organization, through the provincial apparatus, to the municipal and, ultimately, neighbourhood levels. The principal responsibilities of the Canton Municipal People's Congress, the major decision-making body, include issuing administrative orders, collecting taxes, determining the budget, and implementing economic plans. A standing committee selected from its members recommends policy decisions and oversees the operation of municipal government. Executive authority rests with the Canton People's Government, the officers of which are elected by the congress; it consists of a mayor, vice mayors, and numerous bureaus in charge of public security, the judicial system, and other civil, economic, social, and cultural affairs.

The city is divided into districts (*ch'u*), each of which has a district mayoralty. Under the district, there are police substations and street mayoralties. Neighbourhood associations have various functions, including mediating disputes, conducting literacy campaigns, supervising sanitation and welfare, and promoting family planning.

Health. Health conditions have improved dramatically during the 20th century. Epidemics have been eliminated through the control of disease-carrying pests. The city has many fine hospitals, of which one of the best known is the Kwangtung Provincial People's Hospital.

Education. Canton is one of China's most progressive cities regarding education. In addition to a large number of kindergartens, primary schools, and middle schools, it has many institutions of higher learning, including Sun Yat-sen University, Chinan University, Sun Yat-sen Medical College, Canton College of Traditional Chinese Medicine, Canton Institute of Mechanical Engineering, and South China Institute of Agriculture.

CULTURAL LIFE

Canton is a vibrant city. Large tracts of parkland, many of them created since 1949, help give the city its characteristically lush appearance and provide the citizenry with a wide variety of recreational facilities. The colourful flower show held during the annual Spring Festival is a major highlight. Although the Cantonese are increasingly aware of the modern life-style of Hong Kong, they also prize their historical and cultural roots. Throngs of people are usually found visiting the city's many museums and monuments of historical importance, and productions of Cantonese opera and music are well attended. The Sun Yat-sen Library of Kwangtung Province, with one of the largest holdings in China, has an extensive collection of vernacular-language works. The vitality of the Cantonese is exemplified by their passion for food. Cantonese cuisine is world-renowned, and the city's hundreds of restaurants offer a seemingly endless variety of dishes.

History

THE EARLY PERIOD

The earliest known inhabitants of the Canton area were the Pai Yüeh, a Tai, or Shan, people. At the beginning of the Western Chou dynasty (*c.* 1111–771 BC), their chief built a walled town, known as Nan-wu Ch'eng, in the northern section of the present-day city. In 887 BC the town was taken by the mid-Yangtze kingdom of Ch'u and was known as Wu-yang Ch'eng ("City of Five Goats").

Under the Ch'in dynasty Canton was made the capital of Nan-hai prefecture. Upon the fall of the Ch'in, Gen. Chao T'o (died 137 BC) established an autonomous state known as Nan Yüeh, which was annexed in 111 BC by the Han dynasty. For the next 300 years Chinese assimilation of the Yüeh people proceeded, and integration of the region into the empire took firm root.

During the four centuries from the Three Kingdoms to the founding of the T'ang dynasty in AD 618, when North China was overrun by "barbarian" invaders, Canton remained a part of the Chinese regimes based in Nanking. During this period the city grew in wealth and population; Buddhist temples were erected, and a flourishing community was maintained by Arab and Hindu traders. Peace and prosperity were further augmented under the T'ang (618–907). An auxiliary wall and settlement were built on Yü Hill, but the city suffered much destruction during the civil strife at the end of the dynasty.

Under the Sung dynasty (960–1279) the increase in Canton's population and the growth of foreign trade made it necessary to enlarge the city. A second auxiliary wall and settlement were constructed on P'an Hill in the late 11th century. With the settlements on the twin hills, the city took on the name P'an-yü (hence the name of the county in which Canton is now located). Under the Southern Sung (1127–1279) Chinese seamen and traders sailed to Southeast Asia, thus opening the way for Chinese emigration abroad in subsequent ages. In the late 13th century and throughout the 14th, many Chinese families from North China moved into the Kwangtung region in the wake of the Mongol conquest. A booming economy resulted as the Yüan rulers (1206–1368) encouraged maritime trade and kept Chinese-Mongol race relations under control.

Period of expansion

Under the Ming dynasty (1368–1644) the city underwent considerable rebuilding and expansion. In 1380 the P'an and Yü hills were razed, and the old town and the two auxiliary districts were combined into one large walled city. In 1535 an outer wall was added to incorporate the new commercial districts on the north bank of the Pearl. Meanwhile, the pattern of foreign trade changed as the supremacy of the Arabs ended with the coming of the Europeans. The Portuguese sent their first embassy to Canton in the early 1500s, followed by the Dutch and the British in the 17th century.

Canton came under the rule of the Ch'ing (Manchu) dynasty from 1644 to 1911/12. Recognizing the importance of the city, the government made it the capital of the Viceroyalty of Kwangtung and Kwangsi. The British East India Company established a "factory" (foreign traders' residences and business offices) in Canton in 1685, and annual trading operations began in 1699. Throughout the 18th century French, Dutch, American, and other nationals also established trade relations with the city; the "13 factories" were located on the waterfront.

Trade moved without undue difficulty until friction began to mount in the 1820s. The foreigners found trade restrictions (through licensed Chinese merchants known as Cohong) too irksome, while the Chinese authorities refused to open normal diplomatic relations. The Chinese seized and destroyed large quantities of illegal opium brought in by the British in 1839, and in retaliation the British attacked Chinese positions in the Canton Estuary. The first Opium War (1839–42) ended in humiliating defeat for China, and the city saved itself from destruction only by paying a $6,000,000 ransom.

The Treaty of Nanking (1842) with the United Kingdom opened Canton as a treaty port. In 1844 the French and the Americans obtained similar treaties. Antiforeign sentiment, however, ran high, and the city refused to open its gates until 1857. The coolie trade and the use of foreign flags to protect pirates caused several crises. The second Opium (or "Arrow") War broke out between China and Britain and France in 1856. Canton was occupied by Anglo-French forces until 1861, and Sha-mien was made an Anglo-French concession in 1859.

Amid the woes of foreign imperialism, Canton was deeply shaken by the great antidynastic outbreak of the Taiping Rebellion (1850–64), the leader of which, Hung Hsiu-ch'üan, was born in the northern Canton suburb of Hua-hsien. Many followers of Hung formed secret societies that kept his revolutionary ideals alive even after the failure of the rebellion. For the next 50 years anti-Manchu agitation formed one of the twin forces that gripped Canton; the other was the rise of nationalism.

THE MODERN CITY

Canton came under the spell of its most illustrious son, Sun Yat-sen, from 1885 to 1925. Sun made the city the testing ground for his campaign to overthrow the Manchu dynasty and to establish a Chinese republic. The Canton Uprising of 1911 paved the way for the success of the revolution before the end of the year. Canton became the base of operations for action against the warlords between 1916 and 1925 and served as the headquarters of Sun's party, the Kuomintang. Besides completing his Three Principles of the People, Sun reorganized the Kuomintang in 1924 to reactivate the Nationalist revolution. All manner of people flocked to Canton—the right- and left-wing members of the Kuomintang, the members of the newly formed Chinese Communist Party, and Soviet advisers. Chiang Kai-shek, Mao Zedong, and Zhou Enlai began their careers in Canton under Sun's tutelage.

Headquarters of the Kuomintang

Chiang gained power when he crushed an uprising by the Canton Merchants Volunteer Corps and defeated the disloyal local warlords (1924). With Sun's death in 1925, however, Canton was embroiled in the power struggle between the Communists and the Nationalists. In 1927 a Communist-led coup attempted to set up a workers' government in the city, only to be crushed by Chiang. From 1928 to 1937 Canton was officially under the control of the Nationalist government, but it was actually controlled by independent leaders, who criticized Chiang's dictatorship and threatened secession from Nanking. In 1937, when war against the Japanese broke out, Canton became a prime target of Japanese air raids. Canton fell in 1938 and remained under Japanese occupation until 1945. Recovery did not begin until the Communist government took control in 1949. The modernization begun in the 1920s continued, although there were periods of hardship during the Great Leap Forward (1958–60) and Cultural Revolution (1966–76). New housing and government offices have been built, heavy industry has been introduced, and the city has developed into one of China's centres of foreign trade.

Post-1949 period

Cape Town

The city of Cape Town (Afrikaans: Kaapstad) is the legislative capital of the Republic of South Africa and the capital of Cape Province. The city lies at the northern end of the Cape Peninsula some 30 miles (50 kilometres), at its southernmost boundary, north of the Cape of Good Hope. Because it was the site of the first European settlement in South Africa, Cape Town is known as the country's "mother city."

Cape Town has a beautiful setting: parts of the city and its suburbs wind about the steep slopes of Table Mountain (3,563 feet [1,086 metres] high) and neighbouring peaks and rim the shores of Table Bay; other parts lie on the flats below the slopes or stretch southward across the flats to False Bay. The city covers an area of 116 square miles (300 square kilometres).

This article is divided into the following sections:

Physical and human geography

THE CHARACTER OF THE CITY

The city of Cape Town had its origin in 1652 when the Dutch East India Company established a refreshment station for its ships on the shores of Table Bay. The location was magnificent, on well-watered, fertile soil, beneath the precipitous walls of Table Mountain. The indigenous inhabitants provided cattle but not labour, and the company imported slaves, mainly from East Africa, Madagascar, and the Bay of Bengal area. The slaves brought with them something of their culture and, especially the Muslims from the East Indies, their religion. Miscegenation of brown, black, and white took place, but strong racial and ethnic characteristics remained. In 1781 the French established a garrison to help the Dutch defend the city against British attack, and the French presence influenced local architecture and culture. British occupation in the 19th century brought new parliamentary and judicial concepts and freedom for the slaves. Cape Town was the gateway to Europe's penetration of the South African interior, and close ties with continental Europe were maintained.

Today Cape Town is a modern city with high-rise office buildings and pedestrian malls. Although it is a major political and economic centre, its reputation still rests on its beautiful situation between mountain and sea, its cosmopolitan population, and the liberal outlook of many of its citizens.

THE LANDSCAPE

The city site. The first settlement of Cape Town was situated between Table Mountain and Table Bay. It was bounded on the northwest by the ridges known as Lion's Head and Lion's Rump (later called Signal Hill), on the north by Table Bay, on the south by Devil's Peak, and on the east by marshlands and the sandy Cape Flats beyond. The nearest tillable land was on the lower eastern slopes of Devil's Peak and Table Mountain and, farther to the southeast, at Rondebosch, Newlands, and Wynberg. From the fortress that protected the settlement, a track led south past these lands to False Bay on the eastern side of the Cape Peninsula and on beyond Muizenberg and Kalk Bay to Simon's Bay, where the East Indiaman trade ships could find shelter from northwesterly winter gales. The constraints of mountain, sea, and sand shaped the direction of Cape Town's growth, and the pattern was followed in subsequent road and rail construction. A railway line reached Wynberg in 1864 and Muizenberg in 1883, and another line ran eastward from Cape Town across the Flats to the interior.

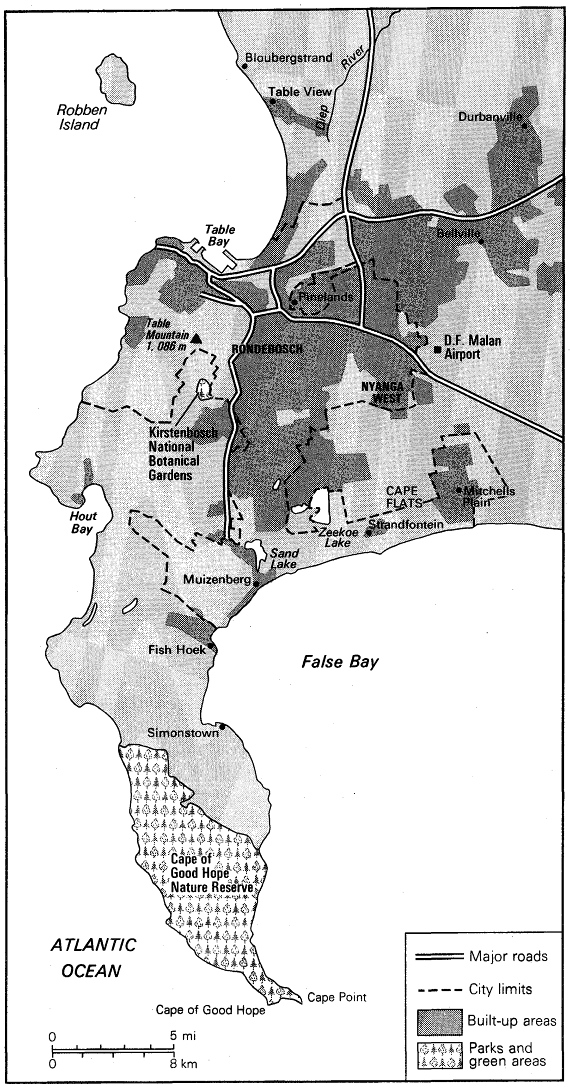
Climate. The climate of Cape Town is Mediterranean in type; it is locally modified by the mass of Table Mountain and by the cold Benguela Current of the South Atlantic. The average high temperature is 70° F (21° C), in January and February, and the average low is 55° F (13° C), in July, but temperatures are cooler on the mountain slopes and on the coast. Freezing occurs infrequently. On the average, rain falls on 69 days of the year; about half of the 26 inches (660 millimetres) of annual rainfall occurs between June and August, the southern winter. The amount of rainfall varies with proximity to the mountain, those areas close to the slopes receiving as much as twice the precipitation of areas farther away. The winds, generally strong, come from the northwest in winter and vary from between southeast and southwest in summer. Southerly winds produce a cloud covering of condensed moisture over Table Mountain known as the "tablecloth." These winds are collectively referred to as the "Cape doctor" because they keep air pollution at a low level.

The "Cape doctor"

The city layout. The narrow streets of the early settlement ran parallel to the shore. The road that led from the shore inland to the Company's produce garden became the main thoroughfare. Originally called the Heerengracht, after the canal in Amsterdam of that name, it was renamed Adderley Street in 1850. Other main roads paralleled it as the town grew. In Strand Street, on what once was the shore of Table Bay, stands the Castle of Good Hope, built by the Dutch East India Company between 1666 and 1679. Near the Castle are the Botanic Gardens, which are bisected by Government Avenue and overlooked by government buildings. A parliament building, constructed for the use of the colonial government and first occupied in 1885, became the seat of the Parliament of the Union of South Africa in 1910 and of the Republic of South Africa in 1961. Additions to the building were opened in 1987.

The opening of the Alfred Dock in 1870 led to renewed development along the shore. The breakwater was lengthened and piers were built in 1890–95, and the newly sheltered area was named Victoria Basin. Dredging for the Duncan Dock, built between 1938 and 1945 to accommodate larger vessels, and for the Ben Schoeman Dock in 1977, resulted in the reclamation of 480 acres (194 hectares) along the shore, referred to as the Foreshore. Adderley Street was extended to the new harbour, and the extension was named the Heerengracht.

The building of a modern system of freeways has greatly facilitated communication between the city and its suburbs. There has been a considerable increase in population and commercial activity in the southern suburbs, especially in Claremont and Wynberg. Particularly favoured



Cape Town and surrounding area.

residential areas are on the slopes east of Table Mountain and on the slopes of Signal Hill, overlooking Bantry Bay and the beaches of Clifton.

Architecture

Much of Cape Town's early architecture reflected prototypes from the Netherlands that were modified for the region. Characteristics included flat roofs, projecting porches, and distinctive gables. Louis-Michel Thibault, a French architect who arrived in 1783, designed much that was then fashionable, including the Old Supreme Court building, now the South African Cultural History Museum. Notable buildings of the period include the Old Town House and the Lutheran Church. Of the original Groote Kerk (Great Church), opened in 1704, only the steeple and vestry remain; the rest was rebuilt in the 1830s. Today, buildings in the central business district and on the Foreshore follow modern international trends in architecture.

THE PEOPLE

Cape Town's population is subject to South Africa's racial classification system, which recognizes the white group, the black group, the Coloured group (legally defined as any person who is not a member of the white group or the black group), and the Asian group (Indians and Chinese). More than half of the residents of the city and metropolitan area are Coloured, about one-fourth are white, about one-fifth are black, and the remainder are of Asian origin. In the metropolitan area Afrikaans is the first language of almost one-half of the Coloureds and whites. Almost one-quarter speak English as a first language, and another quarter are equally at home in both languages. The blacks are predominantly Xhosa-speaking. The majority of the residents are members of Protestant churches, but there are also sizable communities of Roman Catholics and Muslims.

South Africa's Group Areas Act of 1966 consolidated earlier acts aimed at enforcing the policy of racial segregation known as apartheid, and it provided for the reservation of certain areas for residence and occupation by specific racial groups within the population. The act brought about many changes in Cape Town's residential areas. For example, a mixed but predominantly Coloured neighbourhood known as District Six, south of the Castle, was cleared by bulldozers. Special legislation permitted Coloureds who were living in Cape Town's Malay Quarter to remain, but other Coloured and Asian families were forced to move to designated areas, mostly east of the Cape Town–Muizenberg railway line and onto the Cape Flats. According to figures submitted to Parliament, by the end of 1980 some 29,300 Coloured and 1,500 Indian families, but only 195 white families, had been resettled on the Cape Peninsula. Because housing in the prescribed areas was inadequate, in 1975 the city undertook construction with government funding of a model township of 40,000 houses for Coloured families at Mitchells Plain, southeast of the city. Indian families were installed at Rylands and Pelikan Park. In 1990 the government did an about-face over District Six, opening it to residence by all sections of the Cape Town community.

Government legislation controls the presence and employment of blacks outside their designated black states (homelands). Nearly all blacks in Cape Town are confined to Guguletu and Nyanga West within the city limits and to neighbouring Nyanga and Langa. With the abolition of influx controls in the 1980s, a great movement of blacks into Cape Town and other urban areas from impoverished black states began, and camps of squatters were soon overcrowded. The government established a township for blacks at Khayelitsha, east of Mitchells Plain, and squatter camps were then demolished in 1986 in an attempt to direct the blacks there.

THE ECONOMY

Industry and commerce. Cape Town was South Africa's economic base until the discovery and exploitation of minerals in the interior; today it is one of the nation's most important industrial centres and a major seaport. About 90 percent of the fish eaten in South Africa is distributed through Cape Town, and Table Bay is one of the world's largest fruit-exporting harbours. A petroleum refinery and chemical, fertilizer, cement, and automobile-assembly factories are situated in the metropolitan area. In the city the basic industries are connected with ship repair and maintenance, food processing, and wine making and with the manufacture of clothing, plastics, and leather goods. Tourism is of growing importance.

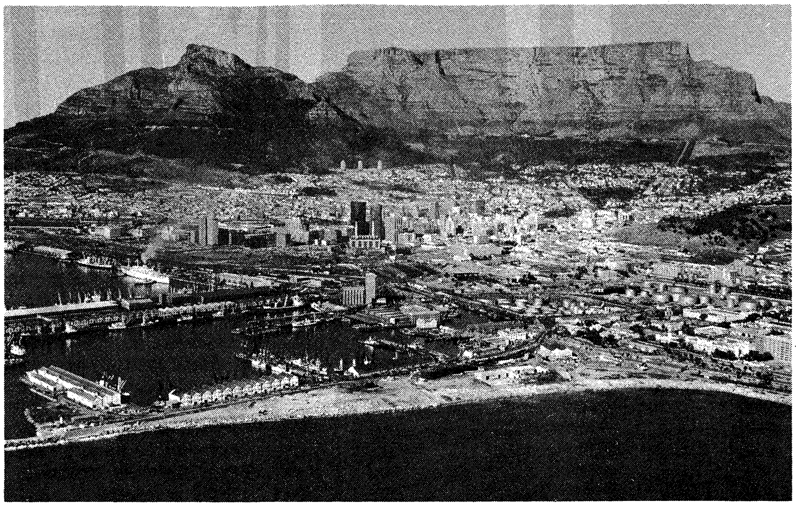
Major industries

Cape Town is well served by department stores and supermarkets. A number of nationwide commercial concerns have their head offices in Cape Town, including oil and insurance companies.

Transportation. The port of Cape Town handles some 5,000,000 tons of cargo annually. The port does not admit ships of more than 40-foot draft at low tide, but its repair facilities and dry dock are important to interoceanic traffic. The Ben Schoeman Dock accommodates container traffic.

The D.F. Malan Airport has regular flights to Europe and South America. The bulk of its flights, however, are domestic. Cape Town is the terminus of a railway network that extends northward to Zimbabwe and beyond.

Two main radial freeways lead southward to False Bay. Supplementing these are two national routes and a beltway circling the central business district. An elevated freeway extends across the city's shore area. Most whites and the more prosperous Coloureds and blacks own motor vehicles. Public transport is particularly important for those forced by law to live far from their place of employment. Spoornet, which operates suburban trains, and a private bus company serve the Cape Town area. There also are minibuses that provide cheap, fast transportation.



Cape Town on Table Bay. Devil's Peak is on the left, Table Mountain on the right.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. The city council consists of two councillors from each of 17 wards, elected by adults owning or occupying property. The mayor has largely ceremonial duties, and an executive committee of council members is directly responsible for the administration of the city. Some council decisions are subject to appeal to the administrator of the Cape Province, who assumed the powers of the provincial council upon its dissolution in 1987. At that time local government fell under the Regional Services Council of the Western Cape, on which the Cape Town city council was obliged to serve, although it did so under protest as the Regional Services Council was constituted along apartheid lines.

At one time there were no racial bars in Cape Town, and both whites and nonwhites could vote and hold office. In 1972 (when there were six nonwhite councillors) national legislation removed nonwhites from the electoral rolls against protests from the citizens. The municipality has continued to oppose apartheid legislation and in 1985 formally reiterated its belief that all people, regardless of race, colour, or creed, have the democratic right to participate fully in the affairs of the city and its council. A peaceful protest march of some 40,000 people in September 1989 helped to create the climate for similar marches in other parts of South Africa and for the subsequent release from prison of black nationalist leader Nelson Mandela and for moves away from the system of apartheid.

Services. Most of Cape Town's electricity is produced at the national Electricity Supply Commission's nuclear power station at Koeberg, north of the city. Cape Town has its own coal-fired power station and two gas turbines to assist in emergencies and at peak periods. A hydroelectric facility at Steenbras also generates power when needed. The city's water, which once came from dams on Table Mountain and at Steenbras, now also comes from Riviersonderend, Voëlvlei, and Wemmershoek. The city provides ambulance, fire, and other services to nearby municipalities and local authorities, including black squatter camps, when requested and permitted.

Sources of water

Health. The city's Health Department offers comprehensive health services and runs a system of polyclinics and specialized clinics. The major medical problem in Cape Town, as in every urban centre in South Africa, is pulmonary tuberculosis, a disease that is spread easily where nutrition and hygiene are poor and housing is overcrowded. Public hospitals are the responsibility of the broader provincial administration. Groote Schuur Hospital, where the world's first heart transplant took place, is one of South Africa's largest hospitals. There are other smaller provincial hospitals and an increasing number of private hospitals in the city.

Education. The provincial administration is responsible for the schooling of whites; schooling for blacks is provided by a central government department. Education for Coloureds and Indians is the responsibility of the national House of Representatives (the Coloured house of the parliament) and the House of Delegates (the Indian house of the parliament). Private schools are permitted to accept students of all races, but the fees are high. In 1990 provision was made for the opening of some provincial schools on certain conditions to all races.

The most renowned institution of higher learning is Diocesan College (founded in 1849), located in Rondebosch. The University of Cape Town, also in Rondebosch, developed from South African College (founded in 1829) and formally came into being in 1918. The university has always demanded the right to admit students of all races, conditional only on the basis of academic merit, and an increasing number of nonwhites are being accepted. Lack of space and funding, however, has caused the university to restrict its growth. The University of the Western Cape, originally built to serve the Coloured community, is located in the nearby municipality of Bellville. The facilities of the Cape College for Advanced Technical Education are being centralized in new buildings in District Six; the first complex was opened in 1987. Many residents of the city, especially nonwhites, receive academic degrees through correspondence courses offered by the University of South Africa.

CULTURAL LIFE

The South African Cultural History Museum controls several satellite museums, including Groot Constantia (the manor house built by Governor Simon van der Stel in about 1685), the 18th-century Koopmans de Wet House, the Bo-Kaap Museum (a reconstruction of a Cape Muslim house), the Bertram House (Georgian), and, in the old harbour area, the South African Maritime Museum. There are several collections of art. The William Fehr Collection in the Castle of Good Hope displays paintings and prints related to Cape history, as well as Cape antique furniture, silverware, and glassware. At Rust en Vreugd, an 18th-century house near the Castle, another part of the Fehr Collection displays watercolours and prints of historical interest. Paintings by European masters are on exhibit at the Old Town House, and modern and contemporary paintings are on view at the South African National Gallery. The South African Museum, with extensive additions opened in 1987, is devoted mainly to natural history.

The Fehr Collection of art

The Cape Town Symphony Orchestra was for some time the only municipal orchestra in South Africa. The Cape Performing Arts Board, based in the Nico Malan opera-house-and-theatre complex, has a permanent orchestra, soloists, and chorus. It is known for its opera and ballet productions. The Baxter Theatre, opened in 1977 on the campus of the University of Cape Town, contains a theatre, a concert hall, and a studio theatre, and stages as many as 1,000 performances a year.

Sports and recreation

The cricket and rugby grounds at Newlands are the traditional homes of these sports in South Africa. Soccer matches are held in the Hartleyvale and Green Point stadia, which are also used for cycling and other sports. National tennis competitions are held in Rondebosch. The Good Hope Centre, designed by the 20th-century Italian architect Pier Luigi Nervi, is used for exhibitions, indoor tennis, boxing, and wrestling. Squash courts are located at the University of Cape Town's indoor sports centre. A race track and four golf courses lie within the city boundaries. Zeekoevlei and Sandvlei, two lakes in the southeast near False Bay, are popular for water sports, especially sailing and windsurfing (board sailing). Cape Town's harbour is an important base for yachting; many international yachting events are hosted there. The city has numerous public swimming pools, and its beaches, open to all races, are popular. Table Mountain and the mountains above Muizenberg provide hiking and climbing for nature lovers and mountaineers. The National Botanic Gardens at Kirstenbosch flank a boundary of the city.

History

The first European to anchor at Table Bay and climb Table Mountain was the Portuguese navigator António de Saldanha. He encountered a few hundred indigenous inhabitants, a Khoikhoin people whose economy was based on herding, hunting, and gathering. After Saldanha's visit, European ships continued to put in at Table Bay to take on fresh water, meat, and other provisions. Survivors of the Dutch vessel *Haerlem,* wrecked in Table Bay in 1647, brought back such glowing reports of the region that the directors of the Dutch East India Company ordered that a station to supply ships rounding the Cape be established there. On April 6, 1652, the company's representative, Jan van Riebeeck, stepped ashore to select sites for a fort and a vegetable garden. In 1657 the company began to release men from its employ so that they could become free burghers and farmers, and in 1658 the company began to import slaves. Inland from Table Mountain, a second company farm was established at Newlands, and vines were planted on the slopes of Wynberg ("Wine Mountain").

Van Riebeeck and his senior officials constituted a council of policy and court of justice. Free burghers were invited to join the court when matters concerning burghers were at issue, and burgher-councillors eventually took responsibility for services such as fire protection, road maintenance, and the preservation of order. The colony began to spread beyond the Cape Peninsula, and the council of policy came to rely increasingly on the burgher-councillors for fact-finding and for advice on town affairs.

The importation of slaves, the introduction of political exiles from the Dutch East Indies, and miscegenation with indigenous Khoikhoin (whom the Dutch called Hottentots) increased the population, but at the beginning of the 18th century the town, known as De Kaap ("The Cape"), still consisted of only 200 houses. Its growth was accelerated by rising international tensions and growing appreciation of the strategic importance of the Cape. During the Seven Years' War (1756–63), in which the major European powers were involved, many French and British ships called at the port, which from 1773 onward was referred to by British visitors as "Cape Town." During the U.S. War of Independence, which exacerbated tensions between rival European powers, a British fleet sought in 1781 to occupy the Cape, which directors of the English East India Company described as "the Gibraltar of India." A French fleet, however, reached the Cape first and established a garrison there to help the Dutch defend it. The French presence brought prosperity and gaiety to Cape Town and initiated a surge of building.

Garrisoned by the French

Suburban development, largely inland to the east and down the Cape Peninsula to the south, followed the radial roads and the railway line, construction of which began in 1859. The Alfred Dock, opened in 1870, encouraged shipping. An influx of people followed the discovery inland of diamonds in 1870 and gold in 1886. These developments, as well as the South African War (1899–1902) between Britain and the combined forces of the Boer Republics, brought about a modest industrialization in Cape Town.

The years after World War II were marked by increased urbanization and by enormous growth in both industry and population. The harbour and industrial sites were extended again, and modern buildings rose in the central business district. Handsome residential areas spread along the lower mountain slopes, and modern freeways were constructed.

The degree of local control over Cape Town's affairs has varied considerably throughout its history. Burgher representation on the council increased to six, and from 1785 onward a committee of three burghers and three officials formally advised the council on urban matters. This committee acquired official status in 1793. By the time a British force occupied the Cape in 1795, the committee, known as the burgher-senate, had assumed responsibility for the town, which then had 1,000 houses and a population of some 14,000. In 1803 the colony reverted to the Netherlands. In the following year the town received its coat of arms, embodying an anchor, symbolizing "good hope," on a field of gold, and three golden rings from van Riebeeck's personal coat of arms.

Britain reoccupied the Cape in 1806, and its title was confirmed in 1814. In 1828 the burgher-senate was abolished, and two residents were appointed to the governor's council of advisers. Slaves were freed in 1834, but they were required to serve four years of indenture. In 1840, when the town's population had reached some 20,000, the municipality of Cape Town came into existence; it incorporated the suburbs of Green Point and Sea Point to the north and west of Signal Hill. The municipality was administered by a board of commissioners and ward masters elected in 12 districts by citizens owning or occupying premises valued at £10 or more per annum, and it was financed by property taxes. In 1867 Cape Town obtained full municipal government, with three councillors from each of six districts; the chairman of the council became mayor.

From 1881 onward a number of separate municipalities came into being, among them Woodstock, Rondebosch, Claremont, Newlands, Wynberg, and Kalk Bay. The improved roads, the introduction of an electric tramway, and a common concern for water supplies and sewers prompted proposals for amalgamation of the urban sprawl. It was not until 1913, however, three years after the formation of the Union of South Africa, that the town councils of Cape Town and several of the adjacent towns combined to form the City of Greater Cape Town.

BIBLIOGRAPHY. Overviews of the city are provided by JOHN R. SHORTEN, *Cape Town* (1963); and A.H. HONIKMAN (ed.), *Cape Town: City of Good Hope* (1966). See also T.V. BULPIN, *Discovering Southern Africa,* 3rd ed. enl. and rev. (1983), ch. 1, "Cape Town," pp. 13–26; and relevant portions of J.J. MALHERBE, "Khoikhoi in Cape Town," *Cabo,* 3(2):4–10 (1983). Statistical information can be found in the census reports of South Africa's Bureau of Statistics. Also valuable are annual and special reports by various departments of the city of Cape Town.

(E.A.)

Caracas

Caracas, capital of the Republic of Venezuela, is one of the principal cities of South America. It is by far Venezuela's largest urban agglomeration and the nation's primary centre of industry, commerce, education, and culture. Founded in 1567 as Santiago de León de Caracas, the city grew slowly until the 1940s, after which it expanded by monumental proportions and its influence came to extend to even the remotest parts of the country. In addition to its role as the national capital, Caracas serves as the seat of government for the Federal District, comprising an area of 745 square miles (1,930 square kilometres). The city itself, however, spreads across the Federal District boundary, a considerable part of its area lying in the state of Miranda, which borders the district on the east and the south.

The physical setting of Caracas is impressive. Steep mountains of the Venezuelan coastal range rise abruptly from the Caribbean Sea, affording little level land for urban development. About 7 miles (11 kilometres) southward, beyond this mountainous wall, the city spreads out in a valley. Its elevation at the centre of Caracas is 3,025 feet (922 metres), and the valley extends about 15 miles in an east–west direction. Almost all of its inhabitable area is occupied by the city, and this once green and peaceful valley is now crisscrossed by streets and highways.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

The physical setting

The city site. The Andes Mountains extend eastward from Colombia across all of northern Venezuela to the island of Trinidad. The site of Caracas is a high rift valley within this system; hence, mountains enclose the city at all cardinal points. The Cordillera del Litoral, which rises above 8,600 feet at the Pico Oriental and above 7,000 feet at El Avila, towers high above the city and limits its expansion northward. The Serranía del Interior, to the south, is lower but nevertheless rugged. The principal river draining the valley is the Guaire, once relatively large but now reduced in volume and highly polluted. Its principal affluent in the metropolitan area is the Río El Valle, and others include the Quebrada Baruta and Quebrada Anauco.

Climate. Climatic conditions and natural vegetation in the coastal range form an extremely complex pattern. Temperatures generally decrease with increasing elevation, and rainfall and humidity are high on slopes that face eastward toward the prevailing winds. The decisive climatic factor in the valley is altitude. Temperatures range from 45° to 91° F (7° to 33° C), the annual mean being about 70° F (21° C). In contrast, the average temperature at La Guaira, at sea level, just 10 miles away, is 81° F (27° C). The seasonal range of temperature in Caracas between the average of the coldest month (January) and that of the warmest month (May) is only 5° F, considerably less than the normal diurnal range. Annual rainfall totals about 32 inches (813 millimetres). There is a distinct rainy season from May through November, which accounts for more than 80 percent of the total annual precipitation and features warm, humid weather. In contrast is the dry season, from December through April, characterized by clear skies and pleasantly cool temperatures.

The higher mountain slopes, especially to the north, often have a thick cloud cover. There a fairly abundant vegetation, including forest remnants, remains green throughout the year. Other patches of luxuriant vegetation are preserved in the major parks of the city and in its various gardens, including the Jardín Botánico. Where barren slopes prevail, erosion is a serious problem. Bird life, once exceeding 100 species in the valley, has been reduced dramatically.

The old city centre

The city layout. The nucleus of Caracas is near the western margin of the valley adjacent to the hill of Parque El Calvario, which offers a panoramic view of the city. There, centred around the Plaza Bolívar, are many historic buildings reflecting the colonial past, including the Catedral de Caracas, the Capitolio Nacional, the Concejo Municipal (Municipal Council) building, the birthplace of Simón Bolívar, and Palacio de Miraflores, which serves as the official residence of the president of the republic. Only a short distance away is the Panteon Nacional, with the tomb of Simón Bolívar and those of other national heroes. The twin towers of the Centro Simón Bolívar are also located nearby. Once the tallest buildings in the country, these 30-story structures house various ministries of the national government.

Increasingly, the civic centre of Caracas is moving eastward toward the Parque Central and Plaza Venezuela. This district focusses around a monument to Christopher Columbus, but more conspicuous is a cluster of skyscrapers, including another set of twin towers that are among the tallest buildings in all of Latin America. Begun in 1971, these structures of 62 stories each soar to a height of 656 feet above street level. Planned to house the main offices of the national government, each building is equipped for helicopter landings on its roof and affords a spectacular view of the entire valley. Nearby are a number of other important city landmarks, including the Jardín Botánico, several museums, Parque Los Caobos, and the Universidad Central de Venezuela.

Still farther eastward the principal landmarks of the city are the Caracas Country Club, the Parque Nacional del Este, and the Francisco de Miranda Airport. The city has also expanded southward over the hillsides and along valleys tributary to the Río Guaire.

THE PEOPLE

Immigration and the *barrios*

The people of Caracas, like those of Venezuela as a whole, are primarily mestizo. To this mixture of white and native Indian ancestry is added a lesser strain of black African origin. There are few people of Asian background, but since World War II there has been a relatively heavy influx of Europeans. During the 1950s, particularly, large numbers of Spaniards, Portuguese, and Italians settled in Caracas. By 1956, Caracas and the Federal District were the home of 42 percent of Venezuela's 438,000 foreign residents. These immigrants and their descendants have tended to concentrate in certain *barrios,* or neighbourhoods, of the city. Internal migration has added significantly to the population growth rate of the capital city, as has a high index of natural fertility. The primary source of migrants is the western Andean region, particularly the states of Táchira, Mérida, and Trujillo, although Caracas likewise serves as a magnet attracting people from all other parts of the republic.

Social class divisions are quite sharp in Caracas, as elsewhere in South America, and are reflected in the occupancy of residential areas. Members of the upper class first gained wealth and status in Venezuela through landownership and more recently through industry, commerce, and urban real estate. Their homes are luxurious and generally occupy the eastern margins of the valley and the Caribbean coast. The middle class has developed largely in relation to the nation's petroleum wealth and recent European immigration. Middle-class housing occupies the central core of the city, plus certain residential suburbs. The lower social class, composed of labourers, servants, and the unemployed, occupy the hillside shantytowns overlooking the city from the west and south.

Roman Catholicism has been the predominant religion of Caracas since the earliest settlement, but other religions are practiced. Spanish is the universally spoken language, although English is also commonly used in hotels, restaurants, and other tourist-related facilities.

THE ECONOMY

Industry. Caracas is in many ways the centre of everything Venezuelan. This was particularly true in relation to industry and commerce until the 1950s, when the national government began to promote industrial decentralization. It remains the leading manufacturing centre, with emphasis on textiles and clothing; processed foods and beverages; tobacco products; wood, paper, and printing; clay and stone products; rubber and leather goods; glass, chemicals, and pharmaceuticals; and metalware and plastics. More than 20 percent of Venezuela's manufacturing establishments are located within the greater metropolitan area of Caracas, as is 30 percent of the nation's industrial labour force. The relative importance of manufacturing has decreased rapidly, however, as new industries have been developed elsewhere in the republic and those that pollute the environment are required to move from the city to less populated areas.

Centre of commerce and industry

Commerce and finance. Most important in the economic life of Caracas is the tertiary, or service, sector. This includes wholesale and retail trade, transportation and public utilities, education and health care, and especially government. The city serves as headquarters for most of Venezuela's commercial and industrial firms, its banks and insurance companies, and government agencies both foreign and domestic. Nearly all nations of the world maintain embassies or consulates within the city. Tourism is of growing significance to Venezuela and is likewise centred in Caracas, where hotels and tourist agencies abound. In Caracas, as in any city of dynamic growth, the construction trades are yet another source of livelihood. Chronic unemployment nevertheless remains and is only partially relieved by activities such as street vending, peddling, and shoe shining.

Transportation. Caracas is linked directly with other major urban centres of the world by air and ocean transport. Maiquetía Airport, located 10 miles by road from Caracas on the coast, provides international connections as well as domestic flights to all parts of the republic. Two smaller airports, La Carlota and Francisco de Miranda, also serve the city. La Guaira and, to a lesser extent, Puerto Cabello are the natural seaports for Caracas and handle most of its import and export trade. A modern superhighway, including two long tunnels through the mountains, leads from Caracas to Maiquetía, La Guaira, and various beaches and resort areas along the coast. It was opened in 1953 to replace a tortuous 21-mile zigzag route.

Increasing problems of vehicular congestion

Within the city large numbers of buses, private automobiles, and taxis provide transportation, but during rush hours they clog the streets in what has become an increasing problem of traffic congestion. The public transportation system, although deficient, improved greatly with the inauguration, in 1983, of a modern subway system. Traffic also is facilitated by a system of *autopistas,* multilane divided highways extending east–west through the valley and connecting the city with interior locations. Most urgently needed is improved communication with the Caribbean coast, either by adding lanes to the existing *autopista* to La Guaira or by building an additional route farther eastward, a quite costly alternative. Railroads, which once provided Caracas with vital links to the sea and to interior valleys, have been abandoned in favour of highway transportation.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Caracas is the seat of the national government, which includes executive, legislative, and judicial branches. Among its residents are more than 40 percent of all government employees within the nation. The city itself is governed through the Libertador Department of the Federal District, but the urban area has expanded across many other minor civil divisions of the district and the state of Miranda. The governor of the Federal District, like those of the states and territories, is appointed by the president of the republic and may also be removed by him. A primary responsibility of the Federal District, and of each state, is the preservation of public order within its boundaries. It maintains its own police force and determines which law enforcement agencies will function under municipal control. The Federal District police headquarters is based in Caracas and reports directly to the governor. Also influential in local affairs, since the early days of colonial settlement, is the Concejo Municipal of Caracas. Planning for the city is conducted and coordinated through a Comisión Metropolitana de Urbanismo. Caracas has been the seat of a bishopric of the Roman Catholic Church since 1535 and of an archbishopric since 1804.

Services and health. For almost three centuries of settlement in the valley, local water supplies were considered abundant. Not until 1940 did water shortages become critical, but since that date a continued search for new sources has been required to meet the city's growing demand. La Mariposa and Agua Fría dams were completed in 1949, and in 1956 an aqueduct from the Río Tuy to La Mariposa reservoir brought water for the first time from a source outside the valley. Water supply remains one of the most critical problems to be resolved as the city continues to grow. Also of major concern are waste disposal, contamination, and pollution. Raw sewage is discharged directly into the Río Guaire, and air pollution results from industry and severe traffic congestion within the relatively small, enclosed valley.

Critical concerns of water supply

Caracas has had electric power since 1897 and is now included within a national electrification grid. Natural gas is supplied by pipelines from Guárico and Anzoátegui states in the eastern Llanos region of Venezuela.

In the last half of the 20th century, both government and private investments in Venezuela have focussed on Caracas, with the result that this city has prospered beyond all others. In 1936 the population of Caracas was more than twice that of Maracaibo, the nation's second largest city; by 1971 its population was more than three times greater. Immigrants have come in massive numbers from all other parts of Venezuela, as well as from most European nations. A high birth rate contributes an additional dimension to population growth and to a severe housing problem.

Increasingly, Caracas has become a city of high-rise apartments that provide clean, modern, and attractive housing. Yet, sprawled across the hillsides are countless thousands of *ranchitos,* homes constructed of corrugated metal, cardboard, or other scrap materials. The construction of new housing is impressive but remains totally inadequate to meet the continually increasing demand. Since the 1960s, large blocks of uniform dwellings have gradually replaced old homes in the Spanish colonial style, of which few now remain.

Health facilities in Caracas, like those of most large urban centres, have been challenged by the rapidly growing population, pollution, and the problems of treating a large poor population. Within the metropolitan area there are numerous clinics, sanatoriums, hospitals, and rest homes that provide health care for the capital's inhabitants.

Education. Considerable emphasis has been placed on education in Caracas. There are five sectors of education, both public and private: primary, secondary, normal, arts and trades, and university. The city also has numerous kindergartens and day-care centres for those under six years of age. The leading institution of higher education is the Universidad Central de Venezuela (also known as the Universidad de Caracas), founded in 1725. Its buildings form a modern enclave, called Ciudad Universitaria (University City), in the centre of the valley. Other universities are Simón Bolívar, which is public and oriented toward science and technology, and the private universities Andrés Bello Catholic, Metropolitan, and Santa María. Among other noteworthy educational centres are an institute of hygiene, a polytechnic institute, normal schools for girls and for boys, and a military academy.

CULTURAL LIFE

Like many world capitals, Caracas is the main focus of the country's cultural life. Among the numerous types of cultural activities are theatre, exhibitions of painting and sculpture, concerts, dance, and film. The principal cultural institutions include the Ateneo de Caracas, an ultramodern theatre inaugurated in 1983; the academy of the language; and the academies of history, medicine, and political and social sciences. Also located in Caracas are the national library, numerous other libraries, natural and fine arts museums, art galleries, municipal and national theatres, and an institute of cultural and fine arts.

Centre of Venezuelan communication

Caracas is amply served by radio, television, and the press. Venezuela's first newspaper, the *Gaceta de Caracas,* was published in 1808 and was dedicated to the cause of national independence. The major newspapers of today are still based in Caracas, including *Ultimas Noticias, El Nacional, El Mundo,* and *El Universal.* These papers are distributed throughout the republic by air transport, hence printing and publishing elsewhere in Venezuela are much less developed. There is a wide variety of radio broadcasting from many stations, and the national radio broadcasting organization is headquartered in Caracas; television, first broadcast in 1953, is popular at all sociocultural levels.

Caracas, with its mild climate and excellent facilities, affords its citizens ample opportunity to express their interest in sports and recreation. Baseball and soccer, the leading national sports, are concentrated in Caracas. The city also has a 30,000-seat horse-racing facility, widely renowned for its beauty, and a bullring that is the site of 10 to 12 events per year. There are many golf courses, swimming pools, and tennis courts, plus mountains and beaches along the Caribbean coast. The city fairly abounds with public gardens and plazas and scores of people are attracted to its zoo, museums, historic buildings, and boulevards. The most popular parks are the huge Parque Nacional el Avila (a forest preserve on the Cerro El Avila), Parque Los Caobos, the Jardín Botánico, and the Parque del Este, in La Floresta.

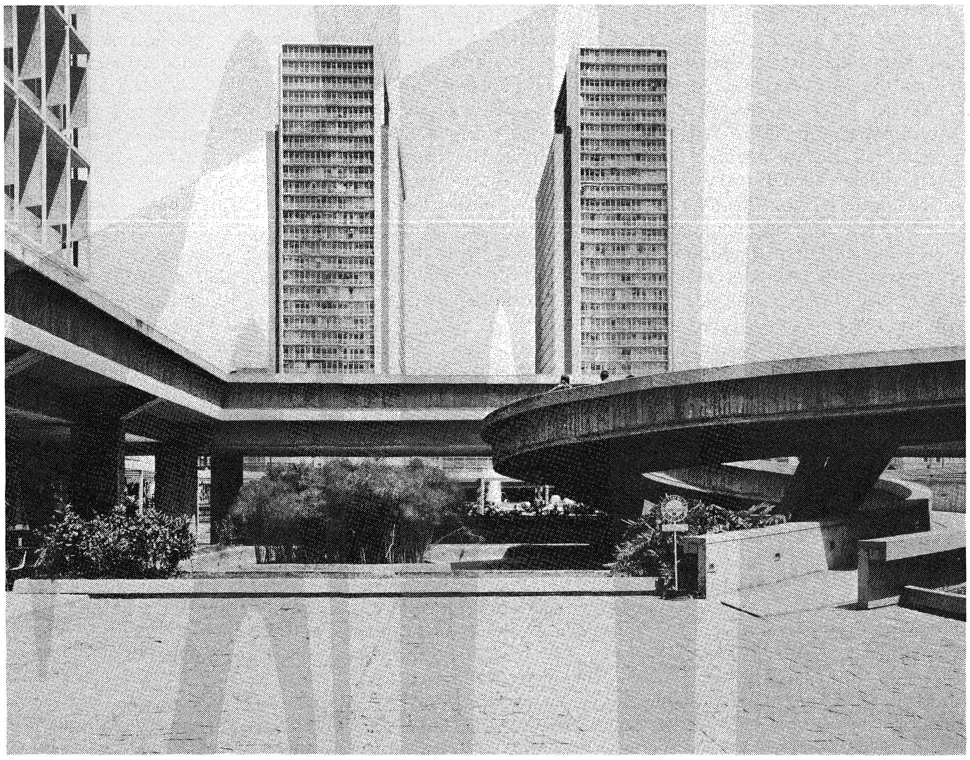
History

Early settlement

The settlement of Caracas occurred more than 40 years after that of Cumaná (1523), in the east, and Coro (1527), to the west. A ranch was established in the valley in 1557 by Francisco Fajardo, the son of a Spanish captain and an Indian chief's daughter, and in 1561 Juan Rodríguez Suárez founded a town on the site of the ranch; but the town was soon destroyed by Indian attacks. The conquest and resettlement of the region began in 1566, and Diego de Losada is credited with the actual founding of the city in 1567. He named it Santiago de León de Caracas in honour of the apostle James, who is the patron saint of Spain; of Don Pedro Ponce de León, who was the provincial governor; and of the Caracas Indians, who inhabited the region.

In 1578 the city was a quadrilateral formed of 24 squares centred on a plaza. The streets were straight and cobbled, and rivulets of water from the hills ran along their margins. Three houses were made of brick, each of two floors, with straw roofs; most houses had walls of *bajareque* (cane and earth), packed earth, or adobe and roofs of straw or tile. During this era, the average house of the upper class was large, with tree-filled patios and arcades and with separate slave quarters and stable. Initial growth was along the road to the north and then to the south. Later, development advanced to the west and east.

The *cabildo,* or town council, of Caracas increasingly exercised authority over the entire central portion of Venezuela, and an elite group emerged to manage the



Eric Carle—Shostal Associates

The older Centro Simón Bolívar in downtown Caracas.

Emergence as the nation's first city

political and economic affairs of the city. In 1577 Caracas acquired its status as a provincial capital. The city was sacked by English buccaneers in 1595, and its buildings were almost totally destroyed by two earthquakes in 1755 and 1812. During the 17th and 18th centuries, however, Caracas gradually emerged as the predominant urban centre of Venezuela. The Indian resistance to settlement was quickly overcome, in part due to an epidemic of smallpox that decimated the native population. The valley was relatively free from pirate attacks, although centrally located near the north coast of the country. The valley itself and adjacent valleys produced some gold and then became important for exportation of cacao, the source of chocolate. In addition, Caracas offered a healthful, comfortable climate and an abundance of fresh water.

Simón Bolívar, the greatest of South American heroes, was born in Caracas on July 24, 1783, into a family long prominent in Venezuelan affairs. From his tutors, he gained the zeal to achieve independence for Spanish America. With a small military force recruited in Colombia, he invaded Venezuela and captured Caracas in August 1813, at which time the city conferred on him the title El Libertador (The Liberator). A year later the patriotic forces were in full retreat, but when Venezuela was finally established as an independent nation, in 1830, Caracas was its capital.

Late 19th-century transformation

In 1870, the urban transformation of Caracas began under Pres. Antonio Guzmán Blanco. When not actually residing in Paris, and ruling Venezuela through a puppet president, Guzmán Blanco was busily trying to make Caracas a replica of the French capital. The French architectural taste of this period replaced the Spanish colonial style. Avenues were built, and some streets were widened to encourage the city's growth. The Caracas and La Guaira Railway was inaugurated, with pomp and ceremony, in 1883. This railroad climbed the steep coastal range and connected the nation's capital with its Caribbean seaport. In the early 20th century, the first urban real estate development, designed for the upper class, was built in suburban El Paraíso. A short time later, a development for the middle class was begun in Catia, to the west.

Beginning in 1936, after the death of Gen. Juan Vicente Gómez, who had been dictator for 27 years, the country experienced a new era of prosperity based on petroleum. Caracas grew in population, and construction was extended as far as geographically possible. In the downtown area of the city, El Silencio district was transformed into a huge middle-income residential-commercial building complex. This development, programmed in 1939 together with a Regulating Plan for Caracas, was the first work of such magnitude in the country; it marked the beginning of the city's modern architectural trend.

Modern Caracas

From 1951 to 1957 Venezuela came under the rule of another military dictator, Marcos Pérez Jiménez, who devoted primary attention to the modernization of Caracas. Slums were cleared and replaced by colourful high-rise apartments, and superhighways were built to connect Caracas with the coast and with the interior. The change in the appearance of Caracas was abrupt and overwhelming. The old city began to disappear. Numerous suburbs sprang up overnight on the hillsides, and commercial and government buildings were erected at a feverish pace in the valley. As early as 1956, a plan was formulated for the decentralization of Caracas and the development of secondary urban-industrial centres. Caracas has continued to grow and develop despite its geographic limitations, and it has come to completely dominate the urban structure of the Venezuelan nation.

Caricature, Cartoon, and Comic Strip

Caricature, cartoon (in the satirical sense), and comic strips (including comic books) are related forms. Historically, they arose in the order given, but they all have flourished together. All use the same artistic mediums of drawing and printmaking; caricature and the element of satire are usually present in each. This article covers their history and development.

The article is divided into the following sections:

DEFINITION OF TERMS

Caricature. Caricature is the distorted presentation of a person, type, or action. Commonly, a salient feature or characteristic of the subject is seized upon and exaggerated, or features of animals, birds, or vegetables are substituted for parts of the human being, or analogy is made to animal actions. Generally, one thinks of caricature as being a line drawing and meant for publication for the amusement of people to whom the original is known; the personal trait is usually present.

Origin of the word caricature

The word caricature derives from the Italian verb *caricare* ("to load," "to surcharge" as with exaggerated detail) and seems to have been used first by Mosini in *Diverse Figure* (1646). The 17th-century sculptor-architect Gian Lorenzo Bernini, who was a skilled caricaturist, seems to have introduced the word *caricatura* into France when he went there in 1665. There is perhaps, in the choice of the verb *caricare* as a source for the noun, some influence from the idea of *carattere* (Italian: "character") or even from *cara* (Spanish: "face"). At any rate, the face is the point of departure for most caricatures. It is conceivable that underlying the series of overlapping profiles with varieties of extraordinary noses and chins and brows which Leonardo da Vinci and Albrecht Dürer drew independently about 1500 was an observation not only of contemporary human types but of the fact that the heads of rulers on coins and medals, when worn with age, often became ridiculous. A latter-day case is the penny showing Queen Victoria, whose coiffure began to look like an elephant's head when the coin was well worn down.

Caricature, after its spread as idea and practice from Italy and France to Great Britain in the 18th century, became rather a broad term. In the late 19th century, Gilbert and Sullivan, the English creators of comic operettas, spoke of one of their subheroines as having "a caricature of a face." Perhaps, therefore, it is not surprising that, although cartoons as they are now known developed gradually out of caricature from the 15th century, cartoon is a 19th-century word.

Satirical deformations and comic analogies in sculpture, the drama, and vase painting are older than purely graphic caricature. The ancient Egyptians represented men as animals; Greek comedy had by-products in burlesqued figures on vases and in terra-cotta statuettes; Romanesque and Gothic sculptors made fun of human failings in stone capitals and wood miserere seat carvings all through the Middle Ages. The marginal flourishes of illuminated manuscripts contain grotesque faces and occasional exaggerated scenes from daily life, or references to the morality plays, which have the same relationship to those plays as Greek clay representations have to the stage. All such works verged upon caricature in the narrow personal sense; some were caricature in a broad sense. In the generations since caricature became a clearly defined idea, there have been occasional examples in painting and sculpture alongside the more usual drawing for reproduction.

Cartoon. A cartoon originally was and still is a drawing, a full-size pattern for execution in painting, tapestry, mosaic, or other form. The cartoon was the final stage in the series of drawn preparations for painting in traditional Renaissance studio practice. In the early 1840s, when that studio practice was rapidly decaying, cartoon rather suddenly acquired a new meaning: that of pictorial parody, almost invariably a multiply reproduced drawing, which by the devices of caricature, analogy, and ludicrous juxtaposition (frequently highlighted by written dialogue or commentary) sharpens the public view of a contemporary event, folkway, or political or social trend. It is normally humorous but may be positively savage. Just as the personal caricature was for an audience that knew the original, so the cartoon was and is based on wide acquaintance with the subject. It serves as a capsule version of editorial opinion when it makes political satire, and it is a running commentary on social change, sometimes intended as a corrective to social inertia. (For treatment of animated cartoons, see MOTION PICTURES: *Animation.*) (W.Am.)

Comic strip and comic book. The comic strip consists of a series of adjacent drawn images, usually arranged horizontally, that are designed to be read as a narrative or a chronological sequence. The story is usually original in this form. Words may be introduced within or near each image; they may also be dispensed with altogether. Words should never functionally dominate the image, which then would become merely illustration to a text. The comic strip is essentially a mass medium, printed in a magazine, newspaper, or book.

A comic book is a bound collection of strips, typically telling a single story or a series of different stories. Most of the better newspaper strips eventually appear also in book form.

Misleading use of "comics"

The word comic in connection with these strips is used only in the English language. Although now firmly established, it is misleading, for the early (pre-19th-century) strip was seldom comic either in form or content, and many contemporary strips are in no sense primarily humorous. The terms comics and comic strip became established around 1900 in the United States, when all strips were indeed comic. The French term is *bande dessinée* (*i.e.,* "drawn strip," or BD for short). The older German term is *Bildergeschichte* or *Bilderstreifen* ("picture story," "picture strip"), but the Germans now tend to employ the English word. In Italy the term is *fumetto* (meaning literally "little puff of smoke," after the balloon within which most modern strips enclose verbal dialogue). In Spanish the comic book is called *historieta.* (D.M.Ke.)

ORIGINS OF CARICATURE AND CARTOON

Individual satire. Caricature was a product of the Renaissance and Reformation emphasis on the importance of the individual. If a man was seen officially as an emperor, he was seen unofficially to have feet of clay or to be wearing no clothes. From about the first third of the 16th century the emphasis on decorum was so strong in Italy and spread so fast northward and westward, reinforced by a still more solemn decorum from Spain, that it produced a reaction. Desiderius Erasmus' *In Praise of Folly* was both a Renaissance effort at satire and a carryover of medieval mockeries; the marginal drawings made in one copy of it by early 16th-century members of the German-Swiss Holbein family are neither caricature nor cartoon in the modern sense, but they are in the same stream of subjective comment on objective observation as the series of exaggerated profiles drawn by Leonardo and Dürer. In the 16th century the work of the Flemish painter Pieter Bruegel the Elder is full of near caricature, as in the familiar drawing of an artist who is troubled at his easel by a nosy peering connoisseur behind his shoulder. In the work of Bruegel and that of his contemporary, the Dutch painter Hieronymus Bosch, there are witty and sometimes horrendous dislocations of parts of the body, combinations of human anatomy with fishes, birds, animals, and windmills, and exaggeration of obese or emaciated physical types that are likewise near cartoons.

Yet true caricature in the sense of the satirical portrait of an individual is almost impossible to identify before the work of a late 16th-century Bolognese painter, Agostino Carracci. The first caricatures of persons whose names are still known today are by Bernini. Artists of their time could at last afford to be easy about their position and occupation, about what was objective and what was subjective. They impartially caricatured one another in the studio and the types in the street. The rise of connoisseurship and collecting in the 17th century soon produced appreciation of these caricatures outside the studio, leading to the gathering of such drawings into albums and their transformation into multiple etched or engraved publications.

Development of the modern cartoon

Social satire. The less personal and caricature-like features of the modern cartoon developed slowly through the 16th century and up to the last third of the 17th. In part consciously based on Bosch and Bruegel, in part an autonomous protest against the Renaissance belief in order, symmetry, and fixed canons of beauty, there rose a European family of grotesqueries with sources as mixed as its appearance. Its only visible overall characteristic might be said to be that it reacted, from the depth of old folkways, against the novelty of the Renaissance, the New World, and the various hierarchies. Echoes of the dark Gothic forests mixed with fantastic reports of travel (some of them not really new but rehashed from Marco Polo) and with travesties of the Renaissance ornament of such works as Raphael's decorations for the loggias of the Vatican Palace. One result was the double images of faces and landscape or of human figures built of books, fish, or pots and pans by the 16th-century Italian painter Giuseppe Arcimboldo. In a slightly different area lay two types of pictorial comedy. The first type was the conscious satire by professional printmakers, illustrating such works as the *Ship of Fools* (1494), an allegory by the German poet Sebastian Brant, or issued as independent prints. Some of them were tendentious to the point of libel (such were Lucas Cranach's attacks on the papacy, inspired by Martin Luther); others were merely mockery, such as the 16th-century German painter Hans Beham's satirical view of mercenary soldiers and their camp followers. The second type was the unconscious pictorial comedy by comparatively untutored practitioners of woodcut or etching, hastily made and issued as newspaper extras might be issued now. These works were the ancestors of 18th- and 19th-century broadsides.

Class distinctions in caricature

If caricature deals with the individual and with what makes him individual, cartoons may be said to deal with groups and with their corporate characteristics; both are connected with the Renaissance love of classification and categorizing. Up to the time, in the mid-17th century, when both caricature and cartoon jelled in forms which answer to the modern definition, caricature had been prepared on the whole by knowledgeable artists; and cartoons had been prepared (though often with the assistance of professional artists) at a somewhat lower level. Thereafter, cartoons (in the modern sense of the term) came to be created in response not merely to artistic impulses but to the same sorting-out impulses that were creating the modern state and its society, its science, and its religion. Besides the sublime–ridiculous and the artist–layman dualisms in this field, there is a sort of class dualism that is a result of historical factors rather than of general human disposition. The history of caricature and cartoon is intimately connected with the history of the way in which one class has looked at another. Dürer looked down on the heavy-bodied man whom he called farmerish; yet within two generations Bruegel was drawing peasants in a sympathetic manner. A 16th-century Swiss engraver, Jost Amman, treated trades and professions dispassionately, as did the 17th-century French engraver Abraham Bosse, although Bosse did create some lampoons on unpopular types and callings. Jacques Callot, an early 17th-century French etcher, satirized dandies, beggars, and all classes between, and he even made the generally detested Gypsies (who were not yet romantic) almost sympathetic.

A rather comfortable social climate developed in the 17th century: the wars of religion had quieted in France and the Low Countries, though civil war occupied Britain in the middle of the century. But by the time the Restoration had quieted Britain, a general European threat appeared in the form of Louis XIV. Against his absolutism and against his influence through agents in Britain and the Netherlands, the first modern cartoon campaign was made. It was modern in that it was on a large scale—cartoons were published on a fairly regular serial basis, much like that of the modern daily newspaper's editorial cartoon (though the newspaper was still in the letter-and-gazette stage); and it was based on a fairly large and general acquaintance with the persons satirized if not always with the literary

analogies used. The cartoons, which as yet made no particular use of personal caricature (that was still on a friendly studio footing), were prints made in Holland by a group of artists of whom Romeyn de Hooghe was the chief, and they were sold cheap. There had been Dutch political cartoons before, but they were laborious and appeared irregularly. The Dutch–English connection in the person of William III, the continuing threat of Louis XIV, and a succession of shattering events in various spheres stimulated a vast production of cartoons from the 1680s on.

Separation of cartoon and caricature

As the cartoon spread—along with its almost indispensable element, caricature—it began to divide; and although the periodical carrying cartoons was not to appear regularly until the third quarter of the 18th century, nor the true comic periodical until early in the 19th century, the divisions were real enough to follow from that time.

PERSONAL AND POLITICAL SATIRE (PURE CARICATURE)

18th century. About 1740 the English printmaker Arthur Pond published together 25 caricatures after original drawings by a number of artists. This collection must have been effective in spreading the idea and the word, for it was an excellent publication. Pier Leone Ghezzi, one of the artists included, was probably the first professional caricaturist, for he made a living with his pen portraits of Romans and visitors to Rome, many of which he engraved. He was a minor master in comparison to his contemporary the Venetian artist Giovanni Battista Tiepolo, yet the caricatures by the latter, delightful though they are, appear to deal with types or at least with anonymous individuals rather than with nameable ones. Tiepolo's pen-and-wash drawings were a small side issue in his enormous production, and they were not engraved or otherwise multiplied in his lifetime. Both artists had an eye for ungainly legs and posture and for odd clothing and the obvious features of the face.

On the heels of Pond's reproductions came handbill-like personal caricatures. Apparently begun in the 1760s by the Englishman George Townshend (later Marquess Townshend), these were comic portraits with punning titles or accessories, intended by disingenuous means to avoid being outright libellous. A flood of imitations followed. Soon Townshend's cards became comic illustrations in magazines such as *The London Magazine,* the *Political Register,* and the *Town and Country Magazine.*

Rowlandson's comic images

Early 19th century. *Great Britain.* Thomas Rowlandson created the comic images of a great many public characters in his day: royal dukes, actresses, auctioneers, hack writers of Grub Street. He was the perfect professional to carry on what the amateur Townshend had begun. Like Tiepolo, he was able to make the person and the costume assume a homogeneously ludicrous or pathetic–bathetic look, with factitious coiffures, wildly frogged uniforms, enormous bosoms and bottoms, and the dejected attitudes of trailing handkerchiefs.

Rowlandson's contemporary James Gillray was less of an artist and more of a professional cartoonist in the modern sense. Coming from the theatre to the political scene, he brought a highly dramatic sense of situation and analogy, but he was peculiarly violent and often scurrilous or scatological. His greatest talent was with patterns and ornaments of costume, which he would allow to take on a luxuriant life of their own. The Swiss-born English painter and teacher Henry Fuseli, though hardly a professional caricaturist, stood halfway between the painted Italianate caricature groups of Sir Joshua Reynolds, an academic English painter, and the Rowlandson–Gillray drawings and etchings; he had something of Gillray's theatrical manner, but his satirical drawings were more often sensual than scatological.

France. The French painter and engraver Philibert-Louis Debucourt might have equalled Rowlandson if he had not been so occupied with the intricacies of colour prints; but he produced a few superb cartoons of the Paris of his day, full of caricatures of fashionable personages.

The whole Napoleonic period gave rise to such passion that a school of French caricature was generated, the effect of which was to come after the Restoration. Two members of an older generation, Louis-Léopold Boilly and Jean-Baptiste Isabey, really began the work. Boilly, starting where Debucourt left off, satirized the modes and manners of the French. He was not in the direct sense a

political caricaturist but frequently used satirical portraits.

Isabey was primarily a portrait painter, but he was in contact with all the great continental political personalities of the first half of the 19th century, and he caricatured many of them privately. Most of the caricatures were not published, but they had an effect among artists, as did the satirical prints of Francisco de Goya.

The cartoon as political complaint

The tendency of the Restoration to suppress Napoleonic enthusiasms provided another rich ground for cartoon as political complaint. As soon as the first stage was over (in 1830), a change of administration was accompanied by the appearance of Charles Philipon's periodical *La Caricature,* the first great vehicle of Honoré Daumier, Henri Monnier, "Grandville" (J.-I.-I. Gérard), and others. The presiding genius had great politico-legal skill and knew exactly how far he and his artists could go. The famous likening of Louis Philippe to a pear, which was both a visual and a verbal pun, was not the least of *La Caricature's* successes. Daumier's colossal gifts included personal caricature, though in his later life he dealt almost entirely in more general social satire. In the early '30s he created for Philipon "Le Ventre legislatif" ("The Legislative Belly"), at once a political indictment, a rogue's gallery of caricatures, and a monumental composition; not to mention a long series of more detailed single antiportraits. Daumier's composite sociopolitical villain, Robert Macaire, and Monnier's Joseph Prudhomme, the sum of bourgeois pettiness, served as butts of satire when censorship caught up with directly personal caricature in Philipon's three or more overlapping papers.

Middle 19th century. *Great Britain.* The specifically cartoon-bearing journal was by this time an established fact. The *Monthly Sheet of Caricatures* had begun publication in London in 1830, lithographed like Philipon's journals. In these and other ventures, the publisher Thomas McLean issued hundreds of political caricatures during a great formative period of modern legislation; his artist, Robert Seymour, was in the Gillray line rather than the later one of John Doyle, who also worked for McLean. John Doyle's son Richard became one of the masters of the mid-century British school of subtler cartooning. The younger Doyle was one of the initial staff of *Punch* when Henry Mayhew started it in 1841.

First caricaturists of *Punch*

Punch began as a fiercely democratic weekly which applied to the young Queen Victoria and her growing family, as a matter of course, the same savage treatment that had been given by caricaturists of the previous hundred years to the Hanoverians. *Punch* was born in the years when the new Westminster Palace (Houses of Parliament) was under construction. Prince Albert and his team of artistic advisers, wishing to revive fresco painting as a means of decorating the vast wall spaces of the new buildings, opened a competition. When the cartoons (in the original sense of the word) of the proposed compositions were exhibited, it was evident that many of the painters were unfamiliar with work on so heroic a scale, and some of their designs were ludicrous. *Punch* was quick to satirize them in a series of "*Punch*'s Cartoons." One of the reasons for "*Punch*'s Cartoons" on the Westminster hall exhibition was that the unpopular foreign Prince Albert had fomented the competition. But *Punch* was not so much merely antiroyal as it was antihumbug (the novelist W.M. Thackeray, after all, was another of the staff). Though its first few years were marked by some of the worst puns in a punning age, it not only kept up, with its fairly small fixed staff, a remarkable fire of lampoon but soon developed the weekly full-page political cartoon, certainly one of the chief ancestors of the modern editorial cartoon. Nineteenth-century British and general European politics might be briefly comprehended in a few dozen of these. The most famous is probably still that farewell to Otto von Bismarck, "Dropping the Pilot," by Sir John Tenniel.

The woodcut technique used for many decades in *Punch* caused the cartoons on the political page, the largest in scale of the cartoons, to be almost invariably dull in surface. The speed required of the divided-labour teams which produced the cuts from the artists' drawings did not allow for subtleties.

Other countries. The earliest really impressive makers of personal caricature and political cartoon in the United States were David Claypoole Johnston and Thomas Nast. Nast first made his name with American Civil War cartoons in *Harper's Weekly,* which like *Punch* used the woodcut process with an elaborate division of labour in the back shop for the rapid reproduction of cartoons.

The middle and late century produced in Italy the brilliant political caricaturist Virginio, who was to the rise of Italian nationalism what Nast had been to the North in the American Civil War; he worked for *Il Fischietto* of Turin. In 1848 *Kladderadatsch* started in Berlin. Munich had *Fliegende Blätter* and *Punsch. Punsch* was more political than the others, which were long-lived comic weeklies in the social-comment style. J. C. Schleich's *Punsch* cartoons were a running Bavarian comment on Prussianism.

Nast's personal satire

Late 19th century. *The United States.* In the boom days of the 1870s, Nast became a master of personal satire; his long practice in dealing with the professional wood engravers gave him at last a style and scale that triumphed over finicky crosshatching and gave full effect to his ruinous attacks on William Marcy "Boss" Tweed and other grafters; he was one of the most fertile of symbol makers outside the personal field and is probably the creator of the donkey of the Democratic Party as well as of the Tammany Hall tiger of the New York Democratic organization.

In 1876 *Puck* was founded. It was soon to develop new artists, notably Joseph Keppler and Bernhard Gillam. They worked in a lithographic style of considerable artistic competence, without the force of Nast or the effortless flow of Daumier, but with plenty of clever analogies and with an understanding of the sort of likeness required in caricature.

Harper & Row, New York

"Who Stole the People's Money?—Do Tell. 'Twas Him," by Thomas Nast (1840–1902).

England. *Punch* meanwhile had settled into its richest period, with Tenniel and Harry Furniss as political cartoonists. *Vanity Fair* (from 1868) offered some competition, especially at first with its regular coloured lithographic antiportraits. These were signed "Ape" (Carlo Pellegrini) and "Spy" (Leslie Ward, later knighted); they kept up a steady supply of big-headed comic figures against an almost invariably blank background. They also kept up the old device of never quite naming the subject in so many words, but as they were directed at a public which was "in the know," this was part of the fun. These colour caricatures were much loved, and were often framed and hung on private walls. Max Beerbohm (knighted in 1939) devoted himself largely to social and literary satire but almost always on a basis of personal caricature. His deceptively understated outlines and pallid washes, the latter used as local colour for the sake of the overall design, were the perfect means for parodying the good taste of the *fin de siècle.* His symbols for the writers G.K. Chesterton, G.B. Shaw, Joseph Conrad, and W. Somerset Maugham have become almost the standard views of those writers.

Influence of photomechanical reproduction

Technical developments. Toward the end of the century there was a rebirth of personal satire which accompanied new techniques of reproduction and perfected enrichments of such older techniques as colour lithography. Photomechanical reproduction, especially after the development of halftone, allowed direct reproduction of the artist's drawing without personal interpretation by wood engravers or other technicians. Colour lithography, which had been either limp or turgid on the whole, found a new life. The caricaturists who had been able to draw directly on the stone, as Daumier did, had always had more freedom and better control over results than those who worked with pen and paper; now the latter could depend upon themselves and a photomechanical process.

France. Henri de Toulouse-Lautrec produced large-scale posters and, earlier, polychrome lithographs for the Parisian publication *Le Rire* (from 1894) and for independent distribution. He created a new style of informal composition, somewhat influenced by Japanese prints, with bright clear colour, broad, rather casual outlines drawn largely with the brush, a trick of making tone by means of spatter, and a wit that saw through ugliness to a new sort of eloquence. His view of Oscar Wilde was economical and devastating, and his caricatures of theatre and music hall personalities are unmatched. Another French artist, Caran d'Ache (Emmanuel Poiré), worked on a smaller scale with pen and brush and was one of the most effective continental commentators on the South African War.

Germany. The artists of the Munich satirical publication *Simplicissimus* (from 1896) were all somewhat influenced by Toulouse-Lautrec in their use of white space, spatters, and often random outline; they all commented on those features of German life that were most disliked outside Germany—the didactic professor, the tourist, and the military dandy. Their caricatures in the last field were very thinly veiled; Eduard Thöny, one of this group, was especially popular for the way he conveyed the upper-class boorishness of Prussian officers.

20th century. *The United States.* Charles Dana Gibson was a virtuoso of the pen, using the manner of *Punch*'s Phil May as a point of departure. He used the pen as he pleased, sometimes in a direct descriptive manner, sometimes with colouristic suggestion, sometimes almost antigraphically. Though he helped to create the caricature types of Theodore Roosevelt and Woodrow Wilson, he was more a social than a personal caricaturist. He is mentioned chiefly because he introduced American physical types called Gibson girls and Gibson men.

Role of *The Masses*

A position much like that of *Simplicissimus* was occupied in the years 1911–17 by *The Masses* of New York, which had an editorial policy based on socialist idealism. It was served by a group of artists whose fine drawing made their often sharp propaganda tolerable in quarters where it might not otherwise have gotten a hearing. John French Sloan, George Bellows, Boardman Robinson, and Art Young were as likely to deal in social terms as in personal ones, for by this time personal caricature was moving into the newspaper editorial cartoon or the pages of theatrical or sporting news.

Photomechanical reproduction not only allowed greater freedom for comic artists; it made possible the daily newspaper cartoon and later the syndicated editorial cartoon and the comic strip. About the same time as the new generation of weeklies there was a rise in the use, the autographic character, and the influence of pictorial journalism. John T. McCutcheon of the *Chicago Tribune,* though he used a rather dry and old-fashioned pen technique, was able to range over politics, the "good old days," the mores of the moment, and sports. His cartoon world, like that of *The Masses,* was almost entirely urban, but he was one of the first of a generally imperturbable type of American

"Tricks or Treaties,"—from *Straight Herblock* (Simon & Schuster, 1964)

"Tricks or Treaties," by Herbert Block.

cartoonist, whose view is amused rather than aroused. His career ran from before Theodore Roosevelt to after Franklin D. Roosevelt's time. In his line of succession stood such men as Edwin Marcus and S.J. Woolf in *The New York Times,* Oscar Cesare of *The Sun,* Herbert Block ("Herblock") of *The Washington Post,* Daniel Fitzpatrick of the *St. Louis Post-Dispatch,* Rollin Kirby of the *New York World-Telegram,* Bill Mauldin of the *Chicago Sun-Times,* John Fischetti of the *Chicago Daily News,* and others too numerous to list.

Dominance of David Low

England and the Continent. The outstanding political commentator of the first half of the 20th century was David Low, a New Zealander, who worked for the *Sydney Bulletin* before going to Britain. Low was perhaps the best all-around man in the field of caricature since Daumier. His brush drawing was of an Oriental economy, his invention of analogy gleeful without being really outside the classic British educated tradition, and his hatred reserved for a few needful occasions. Like many before him, he employed hackneyed devices (*e.g.,* the heads of a pack of British politicians on dogs' bodies) but by slyness of expression always managed an original twist. There was almost no one in the political field to touch Low except for the Dutchman Louis Raemaekers during World War I, and Raemaekers was bitter where Low was dry and crisp, with footnotes of rumbling laughter. Jean-Jacques Sennep (pen name of J.-J.-C. Pennès) of Paris' *Le Figaro* and Fritz Meinhard of the *Stuttgarter Zeitung* were important French and German caricaturists of the 20th century.

COMEDIES OF MANNERS (THE CARTOON)

Types and groups, rather than politics and the politician or any nameable individuals, are the concern of the comedian of manners. He may love mankind for its imperfections or set out to seek improvement, but his method will be much the same. He does not need, as the political cartoonist does, to set up allegories and analogies or to write names on labels, but he may sometimes sharpen his comment by treating human beings as animals (monkeys and apes for obvious reasons have long been the favourites, along with dogs and birds). If the personal caricature is an antiportrait, the cartoon on human foibles is often a sort of anti-sumptuary law or a countergrammar which says, "The exceptions are more fun than the rules."

16th to 18th centuries. Bruegel and Callot were certainly comedians of manners. Bruegel's picturizing of Flemish proverbs, themselves often comments on foibles, and his prints of the Seven Deadly Sins with satirical examples filling the backgrounds combine a bit of moralizing with the delighted empathy of a participant. Callot is slightly more detached, possibly because of his more conscious style and because he was himself the printmaker (Bruegel drew for professional engravers and woodcutters); but in the catalogs of byplay in his panoramic scenes of fairs and in his trick of making the beggar wear his rags handsomely, he is always balancing and measuring.

Parallel to two-dimensional comment in this vein ran the theatre, notably the commedia dell'arte, puppet theatre, and the performances of the jester and clown. Both appeared in the late 17th and early 18th centuries in the rather courtly comic drawings of the Frenchman Claude Gillot, Antoine Watteau's predecessor. These are not really comedies of manners, for the clowns are used as if they were monkeys aping human ways at a remove toward greater elegance rather than toward apishness. They point the way to a good many 18th-century practices: Gillot and Watteau both made decorations that included monkeys (singerie) just as Francois Boucher and later artists were to use pseudo-Chinese scenes (chinoiserie) occasionally as ways of commenting on contemporary European life.

Hogarth's cartoons of manners

It is with William Hogarth that the cartoon of manners reached great stature. His series "Marriage à la Mode," "A Rake's Progress," "A Harlot's Progress," the "Four Stages of Cruelty," and the unfinished "Industrious and Idle Apprentices" were loaded with observation not only of human beings but of objects and their ecology, as if he were using his own proliferation of comic images in protest against waste of time, talents, life, and pride. Hogarth, like Sir Joshua Reynolds after him, even painted comic subjects, but he kept to social satire and avoided personal caricature. His pictures of depravity and ferocity are hard to beat, but he could put an expression of by no means unholy delight on a wicked face. In the "Laughing Audience" he gave a full measure of laughter. Hogarth's engravings ran to very large editions and were recut and reissued and then copied at reduced scale for books of the *Complete Works.*

19th century. *Spain.* Francisco de Goya is hard to place in the historical development of the comedy of manners. His "Caprichos" (1796–98), etchings prepared by some of the most simple and trenchant brush drawings ever made, appeared in the last years of the 18th century and

The folk wisdom of Goya

can be called comedies of manners only insofar as they are related to folk sayings and the bittersweet Spanish folk wisdom. Thus, they stand in the line of Bosch and Bruegel, so many of whose paintings were in Habsburg collections in Madrid. The "Proverbios" of 1813–19 are even more monumental transfigurations of various states of the human condition. Like the "Caprichos," they used the caricaturist's means for irony and satire, but there was little of the comic left in them and none at all in the "Desastres de la guerra" (1810–14, "Disasters of War"), which used the Peninsular phase of the Napoleonic Wars as a point of departure. They are closer to universality than even Callot's similarly inspired series and are searching comments on more stages of cruelty than Hogarth covered. In them, Goya was really a political cartoonist using no names; yet he was hardly a public cartoonist in the normal sense because censorship and other factors allowed only a very small circulation of his later work until a sizable edition was printed a generation after his death. The earlier work, which contains elements of comedy, did get abroad and had influence in France and England probably before Goya's death. Artistically, if not politically, his work would have had the same powerful effect whenever "discovered" or circulated.

France. "Paul Gavarni" (Sulpice-Guillaume Chevalier) was more purely a comedian of manners than Daumier, though he was no less perceptive and no less sympathetic with the *petit parisien.* He had a grace derived from his apprenticeship in fashion illustration that produced enchanting jokes on young people in love, dandies, and the theatre and circus. He worked late in life for the *Illustrated London News,* as did Constantin Guys, the French foreign correspondent who reported the Crimean War to the British. Guys, a prolific draftsman who always kept a comic touch, was peculiarly subtle in reporting the great but contrived elegance of Napoleon III's court. He helped both British and French to see themselves as others saw them. "Grandville" was a comic artist on *La Caricature* whose work recalls some of the complicated inventions of Arcimboldo.

Daumier was, of course, the great master of social comedy with or without political content. His series of affectionate if disenchanted comments on married life, the theatre, the courts, concierges, musicians, painters, bluestockings, bathhouses, and children constitute as full a report on Paris in his time as Rembrandt's drawings were for 17th-century Amsterdam. The words were often important, especially when Daumier was indicating in his text the unspoken thoughts of his characters (thus anticipating the 20th-century cartoon in which a thought or vision is indicated as a balloon with cloud-scalloped edges and a picture rather than words inside). His often untidy line and knowingly casual accents of tone produced (at will) sensations of chill weather, of ecstasies of gluttony, of juvenile pride, or of legal craftiness.

England. Rowlandson, as noted earlier, was a political caricaturist part of the time, but above all he was a lampooner of ludicrous and excessive behaviour. He created almost unaided a gallery of types missed by Hogarth, many of which persist in British life—the antiquarian, the old maid, the harried foreign servant, the pleasantly blowzy barmaid, the decent old parson. He was by no means as bawdy as he is supposed to have been, but he liked to push action, like appearance, to an extreme. His *Dr. Syntax* may be called an ancestor of comic strips.

George Cruikshank carried Rowlandson's methods almost beyond extremes in his youth. He used superfantastic costume and sometimes that device of enormous heads which some 17th-century caricaturists used and which is still used by sports-page cartoonists and comic advertising artists.

Humorists of *Punch*

The longest continuing habit and tradition of humorous comment on the passing world has been made by the English humour magazine *Punch.* Though it began in puns and peevishness, it warmed up during the 19th century with John Leech, Charles Keene, George Du Maurier, and in the 20th century with George Belcher, "Fougasse" (Kenneth Bird), H.M. Bateman, Nicolas Bentley, E.H. Shepard, and Osbert Lancaster. Leech was in a sense the pictorial equivalent of Thackeray (Thackeray was an excellent comic draftsman but better at getting the feel of past time with a comic flavour than at considering his contemporaries other than in words). Leech and Keene belong to the era of wood-engraved reproduction; when one sees their original drawings and manuscript captions or dialogue, it is apparent that something was lost in detail and finesse of line but nothing in sense of comedy, in the affectionate tone. The enormous self-confidence of the optimistic Victorians, expressed at first through the violent or bumptious Regency manner of the young Cruikshank, was tempered by the staff-meeting or meeting-of-minds conduct of *Punch.* The "manners" part of the phrase "comedy of manners" became subjective as well as objective. *Punch* became an upper-class weekly and continued as such for three or four generations, reflecting the large knowledge of all classes it was possible for its staff to offer its readers, and the large delight of the upper class in seeing its own foibles and those of its servants, tradesmen, lame ducks, and "climbers" exposed. The swing of a crinoline by Leech and the curl of a cabdriver's hat brim by Keene were perfect selective imitation, themselves almost inimitable; the crinoline and the hat are gone with those who knew how to wear them, but the picture in *Punch* remains.

Photomechanical reproduction came in during Du Maurier's day but hardly affected his generation of artists. May's pen was better served by the camera and the zinc block than Leech's had been by end-grain boxwood and gravers, but the general language was the same. With the generation of Belcher there was a great change. His own crumbly charcoal or crayon strokes were perfectly adapted to the new process—indeed it was mutual—as were the fat black lines of the Frenchman Jean-Louis Forain and the mid-20th-century cobwebs of Rowland Emett. Fougasse's highly personal little curly stick men, drawn perhaps with a signwriter's pen, could be reproduced by almost any method, but the sharp lines and solid black areas of Bateman (deriving ultimately from Aubrey Beardsley's decorative style) and the thick–thin pen strokes of Shepard (more in the Keene tradition) were well served by modern processes. Shepard was more truly an illustrator than a cartoonist, but Bateman's towering humours and bulging-eyed apoplectic businessmen were in the direct line from Edward Lear to such frantic American cartoonists as Virgil Partch.

Contributions of Edward Lear

Lear practiced as a comic draftsman an economy and geniality that are hard to improve upon, but like Daumier he supposed that his own best gifts lay in another field. Humour had been brought into satire by Hogarth; a truly funny style of drawing was brought into cartooning by Lear. Hitherto, standard drawing techniques had been applied to grotesque shapes and comic situations, but Lear's line went wandering off into a sort of joke on calligraphy. Furthermore, he travelled into areas of fantasy previously barely hinted at.

Aubrey Beardsley used a caricaturist's methods, but little of his work, except perhaps the illustrations to *The Rape of the Lock,* was actually in intent or effect caricature or cartoon. If some of Cranach's prints can be called illustrated libels, some of Beardsley's can be called illustrated yearnings by unfrocked lechers. They are important in this connection because their combination of large white spaces, clear lines, and solid or slightly irritated blacks could be reproduced successfully in a choice of dimensions and thus laid down a discipline for illustration, commercial art, and the comic strip.

20th century. The whole tenor of pictorial comedy was shifted by World War I and by the boom times thereafter. Some previously forbidden subjects became admissible. Political caricature during and after the war was excessively partisan, while the cartoons about the war itself tended to alleviate the pain of the struggle. Bruce Bairnsfather's Old Bill and his colleagues in Britain got through it by joking. After it was over, the public for comic publications was greatly enlarged; while the newly rich were standard butts for cartoonists catering to all classes, they were themselves buying comic weeklies.

In the United States the usually monthly comic magazines of universities and colleges had a sudden flowering, to such an extent that an anthology for their cartoons called *College Humor* was published for several years in the 1920s and '30s. The tendency of previously serious weeklies to use small cartoons here and there or to insert a funny page somewhere created not only new markets for cartoonists but also a temporary decline in the purely humorous magazines, and *Punch, Life,* and *Judge* had difficulty surviving the Depression of the 1930s. The title of *Puck* had already passed to a newspaper chain which used it for a Sunday supplement, and the title of *Life* eventually passed to a periodical of different character. *Simplicissimus* never quite rose between wars to its pre-1914 stature; the effort which went into Dada and Surrealist publications in Germany and France in the '20s, when art itself became an object of social satire, meant a loss to other comic publications. Meanwhile, the public in general gradually became aware of modern art, and its presumed incomprehensibility became almost as routine a subject by 1940 as mothers-in-law or freshly painted park benches.

In the United States an older generation of humorists somewhat of the upper-class *Punch* style lingered briefly after World War I. Of such were Oliver Herford, whose *Alphabet of Celebrities* and other comic verses with pictures were published as small books; Peter Newell, whose highly original *Slant Book, Hole Book,* etc., had a sharp eye to late prewar costume, and Gelett Burgess, whose *Goops* for children were spaghetti-like little figures whose behaviour illustrated a moral.

But to these was now added a new generation of sophisticated but slightly flashier performers, many of them with theatrical connections, many at first employed by the fashion magazine *Vanity Fair* and later by *The New Yorker* (beginning in 1925); Ralph Barton, who did superb roués; Rea Irvin of the thin trembly line, poached eyes, and almost oriental splendour; John Held, Jr., whose angular young women helped define the Jazz Age; Gluyas Williams and Ellison Hoover, who satirized business, industrial labour, and other subjects not well known to the *Punch* tradition; and Alfred Frueh, whose caricatures of theatre people recalled Toulouse-Lautrec. The Depression of the 1930s brought forward a few artists with a genius for social protest, few of whom had any real sense of comedy because tragedy was not to them, as it had been to Daumier, the other side of the same coin. In the United States the Communist *Daily Worker* had the services of William Gropper, a distinguished lithographer and editorial cartoonist who was sometimes able to capture something of the humorous tone of the prewar *Masses.* And it gradually became known that in the Soviet Union a comic magazine called *Krokodil* was allowed to gibe at the ways of its brothers and even occasionally of its masters.

Cartoons of the Depression years

The two most interesting features of cartoon and caricature in the first half of the 20th century were the rise of the one-line joke and of the pictorial joke without words, and the enormous diversity of styles of drawing. *The New Yorker* was probably the inventor or reinventor of the one-line joke and certainly its chief fomenter. Five-decker dialogues with headings were swept away even from *Punch,* and there was a greater unity of words with picture, paralleling the tendency toward tabloid newspapers with large photographic halftones and very pithy text. The joke without words, often in two or more frames, was the extreme of economy of language. One result of this change was that the comedy-of-manners cartoon must convey its comment entirely through costume, setting, and (to a lesser extent) situation, and the emphasis thus tended to fall more on comic situation than on plays on words, class differences, or marked action. *The New Yorker* and magazines whose cartoons had been influenced by it aimed at a sophisticated audience. *The New Yorker* itself, while enjoying in its maturity a position equivalent to that of *Punch* in the 1880s, aimed its advertising and much of its writing at upper-income classes, but its cartoons were aimed at the classes described as highbrow and upper-middle-brow. Such features of the old-fashioned British-style upper class as servants were always treated by *New Yorker* cartoonists (notably Mary Petty) as necessarily comic fossils of an old order and hence in, rather than out of, that old upper class. Whole new areas of social-comedy subject matter arose in this magazine: the life of the Jewish community, the fauna of bars, the managerial class and its flavour, the lighter side of the well-kept woman, commercialized sports, the imagined life of colonies or races of antisocial beings, and what might be termed the comedy of the upwardly mobile.

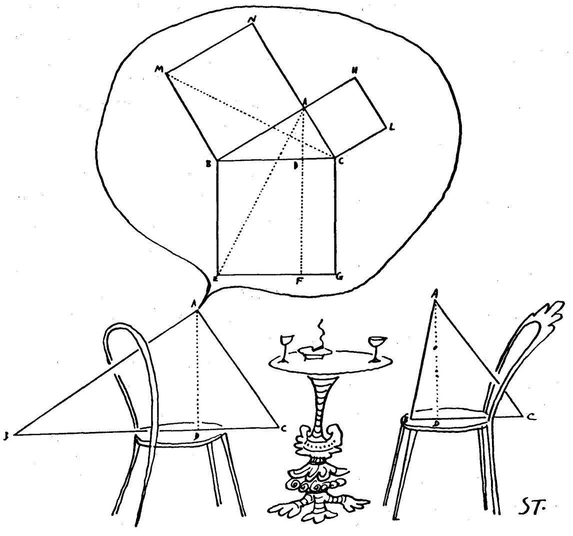
"For heaven's sake, can't you do anything right?" by Charles Addams.



Captionless cartoon by Saul Steinberg.

© 1961 Saul Steinberg from *The New World* (Harper & Row). Originally in *The New Yorker*

The diversity of styles of drawing reflected the influence of Postimpressionist art quite as much as did the use of modern art as a subject for jokes. The great draftsmen who were on the edges of Impressionism (such as Toulouse-Lautrec) had much influence on caricature and cartoon; while the same photomechanical reproduction that advanced the latter communicated modern painting to a vast public. The loose, almost deliberately ugly method of the Expressionists got into some of the single-cartoon commentators to such an extent that their shorthand was sometimes difficult for those who did not read them daily. The meandering willful line of the 20th-century Swiss painter Paul Klee certainly influenced Saul Steinberg; the Cubists' studies in African sculpture were echoed in cartoons by Miguel Covarrubias and Partch; the "classical" period of Pablo Picasso in Richard Taylor and others; the curving economical line of Henri Matisse (oddly enough) in Richard Decker. Occasionally, cartoonists parodied one another: Oliver Herford once presented Gibson girls as paper dolls without expression; Al Capp in the comic strip "Li'l Abner" parodied "Dick Tracy" and "Mary Worth." *Mad* magazine parodied everybody: style, subject, everything from politics to pornography.

The cartoon of predicament or situation

The comic strip having taken over the comic presentation of events almost completely, especially since the rise of the one-line joke or picture caption, the modern cartoon became one largely of situation or of predicament that was stated without a solution's being worked out or suggested. The mother of a sideshow circus family, confronted with more than she can manage, simply says that after all she has only three hands; a young girl is in ecstasies over a sunset, while behind her a bearded artist-stereotype says, "Too much purple." Meanwhile, the longer sort of comic anecdote retreated to a purely oral–aural life or to the bound volume of jokes, where it sometimes had a vignette-like illustration.

The cartoon of situation was certainly not new, but it predominated in the first half of the 20th century. A Daumier lithograph showing a very fat woman in a crinoline climbing into an omnibus bore no dialogue, but simply the caption, "A mere nothing, and the bus is full." This was a cartoon of predicament. There has tended to be a cluster of these situation subjects: the desert island no larger than a hearthrug, the man who meets a woman walking and (in a scalloped balloon) imagines her naked, the flying carpet with novel chauffeur or passenger, the picture gallery with mutual reaction between work of art and viewer, the psychoanalyst's couch, the big-game hunter's trophy room. If the situation was clear, not even one line of joke was required. Such cartoons had a sort of family connection with the earliest caricatures, but they were not merely antiportraits of types, they were portraits with accessories that created the predicament. So were the tiny single woodcut figures that were inserted as pictorial puns into the text pages of *Punch* in the 1840s. But the latter-day predicament may be highly complicated; in the hands of such a cartoonist as George Price, whose split pen line built up tattered edifices of dowdiness, or Emett, whose fantastic locomotives and wispy codgers were half infernal and half heavenly, the comedy came from an accumulation of frustrating but ludicrous detail. Frustration, that renowned companion of modern life, was dissolved by laughter. Even the presumably invincible American businessman was often represented in cartoons in frustrating situations, often briskly indicated by the graphic lines on the charts in his office (Whitney Darrow excelled in this genre). André François, who worked for both French and British papers, was a master of the rapidly sketched situation; so was "Anton" of *Punch* (a man and a woman jointly using the name), who kept up the tradition of satire through clothes, being particularly good at pseudo-Edwardian nattiness. Herb Stansbury's "Smart Chart," a one-frame comic for the financial page, satirized stock market graphs. In the drawings of the Romanian-born Saul Steinberg there was almost a parody of the cartoon of situation, for his lines doubled back on themselves and bit their own tails: the hand was indicated as drawing the portrait of which it was a part, or the frustrating details positively engulfed the subject (a wicker chair taken over entirely by its curlicues; tattooing extended beyond the tattooed man; the woman with a lozenge-shaped face, on her lap a baby whose lozenge-shaped face is one-quarter of the larger lozenge).

Unique style of Steinberg

Yet there were also extraordinarily simple performances; the unassuming little people of Jean Effel (François Lejeune) moved gently through the trials of Adam and Eve; Jacques Faizant's bad children produced hilarious effects by conveying their concentration in a few lines; Otto Soglow's stenographic vocabulary of forms for human bodies (perhaps slightly indebted to Burgess' *Goops*) was so graphic that it could be used in minuscule dimensions with perfect legibility. On the other hand, Peter Arno's large-scale and heavy outlines, despite simple straightforward design, made his beaky and bosomy figures almost jump off the page (for many years one of his near-bawdy cartoons almost invariably occupied a position in *The New Yorker* on the full page immediately after "The Talk of the Town," which suggested that the political cartoon of *Punch* was being ridiculed). Ronald Searle, after a long British career of making spiky and raffish pseudo-Edwardians and fiendish schoolgirls, had a success as an artist for American advertising. A pair of delightful opposite numbers were W. Heath Robinson and the slightly later Rube Goldberg, who on both sides of the Atlantic created wild half-anthropomorphic parodies of intricate machinery. During World War II, Bill Mauldin's disenchanted soldiers were proper descendants of Bairnsfather's. (W.Am.)

COMIC STRIPS AND COMIC BOOKS

Early strips. The comic strip, defined as a mass medium, cannot reasonably be said to exist before the invention of printing. In the early period two principal forms may be observed: the series of small images printed on a single piece of paper (narrative strip proper), and the series composed of several sheets of paper, with one image per page, which when displayed on the wall of a house formed a narrative frieze or picture story.

Early German woodcuts

From the outset two basic groups of themes emerge: political morality and private morality. Surviving pre-1550 strips, most of which are German woodcuts, deal with such subjects as the lives of saints (subdivided in the manner of late medieval painted altarpieces, an arrangement that may be considered a decisive factor on the compartmentalization layout of broadsheets); accounts of contemporary miracles; mockery of worldly love; and politically inspired accusations against the Jews. The Reformation and the ensuing wars of religion through the 17th century, particularly in Protestant Germany and the Netherlands, gave rise to many propagandistic and patriotic strips based on contemporary political events. In the course of the 17th century the narrative strip, hitherto an ill-defined and irregular phenomenon, became stabilized and typically took the form of an allegorical centerpiece

"Profanation of the Host by Jews at Passau 1477." German broadsheet, *c.* 1490.

surrounded by narrative border strips. Although generally crude in style, these strips manage to render accounts of political intrigue and moving descriptions of military terror; the best known in the latter category is the exquisitely executed and carefully cadenced narrative of the Thirty Years' War by Callot. Little known, but as powerful in their way, are De Hooghe's indictments of Huguenot persecution under Louis XIV. Romeyn, the first named artist to devote himself consistently to the narrative strip, also left colourful, forceful, and elaborate accounts of the accession of William III to power in Holland and England. English engravers, inspired by the Dutch example and led by Francis Barlow, retailed the complex political events of the period in the form of playing cards, which were often sold in uncut broadsheets.

The earliest strips concerning private morality are German and recount atrocious forms of murder and their public punishment, the emphasis shifting from the latter (in the 16th century) to the former (in the 18th century). The crime strip eventually developed into the more or less exaggerated and romanticized life of the famous brigand, which is the precursor of the modern detective strip. Narratives based on a wider spectrum of ideally immoral behaviour took as their point of departure illustrations for the parable of the Prodigal Son, woodcut versions of which, independent of the biblical text, were first produced by Cornelis Anthonisz of Amsterdam. The riotous living of the Prodigal, enriched with elements from illustrations for the Seven Deadly Sins and the Ten Commandments, was distilled in various Italian lives of harlots and rakes, the most comprehensive and drastic of which are mid-17th century Venetian. A generation later, the Bolognese artist G.M. Mitelli was giving his narrative and semi-narrative satires almost caricatural moral emphasis. German artists in the 17th century specialized in satirically exposing the tyranny of shrewish wives and proposing violent remedies. The Dutch at this time produced frankly farcical strips of primitive design expressly for children. By mid-18th century the Russians, too, were making satirical strips.

Hogarth's picture stories

The various social and moral themes that had been crudely treated in different countries and at different times were the raw material for the English artist Hogarth, who raised the anonymous broadsheet picture story to an aesthetic level which rarely has been surpassed. With a social insight both broad and deep, with an unrivalled sense of satirical counterpoint and topicality of reference, and with exceptional physiognomic finesse, Hogarth dealt with types from all classes of society. His narrative richness is entirely visual, for he dispensed with all the broadsheet paraphernalia of caption–balloon–legend–commentary, permitting only such inscriptions as can be introduced naturalistically into the scene. Hogarth's moral attitude was also new: he depicted the follies and the punishment of his protagonists with a measure of sympathy, reserving the full fire of his satire for those who exploit them. Among Hogarth's many followers, two stand out: the German Daniel Chodowiecki, who reduced the Hogarthian picture story within the compass of almanac illustrations, and the Englishman James Northcote, who tried to combine Hogarthian realism with a Neoclassical sentimentality ("Diligence and Dissipation," 1796).

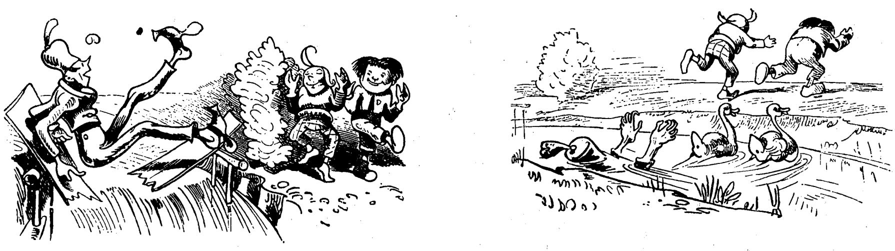
It was the introduction into the broadsheet of the essentially comic mechanism of caricature that established the "comic strip" as basically comic in both form and content. The major exponents of the caricatural strip during the "Great Age" of English caricature around 1800 were minor artists such as Henry Bunbury, George Woodward, and notably Richard Newton, who in his brief career combined elements of Hogarthian satire with the grotesque exaggerations of Rowlandson and Gillray. Economy of line, instantaneousness of comic effect, and visual and verbal wit now became the hallmark of the strip. With the story concentrated on a single page, backgrounds and narrative incident were minimized in favour of striking facial expressions and silhouetted poses.

Rodolphe Töpffer

19th century. The heir to the experiments of the English caricaturists, and the father of the comic strip in its modern sense, was Rodolphe Töpffer, a schoolmaster of Geneva, whose life spanned roughly the first half of the 19th century. Exempt from the personal–political preoccupations of the English caricaturists, Töpffer created a species of absurdist antiheroes who struggled desperately, fruitlessly, and farcically against the caprices of fate, nature, and an irrational, mechanistic society. The stories (lithographed in little oblong albums containing up to 100 pages) are purposefully purposeless, flow with calculated non sequiturs, and make digression a narrative principle. The pace is sustained by another revolution in draftsmanship, for Töpffer discovered how to turn systematic doodling to account, how to exploit the accident, and how to vary physiognomies experimentally. By abandoning anatomical, three-dimensional drawing, he showed how to render movement for movement's sake. Töpffer's strips are also morally mobile: the normal relationship between cause and effect or crime and punishment, which had underpinned all the older stories, disintegrated.

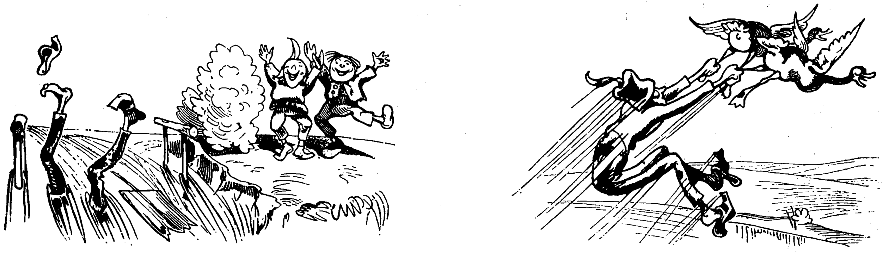
The Töpfferian mode was introduced into the new French satirical periodical journalism by various minor artists. By entering the regular newspaper press, the old broadsheet cartoon exchanged independence for security and became, for better or worse, subject to editorial control. Cham (pseudonym of Amédée de Noé) published several albums modelled on Töpffer in the 1840s, before settling for a style nearer to that of Daumier. The photographer Nadar (pseudonym of Gaspard-Félix Tournachon), among others, flirted intermittently with the new mode, rendering style and story line more realistic and therefore heavier. Léonce Petit, who had Töpffer's lightness of touch but not his imaginative flair, specialized in rustic farce. A special place is occupied by the illustrator Gustave Doré, who developed a new method owing relatively little to Töpffer (shown in, *e.g., Histoire de la Sainte Russie,* 1854). This was the illustrated chronicle in which a startling hodgepodge of picturesque effects was arranged casually or with deliberate incongruity into a loose chronological sequence.

The most original contribution by the British was the creation by Charles Ross and his wife, Marie Duval, of "Ally Sloper," which appeared in *Judy* (1867–76). Ally was the first real continuing comic strip character; the schemes of this proletarian loafer were depicted in rather formless forerunners of the modern gag strip. He was then mock-gentrified by W.G. Baxter and W.F. Thomas in a maga-



Und schon ist er auf der Brücke,
Kracks! die Brücke bricht in Stücke;

Grad als dieses vorgekommen,
Kommt ein Gänsepaar geschwommen,
Welches Böck in Todeshast
Krampfhaft bei den Beinen faßt.



Wieder tönt es: „Meck, meck, meck!"
Plumps! da ist der Schneider weg!

Beide Gänse in der Hand,
Flattert er auf trocknes Land. —

"Max und Moritz" by Wilhelm Busch.

zine named after him, *Ally Sloper's Half-Holiday* (1884–1923). In *Fun*, another *Punch* imitator, J.F. Sullivan ran a series of attacks on working-class and petty bourgeois types under the title *British Working Man* (1878), and *British Tradesman* (1880).

Dominance of Wilhelm Busch

The dominant figure of the late 19th century is the German Wilhelm Busch, whose immense popularity in his own day has survived into the late 20th century. At first in periodicals, then in separately published albums, Busch quickly established himself as the first fully professional and truly popular comic-strip artist, appealing to educated and simple, young and old alike. Not being bound to journals, he could, like Töpffer, develop much longer stories than his French contemporaries, whose strips rarely exceeded 50 or so scenes running over three successive issues of a magazine. His graphic and narrative line appears more controlled, more predictable than that of Töpffer; it is comic in an earthier and more rational way. He revived the tradition of realistic social satire, although only two of his stories (*Helen* and *St. Anthony*) have a simply definable satiric butt (religious hypocrisy). Busch appears as a man obsessed with the farcical situation and its potential for physical violence. Happiness appears to lie in the avoidance of the petty annoyances of life and in the repression of instinctual behaviour. His cautionary tales of naughty children and animals may be regarded, on one level, as sophisticated parodies of the didactic juvenile literature of Germany and, on another, as condemnations of the childish sadism that is assumed to lie in everyone. On yet another level, all his work can be viewed as essays on the vulnerability of human dignity. His best known characters, the infant pranksters Max and Moritz, have spawned innumerable progeny down to our own day. Busch's graphic inventiveness was tremendous: his use of patterns of oscillation to represent movement and new conventional signs to express shock, pain, and other emotions constitute a vocabulary that has served the humorous strip cartoonist down to our own times. The rolling rhythm of Busch's graphic line has its counterpart in his facile comic verse, which is both independent and complementary. Variation in the amount of this verse accompanying each picture plays an essential part in the pace of the narrative.

The only German follower of Busch worthy of the name was Adolf Oberländer, a sharp observer of human behaviour. The heir to Busch in France was Caran d'Ache, who in supplements to *Le Figaro* in the later 1880s drew the first strips to appear in a general-interest daily newspaper rather than in a weekly satirical magazine of relatively restricted readership. Always witty in a purely graphic sense, he frequently dispensed with captions altogether. In this respect, as in his technique of motif accumulation—his manner of letting a motif or movement snowball or crescendo ad absurdum—he taught much to later cartoonists, especially to Bateman in the 1920s.

Influence of the *Imagerie d'Épinal*

The influence of Busch on the development of the American newspaper strip was decisive; but European children's illustrated literature derived more from *Imagerie d'Épinal* and from the comic-strip artist Christophe. Throughout the 19th century the common people in France and The Netherlands, especially in rural areas, had subsisted on *Imagerie d'Épinal,* single broadsheets emanating from the town of Épinal, France, and hawked about the countryside. They covered, often in narrative form, such topics of folk interest as religious stories, patriotic histories, and fairy tales. The severe and simple didactic plates had a more or less realistic social emphasis. Some *Imagerie d'Épinal* are comic in content, although not always comic in style, relating, for instance, the folly of certain traditional social stereotypes or satirical characters from folklore and literature like Tyl Eulenspiegel and Baron Munchhausen. Christophe (pseudonym of Georges Colomb) raised this type of popular imagery to the level of the intelligent, urban child, first in the children's periodical, then in various albums published separately. These were originally designed, like Töpffer's, for the children of his own household and the pupils of his school. Christophe's gentle mockery of such types as the naïve bourgeois and the absent-minded professor is now implanted in French folklore. Christophe established a format for English and French children's comics which survived down to World War II, whereby the text is excluded from the image instead of being incorporated in the balloons of American usage.

First newspaper strips

20th century. *United States.* The modern newspaper strip was born in the heat of rivalry between giants of the American press. In January 1894 a comic strip filled, for the first time, a full-colour page of Joseph Pulitzer's newspaper the *New York World;* in October 1896 the publisher William Randolph Hearst announced in his rival paper, the *Morning Journal,* the first regular weekly full-colour comic supplement. This supplement ran to eight pages and included the "Yellow Kid" of Richard Outcault, whom Hearst had enticed away from the *New York World.* The "Yellow Kid" was the first continuous comic character in the United States. Outcault established earthy, strictly urban farce as the keynote of the early American strip, which thereafter grew in sophistication and sentimentality. The "Yellow Kid" also standardized the speech balloon, which had fallen largely into disuse since the 17th century and

its occasional appearance in the English caricatural strip around 1800. In 1897 Rudolph Dirks, at the instigation of Hearst, who had enjoyed the work of Busch as a child, worked up a strip based on "Max und Moritz," called the "Katzenjammer Kids," which proved an instant success. It had, for the first time, the fully developed form of the newspaper strip; *i.e.,* it used balloons, had a continuous cast of characters, and was divided into small regular panels (dispensing with the full panoramic scenes in which the "Yellow Kid" had appeared). The spread of comics to other newspapers was rapid and was aided by the development of newspaper syndication. The aesthetically outstanding strip of the early years was Winsor McCay's "Little Nemo in Slumberland" (first appearance 1906), which created a dreamworld at once gentle, exciting, and humorous. The strip was executed in fairy-tale illustration style, with a conscious display of colouristic effects.

The daily strip in black and white, indispensable to all major newspapers since 1915, was inaugurated in 1904 in the Chicago *American* with Claire Briggs' "A. Piker Clerk," in which a character gave tips on horse races. Harry C. "Bud" Fisher's "Mr. A. Mutt" (later "Mutt and Jeff") appeared in 1907. Initially a tip sheet, it soon became a general-interest comic.

Establishment of subject categories

During the years 1907–20 most of the major categories of American comics were established, including the first aviation, ethnic-character, and career-girl strips. The most important gag strip was George McManus' "Bringing up Father," dating from 1913. It was the first American strip to achieve international fame. Outstanding among the family-saga or domestic-problem strips that burgeoned during the '20s was Frank King's "Gasoline Alley," which dated from 1919. It strove for realism rather than farcical effects, and had a strict continuity (as opposed to the daily gag), during which, moreover, characters actually grew older. The first career-girl strip (Martin V. Branner's "Winnie Winkle") appeared in 1920. It was followed by the fashion-conscious "Tillie the Toiler" in 1921 by Russ Westover. Another major group of the '20s were fantastic, satirical, and parodistic. Elzie Crisler Segar's "Popeye" (first appearance 1919) still depended upon slapstick, but George Herriman's "Krazy Kat" (1911–44) created a tender world of poetry, at once surreal and humorous. Drawn with the greatest of graphic economy, the absurd interrelationships of a tiny cast of characters (basically three) were presented using the thinnest imaginable plot line. "Krazy Kat" was the first newspaper strip anywhere to be aimed at relatively intellectual adults.

During the 1930s the comics page expanded both in quantity of strips and in range of subject matter. Several of the strips created then have survived for more than 40 years. One of these, Chic Young's domestic comedy strip "Blondie" (first appearance 1930), has achieved unparalleled international renown.

A new category of immense significance emerged: the continuous-action adventure strip. This category took many forms: domestic and detective drama, science and space fiction, and, by 1938, war and supermen strips. The earliest adventure strip was "Tarzan" (first appearance 1929) whose creator Harold Foster broke completely with the prevailing caricatural style, adopted cinematic techniques, and sought picturesque, documentary realism. No less concerned with classic aesthetic effects was Alex Raymond, first master of the exotic space strip ("Flash Gordon," first appearance 1933). An aggressively cinematic, adventure strip, meticulously researched, was evolved by Milton Caniff in his "Terry and the Pirates," which appeared in 1934. Caricatural simplifications and grim forms of humour were introduced into the genre by Chester Gould's "Dick Tracy" (first appearance 1931), the detective strip par excellence, which is laced with science-fiction gadgetry and bizarre eroticism. Truly satirical forms of exaggeration returned to the strip with Capp's "Li'l Abner" (first appearance 1934).

The comic book

The demand for adventure stories spawned a new and highly lucrative vehicle for the comic strip: the cheap, staple-bound comic book. The first true comic books were marketed in 1933 as give-away advertising premiums. These had a 7½- by 10¼-inch (19- by 26-centimetre) page size, a format that has continued. By 1935 such titles as *Famous Funnies, Tip Top Comics, King Comics,* at first chiefly reprints of newspaper strips, then with original stories, were selling in large quantities. Specialization soon set in: *Detective Comics* (1937) and *Action Comics* (1938). "Superman," which appeared first in *Action Comics,* was the creation of Jerry Siegel (scenario or text) and Joe Shuster (art); it was soon syndicated and transposed to other media. The "Superman" formula of the hero who transcends all physical and social laws to punish the wicked, was widely imitated. The animated cartoon characters of Walt Disney also took root in the comic book.

World War II hastened the development of strips and comic books dealing with war and crime, the latter finding a new and avid readership among American soldiers stationed abroad. Being outside the control of newspaper editors, the comic book became increasingly violent and gruesome. The sadism of the American comic became proverbial; the "comic" became equated by Europeans with the "horror comic," and voices of educators were raised against it on both sides of the Atlantic. United States

Congressional investigations in 1951 and 1954 blamed rising juvenile deliquency on the pernicious influence of the comic book. The industry responded by instituting systems of self-censorship, administered by several organizations; the more vicious-looking material was restrained, but, in Europe, some U.S. adventure strips continued to be criticized for their pursuit of violence and for their racist, militarist, and fascist tendencies.

Perhaps as a reaction, there was a parallel, postwar development in newspaper strips devoted to sentimental domestic drama—such as "Rex Morgan, M.D.," "Mary Worth," and "The Heart of Juliet Jones"—and simple-looking, but subtly conceived gag strips—such as "Beetle Bailey," the incorrigible draftee, and "Dennis the Menace," a sophisticated Katzenjammer. "Pogo" (first appearance 1946) by Walt Kelly was generally considered the most humorous and most cerebral. Drawn in a style reminiscent of Walt Disney, the strip transcended Disney's moral simplism, presenting a highly nuanced world populated with an almost Dickensian multitude of comic characters. "Pogo" exuded a tender, nostalgic air, perpetually ruffled by the breezes of sociopolitical allusion. Kelly's dialogue was also much admired, particularly since it appeared at a time when the comic strip was widely criticized for verbal poverty.

Literate strips of the 1950s

The literate strip with philosophical, psychological, and sociological overtones was the principal innovation of the later 1950s. Most successful in this group was Charles Schulz's "Peanuts" (first appearance 1950), a strip in which all the characters were children, dispensing with the adult foil. Of comparable psychological finesse, and imbued with truly satirical flashes, was Johnny Hart's "B.C." (first appearance 1958) and "Wizard of Id" in collaboration with Brant Parker (first appearance 1964), which had prehistoric and medieval settings, respectively. The major strip of political satire, "Feiffer" by Jules Feiffer (first appearance 1956), appeared weekly and was not run on the comics page but on editorial pages of the more liberal or "left" papers. In this strip the dialogue was more important than the drawings, which were deliberately repetitive; the content played upon the logic-twisting rhetoric of politicians and the neurotic relationships between social competitors and lovers.

The most significant innovation since about 1965 has been in the parodistic, erotic, and surrealistic comic. Parody and burlesque of the newspaper strip were pioneered by *Mad* magazine (first published in 1952). The erotic, laced with parody, found a home in the liberal periodical press ("Little Annie Fannie" in *Playboy* in 1962 and "Phoebe Zeitgeist" in *Evergreen Review* in 1968). Comic books satirizing a cultural underworld "liberated" by sex and drugs became popular, particularly among college students. These comics were pioneered in San Francisco by Robert Crumb, Rick Griffin, and S. Clay Wilson. The major drug-oriented strip, Gilbert Shelton's "Fabulous Furry Freak Brothers," circulated widely in the *Los Angeles Free Press*.

Europe. The first recurrent British comic characters, after Ally Sloper appeared in 1884, were Tom Brown's tramps "Weary Willie and Tired Tim." The strip was sponsored in 1896 by the publisher Alfred Harmsworth and was originally intended for the newly literate and semiliterate masses, but it developed into children's fare.

Strips for young children in Great Britain

Distinctive British contributions were the magazine of strips designed for preliterate children (*Tiger Tim's Weekly,* first published in 1920, and *Playbox,* which first appeared in 1925); the picture paper based on film comedy (*Film Fun, Kinema Comic*); and the multitude of children's magazines containing both articles and comic strips. The first strip for young children to appear in an adult newspaper was "Rupert, the Adventures of a Little Lost Teddy Bear," created by Mary Tourtel for the *Daily Express* in 1920. The text is fitted in below the balloonless pictures, in order to facilitate reading aloud by adults. The first British adult newspaper strip and after *Krazy Kat* the first daily strip anywhere designed exclusively for adults was the witty "Pop" by John Millar Watt, which first appeared in 1921. "Pop," together with Reginald Smythe's "Andy Capp" (first printed in 1957), were among the very few European strips to be exported to the United States. A notably original strip was Norman Pett's "Jane," published first in the *Daily Mirror* in 1932. It used an artful striptease theme and had great popularity with servicemen during World War II. The mildly satirical strip was pioneered in 1949 in the *Daily Express* by "Flook," a continuing narrative of various kinds of adventure (drawn by Wally Fawkes and written since 1958 by George Melly), and by Frank Dickens' "Bristow," a daily gag strip set in a business office. The outright satirical and political strip flowered in the new satirical magazines such as *Private Eye* (first published in 1961).

Comics in France and Italy

In France, Jean-Pierre Pinchon's "Bécassine" (first appearance 1905), modelled on Christophe, depicted the humorous adventures of a stupid but well-intentioned Breton servant; Louis Forton's "Bande des pieds-nickelés" (first appearance 1908), although ostensibly for children, had political touches and a mocking tone that appealed to adults as well. The first European strip to be fully developed in the American sense (notably as regards the use of balloons) was Alain de Saint-Ogan's "Zig et Puce" (first appearance 1925). France had no daily comic strip until 1934. There and in Italy, even more than in England, the market was smothered in the 1930s and '40s by American imports and imitations. An outstanding and hardy domestic product was "Tintin," created by the Belgian Hergé (pseudonym of Georges Rémi), a realistically conceived and relatively didactic adventure strip with a kind of Boy Scout hero. The immense popularity of "Tintin" has (since about 1964) been challenged by a warrior of ancient Gaul called "Astérix," the work of the writer (and comic-strip theorist) René Goscinny and the artist Albert Uderzo. "Astérix," besides being simply humorous and adventurous, indulges in sophisticated puns, witty anachronisms, and satirical flashes.

Colour, previously distorted and cheapened on the coarse newsprint of weekend papers and children's magazines, at last began to change the whole aesthetic character of the picture story—and improve it beyond recognition. In the 1960s Italian and French strips for adults by such artists as Guy Peellaert ("Jodelle"), Guido Crepax ("Valentina"), and Nicholas Devil ("Saga de Xam") paved the way for a new era in the comic strip, in which aesthetic expression aligned itself with contemporary art movements such as Pop, Op, and psychedelic art and availed itself of the most advanced printing techniques. The influence worked both ways. American art, particularly the Pop movement, was profoundly affected from about 1963 by comic-strip imagery. In Europe, where leading filmmakers admitted their debt to the comics, it was predicted that film, graphic art, and the comic strip would fuse into a new medium.

Dissemination of comics

The comics industry. The newspaper strip and comic book have become arguably the largest and most influential iconographic field in history, with literally millions of pictures produced since 1900. They certainly represent the dominant graphic mythology of the 20th century. Not even the film or television can boast of reaching a third of humanity, as can the comic strip. More than 100,000,000 Americans, young and old, educated and not, read one or more comic strips in their Sunday and daily newspapers. In 1963 there were more than 300 different strips in the United States. "Blondie" is syndicated in about 1,200 newspapers all over the world, "Peanuts" in about 1,000; "Pogo" reached and "Dick Tracy" reaches more than 50,000,000 readers in more than 500 newspapers. *Superman* comics circulated in the 1950s at the rate of 1,500,000 monthly; in 1943 U.S. comic books totalled 18,000,000 monthly copies, constituting a third of total magazine sales, to a value of $72,000,000.

Not surprisingly, reader participation has reached extraordinary heights; readers truly laugh and suffer with their favourite characters. Young received 400,000 suggestions for a name for Blondie's new baby.

Perhaps in no other form of art has the creator become to such an extent prisoner of his creation, to which he may be locked for his lifetime and which becomes in a real sense independent of his own existence, for the successful strip will almost always be continued by other artists if the original creator should die or lose interest in it. Traditionally, the newspaper strip is also in fief to the syndicates, publishers, and editors who regard it primarily as a circulation booster. The conventional view has been that it must not offend any conceivable readership or commercial-interest group and therefore must observe strict, conservative codes of morality and decorum. This explains the extent to which the newspaper strip generally has avoided controversial issues of the day. It was against such restrictions that the American underground comic and the European *bande dessinée pour adultes* ("adult strip") struck out, and in their wake some innovative newspaper strips, notably G.B. Trudeau's "Doonesbury," began to break new ground. (D.M.Ke.)

ABEL (eds.), *The Funnies: An American Idiom* (1963), articles by critics, creators, and scholars, a comprehensive bibliography of articles in professional, specialized, and general periodicals, and of theses and special studies; FREDERIC WERTHAM, *Seduction of the Innocent* (1954, reprinted 1972), on the theory that the horror comic has contributed to juvenile delinquency. (W.Am./D.M.Ke.)

Descartes and Cartesianism

René Descartes (Latin: Renatus Cartesius) is known as the father of modern philosophy. A 17th-century French mathematician, scientist, and philosopher, he was the first to oppose Scholastic Aristotelianism. He began by methodically doubting all forms of knowledge, then found certainty in the intuition that, when he is thinking, he exists; this he expressed in the famous statement "I think, therefore I am." He developed a dualistic system in which he distinguished radically between mind, the essence of which is thinking, and matter, the essence of which is extension in three dimensions. Descartes's metaphysical system is intuitionist, derived by reason from innate ideas, but his physics and physiology, based on sensory knowledge, are mechanistic and empiricist.

This article is divided into the following sections:

LIFE AND WORKS

Family and regional background. Descartes was born in La Haye (now Descartes), Fr., on March 31, 1596. Although La Haye is in Touraine, Descartes's family connections were south across the Creuse River in Poitou, where his father, Joachim, owned farms and houses in Châtellerault and Poitiers. Because Joachim was a councillor in the Parlement of Brittany in Rennes, Descartes inherited a low rank of nobility. Descartes's mother died when he was one year old. His father remarried in Rennes, leaving him in La Haye to be raised by his maternal grandmother and a nurse and probably also by his great-uncle Michel Ferrand, lieutenant general (court judge) in Châtellerault. The Descartes family was Roman Catholic, but Poitou was a Huguenot stronghold and Châtellerault a "secure city," in which the Edict of Nantes, which gave Protestants freedom of worship in France, was worked out in 1597–98. Descartes returned to Poitou regularly until 1628.

Jesuit education

Education, travels, and early influences. In 1606 Descartes was sent to the Jesuit college at La Flèche, established in 1604 by Henry IV. At La Flèche 1,200 young gentlemen were trained for careers in military engineering, the judiciary, and government administration. Besides classical studies, science, mathematics, and metaphysics, students were taught acting, music, poetry, dancing, riding, and fencing. Descartes's philosophy professor was Father François Véron, known later as the scourge of the Protestants. Aristotle was taught from Scholastic texts. In addition, Descartes received special attention from a relative, Father Charlet, later rector of La Flèche. In 1610 Descartes participated in an imposing ceremony, in which Henry IV's heart was placed in the cathedral of La Flèche. Henry IV's assassination had destroyed the hope of religious tolerance in France and Germany.

In 1614 Descartes went to Poitiers, where he took a law degree in 1616. At this time Huguenot Poitiers was in virtual revolt against Louis XIII. Descartes's father probably expected him to enter Parlement, but, because the legal age for that was 27, Descartes had seven years to wait. In 1618 he went to Breda in Holland for 15 months as a student in mathematics and military architecture in the peacetime army of the Protestant ruler, Maurice, prince of Orange. There Descartes met the physician Isaac Beeckman, who encouraged him in science and mathematics and for whom Descartes wrote his *Musicae Compendium* (written 1618, published posthumously; *Compendium of Music*).

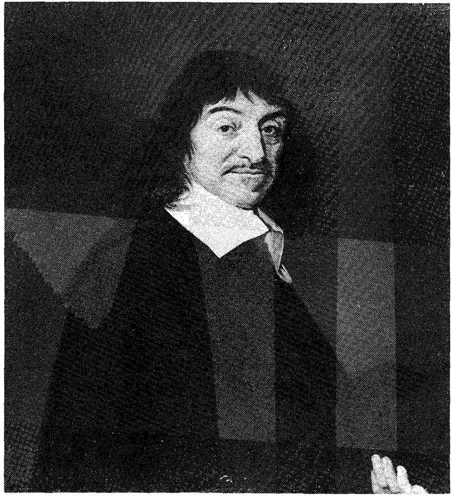
During the period 1619 to 1628 Descartes traveled in northern and southern Europe, saying that he was studying the book of the world. While in Bohemia in 1619 he had three dreams that defined for him his career as a scientist and a philosopher seeking knowledge for the benefit of humanity. By 1620 he had conceived of a universal method of deductive reasoning, applicable to all the sciences. He had also investigated reports of esoteric knowledge such as theosophical claims to command nature. Although disappointed with the followers of the magician Raymond Lulle and the alchemist Cornelius Agrippa, Descartes was impressed by the German mathematician and Rosicrucian Johann Faulhaber.

Affinities with Rosicrucian goals

Descartes shared a number of Rosicrucian goals and habits of life. Like Rosicrucians, he lived a single, secluded life, changing residence often (during his 22 years in Holland he lived in 18 different places), practiced medicine without charge, tried to increase human longevity, and expressed optimism about the ability of science to improve the human condition. At the end of his life he left a chest of personal papers—none of which have survived—with his close friend, the Rosicrucian physician Corneille van Hogelande, who handled his affairs in Holland. But Descartes rejected the Rosicrucians' magical and mystical beliefs. For him it was a time of hope for revolution in science. The English philosopher Francis Bacon, in *Advancement of Learning* (1605), had already proposed a new science of observation and experiment to replace the traditional Aristotelian science, as did Descartes later.

In 1620 Descartes was in the Roman Catholic army of Maximilian I, duke of Bavaria, who defeated the Protestants in Bohemia. There is, however, no evidence that Descartes ever participated in any battles. He said military life was idle, stupid, immoral, and cruel.

Cliche Musees Nationaux, Paris



Descartes, oil painting by Frans Hals, 1649. In the Louvre, Paris.

In 1622 Descartes moved to Paris. There he gambled, rode, fenced, and went to the court, concerts, and the theatre. Among his friends were the poets Jean-Louis Guez de Balzac, who dedicated his *Le Socrate chrétien* to Descartes in 1650, and Théophile de Viau, who was burned in effigy and imprisoned in 1623 for writing verses mocking religious themes. He also made friends with the mathematician Claude Mydorge and with Father Marin Mersenne, a man of universal learning who during his lifetime wrote thousands of letters to hundreds of scholars, writers, mathematicians, and scientists, keeping everyone aware—despite his almost unreadable handwriting—of what everyone else was doing. Mersenne was Descartes's main contact with the larger intellectual world. Descartes regularly hid from his friends in order to work, writing treatises, now lost, on fencing and metals. He acquired a high reputation long before he published anything.

Cardinal de Bérulle

At a talk in 1628 Descartes denied the alchemist Chandoux's claim that probabilities are as good as certainties in science and demonstrated his own method for attaining certainty. The Cardinal de Bérulle, who had founded the Oratorian teaching order in 1611 to rival the Jesuit order and who was forming the Compagnie du Saint-Sacrement, a militant, secret society of laymen to fight Protestantism, was impressed and invited Descartes to a conference. Bérulle was a strange combination of astute politician, courtier, and mystic who often advised the Queen Mother and talked familiarly with God and angels every day. Many commentators speculate that Bérulle urged Descartes to write an Augustinian metaphysics to replace Jesuit Thomism. There can be no question that in one way or another Bérulle tried to recruit Descartes to the Catholic cause. The result, however, was that within weeks Descartes left for Protestant Holland, took great precautions to conceal his whereabouts, and did not return to France for 16 years. Rather than taking Bérulle as director of his conscience, as some argue, it is probable that Descartes—who was a Roman Catholic but not an enthusiast, who was accused of being a Rosicrucian, who was from a Huguenot province, who glorified reason, and who advocated religious tolerance—was frightened by the mystical, militant Bérulle.

Choice of Holland as residence

Descartes said that he went to Holland to enjoy a greater liberty than was available anyplace else and to avoid the distractions of Paris and friends so that he could have the leisure and solitude to think. (He had inherited enough money and property to live independently.) Holland was a haven of tolerance. Descartes could be an original, independent thinker there without fear of being burned, for example, for giving natural explanations of miracles, as was Lucilio Vanini in 1619, or of being drafted as a soldier for the Roman Catholic Counter-Reformation. He opposed vows that restricted liberty and said, when accused of having illegitimate children, that, after all, he was a man and had taken no vows of chastity. In France, by contrast, religious intolerance was mounting. The Jews were expelled in 1615, and the last Protestant stronghold, La Rochelle, was crushed—with Bérulle's participation—only weeks before Descartes's departure. Catholic commentators insist that Descartes would have been safe in France, but the Parlement of Paris passed a decree in 1624 forbidding attacks on Aristotle on pain of death. Although the Catholic priests Mersenne and Pierre Gassendi did publish attacks without being persecuted, heretics continued to be burned, and laymen lacked church protection. Descartes may have felt in some jeopardy because of his friendship with such libertines as Father Claude Picot, a bon vivant known as the Atheist Priest, with whom Descartes left his financial affairs in France.

Residence in the Netherlands. In 1629 Descartes went to the university at Franeker, where he stayed with a Roman Catholic family and wrote the first draft of his *Meditations.* He registered at the University of Leiden in 1630, where he gained as a disciple the physician Henri Reneri. In 1631 he visited Denmark and in 1633–34 was in Germany with the physician and alchemist Étienne de Villebressieu, who invented siege engines, a portable bridge, and a two-wheeled stretcher. The physician Henri Regius taught Descartes's views at the University of Utrecht in 1639, starting a fierce controversy with the Calvinist theologian Gisbertus Voetius that continued until the end of Descartes's life. In his *Letter to Voetius* of 1648 Descartes made a plea for religious tolerance and the rights of man. He said that he wrote not only for Christians but also for Turks—meaning libertines, infidels, deists, and atheists. He argued that because Protestants and Catholics worship the same God, both can hope for heaven. But when the controversy became intense, Descartes sought the protection of the French ambassador and of his friend Constantijn Huygens, secretary to Prince Frederick Henry, ruler of the Dutch Republic.

In 1635 Descartes's daughter Francine was born to Helena Jans and was baptized in the Reformed Church in Deventer. Although Francine is referred to as Descartes's illegitimate daughter, her baptism is recorded in a register for legitimate births. Descartes said that his greatest sorrow was Francine's death of scarlet fever at the age of five and that he was not a philosopher who believed that one must refrain from tears to prove oneself a man.

The World, Rules,* and *Discourse on Method. In 1633 Descartes was about to publish *Le Monde* (published posthumously; *The World*), when he heard that the Italian astronomer Galileo Galilei had been condemned in Rome for publishing the view that the Earth revolves around the Sun. Because this Copernican position is central to Descartes's cosmology and physics, he suppressed *The World,* hoping that the church would retract its condemnation and make it possible for him to publish his work later. He feared the church, but he also hoped that his physics would one day replace Aristotle's in church doctrine.

Discourse on Method

In 1637 Descartes published *Discours de la méthode* (*Discourse on Method*), one of the first important modern philosophical works not written in Latin. Descartes said that he wrote in French so all who had good sense, including women, could read his work and learn to use their reason to think for themselves. He believed that everyone could tell true from false by the natural light of reason. In three essays forming part of the *Discourse* he illustrated his method for utilizing reason in the search for truth in the sciences. In *Optics* he then presented the law of refraction, in *Meteorology* he explained the rainbow, and in *Geometry* he gave an exposition of analytic geometry, which is a method of representing geometric figures with algebraic equations that made many previously unsolvable problems solvable. He also introduced the conventions of representing known numerical quantities with $a, b, c, \ldots,$ unknowns with $x, y, z, \ldots,$ and squares, cubes, and other geometric figures with numerals, as in $x^2, x^3, \ldots,$ which made algebraic notation much clearer than it had been before.

In *Discourse* and *Regulae ad Directionem Ingenii* (*Rules for the Direction of the Mind*), written by 1628 but not published until after his death, Descartes gave four rules for reasoning: (1) Accept nothing as true that is not self-evident. (2) Divide problems into their simplest parts. (3) Solve problems by proceeding from simple to complex. (4) Recheck the reasoning. These rules are a direct application of mathematical procedures. Descartes insisted that key notions and the limits of each problem must be clearly defined.

In *Discourse* he also provided a provisional moral code (later presented as final) for use while seeking truth: (1) Obey local customs and laws. (2) Make decisions on the best evidence and then stick to them firmly as though they were certain. (3) Change desires rather than the world. (4) Always seek truth. This code exhibits Descartes's prudential conservatism, decisiveness, Stoicism, and dedication. For Descartes all knowledge was like a tree—with metaphysics forming the roots, physics the trunk, and medicine, mechanics, and morals the branches—on which the fruit of knowledge is produced.

Meditations. In 1641 Descartes published in Latin—because it was dedicated to the Jesuit professors at the Sorbonne in Paris—*Meditationes de Prima Philosophia* (*Meditations on First Philosophy in Which Is Proved the Existence of God and the Immortality of the Soul*). Mersenne submitted it before publication to eminent thinkers, among whom were the Jansenist philosopher and theologian Antoine Arnauld, the English philosopher Thomas Hobbes, and the Epicurean atomist Gassendi. Mersenne collected their critical responses and published them under the title *Objectiones Septimae* (1642; *Objections and Replies*). Even though Descartes said that the Jesuit priest Pierre Bourdin, one of the respondents, was a fool, *Objections and Replies* is a landmark of cooperative discussion in philosophy and science at a time when dogmatism was the rule.

Cogito, ergo sum

Descartes begins *Meditations* with methodic doubt, rejecting as though false all forms of knowledge by which he was ever deceived. His arguments derive from the Pyrrhonism of the Greek skeptic Sextus Empiricus as reflected in the skeptical writings of Michel de Montaigne and Pierre Charron. Thus knowledge based on authority is set aside because even experts are sometimes wrong. Knowledge from sensory experience is declared untrustworthy because people sometimes mistake one thing for another, as with mirages. Knowledge based on reasoning is rejected as unreliable because one often makes mistakes as, for example, when adding. Finally, knowledge may be illusory because it comes from dreams or insanity or from a demon able to deceive men by making them think that they are experiencing the real world when they are not. Descartes finds certainty in the intuition that when he is thinking, even if deceived, he exists: *Cogito, ergo sum* ("I think, therefore I am"). The *cogito* is a logically self-evident truth that gives certain knowledge of a particular thing's existence: one's self. But the *cogito* justifies accepting as certain only the existence of the person who thinks it. If all one ever knew for certain was that he exists, and if one adhered to Descartes's method of doubting all that is uncertain, then he would be reduced to solipsism, the view that nothing exists but the individual and his thoughts. To escape this, Descartes argues that all ideas that are as clear and distinct as the *cogito* must be true, for if they were not, the *cogito* also, as a member of the class of clear and distinct ideas, could be doubted. But "I think, therefore I am" cannot be doubted. Therefore all clear and distinct ideas must be true.

On the basis of clear and distinct innate ideas Descartes then establishes that each mind is a spiritual substance and each body a part of one material substance. The mind or soul is immortal because it is unextended and cannot be broken into parts, as can extended bodies. Descartes also advances proof for the existence of God. He begins with the statement that he has an innate idea of God as a perfect being and then intuits that God necessarily exists, because if he did not, he would not be perfect. This ontological proof for the existence of God is at the heart of Descartes's rationalism, for it establishes certain knowledge about an existing thing solely on the basis of reasoning from innate ideas, with no help from sensory experience. Descartes then argues that because God is perfect, he does not deceive human beings; therefore the world exists. Thus Descartes claims to have given metaphysical foundations for the existence of his own mind, of God, and of the world.

Objections to Descartes's procedure

A famous objection to Descartes's procedure is Arnauld's Cartesian Circle, which exposes the circularity inherent in Descartes's reasoning. To know that God exists, one must trust the clear and distinct idea of God; but to know that clear and distinct ideas are true, one must know that God exists and does not deceive man. Descartes the rationalist rejected magic, but he failed to see that his ontological proof is word-magic based on the superstition that things can be determined by ideas and thoughts. In opposition to Descartes's rationalism, empiricists hold that descriptions of things must come after, not before, one knows by experience that they exist.

Physics, physiology, and morals. Descartes's goal was to be master of nature. He provided understanding of the trunk of the tree of knowledge in *The World, Optics, Meteorology,* and *Geometry* and revealed its roots in *Meditations;* he then spent the rest of his life working on the branches of mechanics, medicine, and morals. Mechanics is the basis of his medicine, or physiology, which in turn is the basis of his moral psychology. Descartes believed that all material bodies, including the human body, are machines that operate by mechanical principles. In his physiological studies he dissected animal bodies to show how their parts move. He argued that because animals have no souls, they do not think or feel; thus vivisection, which Descartes pioneered, is permitted. He also described the circulation of the blood but came to the erroneous conclusion that heat in the heart expands the blood, causing its expulsion. Descartes's *L'Homme, et un Traité de la formation du foetus* (*Man, and A Treatise on the Formation of the Foetus*) was published after his death.

In 1641 Descartes was visited by Picot and Jacques Vallée Desbarreaux, known as the Grand Debauché, who had published the libertine poet Théophile. Descartes used them as models for characters (he was himself model for a third) in his dialogue *Search After Truth.* In 1642 Samuel Sorbière, the French translator of Sextus and Hobbes, visited Descartes and wrote a charming description of him as host. Descartes then lived in the small but very elegant château of Endegeest, outside Leiden, near the court in The Hague.

Interaction of mind and body

In 1644 Descartes published *Principia Philosophiae* (*Principles of Philosophy*), a compilation of his physics and metaphysics. He dedicated this work to Princess Elizabeth, daughter of Elizabeth Stuart, titular queen of Bohemia, who was in exile in The Hague, for he had developed his moral philosophy in correspondence with her. According to Descartes, a human being is a union of mind and body, two dissimilar substances that interact in the pineal gland. He reasoned that the pineal gland must be the uniting point because it is the only non-double organ in the brain, and double reports, as from two eyes, must have one place to merge. He argued that each action on a person's sense organs causes subtle matter to move through tubular nerves to the pineal gland, causing it to vibrate distinctively. These vibrations give rise to emotions and passions and also cause the body to act. Bodily action is thus the final outcome of a reflex arc that begins with external stimuli and involves first an internal response, as, for example, when a soldier sees the enemy, feels fear, and flees. The mind cannot change bodily reactions directly—for example, it cannot will the body to fight—but it can change the pineal vibrations from those that cause fear and fleeing to those that cause courage and fighting.

Descartes furthermore argued that men can be conditioned by experience to have specific emotional responses. He, for example, had been conditioned to be attracted by cross-eyed women because he had loved a cross-eyed playmate as a child. But when he remembered this fact, he was able to rid himself of his passion. This insight was the basis for Descartes's defense of free will and of the mind's ability to control the body. But, despite such arguments in defense of free will, Descartes's *Les Passions de l'âme* (*Passions of the Soul*), dedicated in 1649 to Queen Christina of Sweden, holds that most of man's bodily actions are determined by external material causes.

Descartes's anti-Christian morality

Descartes's morality was anti-Christian in that, in contrast to Calvinists and Jansenists, he suggested that grace is not necessary for salvation but that human beings are virtuous and able to achieve salvation when they do their best to find and act upon truth. His optimism about the ability of human reason and will to find truth and reach salvation is in stark contrast with the pessimism of the Jansenist (predestinarian) apologist and mathematician Blaise Pascal, who believed that salvation comes only as a gift of God's grace. Descartes was accused of adhering to an error of the 12th-century Arabic philosopher Averroës, who said that virtuous behaviour depends on free will rather than on grace. Descartes agreed, however, that unless people believe in God and immortality they will see no reason to be moral.

Free will, Descartes stated, is the sign of God in human nature, and human beings can be praised or blamed according to their use of it. People are good only if they act in goodwill for the good of others; such generosity is the highest virtue. Descartes was Epicurean in his assertion that human passions are good in themselves and an extreme moral optimist in his belief that to understand the good is to want to do it; because passions are willings, to want something is to will it. But he was also a Stoic in his admonition that human beings should control their passions rather than change the world.

Although Descartes wrote no political philosophy, he approved of Seneca's admonition to acquiesce in the order of things. He rejected Machiavelli's recommendation to lie to friends, because friendship is sacred and life's greatest joy. Human beings cannot exist alone but must be parts of social groups, such as nations and families, and it is better to do good for the group than for oneself.

Descartes had been a puny child with a weak chest and was not expected to live. He therefore watched his health carefully and became a virtual vegetarian. In 1639 he bragged that he had not been sick for 19 years and expected to live to be 100. He told Elizabeth to think of life as a comedy; bad thoughts cause bad dreams and bodily disorders. Because there is always more good than evil in life, one can always be content, no matter how poorly off one is.

In his later years Descartes said that he had once hoped to learn to prolong life to a century or more. But he then saw that in order to achieve that goal the efforts of many generations would be required; he himself had not even learned to prevent a fever. Thus, he said, instead of continuing to hope for long life, he had found an easier way, namely to love life but not fear death. It is easy, he claimed, for a true philosopher to die tranquilly.

Final years and heritage. After 16 years in Holland Descartes returned to France for brief visits in 1644, 1647, and 1648, on financial business and to oversee the translation into French of *Principles, Meditations,* and *Objections and Replies* (the translators being, respectively, Picot, the Duke du Luyons, and Claude Clerselier). In 1647 he also met with Gassendi and Hobbes and suggested to Pascal the famous experiment of taking a barometer up Mount Puy-de-Dôme to determine the influence of the weight of the air. In Paris Descartes joined with Pierre d'Alibert, treasurer general of France, in a plan to establish a workshop school of arts and crafts in the Royal College. Picot returned with Descartes to Holland for the winter of 1647–48. During Descartes's final stay in Paris in 1648 the revolt of the nobility against the crown, known as the Fronde, broke out. As a result Descartes left Paris precipitously on Aug. 17, 1648, only days before his mortally ill old friend Mersenne died. Back at his retreat in Egmond, in Holland, Descartes was visited by the young Francis Burman, whose *Conversations* gives a genial and illuminating picture of Descartes.

Hector Pierre Chanut, Clerselier's brother-in-law, helped to procure a pension for Descartes from Louis XIV (which was never paid). Then Chanut, who was French resident and later ambassador to Sweden, gained an invitation for Descartes to the court of the Swedish monarch, Queen Christina, who by the close of the Thirty Years' War had become one of the most important and powerful monarchs in Europe. Descartes went reluctantly, arriving early in October 1649. He may have gone because he needed protection; the Fronde seemed to have destroyed his chances in Paris and the Calvinist theologians were still harassing him in Holland.

The 22-year-old Christina perversely made the 53-year-old Descartes rise at 5:00 AM to give her philosophy lessons, even though she knew of his habit of meditating in bed until 11 o'clock in the morning. She also ordered him to write verses for a ballet, *La Naissance de la paix* (1650; *The Birth of Peace*), a virtual pacifist tract celebrating Christina's role in the Peace of Westphalia, which ended the Thirty Years' War, and a comedy in five acts, now lost. In addition he wrote the statutes for a Swedish Academy of Arts and Sciences. While delivering these statutes to the Queen at 5:00 AM on Feb. 1, 1650, Descartes caught a chill. In this land, where he said that in winter men's thoughts freeze like the water, Descartes developed pneumonia. He died in Stockholm on Feb. 11, 1650. Many pious last words have been attributed to Descartes, but the most trustworthy report is probably that of his German valet, Schulter, who said that Descartes was in a coma and died without saying anything at all. The last thing Descartes wrote was a letter asking his brother to continue the pension Descartes had been paying to their old nurse.

Descartes's papers

After his death Descartes's papers came into the possession of Clerselier, a pious Catholic, who began the process of turning Descartes into a saint by cutting, adding to, and selectively publishing his letters. This cosmetic work culminated in 1691 in the massive biography by Father Adrien Baillet, who had previously published a 17-volume *Lives of the Saints.* But even while Descartes was still alive, there were questions as to whether he was a Roman Catholic apologist, primarily concerned with supporting Christian dogma, or an atheist, concerned only with protecting himself with pious sentiments while establishing a deterministic, mechanistic, and materialistic physics.

These questions remain difficult to answer, not least because many papers and manuscripts available to Clerselier and Baillet are now lost. The Roman Catholic Church made its decision in 1667 by putting Descartes's works on the Index of Forbidden Books on the very day his bones were ceremoniously placed in Ste. Geneviève-du-Mont in Paris. During his lifetime Protestant ministers in the Netherlands called him a Jesuit and a papist—*i.e.,* an atheist—but he said that they were intolerant, ignorant bigots. Up to about 1930 the majority of scholars, many of whom were religious men, believed that Descartes's major concerns were metaphysical and religious. By the late 20th century, however, numerous commentators had come to believe that Descartes was a Catholic in the way he was a Frenchman and a royalist, that is, by birth and by politics.

Descartes himself said that good sense is destroyed when one thinks too much of God. He once told the German protégée Maria van Schurmann that she was wasting her intellect studying Hebrew and theology. He also was perfectly aware of, although he tried to conceal, the atheistic potential of his materialist physics and physiology. Descartes also seemed indifferent to the emotional depths of religion. Whereas Pascal trembled when he looked into the infinite universe and perceived the puniness and misery of man, Descartes rejected the view that human beings are essentially miserable and sinful. Instead he exulted in the power of human reason to understand the cosmos and to promote human happiness. He held that it was impertinent to pray to God to change things, insisting rather that human beings must try to improve themselves.

CARTESIANISM

Certain versus probable knowledge

The Cartesian system. Cartesianism is a set of philosophical traditions and scientific attitudes. Metaphysically, Cartesianism is rationalist and Platonic, meaning that certain knowledge is derived by reason from innate ideas. This opposes the empiricist Aristotelian view that all knowledge is probable and is based on sense experience. In practice, however, Cartesians developed probabilistic scientific views from observation and experiment, as did empiricists. Cartesians had to be satisfied with uncertainty in science because they believed that God is omnipotent and that his will is entirely free. From this it follows that God, who, in addition to the material world, created all truths (such as those of mathematics and the laws of nature), could, nonetheless, given his infinite intellect and his free will, arbitrarily make even contradictions be true. The human intellect, by contrast, is finite; thus men can be certain only of the *cogito* and of revealed religion. Cartesians, however, did not derive scientific truths from religious knowledge, as did the Roman Catholic Church, and thus in practice they had to accept scientific knowledge as uncertain and probable.

Cartesians divide the world into a metaphysical dualism of two finite substances, mind (spirit or soul) and matter. The essence of mind is self-conscious thinking, the essence of matter extension in three dimensions. God is a third, infinite substance, whose essence is necessary existence, and God unites minds with bodies to create a fourth, compound substance, man. Humans have general knowledge of mind, matter, and God by contemplating innate ideas. But for particular knowledge of events in the world, humans depend on motions, transmitted from the sense organs through nerves to the brain, that cause sensible ideas to arise in the mind. Cartesians thus claimed to know the outer world by way of representative sensible ideas in the mind.

This dualism of mind and matter gives rise to serious problems concerning causal interaction and knowing. Given the essential unlikeness of mind and matter in the compound substance man, how can the body cause the mind to have sensible ideas? How can the mind cause the body to move? And how can the mind know the material world by way of sensible ideas that are mental? Various lines of Cartesian philosophy developed from different answers to these questions.

Cartesian mechanism. The first French Cartesians were physicists and physiologists who gave mechanistic explanations of physical and biologic phenomena. Father Nicolas Malebranche, a French theologian and philosopher who believed that animals are machines, once kicked a pregnant dog and then chastised such critics as Jean de La Fontaine, the French writer of animal fables, for expending their emotions over an unfeeling machine that moves and makes noises, depending merely on how and where it is stimulated, rather than in sympathy with human misery. In Paris the lectures of Pierre-Sylvain Régis on Cartesian physics—accompanied by spectacular demonstrations—created such a sensation that Louis XIV forbade them. Because Cartesianism challenged the traditional Aristotelian science supported by the Roman Catholic Church and because the church stood behind the divine right of kings to rule, the king feared that any criticism of traditional authority might give rise to revolution. (Descartes's stress on each individual's ability to think for himself did provide support for republicanism in the 18th century.)

Advancement in mechanical arts and crafts provided the practical foundation of Cartesian mechanism. In the 17th century mechanical inventions such as statues that walked and talked by application of levers and pullies and organs that played by waterpower were well known. Pascal invented a calculating machine based on principles worked out by clockmakers and by inventors of spinning and knitting machines, such as the Englishman William Lee. The first Cartesian inventors were the French craftsman Ferrier, who made lenses according to Descartes's designs, and Étienne de Villebressieu, who with Descartes's collaboration developed an improved pump.

Mechanism was promoted by Mersenne and derived theoretically from Gassendi's Epicurean atomism and Galileo's experiments with moving bodies. According to Descartes the material universe consists of an indefinitely large plenum of infinitely divisible matter separated into the subtle matter of space and the denser matter of bodies by a set quantity of motion imparted by God. Bodies swirl like leaves in a whirlwind in vortices as great as that in which the planets sweep around the Sun and as small as that of tiny, spinning globes of light. All bodily joinings and separations are mechanical and result from moving bodies bumping into one another. Because the amount of motion is conserved according to the laws of nature, the Cartesian material world is deterministic. After the initial impulse the world evolves lawfully; if the speeds and amounts of motion and the positions of all the whirling portions of matter in the universe were described for any one time, then simple deductions with reference to the laws of motion would allow their descriptions for any other time. But of course only God has the infinite intellect required to make these calculations.

Cartesian determinism

God is the primary cause of the existence of the material universe and of the laws of nature. But all material events—*i.e.,* the actual movements and interactions of bodies—occur as results of secondary causes. God stands merely for the uniformity and consistency of the laws of nature.

Cartesianism was popularized in England by Antoine Le Grand, a French Franciscan, who gave an exposition of the typically ingenious mechanistic explanation of light and colour. Light consists of tiny, spinning globes of highly elastic, subtle matter that fly through the air in straight lines and bounce like tennis balls on angles consistent with the laws of optics. Different colours, in this view, are caused by different speeds and spins of the globes, determined by the texture of the surfaces that reflect or transmit light. The spectrum of colours caused by light passing through a triangular prism is the result of the globes passing more slowly through thicker rather than thinner portions. The same spectrum of colours occurs when light passes through thinner and thicker parts of raindrops, giving rise to rainbows. Such simple mechanistic explanations were shown by Newton and others to be inadequate for explaining the forces of gravitation and chemical bonding. Nonetheless, this explanation of light and colour is in principle like the explanation, now accepted, that light can be separated into colours according to different wavelengths.

The challenge of Newton's physics

By the end of the 17th century Cartesian rationalistic physics had been abandoned for the empirical results of observation and experience, and the explanatory value of Newton's mathematical physics vastly exceeded that of simple mechanism. Cartesians admitted that Descartes's laws of motion were wrong and that the principle of the conservation of motion had to be replaced by the Newtonian principle of the conservation of energy. Although Jacques Rohault's *Treatise* (1671) on Cartesian physics was translated into English in 1723 by Samuel Clarke, a philosopher and theologian and also a friend and disciple of Newton's, and by his brother Thomas Clarke, their corrections and annotations with footnotes turned the treatise into an exposition of Newtonian physics.

Mechanism versus Aristotelianism. Cartesian mechanism was in opposition to the Scholastic Aristotelian science supported by both Roman Catholic and Protestant theologians. These theologians held that because all things are created by God with a given nature, there is no evolutionary development of either the universe or animals. For Aristotelians the motive force of a thing is the internal power of its nature—on the model of willpower—that, for example, makes an acorn become an oak tree. Every individual thing was thus thought to contain an essence or nature, a spirit or soul, that gives it its distinctive being. These souls are what give life to living things, whereas for mechanists, animate bodies are no more than very complicated machines. For Cartesians, the human body, for example, does not die because the soul leaves it, as the Aristotelians say; the soul leaves because the body disintegrates. According to the Aristotelian view, all things have virtues or desires and strive to reach predetermined goals. Thus everything is purposive, and to understand a thing scientifically one must know the end or final cause toward which it aims.

Rejection of the occult

Descartes rejected both the teleological, animistic view and the related theory of alchemy that there are vital forces in things. Cartesians denied the existence of these occult, or magic, forces, insisting instead that only God and humans have spirits, wills, purposes, and ends. They perceived both animate and inanimate bodies as having no goals but as simply being pushed around passively. For Cartesians, science therefore consisted not of looking for final causes but rather for the mechanical laws of moving bodies. Thus Descartes ridiculed the belief that the stars—bodies many times larger than the Earth and immensely far away—exert influences on human beings, as astrologers claim. (Descartes's attack on astrology was made at a time when the Cardinal de Richelieu, Louis XIII's first minister, had horoscopes cast and consulted seers such as Bérulle.) Mechanists also opposed magic by conjuring or magic by incantations—that is, appeals to angels and the supposed spirits in things—and sympathetic magic, because they perceived no mechanical reason why things that look alike should influence one another.

There are no mysteries in Cartesian mechanistic natural science. By insisting on human free will, however, Descartes places the human soul or mind, like God, outside deterministic nature. Because the body is a part of deterministic nature, the mind's control of body movements tends to be miraculous and destructive of mechanistic determinism. In the end, given Descartes's system, the human mind must be perceived as an animistic force and its ability to move the body by willpower as magic.

Mind, body, and man. Most Cartesians believed that the mind and body interact. When asked how, Régis gave the standard Cartesian reply that human beings experience it and that God can and does make interaction take place, even if one cannot understand how. This is to offer a nonphilosophical, mystical answer to a problem that demands a clear explanation. As for the question of how ideas represent objects, the physician Rohault spoke for all Cartesians when he replied that God made ideas that are mental to represent material bodies without resembling them and that no further explanation was necessary. Again, this answer abdicates philosophy for mysticism and theology; it sounds like the reintroduction of Aristotelian forms or natures and thus goes against Descartes's own claim to be able to give intelligible explanations of all natural phenomena.

Thomists (adherents of the philosophical and theological system developed by Thomas Aquinas) say the soul or mind is an Aristotelian form or nature, *i.e.,* a force or power to inform or make neutral matter into a specific thing. In the example of the acorn, the form is what makes the acorn develop into an oak tree. On this view, a human is a unitary substance compounded of a form (the soul) and neutral matter, neither of which can exist independently. The human soul, however, is said to be a substantial form, miraculously able to exist independently of matter and thus to survive the death of the body. Descartes pointed out that this notion of substantial form is contradictory. Cartesian dualism presents the mind or soul as a substance existing in itself, independently of matter, and thus explains immortality without resorting to the miracle of turning the soul-form into a substance. This dualism, however, presented Cartesians with a serious problem about the ultimate nature of humans. The French physician Louis de La Forge concluded that at death the mind or soul is completely severed from all knowledge of individual bodies. This occurs because sensible ideas, for Cartesians, arise from the mind–body union for the sole purpose of preserving the body by presenting harmful things as painful and beneficial things as pleasurable. Human beings learn by experience what to seek and avoid, and the memory of these experiences is preserved in the brain. But once the body dies, both the need for sensible ideas and their memory traces in the brain are destroyed.

The soul after death

What the soul knows of matter after death is only the general idea of extension; that is, it knows mathematics but cannot remember the faces of friends. One problem this view raises is that, because bodily associations and memories are eliminated at death, individual personality is lost; thus it would be impossible to differentiate one soul from another. On Cartesian principles, a human being survives death only as an impersonal soul, identical to all other bodiless souls. Like the notion that animals are mere machines, the Cartesian conclusion that sensible manifestations of this life are neither continued nor remembered in the next was unpopular.

Science and religion. Besides the mind–matter dualism within Cartesian metaphysics, in Cartesianism as a whole there is a dualism between rationalist metaphysics, which depends on the certainty of general reasoning about innate ideas of mind, matter, and the necessary existence of God, and mechanistic physics, which advances scientific knowledge by accumulating probabilities based on observation and experience of the particularities of the material world. This has led some commentators to present Descartes almost exclusively as an apologist for Christianity, while others have argued persuasively that he was an atheist materialist interested only in physics. Descartes publicly denied interest in theology, but in letters he offered mechanistic explanations of transubstantiation. Thomists said that the forms of bread and wine are miraculously sustained as substantial forms (like the Thomistic soul), while their matter is replaced by Christ's flesh and blood. Rohault utilized the Cartesian view that sensible ideas are caused by configurations of the parts of material bodies to argue that if bread and wine were replaced by flesh and blood whose parts have exactly the same configurations as bread and wine, the flesh and blood would look, feel, and taste like bread and wine. While this would require miraculous replacement of bread and wine by flesh and blood, there would be no issue of contradictory substantial forms.

Arnold Geulincx's deterministic Cartesian ethics

The Flemish Calvinist Arnold Geulincx developed a deterministic Cartesian ethics. In his view, although one can do only what God has willed, one is free to accept this willingly or unwillingly. Virtue consists in the humble, diligent, and obedient acceptance of the justice of God's decrees in the light of reason, whereas sin and evil result from man's egotistic (and futile) stand against God. This Stoical ethics, with its affinity to Calvinist and Jansenist predestinarianism, is as deterministic as Cartesian physics; it does, however, contradict Descartes's claim that the human will is free not just to accept or reject the rightness of predetermined bodily actions but also to choose and cause a particular action.

Malebranche and occasionalism. The most important philosophical work stemming directly from Descartes's writings is *Search After Truth* (1674–75) by the Oratorian Malebranche. His position is known as occasionalism, and it was adopted also by Geulincx and the French philosopher Géraud de Cordemoy. Malebranche was convinced by the argument—urged most strongly by the French skeptic and chaplain Simon Foucher—that Cartesian mind and matter because of their essential unlikeness cannot interact. Malebranche held that on every occasion when human bodies interact with the world, God provides the appropriate sensible ideas in their minds. And on every occasion when humans will that their bodies move, God makes them move. Thus there is no direct causal interaction between mind and body; there are only separate but parallel sequences of mental and material events intermediated by God. Foucher also argued that, because ideas that are mental cannot resemble material things, ideas cannot represent bodies. That is, sensible ideas are coloured images, tactile feelings, sounds, odours, and tastes—as sensed—while the properties of material bodies are size, shape, position, and motion or rest; for example, the taste of sweetness is utterly unlike the sugar that causes it. How then do these ideas give man knowledge of the outer world as it really is? Like Descartes before him, Malebranche denied that ideas must resemble their objects to represent them. To the possibility that one might have sensible ideas of a nonexistent world, Malebranche said tersely that the first chapter of Genesis assures the existence of the material world. As to how man's ideas of this world are true, Malebranche offered the Platonic view that ideas of all things reside in the mind of God and that on appropriate occasions God illuminates these ideas for human observation. Thus human beings see all things in God and rest assured in his goodness.

Malebranche denied that he was a Cartesian. Unlike Descartes, he argued that introspection gives no knowledge of the essence of the mind. This led the English philosopher John Locke to suggest that matter might, for all human beings know, be able to think. All Cartesians opposed this possibility because the separation of mind or soul from body supports the Christian doctrine that the human soul survives the death of the body.

Later philosophers. The rationalist metaphysics of the Dutch-Jewish philosopher Benedict de Spinoza derive from Descartes. Spinoza's *Ethics* (1677) was written in mathematico-deductive form, with definitions, axioms, and derived theorems. Spinoza's metaphysics is monistic, pantheistic, and deist in that he argued that there is only one substance, God, which is the world and not (as theists hold) a person. This substance has an infinite number of attributes, each of which expresses the totality of God or the world. The only attributes humans know are mind and matter. All attributes are parallel in every respect, and thus, although mind and matter do not interact, for Spinoza as for Malebranche they appear to do so.

Another rationalist, the German scientist and diplomat Gottfried Wilhelm Leibniz, also gave a parallelistic answer to mind–body problems.

Leibnizian monads

Leibnizian monads, or psychic units of reality—inner forces, or powers, of the sort Descartes banished from the world—are self-complete. Each monad reflects the entire universe from a distinctive point of view. Monads do not interact, but because each is in preestablished harmony with all the others, the appearance of interaction is maintained.

The Irish phenomenalist George Berkeley also presented a monistic system. He vindicated the common-sense belief that material things are like sensible ideas by saying that there is no matter; bodies are only collections of sensible ideas provided to the human mind in lawful order by God. Thus ideas are not representative and open to skeptical objections about whether they provide true knowledge of things. Things or phenomena are known directly, according to Berkeley. There also is no problem of mind–body interaction because bodies are made up of mental ideas, some of which the human mind can control.

Hobbes, by contrast, did away with mind, asserting that only matter exists. Thinking and sensing mind is just a manifestation of brain activity. Thoughts are epiphenomenal (*i.e.,* above and irrelevant to mechanical material interactions); they are like the noise of a squeaky wheel. Thoughts and feelings reflect what is going on in the body just as the squeak indicates that the wheel needs greasing. But thoughts are totally derivative and have no influence whatsoever on the operation of the body machine. Thus Hobbes's monistic materialism also does away with the problem of mind–body interaction.

The way of ideas and the self. Two further lines of influence can be traced to Descartes, one stemming from the Cartesian theory of knowing by way of representative ideas, the other from the Cartesian *cogito.* The former is rooted in Galileo's distinction between real, or primary, properties of bodies—size, shape, position, and motion or rest, all of which are quantitative—and sensible, or secondary, properties—colours, tactile feelings, sounds, odours, and tastes—said to exist only in the mind. As Descartes's theory of light shows, and as Locke later specified, secondary properties of bodies are only distinctive arrangements of primary properties that act on sense organs, causing sensible ideas in the mind. Locke thought that the sensible ideas of size, shape, position, and motion or rest resemble material objects as they are. (Modern science is based almost exclusively on mathematical descriptions of such primary properties.) But one might again object that, because all ideas are mental, none can resemble material objects. How does one know that ideas represent bodies? As stated above, Berkeley's phenomenalism—that only minds and sensible ideas exist—is one heroic solution to this skeptical problem: Bodies are known directly because they are made of sensible ideas. The Scottish philosopher David Hume took this solution one step further by saying that minds also are nothing but collections of ideas. Building on Hume in the 20th century, the English philosophers G.E. Moore and Bertrand Russell, the German positivists Moritz Schlick and Rudolf Carnap, and the Austrian-born Ludwig Wittgenstein called sensible ideas sense data, out of which they made logical constructions of the world. The German philosopher Edmund Husserl attempted to establish a science of phenomenology by describing sensible ideas. Russell and the American pragmatist William James suggested constructing both mind and matter out of neutral monads. All of these systems stem from the Cartesian way of ideas.

The second line of influence derives from the Cartesian *cogito,* with its roots in the Neoplatonic philosophy of St. Augustine. Stress on the self or ego is behind the developmental idealism of the German philosopher G.W.F. Hegel, who envisioned a World Soul coming to consciousness. Focus on the being of the self by the German philosopher Martin Heidegger led to the existentialism of the French philosopher Jean-Paul Sartre, who argued that each individual chooses to come into being out of nothing. Sartre also upheld the Cartesian position that the self is conscious by denying the unconscious proposed by the Austrian psychoanalyst Sigmund Freud.

Contemporary influences. Some aspects of Cartesian metaphysics are still strongly defended in the 20th century. Like Descartes, the American linguist Noam Chomsky argues that all human beings have an innate ability to learn language which distinguishes humans from all other animals. The Australian physiologist John C. Eccles and the English primatologist Wilfred E. Le Gros Clark postulate the mind as a nonmaterial entity. The British philosopher Karl Popper proposes a dualism between the material and the ideational.

20th-century attacks on Cartesian dualism

The strongest 20th-century attack on Cartesian dualism was launched by the British analytic philosopher Gilbert Ryle in *The Concept of Mind* (1949), where he exposes what he describes as the fallacy of the ghost in the machine. He argues that the mind—the ghost—is simply the intelligent behaviour of the body. Like many contemporary analytic philosophers, Ryle maintains that metaphysical questions about being and reality are nonsense because they include reference to empirically unverifiable entities. His position, like that of the Australian philosopher J.J.C. Smart, is ultimately materialist: The mind is the brain. The American pragmatist Richard Rorty in *Philosophy and the Mirror of Nature* (1979) argues that the Cartesian demand for certain knowledge is a holdover from man's mistaken quest for God. Rorty says that philosophy in the Cartesian tradition is the 20th century's substitute for theology and should, like God, be gently laid to rest.

But Descartes's influence is so pervasive that all Western philosophers, even when they deny Cartesianism, can be said to be Cartesians, as they can be said to be Greeks; their positions are necessarily responses to issues posed by Descartes. Descartes also stands at the beginning of modern mathematics; through his invention of analytic geometry he laid essential ground for the invention of the infinitesimal calculus by Newton and Leibniz. Cartesian method was brilliantly elaborated by the Jansenists Pierre Nicole and Arnauld in logic and grammar texts that are fundamental to linguistics. Hume's distinction between fact and value issued from the elevation of the mathematically objective over the emotional and subjective. Descartes's skeptical, mathematical method underpins modern science; his rationality forms Western man's modern consciousness; and his intense desire to control mind and matter corresponds to the ultimate secular goal of contemporary science and society. This stress on mastery of nature, including man, has led to the contemporary sense of "Cartesian" as standing for everything that is crassly materialistic, logical, unfeeling, and inhuman in science, technology, and society. But Descartes himself said that he wanted only to serve humanity.

MAJOR WORKS

The history of the original works and their early translations into English is as follows: *Musicae Compendium* (written 1618, published posthumously; *Renatus Des-Cartes Excellent Compendium of Musick,* 1653); *Regulae ad Directionem Ingenii* (written 1628, published posthumously); *Le Monde de Mr Descartes, ou Le traité de la lumière* (written 1633, published posthumously); *Discours de la méthode pour bien conduire sa raison, & chercher la verité dans les sciences. Plus la dioptrique; les meteores; et la geometrie* (1637; *A Discourse of a Method for the Wel-guiding of Reason, and the Discovery of Truth in Sciences,* 1649); *Meditationes de Prima Philosophia* (1641; and its 2nd ed., with *Objectiones Septimae,* 1642; *Six Metaphysical Meditations; Wherein It Is Proved That There Is a God,* 1680); *Principia Philosophiae* (1644); *Les Passions de l'âme* (1649; *The Passions of the Soule,* 1650).

Descartes's correspondence has been collected in *Lettres de Mr Descartes: Où sont traittées plusieurs belles questions touchant la morale, physique, medecine, & les mathematiques,* ed. by Claude Clerselier, 3 vol. (1666–67); and *Correspondance,* ed. by Charles Adam and Gaston Milhaud, 8 vol. (1936–63, reprinted 1970). A classic edition of complete works is the multivolume *Oeuvres de Descartes,* ed. by Charles Adam and Paul Tannery, published several times since it appeared in 12 vol. with a supplement in 1897–1913. See it in a later edition, 11 vol. in 13 (1974–82). It includes Descartes's correspondence.

Modern translations into English, many with valuable commentaries, include such selections as *Descartes: Philosophical Letters,* trans. and ed. by Anthony Kenny (1970, reprinted 1981); *Descartes' Conversation with Burman,* trans. by John Cottingham (1976); *Descartes, His Moral Philosophy and Psychology,* trans. by John J. Blom (1978); *The Philosophical Writings of Descartes,* trans. by John Cottingham, Robert Stoothoff, and Dugald Murdoch, 2 vol. (1984–85); separate works, *Treatise of Man,* trans. by Thomas Steele Hall (1972); *Le Monde, ou, traité de la lumière,* trans. into English by Michael Sean Mahoney (1979); and *Principles of Philosophy,* trans. by Valentine Rodger Miller and Reese P. Miller (1983). Several translations of the *Discourse* can be recommended: *Discourse on Method,* trans. by Laurence J. Lafleur (1950, reprinted 1986); *Discourse on Method, Optics, Geometry, and Meteorology,* trans. by Paul J. Olscamp (1965); and *Discourse on Method and Meditations on First Philosophy,* trans. by Donald A. Cress (1980).

BIBLIOGRAPHY

Descartes. GREGOR SEBBA, *Bibliographia Cartesiana: A Critical Guide to the Descartes Literature, 1800–1960* (1964), is an informative bibliography covering biographical and doctrinal books and articles. See also VERE CHAPPEL and WILLIS DONEY (eds.), *Twenty-Five Years of Descartes Scholarship, 1960–1984: A Bibliography* (1987).

Life: The basic biographical sources are Descartes's own works and letters. ADRIEN BAILLET, *La Vie de Monsieur Des-Cartes,* 2 vol. (1691, reprinted 1987), is a major source despite its apologetic bias. ELIZABETH S. HALDANE, *Descartes: His Life and Times* (1905, reissued 1966), is an early modern biography; CHARLES ADAM, *Vie & oeuvres de Descartes: Étude historique* (1910), was published as part of the above-mentioned edition of complete works. See also GUSTAVE COHEN, *Écrivains français en Hollande dans la première moitié du XVII^e siècle* (1920, reprinted 1976); CORNELIA SERRURIER, *Descartes: L'homme et le penseur* (1951; originally published in Dutch, 1930); JACK R. VROOMAN, *René Descartes: A Biography* (1970); JONATHAN RÉE, *Descartes* (1974); and LEON PEARL, *Descartes* (1977).

Philosophy: Descartes's philosophical doctrine is studied in many works, beginning with his contemporaries and continuing into present-day scholarship. See BENEDICTUS DE SPINOZA, *The Principles of Descartes' Philosophy,* trans. from Latin by HALBERT HAINS BRITAN (1905, reprinted 1974); MAXIME LEROY, *Descartes: Le Philosophe au masque* (1929); NORMAN KEMP SMITH, *New Studies in the Philosophy of Descartes: Descartes as Pioneer* (1952, reprinted 1987); WILLIS DONEY (ed.), *Descartes: A Collection of Critical Essays* (1967); ANTHONY KENNY, *Descartes: A Study of His Philosophy* (1968, reprinted 1987); FERDINAND ALQUIÉ, *Descartes,* new ed. (1969), in French; HIRAM CATON, *The Origin of Subjectivity: An Essay on Descartes* (1973); MARGARET DAULER WILSON, *Descartes* (1978, reprinted 1982); E.M. CURLEY, *Descartes Against the Skeptics* (1978); NICOLAS GRIMALDI, *L'Expérience de la pensée dans la philosophie de Descartes* (1978); BERNARD WILLIAMS, *Descartes: The Project of Pure Enquiry* (1978); MICHAEL HOOKER (ed.), *Descartes: Critical and Interpretative Essays* (1978); JOHN COTTINGHAM, *Descartes* (1986); PETER J. MARKIE, *Descartes's Gambit* (1986); WILLIS DONEY (ed.), *Eternal Truths and the Cartesian Circle: A Collection of Studies* (1987); GENEVIÈVE RODIS-LEWIS (ed.), *Méthode et métaphysique chez Descartes* (1987); and GREGOR SEBBA, *The Dream of Descartes,* ed. by RICHARD A. WATSON (1987).

Descartes's theology and ontology are explored in J.-R. ARMOGATHE, *Theologia cartesiana: L'Explication physique de l'Eucharistie chez Descartes et dom Desgabets* (1977); MARTIAL GUÉROULT, *Descartes' Philosophy Interpreted According to the Order of Reasons,* 2 vol. (1984–85; originally published in French, 1953); JEAN-LUC MARION, *Sur la théologie blanche de Descartes: Analogie, création des vérités éternelles et fondement* (1981), *Sur l'ontologie grise de Descartes: Science cartésienne et savoir aristotélicien dans les Regulae* (1975), and *Sur le prisme métaphysique de Descartes: Constitution et limites de l'onto-théo-logie dans la pensée cartésienne* (1986). For Descartes the scientist and mathematician, see J.F. SCOTT, *The Scientific Work of René Descartes* (1952, reprinted 1987); STEPHEN GAUKROGER (ed.), *Descartes: Philosophy, Mathematics, and Physics* (1980); DESMOND M. CLARKE, *Descartes' Philosophy of Science* (1982); and GENEVIÈVE RODIS-LEWIS (ed.), *La Science chez Descartes* (1987). Interpretative studies of Descartes's separate works include JEAN-MARIE BEYSSADE, *La Philosophie première de Descartes: Le Temps et la cohérence de la métaphysique* (1979); HENRI GOUHIER, *Descartes: Essais sur le "Discours de la méthode," la métaphysique et la morale,* 3rd ed. (1973); L.J. BECK, *The Metaphysics of Descartes: A Study of the Meditations* (1965, reprinted 1979); ALEXANDER SESONSKE and NOEL FLEMING (eds.), *Meta-meditations* (1965); FREDERICK BROADIE, *An Approach to Descartes' Meditations* (1970); HARRY G. FRANKFURT, *Demons, Dreamers, and Madmen: The Defense of Reason in Descartes's Meditations* (1970, reprinted 1987); and AMÉLIE OKSENBERG RORTY (ed.), *Essays on Descartes' Meditations* (1986).

Cartesianism. Early background analyses include the following: NORMAN KEMP SMITH, *Studies in the Cartesian Philosophy* (1902, reprinted 1987), which covers the failure of rationalism from Descartes through Kant; JEAN P. DAMIRON, *Essai sur l'histoire de la philosophie en France, au XVII^e siècle,* 2 vol. (1846, reprinted 1970); FRANCISQUE BOUILLIER, *Histoire de la philosophie cartésienne,* 3rd ed., 2 vol. (1868, reprinted 1987); GEORGES MONCHAMP, *Histoire du cartésianisme en Belgique* (1886); JOSEPH PROST, *Essai sur l'atomisme et l'occasionalisme dans la philosophie cartésienne* (1907); JOSEPH BOHATEC, *Die cartesianische Scholastik in der Philosophie und reformierten Dogmatik des 17. Jahrhunderts* (1912, reprinted 1966); GASTON SORTAIS, *La Philosophie moderne depuis Bacon jusqu'à Leibniz,* 2 vol. (1920–22), and *Le Cartésianisme chez les jésuites français au XVII^e et au XVIII^e siècle* (1929); GILBERT RYLE, *The Concept of Mind* (1949, reprinted 1984), a critique of Cartesian dualism as a springboard for the presentation of doctrines of contemporary linguistic philosophy and philosophy of mind; E.J. DIJKSTERHUIS *et al., Descartes et le cartésianisme hollandais* (1951); and ALBERT G.A. BALZ, *Cartesian Studies* (1951, reprinted 1987).

Development of Cartesian physics is studied in PAUL MOUY, *Le Développement de la physique cartésienne, 1646–1712* (1934, reprinted 1981); and EDWIN ARTHUR BURTT, *The Metaphysical Foundations of Modern Physical Science* (1932, reprinted 1980). Later scholarship is offered in ARTHUR O. LOVEJOY, *The Revolt Against Dualism,* 2nd ed. (1960), a study of reactions against Cartesian metaphysics; JOHN S. SPINK, *French Free-Thought from Gassendi to Voltaire* (1960, reissued 1969); NOAM CHOMSKY, *Cartesian Linguistics* (1966, reprinted 1983), a historical exposition combined with the important claim that Cartesian rationalism is the best general guide to the study of the language-originating mind of man; LEONORA COHEN ROSENFIELD, *From Beast-Machine to Man-Machine: Animal Soul in French Letters from Descartes to La Mettrie,* new and enl. ed. (1968), an exploration of whether animals have souls, showing Descartes's important influence on modern physiology; ETIENNE GILSON, *Études sur le rôle de la pensée médiévale dans la formation du système cartésien,* 4th ed. (1975); HENRI GOUHIER, *Cartéseanisme et augustianisme au XVII^e siècle* (1978); RICHARD H. POPKIN, *The History of Scepticism from Erasmus to Spinoza,* rev. and expanded ed. (1979); RICHARD RORTY, *Philosophy and the Mirror of Nature* (1979); and RICHARD A. WATSON, *The Breakdown of Cartesian Metaphysics* (1987).

(R.A.W.)

Domestic Cats

All cats are grouped in the family Felidae. From the largest, the tiger, to the smallest, the house cat, felids are characterized by supple, low-slung bodies, finely molded heads, long tails that aid in balance, and specialized teeth and claws that adapt them admirably to a life of active hunting. The family of cats belongs to the mammalian order Carnivora, the "flesh eaters."

Domestic cats (*Felis catus*) possess the features of their wild relatives in being basically carnivorous, remarkably agile and powerful, and finely coordinated in movement. It is noteworthy that the ancestors of the other common household pet, the dog, were social animals that lived together in packs in which there was subordination to a leader, and the dog has readily transferred its allegiance from pack leader to human master. The cat, however, has not yielded as readily to subjugation. Consequently, the house cat is able to revert to complete self-reliance more quickly and more successfully than most domesticated dogs.

For an account of the relationship of the family of cats to other carnivores, see MAMMALS: *Carnivora.*

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* section 313, and the *Index.*

The article is divided into the following sections:

ORIGIN AND HISTORY OF CATS

The "cat pattern," established very early in the evolution of modern mammals, was a successful one: early cats were already typical in form at a time when the ancestors of most other modern mammalian types were scarcely recognizable. They first appeared in the Early Pliocene epoch (5.3 to 3.4 million years ago), and they have continued with remarkably little change into modern times.

Domestication. Although its origin is hidden in antiquity, the domestic cat has a history that dates nearly 3,500 years to ancient Egypt. There are no authentic records of domestication earlier than 1500 BC, but it may have taken place sooner. Although the cat was proclaimed a sacred animal in the 5th and 6th dynasties (*c.* 2465–*c.* 2150 BC), it had not necessarily been domesticated at that time. It is probable that the Egyptians domesticated the cat because they realized its value in protecting granaries from rodents. Their affection and respect for this predator led to the development of religious cat cults and temple worship of cats.

Cats have long been known to other cultures. Wall tiles in Crete dating from 1600 BC depict hunting cats. Evidence from art and literature indicates that the domestic cat was present in Greece from the 5th century BC and in China from 500 BC. In India cats were mentioned in Sanskrit writings around 100 BC, while the Arabs and the Japanese were not introduced to the cat until about AD 600. The earliest record of cats in Britain dates to about AD 936 when Howel Dda, prince of south-central Wales, enacted laws for their protection.

Ancestry of breeds

Even though all cats are similar in appearance, it is difficult to trace the ancestry of individual breeds. Since tabbylike markings appear in the drawings and mummies of ancient Egyptian cats, present-day tabbies may be descendants of the sacred cats of Egypt. The Abyssinian also resembles pictures and statues of Egyptian cats. The Persian, whose colouring is often the same as that of mixed breeds (although the length of hair and the body conformation are distinctive), was probably crossed at various times with other breeds; the tailless Manx cat, like the hairless Sphynx cat and curly-coated Devon rex, is a mutation. The ancestry of Persian and Siamese cats may well be distinct from other domestic breeds, representing a domestication of an Asian wild cat (the ancestor of the Egyptian cat is believed to have come from Africa). In fact, nothing is known of the ancestry of the Siamese types, and there is no living species of Asian cat that would serve as ancestor.

Associations with human culture. The cat has long played a role in religion and witchcraft. In the Bible, "cat" is mentioned only in the apocryphal Letter of Jeremiah. The cat figured prominently in the religions of Egypt, the Norse countries, and various parts of Asia. The Egyptians had a cat-headed goddess named Bast. Thousands of cat mummies have been discovered in Egypt, and there were even mouse mummies, presumably to provide food for the cats. Often the cat has been associated with sorcery and witchcraft, and the superstitions regarding cats are innumerable. Throughout the ages, cats have been more cruelly mistreated than perhaps any other animal. Black cats in particular have long been regarded as having occult powers and as being the familiars of witches.

The cat is a familiar figure in nursery rhymes, stories, and proverbs. The English legend of Dick Whittington and his cat is a particular favourite. The writers Théophile Gautier and Charles Baudelaire paid it homage, and in the 20th century Rudyard Kipling, Colette, and T.S. Eliot wrote of cats.

GENERAL FEATURES AND SPECIAL ADAPTATIONS

The average weight of the household cat varies from 6 to 10 pounds, although among nonpedigreed cats weights up to 28 pounds are not uncommon. Average lengths are 28 inches for males and 20 inches for females. In keeping with a carnivorous habit, the cat has a simple gut; the small intestine is only about three times the length of the body.

The skin of the cat, composed of dermis and epidermis, regenerates and fights off infection quickly. Tiny erector muscles, attached to hair follicles, enable the cat to bristle all over. Thus, although the cat is a relatively small animal, it can frighten enemies by arching its back, bristling, and hissing.

Coordination and musculature. Cats are among the most highly specialized of the flesh-eating mammals. Their brains are large and well-developed. Cats are digitigrade; that is, they walk on their toes. Unlike the dog and horse, the cat walks or runs by moving first the front and back legs on one side, then the front and back legs on the other side; only the camel and the giraffe move in a similar way. The cat's body has great elasticity. Because the vertebrae of the spinal column are held together by muscles rather than by ligaments, as in humans, the cat can elongate or contract its back, curve it upward, or oscillate it along the vertebral line. The construction of the shoulder joints permits the cat to turn its foreleg in almost any direction. Cats are powerfully built animals and are so well coordinated that they almost invariably land on their feet if they fall or are dropped.

Teeth. The cat's teeth are adapted to three functions: stabbing (canines), anchoring (canines), and cutting (molars). Cats have no flat-crowned crushing teeth and therefore cannot chew their food; instead, they cut it up. Except for the canines and molars, the cat's teeth are more or less nonfunctional; most of the cheek teeth do not even meet when the mouth is closed. The dental formula in all cats, for either side of both upper and lower jaws, is incisors 3/3, canines 1/1, premolars 3/2, and molars 1/1. The total number of teeth is 16 in the upper jaw and 14 in the lower. Primary, or milk, teeth number 24; these are replaced by the permanent teeth at about five months. Each half of the jaw is hinged to the skull by a transverse roller that fits tightly into a trough on the underside of the skull, making grinding movements impossible even if the cat had teeth suitable for grinding.

Retraction of claws

Claws. There is a remarkable mechanism for retracting the cat's claws when they are not in use. The claw is retracted or extended by pivoting the end bone of the toe, which bears the claw, over the tip of the next bone. The action that unsheathes the claws also spreads the toes widely, making the foot more than twice as broad as it normally is and converting it into a truly formidable weapon. This claw-sheathing mechanism is present in all species of the cat family except the cheetah. Although there are no nerve endings in the nail itself, blood capillaries are present in the inner part.

Senses. Cats are generally nocturnal in habit. The retina of the cat's eye is made extra sensitive to light by a layer of guanine, which causes the eye to shine at night in a strong light. The eyes themselves, large with pupils that expand or contract to mere slits according to the density of light, do not distinguish colours clearly. Cats have a third eyelid, or nictitating membrane, commonly called the haw. Its appearance is used frequently as an indicator of the cat's general state of health.

The cat's sense of smell, particularly well developed in the adult, is crucial to its evaluation of food, so that a cat whose nasal passages become clogged as a result of illness may appear to lose its appetite completely. Cats can distinguish the odour of nitrogenous substances (*e.g.,* fish) especially keenly.

The sense of touch is acute in cats. The eyebrows, whiskers, hairs of the cheek, and fine tufts of hair on the ears are all extremely sensitive to vibratory stimulation. The functions of the whiskers (vibrissae) are only partially understood; however, it is known that, if they are cut off, the cat is temporarily incapacitated. The toes and paws, as well as the tip of the nose, are also very sensitive to touch.

Cats also have an acute sense of hearing. Their ears contain almost 30 muscles (compared with 6 in humans); as a result, they can turn them many times more quickly in the direction of a sound than can a dog. The ears of cats, although receptive to ultrasonic frequencies up to 25,000 vibrations per second, are slightly inferior to those of dogs, which register 35,000 vibrations per second.

BEHAVIOUR

Special traits. The cat has a subtle repertoire of facial expressions, vocal sounds, and tail and body postures that express its emotional state and intentions. These various signals serve to increase, decrease, or maintain social distance. One distinctive social behaviour involves rubbing the side of the head, lips, chin, or tail against the owner and against furniture. These regions of the cat's body contain scent glands that seem to play a role in establishing a familiar odour in the cat's environment.

The tongue of all cats, which has a patch of sharp, backward-directed spines near the tip, has the appearance and feel of a coarse file; the spines help the cat to lap up liquids and also to groom itself. The disposition to cleanliness is well established in cats, and they groom themselves at length, especially after meals.

Purring

While lions and other big cats roar, domestic cats and other *Felis* species purr. Purring has been described as a low, continuous, rattling hum and often is interpreted as an expression of pleasure or contentment. Purring also occurs in cats that are injured and in pain, however, so that this vocalization can be seen as the cat's "mantra"—that is, as a relaxing, self-comforting sound and a friendly mood-conveying signal.

Behavioral problems. Under conditions of domestication, the cat is subject to a variety of factors that result in behaviour indicative of emotional distress and difficulty in adapting to the home environment. Some behaviours are not abnormal but are difficult for owners to accept.

The most common behaviour problem in companion cats is that they sometimes urinate and defecate outside the litter box in the house. Organic causes include feline urologic syndrome (urinary bladder inflammation and cal-

culi, or stones, in the urinary tract), blocked or impacted anal glands, and constipation. Emotional causes include the addition of a new family member—another cat, a child, or a spouse. Such changes may make the cat feel insecure, so that it deposits urine and feces around the house, possibly as territorial marks for security. Cats are creatures of habit, and any change in the family structure or in daily routines—resulting, for example, from a move or even from rearranging furniture—can be stressful.

Another common behaviour problem in cats is their natural desire to rake objects such as drapes and furniture with their claws. Surgical removal of the front claws to prevent property damage is normally repugnant to cat lovers. Cats can be trained to use carpeted scratching posts in the house to satisfy this behavioral need, which may be a combination of claw cleaning and sharpening and of territorial marking.

Many cats engage in social licking and in the grooming of their feline and human companions, which is a natural display of affection and dependence. Some also engage in nursing behaviour, sucking on people's fingers and earlobes, on their own paws and tails, and on blankets and woolen clothing. Nursing may be a cat's way of regressing and relaxing into kittenish behaviour. It is often more intense in cats weaned too early or in those malnourished in kittenhood. For various emotional reasons some cats may groom themselves to the point of self-mutilation or become compulsive wool suckers and eaters.

Pica—a hunger for nonnutritive substances—may be a symptom of the need for more roughage in the diet or of feline leukemia or other health problems. As with the dog, excessive eating and drinking is frequently associated with endocrine diseases such as diabetes and thyroid dysfunction. Cats often vomit soon after eating, which is most often caused by the accumulation of fur balls in the stomach, although a food allergy, feline leukemia, or other organic cause may be involved.

Active and healthy cats often race through the house as though they were crazed. These "evening crazies" (which can also erupt early in the morning) result from the cat's ancient rhythm of actively hunting around dawn and dusk. In the domestic environment, this normal, instinctive behaviour often still occurs, to the consternation of some owners who fear that their cat may have rabies, a brain tumour, or an unstable personality.

Changes in animals' behaviour should not, therefore, be dismissed as psychological (or as simple disobedience, as when a cat suddenly becomes unhousebroken, for example), since there may be an underlying physical cause. Nevertheless, abnormal behaviour in animals often does have a nonphysical, psychological, or emotional origin, which should always be considered in the diagnosis and treatment of the ailments of companion animals.

Sleep patterns

Other traits. The cat's sleep patterns are different from those of dogs and humans. Dogs and humans have long periods of REM (rapid eye movement) sleep, the stage that is associated with dreaming. In contrast, the cat rarely lapses into REM sleep. Instead, it has a lighter, episodic sleep pattern that enables it to rest but to be instantly alert. When sick, cats have a tendency to withdraw and become inactive, which helps them conserve energy. A sick cat may seem lifeless but recover after a few days of withdrawal, which is one reason cats are said to have nine lives. (A sick cat should always be taken to a veterinarian, however; it is negligent simply to let nature take its course.)

Cats are known to have traveled hundreds of miles to find their owners in new homes to which they themselves have never been. Dogs have also performed such feats of so-called psi (psychic) trailing. Scientists have not been able to find a physiological or psychological explanation for this ability.

CATS AS PETS

The popularity of the cat, especially of pedigreed breeds, has continued to grow. The cat's independent personality, grace, cleanliness, and subtle displays of affection have wide appeal. Typically, cats are creatures of habit; they are inquisitive, but not adventurous, and are easily upset by sudden changes of routine. The ideal household cat has been separated from its mother between the ages of two and four months, raised in a clean home, kept away from unhealthy animals, and inoculated against common infectious cat diseases. Although cats often enjoy the company of other cats, especially when raised together from kittenhood, introducing a strange cat to other cats in the home can cause stress, aggression, and other behaviour problems. Cats are generally less sociable than dogs, who more readily accept a new pack member.

A good disposition and good health are important criteria for choosing a cat. Disposition varies only slightly between male and female cats. There are, however, distinct differences in disposition among the various pedigreed varieties; the Siamese, for example, is vocal and demanding, while the Persian is quiet and fastidious. The mixed breed, or "alley" cat, is a heterogeneous breed of unknown lineage; therefore, its disposition is difficult to assess. By chance, the mixed breed may prove a happier and healthier pet than a pedigreed one. On the other hand, the behaviour and vigour of the direct ancestors of pedigreed cats are indicative of the characteristics the offspring will possess as adults. But, as with the propagation of purebred dogs, the proliferation of pedigreed cats has resulted in an increase in inherited diseases, a major reason many people prefer mongrels or mixed breeds.

NUTRITION

Domestic cats should have a diet similar to that of their wild relatives. They are adapted by nature to be flesh eaters, as is shown by their alimentary tract and their dentition. The cat uses its canines to catch and kill prey, the molars to cut it up. Lack of flat-surfaced teeth prevents it from chewing or gnawing. The cat has a short intestine, and its stomach secretes digestive juices that act primarily on meat. Cats, however, like all meat-eating animals, chew grass and other plants occasionally, and small quantities of vegetables may serve as both a laxative and hairball remover.

Nutritional problems

As the science of feline nutrition has improved, specially formulated commercial diets have been developed. Serious health problems may arise when cats are fed unbalanced diets that consist exclusively of meat or tuna or when they are fed low-quality protein diets deficient in taurine. A deficiency of taurine can cause blindness and heart disease. Prescription diets are available for cats suffering from obesity, diabetes, kidney and heart disease, and urinary bladder calculi. Many cats are allergic to cow's milk, because of its high lactose content, and some are allergic to fish.

REPRODUCTION

Domestic cats reach reproductive age between 7 and 12 months. A breeding female (called a queen) can be in heat, or estrus, as many as five times a year. During these periods, which last about five days, the cat "calls," or caterwauls, intermittently. The gestation period for cats averages 63 to 65 days, and birth usually lasts about two hours. The birth is often called kittening, and the kittens are called a litter. The average litter numbers four; however, the Abyssinian usually has fewer, the Siamese more.

Each kitten is born in a separate amniotic sac that is generally broken open at the moment of birth. If it is not, the mother breaks it. She also severs the umbilical cord and eats the placenta (which in many cases stimulates lactation). The kittens are born blind, deaf, and helpless, as are many other carnivores; their senses begin to function 10 or 12 days after birth. Soon after birth the mother licks her kittens; this action cleans them and helps stimulate their circulation. Kittens at birth lack distinctive colouring, and many do not acquire their characteristic markings and colour for weeks. For example, Siamese kittens are white at birth, while blue Persians have tabby markings and black Persians are brown.

Unlike wild cats that breed once a year, the domestic cat is capable of bearing up to three litters every year. Traditionally, regulation of the cat population was accomplished by the selective killing of the newborn. In modern times, however, sterilization—by means of relatively safe and simple operations known as spaying, neutering, or altering—has become common in affluent societies. Neutering is also viewed as an adaptive measure for indoor life.

Castration of the male, ideally around six or seven months of age, helps control the adult male's tendency to "spray"—to mark objects in and around the house with his own urine. Spaying the female may help reduce the incidence of breast cancer in addition to eliminating uterine diseases and unwanted litters.

Neutered cats live longer than nonneutered ones, partly because they have less desire to roam. The average life expectancy for the domestic cat is 10 to 15 years; the oldest cat on record attained the age of 34 years.

DISEASES AND PARASITES

For many years cat treatments were simply extensions of those given dogs. Now, however, cat disorders of the skin, the eyes, the ears, the various systems (circulatory, respiratory, urinary, digestive, nervous, skeletal), and the blood, as well as contagious cat diseases and external and internal parasites, are studied, so that appropriate preventions and treatments can be developed.

Symptoms

Many cats die because their ailments become serious before their general conditions change sufficiently to reveal symptoms of illness. On the other hand, many symptoms used in diagnosing cat ailments are not definitive for given disorders. For example, signs of illness include general symptoms such as a dull coat, lack of appetite, and listlessness. Diarrhea may be a result of serious illness or simply reflect a change in diet. Tearing of the eyes, especially when accompanied by sneezing, may indicate conjunctivitis or a cold. Since, however, sneezing is the cat's only mechanism for blowing its nose, not all sneezing indicates illness. Open sores, usually at the base of the ear, around the mouth, or on the toes, can point to an ear mite or a ringworm infection or to a fight with another animal.

Cats are attacked by several kinds of external and internal parasites. External parasites are most generally found in kittens, although they can occur in adults. The most frequent parasites are fleas, but lice, ticks, and ear mites also occur. Internal parasites include roundworms, tapeworms, and protozoan coccidia. Modern veterinary medicine has made all of these easy to control.

Panleucopenia, often called feline distemper, is the best-known viral disease in cats. Highly contagious, with a high mortality rate, it is seen most often in young cats. Vaccines are effective protective measures. Rabies is less of a problem with cats than with dogs, but all free-roaming cats should be vaccinated. Vaccines have also been developed for other feline diseases, including feline leukemia, pneumonitis (chlamydiosis), viral rhinotracheitis (cat influenza), and calicivirus infections.

Cats that are permitted to wander freely outdoors are exposed to a variety of health hazards, including accidents, attacks from other animals, poisoning, fleas and other parasites, and contagious diseases such as feline acquired immune deficiency syndrome (AIDS). Cats that kill and eat rodents and other small animals can become infected with the parasitic protozoan *Toxoplasma gondii,* which can be transmitted to humans and causes the disease toxoplasmosis.

GENETICS

Cats have never been bred for economic purposes; their matings are extremely difficult to control unless the animals are completely confined. There has been relatively little scientific breeding of cats, and the facts of inheritance in these animals are not well known.

Cats are genetically far less plastic than dogs and therefore have not offered the same opportunities to breeders. The size differences between breeds in the domestic dog have no parallel in the domestic cat, nor has anything even remotely approaching the wide range of head shapes and body proportions in different breeds of dogs ever appeared among the cats. In cats the physical differences between one breed and another are largely differences in colour and texture of the coat.

Dominance of white

Colour. The most common basic coat colours in nonpedigreed cats are black, yellow, and white, with various combinations and dilutions of these colours, such as tabby or striped. Solid white is dominant to all other colours. The mode of inheritance of black is imperfectly understood, but the possibility that it is sex-linked is widely accepted. Tortoiseshell coloration, a piebald pattern of black, red, and cream that results from crossing black and yellow, is a sex-linked trait; male tortoiseshells have one extra X chromosome, resulting in an abnormal XXY chromosomal pattern. Hence, male tortoiseshells are born only rarely and are usually sterile. Similarly, tortoiseshell-and-white cats (in North America sometimes called calicoes) are almost always female.

Siamese dilution, the typical coloration of Siamese cats, has been described as a case of imperfect albinism and has been compared to the Himalayan pattern in rabbits, but its heredity is not well understood. There are also dilutions of the other ordinary colours: blue is dilute black and cream is dilute yellow. White spotting also occurs and is dominant to uniform colour.

Other characters. The long-haired coat of the Persian appears to be a simple unit character. It is recessive to short hair. Eye colour is known to be inherited, but its mode of inheritance is not thoroughly understood. Blue eye colour seems to be associated with dilution in coat colour; blue-eyed white cats are usually deaf, a fact commented on by Charles Darwin. Asymmetry of eye colour is inherited. Polydactylism, the presence of extra toes, is inherited and behaves as a dominant to the normal condition. It seems to be due to a single gene. The extra toes occur on the inner, or thumb, side of the foot.

BREEDS

The number of recognized show breeds that have defined, inherited characteristics has increased dramatically since the late 1950s as cats have become more popular as home companions. The 30 to 40 distinctive breeds can be grouped into two general categories: the long-haired Persian and the domestic shorthair. Both of these breeds occur in various subcategories based on their coat colour, such as white, cream, chinchilla (or silver), smoke, tortoiseshell, and tabby (red, blue, and so on). Other distinctive and popular breeds include the Siamese (with seal point, blue point, chocolate point, and lilac point colour variations), the long-haired Himalayan, which resembles the Siamese in coloration, and the Abyssinian, Burmese, Manx, rex, and Russian blue. (M.W.Fo./Ed.)

Cells: Their Structures and Functions

As the smallest units retaining the fundamental properties of life, cells are the "atoms" of the living world. A single cell is often a complete organism in itself, such as a bacterium or yeast. Other cells, by differentiating in order to acquire specialized functions and cooperating with other specialized cells, become the building blocks of large multicellular organisms as complex as the human being. Although they are much larger than atoms, these building blocks are still very small. The smallest known cells are a group of tiny bacteria called mycoplasmas; some of these single-celled organisms are spheres about 0.3 micrometre in diameter, with a total mass of 10^{-14} gram—equal to that of 8,000,000,000 hydrogen atoms. Human cells typically have a mass 400,000 times larger, but even they are only about 20 micrometres across. It would require a sheet of about 10,000 human cells to cover the head of a pin, and each human being is composed of 10,000,000,000,000 cells.

This article discusses the cell both as an individual unit and as a contributing part of a larger organism. As an individual unit the cell is capable of digesting its own nutrients, providing its own energy, and replicating itself in order to produce succeeding generations. It can be viewed as an enclosed vessel composed of even smaller units that serve as its skin, skeleton, brain, and digestive tract. Within this vessel innumerable chemical reactions take place simultaneously, all of them controlled so that they contribute to the life and procreation of the cell. As part of a multicellular organism the cell keeps in constant communication with its neighbours. As it receives nutrients from and expels wastes into its surroundings, it adheres to and cooperates with other cells. Cooperative assemblies of similar cells form tissues, and a cooperation between tissues in turn forms organs, the functional units of an organism.

Special emphasis is given in this article to animal cells, with some discussion of the energy-synthesizing processes and extracellular components peculiar to plants. For detailed discussion of the biochemistry of plant cells, see PHOTOSYNTHESIS. The larger units to which cells contribute are discussed in TISSUES AND FLUIDS; and in such specialized articles as MUSCLES AND MUSCLE SYSTEMS. BIOCHEMICAL COMPONENTS OF ORGANISMS gives full information on the compounds making up the cell, and the vital reactions involving these compounds are discussed in METABOLISM. For full-length treatment of the genetic events in the cell nucleus, see GENETICS AND HEREDITY, THE PRINCIPLES OF.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* sections 321, 322, 323, and 331. (B.M.A.)

The article is divided into the following sections:

The nature and function of cells

Specialized compartments, or organelles

A cell is enclosed by the plasma membrane, which forms a selective barrier allowing nutrients to enter and waste products to leave. The interior is organized into many specialized compartments, or organelles, each surrounded by a separate membrane. One major organelle, the nucleus, contains the genetic information necessary for cell growth and reproduction. Each cell contains only one nucleus; other types of organelles are present in multiple copies in the cellular contents, or cytoplasm. The mitochondria are responsible for the energy transactions necessary for cell survival. The lysosomes digest unwanted materials within the cell. The endoplasmic reticulum and the Golgi apparatus play an important role in the internal organization of the cell by synthesizing selected molecules and then processing, sorting, and directing them to their proper locations. (Plant cells, in addition to all the above organelles, contain chloroplasts, which are responsible for photosynthesis, whereby the energy of sunlight is used to convert molecules of carbon dioxide [CO_2] and water [H_2O] into carbohydrates.) Between all of these organelles is the space in the cytoplasm called the cytosol, which is organized around a framework of fibrous molecules constituting the cytoskeleton. The cytosol contains more than 10,000 different kinds of molecules involved in cellular biosynthesis.

These specialized compartments characterize the general class of cells known as eukaryotes. The other general class, the prokaryotes, are simpler and generally smaller than eukaryotic cells, and they lack a defined nucleus as well as the other organelles. However, all cells share a strong similarity in biochemical function.

THE CELL AS A SELF-REPLICATING COLLECTION OF CATALYSTS

From a chemical point of view, a cell is a special collection of molecules, enclosed by a membrane, that has the ability to reproduce itself from the molecules in its surroundings.

Catalytic macromolecules

This reproductive process occurs in two steps: cell growth and cell division. In the first step, the cell ingests certain simple molecules from its surroundings by selectively transferring them through its plasma membrane. Once inside the cell, these molecules are immediately subjected to the action of a large number of highly specialized catalysts, substances that speed up chemical reactions without undergoing permanent change themselves. The catalysts act by binding their surfaces to molecules in specific ways that increase the molecules' reactivity. In a living cell, each catalyst is a large, elaborately folded molecule (called a macromolecule) composed of thousands of precisely arranged atoms. The sculpted surface of the macromolecule binds tightly to one or more small molecules, distorting the chemical bonds between their atoms in a way that speeds up a particular chemical reaction—typically increasing its rate more than a millionfold. These sophisticated catalytic macromolecules are found only in the biologic world, and nothing outside of cells even remotely approaches their specificity of action.

When researchers follow specific molecules with radioactive tracers, they discover that the biologic catalysts create chains of reactions. In other words, the reaction catalyzed by one macromolecule produces the starting material, or substrate, of a second catalyst, and so on. In this way, the catalytic macromolecules use the small molecules brought into the cell from the outside environment to create increasingly complex reaction products (see Figure 1). These final products are a second set of biologic macromolecules identical to the original set in the cell. Once the number of molecules of each type has doubled, the cell goes through step two in the reproductive process, dividing to create two daughter cells, each identical to the original parent cell. Through many such cycles of cell growth and division, each parent cell can give rise to millions of daughter cells, in the process converting large amounts of inanimate matter into biologically active molecules.

The structure of biologic catalysts. Because the carbon atom can form stable bonds with four other atoms, it is uniquely suitable for the construction of complex chain-and-ring molecules. These molecules typically contain hydrogen, oxygen, and nitrogen atoms as well as carbon, and they consist of anywhere from 10 to millions of atoms linked together in specific arrays. Cells are largely composed of these carbon compounds, which form the basis of the field of organic chemistry. Most, but not all, of the carbon-containing molecules in cells are built up from members of one of four different families of small organic molecules: sugars, amino acids, nucleotides, and fatty acids. Each of these families contains a group of molecules that resemble one another in both structure and function. An example of one small molecule in each family is shown in Figure 2. In addition to other important functions, these molecules are used in the construction of larger assemblies: the sugars can be linked to form polysaccharides such as starch and glycogen, the amino acids to form proteins, the nucleotides to form the DNA (deoxyribonucleic acid) and RNA (ribonucleic acid) of the chromosomes, and the fatty acids to form the phospholipids of all cell membranes.

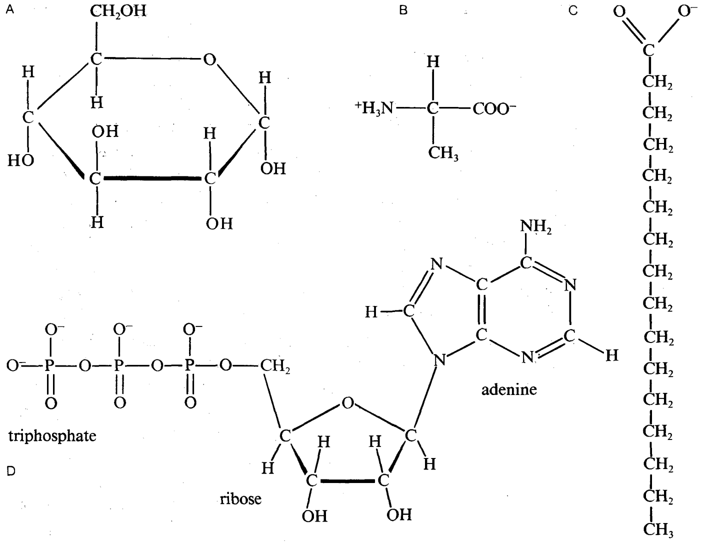

Figure 2: (A) The structure of glucose, a sugar. (B) The amino acid alanine. (C) Palmitic acid, a fatty acid. (D) The chemical structure of adenosine triphosphate (ATP), a nucleotide.

Table 1 lists the approximate proportions of each type of molecule found in a typical cell. Aside from water, which forms 70 percent of its mass, a cell is composed mostly of macromolecules (*e.g.*, proteins, RNA, DNA, and polysaccharides). By far the largest portion of macromolecules are the proteins.

Table 1: Approximate Chemical Composition of a Typical Mammalian Cell

component	percent of total cell weight
H_2O	70
Inorganic ions (Na^+, K^+, Mg^{2+}, Ca^{2+}, Cl^-, etc.)	1
Miscellaneous small metabolites	3
Proteins	18
RNA	1.1
DNA	0.25
Phospholipids and other lipids	5
Polysaccharides	2

Composition and structure of enzymes

Most of the catalytic macromolecules in cells are enzymes, which are proteins composed of 20 different amino acids joined end to end in specific sequences. An average-sized protein macromolecule contains a string of about 400 amino acid molecules. Each amino acid has a different side chain of atoms that gives it a distinct chemical property. The side chains interact with one another in specific ways, usually causing the protein molecule to fold into a compact globular form. In theory, nearly an infinite variety of proteins can be formed, each with a different sequence of amino acids. However, nearly all of these proteins would fail to fold up in the unique way required to form an efficient catalytic surface and would therefore be useless in the growth and division of a cell. The proteins actually present in a cell are products of a long evolutionary history, during which the ancestor proteins were naturally selected for their ability to fold into specific three-dimensional forms useful for cell survival. During this process of evolution, each protein developed a unique surface with a highly specific set of functions.

A second type of catalytic macromolecule in cells are RNA molecules, which consist of linear chains of four different nucleotides. RNA molecules resemble proteins in being able to fold in specific ways to form unique surfaces. As with proteins, the specific sequence of nucleotide subunits in an RNA chain gives each macromolecule a unique character. RNA molecules are much less frequently used as catalysts in cells than are protein molecules, presumably because proteins, with the greater chemical variety of their 20 different amino acid side chains, are more powerful catalysts. However, RNA molecules are thought to have preceded protein molecules during evolution and to have catalyzed most of the chemical reactions required before cells could evolve (see below *The evolution of cells*).

Energy in chemical reactions

Coupled chemical reactions. Cells must obey the laws of chemistry and thermodynamics. When two molecules react with each other inside a cell, their atoms are rearranged, forming different molecules as reaction products and releasing energy in the process. Such chemical reactions can occur only in one direction; that is, the reaction product molecules cannot spontaneously react, in a reversal of the original process, to reform the original molecules. This directionality of chemical reactions is explained by the fact that molecules only change from states of higher free energy to states of lower free energy. Free energy is the ability to perform work (in this case, the "work" is the rearrangement of atoms in the chemical reaction). When work is performed, some free energy is used and lost, with the result that the process ends at lower free energy. To use a familiar mechanical analogy, water at the top of a hill has the ability to perform the "work" of flowing downhill (*i.e.,* it has high free energy), but once it has flowed downhill it cannot flow back up (*i.e.,* it is in a state of low free energy). However, through another work process—that of a pump, for example—the water can be returned to the top of the hill, thereby recovering its ability to flow downhill. In thermodynamic terms, the free energy of the water has been increased by energy from an outside source. In the same way, the product molecules of a chemical reaction in a cell cannot reverse the reaction and return to their original state unless energy is supplied by coupling the process to another chemical reaction.

All catalysts, including enzymes, accelerate chemical reactions without affecting their direction. To return to the mechanical analogy, enzymes cannot make water flow uphill, although they can provide specific pathways for a downhill flow. Yet most of the chemical reactions that the cell needs to synthesize new molecules necessary for its growth require an uphill flow. In other words, the reactions require more energy than their starting molecules can provide.

Cells use a single strategy over and over again in order to get around the limitations of chemistry: they use the energy from an energy-releasing chemical reaction to drive an energy-absorbing reaction that would otherwise not occur. A useful mechanical analogy might be a mill wheel driven by the water in a stream. The water, in order to flow downhill, is forced to flow past the blades of the wheel, causing the wheel to turn. In this way, part of the energy from the moving stream is harnessed to move a mill wheel, which may be linked to a winch. As the winch turns, it can be used to pull a heavy load uphill. Thus, the energy-absorbing (but useful) uphill movement of a load can be driven by coupling it directly to the energy-releasing flow of water.

In cells, enzymes play the role of mill wheels by coupling energy-releasing reactions with energy-absorbing reactions. As discussed below, in cells the most important energy-releasing reaction serving a role similar to that of the flowing stream is the hydrolysis of adenosine triphosphate (ATP). In turn, the production of ATP molecules in the cells is an energy-absorbing reaction that is driven by being coupled to the energy-releasing breakdown of sugar molecules. In retracing this chain of reactions, it is necessary first to understand the source of the sugar molecules.

Photosynthesis: the beginning of the food chain. Sugar molecules are some of the carbohydrates produced by the process of photosynthesis in plants and certain bacteria. These organisms lie at the base of the food chain, in that animals and other nonphotosynthesizing organisms depend on them for a constant supply of life-supporting organic molecules. Humans, for example, obtain these molecules by eating plants or other organisms that have previously eaten food derived from photosynthesizing organisms.

Conversion of solar energy to chemical bond energy

Plants and photosynthetic bacteria are unique in their ability to convert the freely available electromagnetic energy in sunlight into chemical bond energy, the energy that holds atoms together in molecules and is transferred or released in chemical reactions. The process of photosynthesis can be summarized by the following equation:

$$\text{(solar) energy} + CO_2 + H_2O \quad \rightarrow \quad \text{sugar molecules} + O_2.$$

The energy-absorbing photosynthetic reaction is the reverse of the energy-releasing oxidative decomposition of sugar molecules. During photosynthesis, chlorophyll molecules absorb energy from sunlight and use it to fuel the production of simple sugars and other carbohydrates. The resulting abundance of sugar molecules and related biological products makes possible the existence of nonphotosynthesizing life on Earth.

ATP: fueling chemical reactions. Enzymes break down organic foodstuffs into sugars and other small molecules such as amino acids and fatty acids. Some of these small molecules serve as building blocks for the production of the cell's macromolecules, but more than half of them are further degraded in the cytoplasm in order to provide the cell with ATP. ATP, the common carrier of energy inside the cell, is made from adenosine diphosphate (ADP) and inorganic phosphate (P_i; the structure of the molecule is shown in Figure 2). Stored in the chemical bond holding the terminal phosphate compound onto the ATP molecule is the energy derived from the breakdown of sugars. The removal of the terminal phosphate, through the water-mediated reaction called hydrolysis, releases this energy, which in turn fuels a large number of crucial energy-absorbing reactions in the cell. Hydrolysis can be summarized as follows:

$$ATP + H_2O \quad \rightarrow \quad ADP + P_i + \text{energy}.$$

The formation of ATP is the reverse of this equation, requiring the addition of energy. It begins with glycolysis, a form of fermentation in which glucose is broken down step by step in a series of nine enzymatic reactions, each successive reaction involving an intermediate sugar containing phosphate. In the process, the six-carbon glucose is converted into two molecules of the three-carbon pyruvic acid. Some of the energy released through the glycolysis of each glucose molecule is absorbed in the formation of two ATP molecules.

The transfer of chemical bond energy

The second stage in the breakdown of sugars is a set of interrelated reactions called the tricarboxylic acid cycle. This cycle takes the three-carbon pyruvic acid produced in glycolysis and uses its carbon atoms to form CO_2 while transferring its hydrogen atoms to special carrier molecules, where they are held in high-energy linkage.

In the third and last stage in the breakdown of sugars, oxidative phosphorylation, the high-energy hydrogen atoms are first separated into protons and high-energy electrons. The electrons are then passed from one electron carrier to another by means of an electron-transport chain. Each electron carrier in the chain has an increasing affinity for electrons, with the final electron acceptor being molecular oxygen (O_2). As separated electrons and protons, the hydrogen atoms are transferred to O_2 to form water. This reaction releases a large amount of energy, which drives the synthesis of a large number of ATP molecules from ADP and P_i. (For further discussion of the electron-transport chain, see below *The mitochondrion and the chloroplast: Metabolic functions.*)

Most of the cell's ATP is produced when the products of glycolysis are oxidized completely by a combination of the tricarboxylic acid cycle and oxidative phosphorylation, glycolysis alone producing relatively small amounts. Glycolysis is an anaerobic reaction; that is, it can occur even in the absence of oxygen. The tricarboxylic acid cycle and oxidative phosphorylation, on the other hand, require oxygen. Glycolysis forms the basis of anaerobic fermentation, and it presumably was a major source of ATP for early life on Earth, when very little oxygen was available in the atmosphere. Eventually, however, bacteria evolved that were able to carry out photosynthesis. Photosynthesis liberated these bacteria from a dependence on the metabolism of organic materials that had accumulated from natural processes, and it also released oxygen into the atmosphere. Over a prolonged period of time, the concentration of molecular oxygen increased until it became freely available in the atmosphere. The aerobic tricarboxylic acid cycle and oxidative phosphorylation then evolved, enabling sugars to be broken down completely to carbon dioxide and water. The resulting aerobic cells made much more efficient use of foodstuffs than their anaerobic ancestors, because they could convert much larger amounts of chemical bond energy into ATP.

THE CELL AS A REPLICATOR OF INFORMATION

Cells can thus be seen as a self-replicating network of catalytic macromolecules engaged in a carefully balanced series of energy conversions that drive biosynthesis and cell movement. But energy alone is not enough to make self-reproduction possible; the cell must contain detailed instructions that dictate exactly how that energy is to be used. These instructions are analogous to the blueprints that a builder uses to construct a house; in the case of cells, however, the blueprints themselves must be duplicated along with the cell before it divides, so that each daughter cell can retain the information that it needs for its own replication. This information constitutes the cell's heredity.

DNA: the genetic material. During the early 19th century, it became widely accepted that all living organisms are composed of cells arising only from the growth and division of other cells. The improvement of the microscope then led to an era during which many biologists made intensive observations of the microscopic structure of cells. By 1885 a substantial amount of indirect evidence indicated that chromosomes—dark-staining threads in the cell nucleus—carried the information for cell heredity. It was later shown that chromosomes are about half DNA and half protein by weight.

Self-duplication of DNA

In the simplest possible case, each macromolecule in a cell would contain the information for its own duplication. Self-duplication is theoretically feasible, for example, for the nucleic acids in a cell. DNA in particular has a two-stranded polynucleotide structure that could separate into single-stranded chains. Each strand could then form another two-stranded complex by guiding the synthesis of a second polynucleotide chain with a complementary nucleotide sequence. The final products would be two double-stranded molecules, each identical to the parent molecule. The revolutionary discovery suggesting that DNA molecules could provide the information for their own replication came in 1953, when researchers James Watson and Francis Crick proposed a model for the structure of the double-stranded DNA molecule (called the DNA double helix). This scheme, in which each strand serves as a template in the synthesis of a complementary strand, is outlined in Figure 3. Subsequent research showed that DNA actually replicates in this way and that it carries the genetic information for reproduction of the entire cell.

From J.D. Watson *et al., The Molecular Biology of the Gene*, vol. 1, p. 283, 4th ed. (1987); The Benjamin/Cummings Publishing Co.

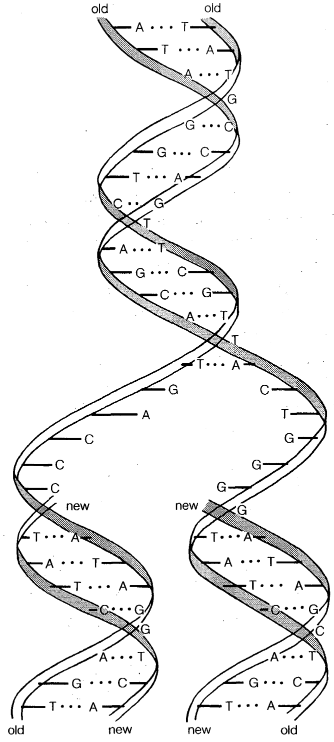

Figure 3: The initial proposal of the structure of DNA by James Watson and Francis Crick, which was accompanied by a suggestion on the means of replication.

All of the genetic information in a cell was initially thought to be confined to the DNA in the chromosomes of the cell nucleus. It is now known that small amounts of additional genetic information are present in the DNA of much smaller chromosomes located in two types of organelles in the cytoplasm. These organelles are the mitochondria in animal cells and the mitochondria and chloroplasts in plant cells. The special chromosomes carry the information coding for a few of the many proteins and RNA molecules needed by the organelles. They also hint at the evolutionary origin of these organelles, which are thought to have originated as free-living bacteria that were taken up by symbiosis.

RNA: replicated from DNA. It is possible for RNA to replicate itself by mechanisms related to those used by DNA, even though it has a single-stranded instead of a double-stranded structure. In early cells RNA is thought to have replicated itself in this way. However, all of the RNA in present-day cells is synthesized by special enzymes that construct a single-stranded RNA chain by using one strand of the DNA helix as a template. Although RNA molecules are synthesized in the cell nucleus, where the DNA is located, most of them are transported to the cytoplasm before they carry out their functions.

Replication of proteins by messenger RNA

The RNA molecules in cells have two main roles. Some fold up in ways that allow them to serve as catalysts for specific chemical reactions. Others serve as "messenger RNA," which provides templates specifying the synthesis of proteins. Ribosomes, tiny protein-synthesizing machines located in the cytoplasm, "read" the messenger RNA molecules and "translate" them into proteins by using the genetic "code." In this translation, the sequence of nucleotides in the messenger RNA chain is decoded three nucleotides at a time, and each nucleotide triplet (called a codon) specifies a particular amino acid. Thus, a nucleotide sequence in the DNA specifies a protein provided that a messenger RNA molecule is produced from that DNA sequence. Each region of the DNA sequence specifying a protein in this way is called a gene.

By the above mechanisms, DNA molecules catalyze not only their own duplication but also that of all protein molecules. A single human cell contains about 10,000 different proteins produced by the expression of 10,000 different genes. Actually, a set of human chromosomes is thought to contain DNA with enough information to express between 30,000 and 100,000 proteins, but most of these proteins seem to be made only in specialized types of cells and are therefore not present throughout the body. (For further discussion, see below *The nucleus.*)

THE CELL AS AN ORGANIZED UNIT

Intracellular communication. A cell with its many different DNA, RNA, and protein molecules is quite different from a test tube containing the same components. When a cell is dissolved in a test tube, thousands of different types of molecules randomly mix together. In the living cell, however, these components are kept in different places, reflecting the high degree of organization essential for the growth and division of the cell. Maintaining this internal organization requires a continual input of energy, because spontaneous chemical reactions always create disorganization. Thus, some of the energy released by ATP hydrolysis fuels processes that organize macromolecules inside the cell.

When a eukaryotic cell is examined at high magnification in an electron microscope, it becomes apparent that specific membrane-bounded organelles divide the interior into a variety of subcompartments. (The proportions of the total cell volume occupied by these compartments are shown in Table 2.) Although not detectable in the electron microscope, it is clear from biochemical assays that each organelle contains a different set of macromolecules. This biochemical segregation reflects the functional specialization of each compartment. Thus, the mitochondria, which produce most of the cell's ATP, contain all of the enzymes needed to carry out the tricarboxylic acid cycle and oxidative phosphorylation. Similarly, the degradative enzymes needed for the intracellular digestion of unwanted macromolecules are confined to the lysosomes.

Table 2: The Relative Volumes Occupied by Some Cellular Compartments in a Typical Liver Cell

cellular compartment	percent of total cell volume	approximate number per cell
Cytosol	54	1
Mitochondrion	22	1,700
Endoplasmic reticulum plus Golgi apparatus	15	1
Nucleus	6	1
Lysosome	1	300

The molecular sorting process

It is clear from this functional segregation that the many different proteins specified by the genes in the cell nucleus must be transported to the compartment where they will be used. Not surprisingly, the cell contains an extensive membrane-bound system devoted to maintaining just this intracellular order. The system serves as a post office, guaranteeing the proper routing of newly synthesized macromolecules to their proper destinations. The molecular details of the many necessary sorting operations are not known, but the sorting of proteins, the most abundant molecules in cells, has been extensively studied.

All proteins are synthesized on ribosomes located in the cytosol. As soon as the first portion of the amino acid sequence of a protein emerges from the ribosome, it is inspected for the presence of a short "endoplasmic reticulum (ER) signal sequence." Those ribosomes making proteins with such a sequence are transported to the surface of the ER membrane, where they complete their synthesis; the proteins made on these ribosomes are immediately transferred through the ER membrane to the inside of the ER compartment. Proteins lacking the ER signal sequence remain in the cytosol and are released from the ribosomes when their synthesis is completed. This chemical decision process places some newly completed protein chains in the cytosol and others within an extensive membrane-bounded compartment in the cytoplasm, representing the first step in intracellular protein sorting.

The newly made proteins in both cell compartments are then sorted further according to additional signal sequences that they contain. Some of the proteins in the cytosol remain there, while others go to the surface of mitochondria or (in plant cells) chloroplasts, where they are transferred through the internal membranes into the organelles. Subsignals on each of these proteins then designate exactly where in the organelle the protein belongs. The proteins initially sorted into the ER have an even wider range of destinations. Some of them remain in the ER, where they function as part of the organelle. Most enter transport vesicles and pass to the Golgi apparatus, separate membrane-bounded organelles that contain at least three subcompartments. Some of the proteins are retained in the subcompartments of the Golgi, where they are utilized for functions peculiar to that organelle. Most eventually enter vesicles that leave the Golgi for other cellular destinations such as the plasma membrane, lysosomes, or special secretory vesicles. (For further discussion, see below *Internal membranes.*)

Intercellular communication. Formation of a multicellular organism starts with a small collection of similar cells in an embryo and proceeds by continuous cell division and specialization to produce an entire community of cooperating cells, each with its own role in the life of the organism. Through cell cooperation, the organism becomes much more than the sum of its component parts.

Differentiation of cells with common genetic inheritance

A fertilized egg multiplies and produces a whole family of daughter cells, each of which adopts a structure and function according to its position in the entire assembly. All of the daughter cells contain the same chromosomes and therefore the same genetic information. Despite this common inheritance, different types of cells behave differently and have different structures. In order for this to be the case, they must express different sets of genes, so that they produce different proteins despite their identical embryological ancestors.

During the development of an embryo, it is not sufficient for all of the cell types found in the fully developed individual simply to be created. Each cell type must form in the right place at the right time and in the correct proportion; otherwise, there would be a jumble of randomly assorted cells in no way resembling an organism. The orderly development of an organism depends on a process called cell determination, in which initially identical cells somehow "read" their positions in relation to their neighbours and differentiate in ways appropriate for cells in their positions. This requires an elaborate system of cell-to-cell communication in early embryos.

The specification of cell differences seems to involve a series of steps. First, cells differentiate according to their positions at an early stage of development. Second, each cell "remembers" its differences and passes the genetic information to its daughter cells. A later generation of cells takes a second reading, creating additional position-dependent differences. These differences are also remembered as the cells grow and divide. By repeating this process and exploiting the ability of cells to remember their past, it is possible to construct a complex organism without requiring that cells be able to communicate with one another over long distances. In fact, the distances over which cells communicate in embryos are estimated to be only one millimetre or less (equal to the width of about 100 cells).

The molecular basis for such biologic pattern formation is not known, although many different theoretical models have been proposed. It is believed that related mechanisms persist in the adult, maintaining the correct proportions of each cell type in a tissue or organ and restoring proper form after disease or injury. (For further discussion, see below *Cell differentiation.*) (B.M.A.)

The plasma membrane

A thin membrane, some .005 micrometre across, surrounds every living cell, delimiting the cell from the environment around it. Enclosed by this plasma membrane are the cell's constituents, often large, water-soluble, highly charged molecules such as proteins, nucleic acids, carbohydrates, and substances involved in cellular metabolism. Outside the cell, in the surrounding water-based environment, are ions, acids, and alkalis that are toxic to the cell, as well as nutrients that the cell must absorb in order to live and grow. The plasma membrane, therefore, has two functions: first, to be a barrier keeping the constituents of the cell in and unwanted substances out; and second, to be a gate allowing transport into the cell of essential nutrients and movement from the cell of waste products.

The dual function of the plasma membrane

CHEMICAL COMPOSITION AND STRUCTURE OF THE MEMBRANE

Most current knowledge about the biochemical constituents of plasma membranes originates in studies of red blood cells. The chief advantage of these cells for experimental purposes is that they may be obtained easily in large amounts and that they have no typical membrane structure, other than the plasma membrane itself, to interfere with study of that structure. Careful studies of these and other cell types have shown that all plasma membranes are composed of proteins and fatty-acid-based lipids. Cell membranes actively involved in metabolism contain a higher proportion of protein; thus, the membrane of the mitochondrion, the most rapidly metabolizing organelle of the cell, contains as much as 75 percent protein, while the membrane of the Schwann cell, which forms an insulating sheath around many nerve cells, has as little as 20 percent protein.

Membrane lipids. Membrane lipids are principally of two types, phospholipids and sterols (generally cholesterol). Both types share the defining characteristic of lipids—they dissolve readily in organic solvents—but in addition they both have a region that is attracted to and soluble in water. This "amphiphilic" property (having a dual attraction, *i.e.,* containing both a lipid-soluble and a water-soluble region) is basic to the role of lipids as building blocks of cellular membranes. Phospholipid molecules have a head (often of glycerol) to which are attached two long fatty acid chains that look much like tails. These tails are repelled by water and dissolve readily in organic solvents, giving the molecule its lipid character. To another part of the head is attached a phosphoryl group with a negative electrical charge; to this group in turn is attached another group with a positive or neutral charge. This portion of the phospholipid dissolves in water, thereby completing the molecule's amphiphilic character. In contrast, sterols have a complex hydrocarbon ring structure as the lipid-soluble region, and a hydroxyl grouping as the water-soluble region.

When dry phospholipids, or a mixture of such phospholipids and cholesterol, are immersed in water under laboratory conditions, they spontaneously form globular structures called liposomes. Investigation of the liposomes shows them to be made of concentric spheres, one sphere inside of another and each forming half of a bilayered wall. A bilayer is composed of two sheets of phospholipid molecules with all of the molecules of each sheet aligned in the same direction. In a water medium, the phospholipids of the two sheets align so that their water-repellent, lipid-soluble tails are turned and loosely bonded to the tails of the molecules on the other sheet. The water-soluble heads turn outward into the water, to which they are chemically attracted. In this way, the two sheets form a fluid, sandwichlike structure, with the fatty acid chains in the middle mingling in an organic medium while sealing out the water medium.

This type of lipid bilayer, formed by the self-assembly of lipid molecules, is the basic structure of the plasma membrane of the cell. It is the most stable thermodynamic structure that a phospholipid–water mixture can take up: the fatty acid portion of each molecule dissolved in the organic phase formed by the identical regions of the other molecules and the water-attractive regions surrounded by water and facing away from the fatty acid regions. The chemical affinity of each region of the amphiphilic molecule is thus satisfied in the bilayer structure.

Membrane proteins. Membrane proteins are also of two general types. One type, called the extrinsic proteins, is loosely attached by ionic bonds or calcium bridges to the electrically charged phosphoryl surface of the bilayer. They are also attached to the second type of protein, called the intrinsic proteins. The intrinsic proteins, as their name implies, are firmly bound within the phospholipid bilayer. Many of them contain 20- to 24-membrane-long amino acid sequences—a length just sufficient to cross the bilayer—that may extend through and bind to the fatty acid internal regions of the membrane.

Membrane-bound intrinsic proteins

Many intrinsic proteins bear on their outer surfaces side chains of complex sugars, which extend into the aqueous environment around the cell. These are involved in cell-to-cell recognition (see below *The cell matrix and cell-to-cell communication*).

Membrane fluidity. One of the triumphs of molecular biology during the decade from 1965 to 1975 was the recognition of the cell membrane as a fluid collection of amphiphilic molecules. This array of proteins, sterols, and phospholipids is organized into a liquid crystal, a structure that lends itself readily to rapid cell growth. Measurements of the membrane's viscosity show it as a fluid a hundred times as viscous as water, similar to a thin oil. The phospholipid molecules diffuse readily in the plane of the bilayer, sliding over the face of the membrane as their loose chemical bonds permit. Many of the membrane's proteins also have this freedom of movement, but others are fixed in the membrane by interaction with the cell's cytoskeleton. Proteins never, and phospholipids only rarely, move from one half of the bilayer to the other. Newly synthesized phospholipids insert themselves easily into the existing plasma membrane. Intrinsic proteins are inserted during their synthesis on ribosomes bound to the inner surface of the membrane, while extrinsic proteins found on the internal surface of the plasma membrane are synthesized on free, or unattached, ribosomes, liberated into the cytoplasm, and then brought to the membrane by diffusion.

TRANSPORT ACROSS THE MEMBRANE

The chemical structure of the plasma membrane makes it remarkably flexible, the ideal boundary of rapidly growing and dividing cells. Yet the membrane is also a formidable barrier, allowing some dissolved substances, or solutes, to pass while blocking others. Lipid-soluble molecules and some small molecules can permeate the membrane, but the lipid bilayer effectively repels the many large, water-soluble molecules and electrically charged ions that the cell must import or export in order to live. Transport of these vital substances is carried out by the membrane proteins, particularly the intrinsic proteins. These molecules form a variety of transport systems: some are open channels, which allow ions to diffuse directly into the cell; others are "facilitators," which, through a little-understood chemical transformation, help solutes diffuse past the lipid screen; yet others are "pumps," which force solutes through the membrane when they are not concentrated enough to diffuse spontaneously. Particles too large to be diffused or pumped are often swallowed or disgorged whole by an opening and closing of the membrane.

Principle of diffusion

Behind this movement of solutes across the plasma membrane is the principle of diffusion. According to this principle, a dissolved substance diffuses down a concentration gradient; that is, given no energy from an outside source, it moves from a place where its concentration is

From Christian de Duve, *A Guided Tour of the Living Cell,* copyright © 1984 the de Duve Trust; reprinted with the permission of Scientific American Books, Inc.

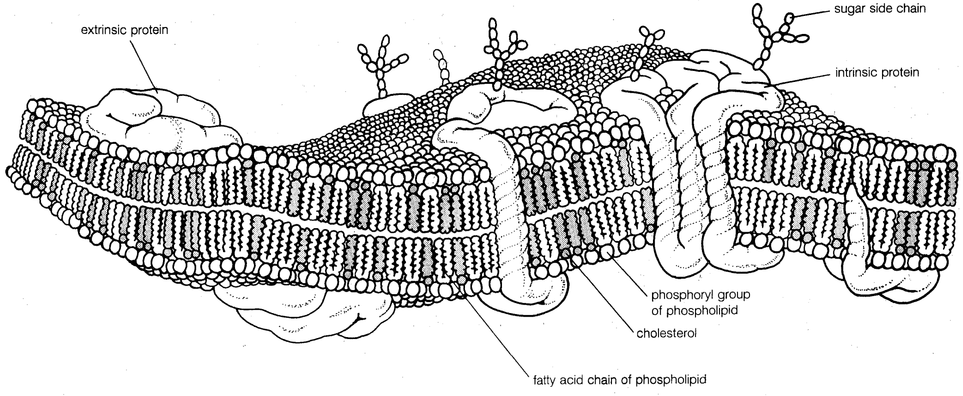

Figure 4: *A molecular view of the plasma membrane.*
Intrinsic proteins penetrate and bind tightly to the lipid bilayer; extrinsic proteins are loosely bound to the phosphoryl surface. Some intrinsic proteins present sugar side chains on the cell surface.

high to a place where its concentration is low. Diffusion continues down this gradually decreasing gradient until a state of equilibrium is reached, at which point there is an equal concentration in both places and an equal, random diffusion in both directions.

A solute at high concentration is at high free energy; that is, it is capable of doing more "work" (the work being that of diffusion) than a solute at low concentration. In performing the work of diffusion, the solute loses free energy, so that when it reaches equilibrium at a lower concentration, it is unable to return spontaneously (under its own energy) to its former high concentration. However, by the addition of energy from an outside source (through the work of an ion pump, for example), the solute may be returned to its former concentration and state of high free energy. This "coupling" of work processes is, in effect, a transferal of free energy from the pump to the solute, which is then able to repeat the work of diffusion. (See also above *The nature and function of cells: Coupled chemical reactions.*)

For most substances of biologic interest, the concentrations inside and outside the cell are different, creating concentration gradients down which the solutes spontaneously diffuse, provided they can permeate the lipid bilayer. Membrane channels and diffusion facilitators bring them through the membrane by passive transport; that is, the changes that the proteins undergo in order to facilitate diffusion are powered by the diffusing solutes themselves. For the healthy functioning of the cell, some solutes must remain at different concentrations on each side of the membrane; if through diffusion they approach equilibrium, they must be pumped back up their gradients by the process of active transport. Those membrane proteins serving as pumps accomplish this by coupling the energy required for transport to the energy produced by cell metabolism or by the diffusion of other solutes.

Permeation. Permeation is the diffusion, through a barrier, of a substance in solution. The rates at which biologically important molecules cross the plasma membrane through permeation vary over an enormous range. Proteins and sugar polymers do not permeate at all; in contrast, water and alcohols permeate most membranes in less than a second. This variation, caused by the lipid bilayer, gives the membrane its characteristic permeability. Permeability is measured as the rate at which a particular substance in solution crosses the membrane.

The barrier function of the lipid bilayer

For all cell membranes that have been studied in the laboratory, permeability increases in parallel with the permeant's ability to dissolve in organic solvents. The consistency of this parallel has led researchers to conclude that permeability is a function of the fatty acid interior of the lipid bilayer, rather than its phosphoryl exterior. This property of dissolving in organic solvents rather than water is given a unit of measure called the partition coefficient. The greater the solubility of a substance, the higher its partition coefficient, and the higher the partition coefficient, the higher the permeability of the membrane to that particular substance. For example, the water solubility of hydroxyl, carboxyl, and amino groups reduces their solubility in organic solvents and, hence, their partition coefficients. Cell membranes have been observed to have low permeability toward these groups. In contrast, lipid-soluble methyl residues and hydrocarbon rings, which have high partition coefficients, penetrate cell membranes more easily—a property useful in designing chemotherapeutic and pharmacological drugs.

For two molecules of the same partition coefficient, the one of greater molecular weight, or size, will in general cross the membrane more slowly. In fact, even molecules with very low partition coefficients can penetrate the membrane if they are small enough. Water, for example, is insoluble in organic solvents, yet it permeates cell membranes owing to the small size of its molecules. The size selectivity of the lipid bilayer is a result of its being not a simple fluid, the molecules of which move around and past a diffusing molecule, but an organized matrix, a kind of fixed grate, composed of the fatty acid chains of the phospholipids through which the diffusing molecule must fit.

Many substances do not actually cross the cell membrane through permeation of the lipid bilayer. Some electrically charged ions, for example, are repelled by organic solvents and therefore cross cell membranes with great difficulty, if at all. In these cases special holes in the membrane, called channels, allow specific ions and small molecules to diffuse directly past the bilayer.

Membrane channels. Biophysicists measuring the electric current passing through plasma membranes have found that, in general, plasma membranes have a vastly greater electrical conductance than does a membrane bilayer composed only of phospholipids and sterols. This greater conductance is thought to be conferred by the plasma membrane's proteins. A current flowing across a membrane often appears on a recording instrument as a series of bursts of various heights. These bursts represent current flowing through open channels, which are merely holes formed by intrinsic proteins traversing the lipid bilayer. No significant current flows through the membrane when no channel is open; multiple bursts are recorded when more than one channel is open.

Chemical composition of membrane channels

A rich variety of channels has been isolated and analyzed from a wide range of cell membranes. Invariably intrinsic proteins, they appear to contain numerous amino acid sequences that traverse the membrane, clearly forming a specific hole, or pore. Certain channels open and close spontaneously. Some are gated, or opened, by the chemical action of a signaling substance such as calcium, acetylcholine, or glycine, while others are gated by changes in the electrical potential across the membrane. Channels may possess a narrow specificity, allowing passage of only potassium or sodium, or a broad specificity, allowing passage of all positively charged ions (cations) or of all negatively charged ions (anions). There are channels called gap junctions that allow the passage of molecules between pairs of cells (see below *The cell matrix and cell-to-cell communication*).

The gating of channels with a capacity for ion transport is the basis of the many nerve–nerve, nerve–muscle, and nerve–gland interactions underlying neurobiological behaviour. These actions depend on the electric potential of the cell membrane, which varies with the prevailing constituents in the cell's environment. For example, if a channel that admits only potassium ions is present in a membrane separating two different potassium chloride solutions, the positively charged potassium ions tend to flow down their concentration gradient through the channel. The negatively charged chloride ions remain behind. This separation of electric charges sets up an electric potential across the membrane called the diffusion potential. The size of this potential depends on, among other factors, the difference in concentrations of the permeating ion across the membrane. A cell's plasma membrane in general contains the channels of widely different ion specificities, each channel contributing to the overall membrane potential according to the permeability and concentration ratio of the ion passing through it. Since the channels are often gated, the membrane's potential is determined by which channels are open; this in turn depends on the concentrations of signaling molecules and may change with time according to the membrane potential itself.

Most cells have about a tenfold higher concentration of sodium ions outside than inside and a reverse concentration ratio of potassium ions. Free calcium ions can be 10,000 times more concentrated outside the cell than inside. Thus, sodium-, potassium-, and calcium-selective membrane channels, by allowing the diffusion of those ions past the cell membrane and causing fluctuations in the membrane's electric potential, frequently serve as transmitters of signals from nerve cells. This diffusion through open channels, however, constantly threatens to alter the concentration of ions necessary for the cell to function. The proper distribution of ions is maintained by the action of ion pumps (see below *Primary active transport*).

Facilitated diffusion. Many water-soluble molecules that cannot penetrate the lipid bilayer are too large to fit through open channels. In this category are sugars and amino acids. Some ions, too, do not diffuse through channels. These vital substances enter and leave the cell through the

Functioning of membrane transporters

action of membrane transporters, which, like channels, are intrinsic proteins that traverse the cell membrane. Unlike channels, transporter molecules do not simply open holes in the membrane. Rather, they present sites on one side of the membrane to which molecules bind through chemical attraction. The binding site is highly specific, often fitting the atomic structure of only one type of molecule. When the molecule has attached to the binding site, then, in a process not fully understood, the transporter brings it through the membrane and releases it on the other side.

This action is considered a type of diffusion because the transported molecules move down their concentration gradients, from high concentration to low. To activate the action of the transporter, no other energy is needed than that of the chemical binding of the transported molecules. This action upon the transporter is similar to catalysis, except that the molecules (in this context called substrates) catalyze not a chemical reaction but their own translocation across the cell membrane. Two such substrates are glucose and the bicarbonate ion.

The glucose transporter. This sugar-specific transport system enables half of the glucose present inside the cell to leave within four seconds at normal body temperature. The glucose transporter is clearly not a simple membrane channel. First, unlike a channel it does not select its permeants by size, as one type of glucose is observed to move through the system a thousand times faster than its identically sized optical isomer. Second, it operates much more slowly than do most channels, moving only 1,000 molecules per second while a channel moves 1,000,000 ions. The most important difference between a membrane channel and the glucose transporter is the conformational change that the transporter undergoes while moving glucose across the membrane. Alternating between two conformations, it moves its glucose-binding site from one side of the membrane to the other. By "flipping" between its two conformational states, the transporter facilitates the diffusion of glucose; that is, it enables glucose to avoid the barrier of the plasma membrane while moving spontaneously down its concentration gradient. When the concentration reaches equilibrium, net movement of glucose ceases.

A facilitated diffusion system for glucose is present in many cell types. Similar systems transporting a wide range of other substrates (*e.g.,* different sugars, amino acids, nucleosides, ions) are also present.

The anion transporter. The best studied of the facilitated diffusion systems is that which catalyzes the exchange of anions across the red blood cell membrane. The exchange of hydroxyl for bicarbonate ions, each ion simultaneously being moved down its concentration gradient in opposite directions by the same transport molecule, is of great importance in enhancing the blood's capacity to carry carbon dioxide from tissues to the lungs. The exchange molecule for these anions is the major intrinsic protein of red blood cells; 1,000,000 of them are present on each cell, the polypeptide chain of each molecule traversing the membrane at least six times.

Secondary active transport. In some cases the problem of forcing a substrate up its concentration gradient is solved by coupling that upward movement to the downward flow of another substrate. In this way the energy-expending diffusion of the driving substrate powers the energy-absorbing movement of the driven substrate from low concentration to high. Because this type of active transport is not powered directly by the energy released in cell metabolism (see below *Primary active transport*), it is called secondary.

There are two kinds of secondary active transport: counter-transport, in which the two substrates cross the membrane in opposite directions; and co-transport, in which they cross in the same direction.

Counter-transport. An example of this system (also called antiport) begins with the sugar transporter described above. There are equal concentrations of glucose on both sides of the cell. A high concentration of galactose is then added outside the cell. Galactose competes with glucose for binding sites on the transport protein, so that mostly galactose—and a little glucose—enter the cell. The transporter itself, undergoing a conformational change, presents its binding sites for sugar at the inner face of the membrane. Here, at least transiently, glucose is in excess of galactose; it binds to the transporter and leaves the cell as the transporter switches back to its original conformation. Thus, glucose is pumped out of the cell against its gradient in exchange for the galactose riding into the cell down its own gradient.

Many counter-transport systems operate across the cell membranes of the body. A well-studied system (present in red blood, nerve, and muscle cells) pumps one calcium ion out of the cell in exchange for two or three sodium ions. This system helps maintain the low calcium concentration required for effective cellular activity. A different system, present in kidney cells, counter-transports hydrogen ions and sodium ions in a one-for-one ratio. This is important in stabilizing acidity by transporting hydrogen ions out of the body as needed.

Co-transport. In co-transport (sometimes called symport) two species of substrate, generally an ion and another molecule or ion, must bind simultaneously to the transporter before its conformational change can take place. As the driving substrate is transported down its concentration gradient it drags with it the driven substrate, which is forced to move up its concentration gradient. The trans-

From B. Alberts *et al., Molecular Biology of The Cell* (1983); Garland Publishing, Inc.

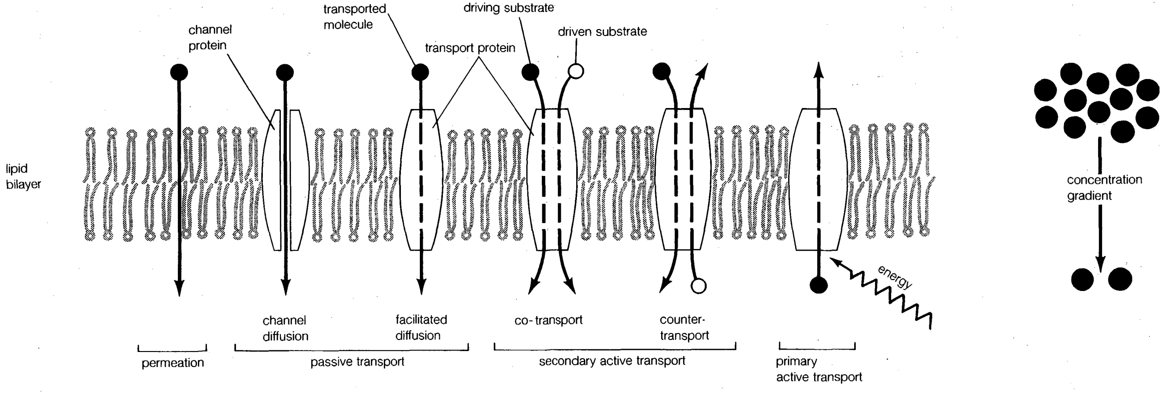

Figure 5: *The permeation and transport of molecules through the lipid bilayer of a cell membrane.*
Some small molecules can directly permeate the lipid bilayer. Many charged molecules, repelled by the bilayer, diffuse through membrane channels. Other charged or large molecules cross the membrane through diffusion facilitated by transport proteins. Channel diffusion and facilitated diffusion are forms of passive transport, as the molecules diffuse under their own energy down their concentration gradients. In secondary active transport, the energy released from the diffusion of one set of molecules (the driving substrate) down its concentration gradient powers the transport of another set (the driven substrate) either down or up its own gradient. In primary active transport, energy released from cellular metabolism powers the transport of molecules up their concentration gradients.

porter must be able to undergo a conformational change when bound to neither substrate, so as to complete the cycle and return the binding sites to the side from which driving and driven substrates both move.

Sodium ions are usually the driving substrates in the co-transport systems of animal cells, which maintain high concentrations of these ions through primary active transport. The driven substrates include a variety of sugars, amino acids, and other ions. During the absorption of nutrients, for example, sugars and amino acids are removed from the intestine by co-transport with sodium ions. After passing across the glomerular filter in the kidney, these substrates are returned to the body by the same system. Plant and bacterial cells usually use hydrogen ions as the driving substrate; sugars and amino acids are the most common driven substrates. When the bacterium *Escherichia coli* must metabolize lactose, it co-transports hydrogen ions with lactose (which can reach a concentration 1,000 times higher than that outside the cell).

Primary active transport. *The sodium pump.* Human red blood cells contain a high concentration of potassium and a low concentration of sodium, yet the plasma bathing the cells is high in sodium and low in potassium. When whole blood is stored cold under laboratory conditions, the cells lose potassium and gain sodium until the concentrations across the membrane for both ions are at equilibrium. When the cells are restored to body temperature and given appropriate nutrition, they extrude sodium and take up potassium, transporting both ions against their respective gradients until the previous high concentrations are reached. This ion pumping is linked directly to the hydrolysis of adenosine triphosphate (ATP), the cell's repository of metabolic energy (see above *The nature and function of cells: Coupled chemical reactions*). For every molecule of ATP split, three ions of sodium are pumped out of the cell and two of potassium are pumped in.

Active transport and ATP hydrolysis

An enzyme called sodium–potassium-activated ATPase has been shown to be the sodium pump, the protein that transports the ions across the cell membrane while splitting ATP. Widely distributed in the animal kingdom and always associated with the plasma membrane, ATPase is found at high concentration in cells that pump large amounts of sodium (*e.g.,* in mammalian kidneys, in salt-secreting glands of marine birds, and in the electric organs of eels). The enzyme, an intrinsic protein, exists in two major conformations whose interconversion is driven by the splitting of ATP or by changes in the transmembrane flows of sodium and potassium. When only sodium is present in the cell, the inorganic phosphate split from ATP during hydrolysis is transferred to the enzyme. Release of the chemically bound phosphate from the enzyme is catalyzed by potassium. Thus, the complete action of ATP splitting has been demonstrated to require both sodium (to catalyze the transfer of the phosphate to the enzyme) and potassium (to catalyze the release of the phosphate and free the enzyme for a further cycle of ATP splitting). Apparently, only after sodium has catalyzed the transferal of the phosphate to the enzyme can it be transported from the cell. Similarly, only after potassium has released the phosphate from the enzyme can it be transported into the cell. This overall reaction, completing the cycle of conformational changes in the enzyme, involves a strict coupling of the splitting of ATP with the pumping of sodium and potassium. It is this coupling that creates primary active transport.

The sodium pump extrudes one net positive charge during each cycle of ATP splitting. This flow of current induces an electric potential across the membrane that adds to the potentials brought about by the diffusion of ions through gated channels. The pump's contribution to the overall potential is important in certain specialized nerve cells.

Calcium pumps. Many animal cells can perform a primary active transport of calcium out of the cell, developing a 10,000-fold gradient of that ion. Calcium-activated ATPases have been isolated and shown to be intrinsic proteins straddling the membrane and undergoing conformational changes similar to those of the sodium–potassium-activated ATPase. When a rise in the concentration of cellular calcium results from the opening of calcium-selective channels, the membrane's calcium pumps restore the low concentration.

Hydrogen ion pumps. Hydrochloric acid is produced in the stomach by the active transport of hydrogen ions from the blood across the stomach lining, or gastric mucosa. Hydrogen concentration gradients of nearly 1,000,000 can be achieved by a hydrogen–potassium-activated ATP-splitting intrinsic protein in the cells lining the stomach. Apart from its specific ion requirements, the properties of this enzyme are remarkably similar to those of the sodium–potassium-activated enzyme and the calcium-activated enzyme. Other hydrogen-pumping, ATP-splitting primary active transporters occur in intracellular organelles, in bacteria, and in plant cells (see below *The mitochondrion and the chloroplast*). The steep gradient of hydrogen ions represents a store of energy that can be harnessed to the accumulation of nutrients or, in the case of bacterial flagella, to the powering of cell movement.

Transport of particles. Molecules of the size of proteins or nucleic acids cannot cross the plasma membrane by simple diffusion or by any of the transport routes considered above. Yet it is certain that such large molecules enter and leave the cell. In bringing about transmembrane movements of large molecules, the plasma membrane itself undergoes concerted movements during which part of the fluid medium outside of the cell is internalized (endocytosis) or part of the cell's internal medium is externalized (exocytosis). The details of these movements are only partly understood, but they seem to involve a fusion between membrane surfaces, followed by the re-formation of intact membranes.

Endocytosis. In this process the plasma membrane engulfs portions of the external medium, forms an almost complete sphere around it, and then draws the membrane-bounded vesicle into the cell. Several types of endocytosis have been distinguished: in pinocytosis, the vesicles are small and contain fluid; in phagocytosis, the vesicles are larger and contain solid matter; in receptor-mediated endocytosis, material binds to a specific receptor on the external face of the plasma membrane, triggering the process by which it is engulfed. Cholesterol enters cells by the last route.

Exocytosis. In this process material synthesized within the cell, and packaged into membrane-bounded vesicles, is exported from the cell following the fusion of the vesicles with the external plasma membrane. The materials so exported are cell-specific protein products, neurotransmitters, and a variety of other molecules. (W.D.S.)

Internal membranes

The presence of internal membranes distinguishes eukaryotic cells (cells with a nucleus) from prokaryotic cells (those without a nucleus). Prokaryotic cells are small (one to five micrometres in length) and contain only a single plasma membrane; metabolic functions are often confined to different patches of the membrane rather than to areas in the body of the cell. Typical eukaryotic cells, by contrast, are much larger, the plasma membrane constituting only 10 percent or less of the total cellular membrane. Metabolic functions in these cells are carried out in the organelles, compartments sequestered from the cell body, or cytoplasm, by internal membranes.

This section discusses internal membranes as structural and functional components in the organelles and vesicles of eukaryotic cells. The principal organelles—the nucleus, mitochondrion, and (in plants) chloroplast—are discussed elsewhere (see below *The nucleus* and *The mitochondrion and the chloroplast*). Of the remaining organelles, the lysosomes, peroxisomes, and (in plants) glyoxysomes enclose extremely reactive by-products and enzymes. Internal membranes form the mazelike endoplasmic reticulum, where cell membrane proteins and lipids are synthesized, and they also form the stacks of flattened sacs called the Golgi apparatus, which is associated with the transport and modification of lipids, proteins, and carbohydrates. Finally, internal cell membranes can form storage and transport vesicles and the vacuoles of plant cells. Each membrane structure has its own distinct composition of proteins and lipids enabling it to carry out unique functions.

GENERAL FUNCTIONS AND CHARACTERISTICS

Like the plasma membrane, membranes of some organelles contain transport proteins, or permeases, that allow chemical communication between organelles. Permeases in the lysosomal membrane, for example, allow amino acids generated inside the lysosome to cross into the cytoplasm, where they can be used for the synthesis of new proteins. Communication between organelles is also achieved by the membrane budding processes of endocytosis and exocytosis, which are essentially the same as in the plasma membrane (see above *The plasma membrane: Transport across the membrane*). On the other hand, the biosynthetic and degradative processes taking place in different organelles may require conditions greatly different from those of other organelles or of the cytosol (the fluid part of the cell surrounding the organelles). Internal membranes maintain these different conditions by isolating them from one another. For example, the internal space of lysosomes is much more acidic than that of the cytosol—pH 5 as opposed to pH 7—and is maintained by specific proton-pumping transport proteins in the lysosome membrane.

Separating incompatible environments and metabolic processes

Another function of organelles is to prevent competing enzymatic reactions from interfering with one another. For instance, essential proteins are synthesized on the rough endoplasmic reticulum and in the cytosol, while unwanted proteins are broken down in the lysosomes and also, to some extent, in the cytosol. Similarly, fatty acids are made in the cytosol and then either broken down in the mitochondria for the synthesis of ATP or degraded in the peroxisomes with concomitant generation of heat. These processes must be kept isolated. Organelle membranes also prevent potentially lethal by-products or enzymes from attacking sensitive molecules in other regions of the cell by sequestering such degradative activities in their respective membrane-bounded compartments.

The internal membranes of eukaryotic cells differ both structurally and chemically from the plasma membrane. Like the plasma membrane, they are constructed of a phospholipid bilayer into which are embedded, or bound, specific membrane proteins (see above *The plasma membrane: Chemical composition and structure of the membrane*). The three major lipids forming the plasma membrane—phospholipids, cholesterol, and glycolipids—are also found in the internal membranes, but in different concentrations. Phospholipid is the primary lipid forming all cellular membranes. Cholesterol, which contributes to the fluidity and stability of all membranes, is found in internal membranes at about 25 percent of the concentration in the plasma membrane. Glycolipids are found only as trace components of internal membranes, whereas they constitute approximately 5 percent of the plasma membrane lipid.

CELLULAR ORGANELLES AND THEIR MEMBRANES

The vacuole. Most plant cells contain one or more membrane-bound vesicles called vacuoles. Within the vacuole is the cell sap, a water solution of salts and sugars kept at high concentration by the active transport of ions through permeases in the vacuole membrane. This high concentration causes the entry, via osmosis, of water into the vacuole, which in turn expands the vacuole and generates a hydrostatic pressure, called turgor, that presses the cell membrane against the cell wall. Turgor is the cause of rigidity in living plant tissue.

In the mature plant cell, as much as 90 percent of cell volume may be taken up by a single vacuole; immature cells typically contain several smaller vacuoles.

The lysosome. Potentially dangerous hydrolytic enzymes functioning in acidic conditions (pH 5) are segregated in the lysosomes to protect the other components of the cell from random destruction. Lysosomes are bound by a single phospholipid bilayer membrane. They vary in size and probably originate by budding from the Golgi membranes. Enzymes known to be present in the lysosomes include hydrolases, which degrade proteins, nucleic acids, lipids, glycolipids, and glycoproteins; they are most active in the acidity maintained in the lysosomes. Lysosomes fuse with vacuoles containing material from inside or outside the cell to be digested. After the material is broken down, lipids and amino acids are transported across the lysosomal membrane by permeases for use in biosynthesis. The remaining debris generally remains within the lysosome and is called a residual body.

Microbodies. Microbodies are roughly spherical in shape, bound by a single membrane, and are usually 0.5 to one micrometre in diameter. There are several types, by far the most common of which is the peroxisome. Peroxisomes derive their name from hydrogen peroxide, a reactive intermediate in the process of molecular breakdown that occurs in the microbody. Peroxisomes contain type II oxidases, which are enzymes that use molecular oxygen in reactions to oxidize organic molecules. A product of these reactions is hydrogen peroxide, which is further metabolized into water and oxygen by the enzyme catalase, a predominant constituent of peroxisomes. In addition, peroxisomes contain other enzyme systems that degrade various lipids.

The peroxisome

The plant glyoxysome is a peroxisome that also contains the enzymes of the glyoxylate cycle, which is crucial to the conversion of fat into carbohydrate.

The endoplasmic reticulum. The endoplasmic reticulum (ER) is a system of membranous vesicles extending throughout the cytoplasm. Often, it constitutes more than half of the total membrane in the cell. This structure was first noted in the late 19th century, when studies of stained cells indicated the presence of some type of extensive cytoplasmic structure, then termed the gastroplasm. The electron microscope made possible the study of the morphology of this organelle in the 1940s, when it was given its present name.

The endoplasmic reticulum can be classified in two functionally distinct forms, the smooth endoplasmic reticulum (SER) and the rough endoplasmic reticulum (RER). The morphological distinction between the two is the presence of protein-synthesizing particles, called ribosomes, attached to the outer surface of the RER.

The smooth endoplasmic reticulum. The functions of the SER, a meshwork of fine tubular membrane vesicles, vary considerably from cell to cell. One important role is the synthesis of phospholipids and cholesterol, which are major components of the plasma and internal membranes. Phospholipids are formed from fatty acids, glycerol phosphate, and other small, water-soluble molecules by enzymes bound to the ER membrane with their active sites facing the cytosol. Some phospholipids remain in the ER membrane, where, catalyzed by specific enzymes within the membranes, they can "flip" from the cytoplasmic side of the bilayer, where they were formed, to the exoplasmic, or inner, side. This process ensures the symmetrical growth of the ER membrane. Other phospholipids are transferred through the cytoplasm to other membranous structures, such as the plasma membrane and the mitochondrion, by special phospholipid transfer proteins.

In liver cells, the SER is specialized for the detoxification of a wide variety of compounds produced by metabolic processes. Liver SER contains a number of enzymes called cytochrome P450, which catalyze the breakdown of carcinogens and other organic molecules. In cells of the adrenal glands and gonads, cholesterol is modified in the SER at one stage of its conversion to steroid hormones. Finally, the SER in muscle cells, known as the sarcoplasmic reticulum, sequesters calcium ions from the cytoplasm. When the muscle is triggered by nerve stimuli, the calcium ions are released, causing muscle contraction.

The rough endoplasmic reticulum. The RER is generally a series of connected vesicles and flattened sacs. It plays a central role in the synthesis and export of proteins and glycoproteins and is best studied in the secretory cells specialized in these functions. The many secretory cells in the body include liver cells secreting serum proteins such as albumin, endocrine cells secreting peptide hormones such as insulin, salivary gland and pancreatic acinar cells secreting digestive enzymes, mammary gland cells secreting milk proteins, and cartilage cells secreting collagen and proteoglycans.

Production of proteins in the ribosomes

Ribosomes are particles that synthesize proteins from amino acids. They are composed of four RNA molecules and about 50 proteins assembled into a large and a small subunit. Ribosomes are either free (*i.e.,* not bound to membranes) in the cytoplasm of the cell or bound to the RER. Lysosomal enzymes, proteins destined for the ER, Golgi, and plasma membranes, and proteins to be secreted from the cell are among those synthesized on membrane-bound ribosomes. Fabricated on free ribosomes are proteins remaining in the cytosol, those bound to the internal surface of the plasma membrane, as well as those to be incorporated into the nucleus, mitochondria, chloroplasts, peroxisomes, and other organelles. In order to segregate their sites of synthesis, the cell must have a mechanism that can differentiate between these two classes of proteins. This mechanism cannot involve the ribosomes themselves, since those ribosomes bound to the ER membrane are no different from those found in the cytoplasm. In 1971 the biochemists Gunter Blobel and David Sabatini suggested that the amino-terminal portion of the protein (the first part of the molecule to be made) could act as a "signal sequence," which would facilitate attachment of the growing protein to the ER membrane and lead it either into the membrane or through the membrane into the ER lumen, or interior.

The signal hypothesis has been substantiated by a large body of experimental evidence. It is now known that "translation" of the blueprint for a specific protein encoded in a messenger RNA molecule begins on a free ribosome. As the growing protein, with the signal sequence at its amino-terminal end, emerges from the ribosome, the sequence binds to a complex of six proteins and one RNA molecule known as the signal recognition particle (SRP). The SRP also binds to the ribosome to halt further formation of the protein. The membrane of the ER contains receptor sites that bind the SRP-ribosome complex to the RER membrane. Upon binding, translation resumes, with the SRP dissociating from the complex and the signal sequence and remainder of the nascent protein threading through the membrane into the ER lumen. At that point, the protein is permanently segregated from the cytosol. In most cases, the signal sequence is cleaved from the protein by an enzyme called signal peptidase as it emerges on the luminal surface of the ER membrane. In addition, in a process known as glycosylation, oligosaccharide (complex sugar) chains are often added to the protein to form a glycoprotein. Inside the ER lumen, the protein folds into its characteristic three-dimensional conformation.

Transport of proteins from endoplasmic reticulum to Golgi apparatus

Within the lumen, proteins that will be secreted from the cell diffuse into the transitional portion of the ER, a region that is largely free of ribosomes. There, the molecules are packaged into small, membrane-bounded transport vesicles, which separate from the ER membrane and move through the cytoplasm to a target membrane, usually the Golgi complex. There the transport vesicle membrane fuses with the Golgi membrane and the contents of the vesicle are delivered into the lumen of the Golgi. This, like all processes of vesicle budding and fusion, preserves the sidedness of the membranes; that is, the cytoplasmic surface of the membrane always faces outward, and the luminal contents are always sequestered from the cytoplasm.

Certain nonsecretory proteins made on the RER remain part of the membrane system of the cell. These membrane proteins have, in addition to the signal sequence, one or more anchor regions composed of lipid-soluble amino acids. The amino acids prevent passage of the protein completely into the ER lumen by anchoring it into the phospholipid bilayer of the ER membrane.

The Golgi apparatus. The Golgi complex is the site of the modification, completion, and export of secretory proteins and glycoproteins. This organelle, first described by the Italian cytologist Camillo Golgi in 1898, has a characteristic structure composed of five to eight flattened, disk-shaped, membrane-defined cisternae, or vesicles, arranged in a stack. Though the mechanisms are not well understood, it is thought that the Golgi is the principal director of protein traffic in the cell. Secretory proteins and glycoproteins, plasma membrane proteins and glycoproteins, lysosomal proteins, and some glycolipids all pass through the Golgi structure at some point in their maturation. In plant cells, much of the cell-wall material passes through the Golgi as well.

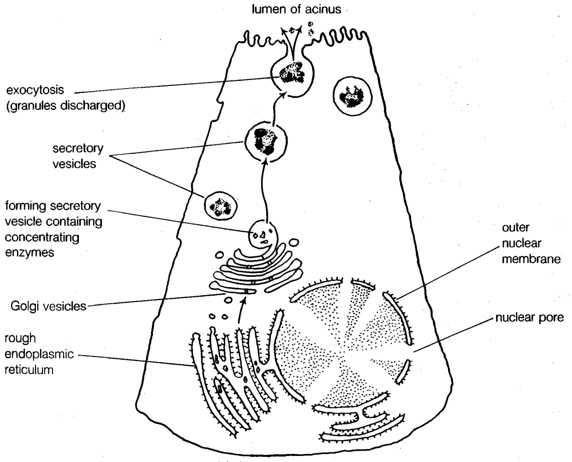

Figure 6: *The path taken by newly synthesized secretory proteins in a rat pancreatic acinar cell.*
Immediately after synthesis, the secretory proteins are found in the lumen of the rough endoplasmic reticulum. Transfer vesicles transport them to the Golgi complex. Next they are concentrated in secretory vesicles. The secretory vesicles are formed under the region of the plasma membrane that faces a ductule of the acinus. Exocytosis of the vesicles releases the contents into the ductule; from there, the contents move to the intestine, where they become digestive enzymes.

From J. Darnell, H. Lodish, and D. Baltimore, *Molecular Cell Biology,* copyright © 1986 Scientific American Books, Inc.; reprinted with the permission of the publisher

The Golgi apparatus itself is structurally polarized, consisting of a "cis" face near the transitional region of the RER, a medial segment, and a "trans" face near the plasma membrane. These faces are biochemically distinct, and the enzymatic content of each segment is markedly different. The cis face membranes are generally thinner than the others.

As the secretory proteins move through the Golgi, a number of chemical modifications may transpire. Important among these is the modification of carbohydrate groups. As described above, many secretory proteins are glycosylated in the ER. In the Golgi, specific enzymes modify the oligosaccharide chains of the glycoproteins by removing certain mannose residues and adding other sugars, such as galactose and sialic acid. These enzymes are known collectively as glycosidases and glycosyltransferases. The role of the oligosaccharide chains is not known. Some secretory proteins will cease to be transported if their carbohydrate groups are modified incorrectly or not permitted to form. In some cases the carbohydrate groups are necessary for the stability or activity of the protein or for targeting the molecule for a specific destination.

Also within the Golgi or secretory vesicles are proteases that cut many secretory proteins at specific amino acid positions. This often results in activation of the secretory protein, an example being the conversion of inactive proinsulin to active insulin by removing a series of amino acids.

Discharge of proteins from the cell

Secretory vesicles. Proteins move from the cis to the trans face of the Golgi in transport vesicles that bud and fuse with other membranes much in the same manner as the transport from the ER to Golgi. Often, this trip across the Golgi acts to concentrate the secretory product. At the trans face, the product may move into one specific area and be enclosed in a vacuole. The vacuole may then become a secretory vesicle that moves to the plasma membrane, where the contents can be discharged from the cell. This is a closely regulated process; discharge takes place only at the appropriate membrane to avoid the dangerous or wasteful discharge of products. For example, pancreatic enzymes are secreted from the acinar cells into ductules, which carry the enzymes not into the blood but into the intestine.

The stimulus for discharge is most often a nervous or hormonal signal. Discharge itself is generally triggered by a rise in the concentration of calcium ions in the cell.

The action is one of exocytosis: the vesicle and the plasma membrane fuse, forming a channel by which the proteins and glycoproteins in the vesicle can be released.

As secretory vesicles fuse with the plasma membrane, the area of the plasma membrane increases. Normal size is regained by the recycling of membrane components through endocytosis. Regions bud from the plasma membrane and then fuse with the membrane of the Golgi or lysosomes.

SORTING OF PRODUCTS BY CHEMICAL RECEPTORS

Not all proteins synthesized on the ER are destined for export. Many, such as the hydrolases in lysosomes, remain inside the cell; others become anchored in the membrane of internal organelles or in the plasma membrane. It is presumed that each protein has some type of marker that fits a specific location in the cell.

Proteins synthesized on free ribosomes may have segments that bind to specific receptors on the outer membrane of mitochondria, chloroplasts, or peroxisomes, allowing these proteins to be taken up only by these organelles. In the case of proteins synthesized on the RER, both the hydrolases destined for lysosomes and the secretory proteins are found initially in the same portion of the ER lumen. Studies have shown that these can be distinguished on the basis of their carbohydrate residues. The carbohydrate residues of lysosomal enzymes become modified in the cis-Golgi by the addition of certain phosphate groups. This critical modification allows the enzymes to bind to specific receptors on the membrane of the Golgi, which then directs them into vesicles leading to a lysosome rather than a secretory vesicle. In the lysosomes, proton pumps create an acidic environment that causes the release of the lysosomal enzyme from the membrane-bound receptors.

It is now thought that much of this sorting activity is mediated by coated vesicles containing the same fibrous outer protein, clathrin, used in endocytosis. These sorting vesicles also contain associated smaller proteins. Some of the smaller proteins may act as receptors for the transported proteins, while others may be markers on the surface of vesicles, allowing the proper receptors on the appropriate target membrane to recognize and accept the coated vesicle and its contents. (H.F.L./Ch.C./M.Cu.)

The nucleus

The nucleus is the information centre of the cell in all higher organisms. It is separated from the cytoplasm by the nuclear envelope, and it houses the double-stranded, spiral-shaped deoxyribonucleic acid (DNA) molecules, which contain the genetic information necessary for the cell to retain its unique character as it grows and divides.

Distinction between prokaryotic and eukaryotic cells

The presence of a nucleus distinguishes the eukaryotic cells of multicellular organisms from the prokaryotic, one-celled organisms, such as bacteria. In contrast to the higher organisms, bacteria do not have nuclei, so that their DNA is maintained in the same compartment as the other cellular components.

The primary function of the nucleus is the expression of selected subsets of the genetic information encoded in the DNA double helix. Each subset of a DNA chain, called a gene, codes for the construction of a specific protein out of a chain of amino acids. Information in DNA is not decoded directly into proteins, however. First it is transcribed, or copied, into a range of messenger ribonucleic acid (mRNA) molecules, each of which encodes the information for one protein (or more than one protein in bacteria). The mRNA molecules are then transported through the nuclear envelope into the cytoplasm, where they are translated, serving as templates for the synthesis of specific proteins.

The nucleus must not only synthesize the mRNA for many thousands of proteins, but it must also regulate the amounts synthesized and supplied to the cytoplasm. Furthermore, the amounts of each type of mRNA supplied to the cytoplasm must be regulated differently in each type of cell. In addition to mRNA, the nucleus synthesizes and exports other classes of RNA involved in the mechanisms of protein synthesis.

STRUCTURAL ORGANIZATION OF THE NUCLEUS

DNA packaging. The nucleus of the average human cell is only six micrometres (6×10^{-6} metre) in diameter, yet it contains about 1.8 metres of DNA. This is distributed among 46 chromosomes, each consisting of a single DNA molecule about 40 millimetres (1½ inches) long. The extraordinary packaging problem this poses can be envisaged by a scale model enlarged a million times. On this scale a DNA molecule would be a thin string two millimetres thick, and the average chromosome would contain 40 kilometres (25 miles) of DNA. With a diameter of only six metres, the nucleus would contain 1,800 kilometres of DNA.

These contents must be organized in such a way that they can be copied into RNA accurately and selectively. DNA is not simply crammed or wound into the nucleus like a ball of string; rather, it is organized, by molecular interaction with specific nuclear proteins, into a precisely packaged structure. This combination of DNA with proteins creates a dense, compact fibre called chromatin. An extreme example of the ordered folding and compaction that chromatin can undergo is seen during cell division, when the chromatin of each chromosome condenses and is divided between two daughter cells (see below *Cell division and growth*).

Histone core of the nucleosome

Nucleosomes: the subunits of chromatin. The compaction of DNA is achieved by winding it around a series of small proteins called histones. Histones are composed of positively charged amino acids that bind tightly to and neutralize the negative charges of DNA. There are five classes of histone. Four of them, called H2A, H2B, H3, and H4, contribute two molecules each to form an octamer, an eight-part core around which two turns of DNA are wrapped. The resulting beadlike structure is called the nucleosome. The DNA enters and leaves a series of nucleosomes, linking them like beads along a string in lengths that vary between species of organism or even between different types of cell within a species. A string of nucleosomes is then coiled into a solenoid configuration by the fifth histone, called H1. One molecule of H1 binds to the site at which DNA enters and leaves each nucleosome, and a chain of H1 molecules coils the string of nucleosomes into the solenoid structure of the chromatin fibre (see Figure 7).

After B. Alberts *et al.*, *Molecular Biology of The Cell* (1983); Garland Publishing, Inc.

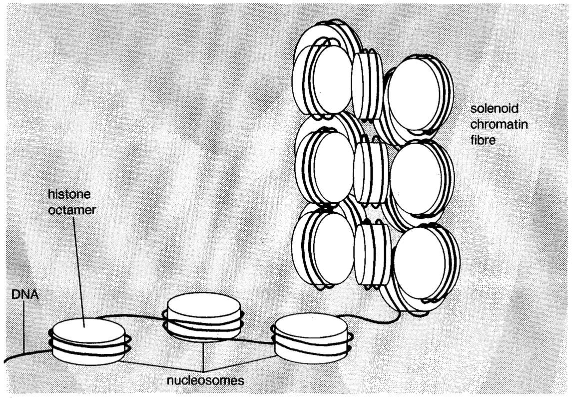

Figure 7: DNA wrapped around clusters of histone proteins to form nucleosomes, which can coil to form solenoids.

Nucleosomes not only neutralize the charges of DNA, but they have other consequences. First, they are an efficient means of packaging. DNA becomes compacted by a factor of six when wound into nucleosomes and by a factor of about 40 when the nucleosomes are coiled into a solenoid chromatin fibre. The winding into nucleosomes also allows some inactive DNA to be folded away in inaccessible conformations, a process that probably contributes to the selectivity of gene expression.

Organization of chromatin fibre. Several studies indicate that chromatin is organized into a series of large radial loops anchored to specific scaffold proteins. Each loop consists of a chain of nucleosomes and may be related to units of genetic organization. This radial arrangement of chromatin loops compacts DNA about a thousandfold. Further compaction is achieved by a coiling of the entire looped chromatin fibre into a dense structure called a chromatid, two of which form the chromosome. (The bands that appear in fluorescent micrographs of chromosomes may correspond to coils of looped chromatin fibre.) During cell division, this coiling produces a 10,000-fold compaction of DNA. After division, the condensed chromosomes partly unfold as a nuclear envelope reforms around them. However, the organization of most DNA into nucleosomes persists within the active nucleus.

The nuclear envelope. The nuclear envelope is a double membrane composed of an outer and an inner phospholipid bilayer. The thin space between the two layers appears to connect with the lumen of the rough endoplasmic reticulum (RER), and the outer layer is an extension of the outer face of the RER.

The nuclear pore

The inner surface of the nuclear envelope has a protein lining called the nuclear lamina, which binds to chromatin and other contents of the nucleus. The entire envelope is perforated by numerous nuclear pores. These transport routes are fully permeable to small molecules up to the size of the smallest proteins, but they form a selective barrier against movement of larger molecules. Each pore is surrounded by an elaborate protein structure called the nuclear pore complex, which probably selects large molecules for entrance into the nucleus. Entering the nucleus through the pores are the nucleotide building blocks of DNA and RNA, as well as adenosine triphosphate, which provides the energy for synthesizing genetic material. Histones and other large proteins must also pass through the pores. These molecules probably have structures on their surface that signal admittance by the nuclear pore complexes. The complexes also probably regulate the export from the nucleus of RNA and subunits of ribosomes.

DNA in prokaryotes is also organized in loops and is bound to small proteins resembling histones, but this structure is not enclosed by a nuclear membrane.

GENETIC ORGANIZATION OF THE NUCLEUS

The structure of DNA. Several features are common to the genetic structure of most organisms. First is the double-stranded DNA. Each strand of this molecule is a series of nucleotides, and each nucleotide is composed of a sugar–phosphate compound attached to one of four nitrogen-containing bases. The sugar–phosphate compounds link together to form the backbone of the strand. Each of the bases strung along the backbone is chemically attracted to a corresponding base on the parallel strand of the DNA molecule. This base pairing joins the two strands of the molecule much as rungs join the two sides of a ladder, and the chemical bonding of the base pairs twists the doubled strands into a spiral, or helical, shape.

The four nucleotide bases are adenine, cytosine, guanine, and thymine. DNA is composed of millions of these bases strung in an almost limitless variety of sequences. It is in the sequence of bases that the genetic information is contained, each sequence determining the sequence of amino acids to be connected into proteins. A nucleotide sequence sufficient to encode one protein is called a gene. Genes are interspersed along the DNA molecule with other sequences that do not encode proteins. Some of these so-called untranslated regions regulate the activity of the adjacent genes, for example, by marking the points at which enzymes begin and cease transcribing DNA into RNA (see below *Genetic expression through RNA*).

A complete set of DNA in all cells of the body

Rearrangement and modification of DNA. Different cells of the body owe their specialized structures and functions to different genes. This does not mean that the set of genetic information varies among the cells of the body. Indeed, for each cell the entire DNA content of the chromosomes is usually duplicated exactly from generation to generation, and in general the genetic content and arrangement is strikingly similar among different cell types of the same organism. The clearest evidence of this comes from several species of plants in which it is possible to grow entire new plants from single cells, indicating that the cells contain all of the genetic information required for the plant's entire life cycle. The closest equivalent experiment in animals is the hatching of tadpoles from frogs' eggs whose nuclei have been replaced by nuclei of other cells from an adult frog. When cells from the intestine of a frog embryo are used as donors of nuclei, it is possible to raise fertile adult frogs carrying genetic markers from the donor intestine cell and none from the recipient egg. These experiments stop short of showing that all the cells of an organism contain copies of all genes, but they do establish that the nuclei of some highly differentiated cells retain functional copies of sufficient genes to specify, in these cases, a complete, swimming tadpole or a fertile adult frog.

Differentiation of cells, therefore, can occur without the loss or irreversible inactivation of unnecessary genes. This conclusion is reinforced by studies showing the presence of specific genes in a range of adult tissues. For example, normal copies of the genes encoding hemoglobin are present in the same numbers in red blood cells, which make hemoglobin, as in a range of other types of cell, which do not.

Despite the general uniformity of genetic content in all the cells of an organism, studies have shown a few clear examples in some organisms of programmed, reversible change in the DNA of developing tissues. One of the most dramatic rearrangements of DNA occurs in the immune systems of mammals. The body's defense against invasion by foreign organisms involves the synthesis of a vast range of antibodies by lymphocytes (a type of white blood cell). Antibodies are proteins that bind to specific invading molecules or organisms and either inactivate them or signal their destruction. The binding sites on each antibody molecule are formed by one light and one heavy amino acid chain, which are encoded by different segments of the DNA in the lymphocyte nucleus. Upon stimulation by an invading particle, these DNA segments undergo slight rearrangements, resulting in the synthesis of a great variety of antibodies.

Trypanosome parasites, which cause sleeping sickness, undergo DNA rearrangement in order to overcome the versatility of their hosts' antibody production. The parasites are covered by a thick coat of glycoprotein (a protein with sugars attached). Given time, host organisms can overcome infection by producing antibodies to the parasites' glycoprotein coat, but this reaction is anticipated and evaded by the selective rearrangement of the trypanosomes' DNA encoding the glycoprotein, thus constantly changing the surface presented to the hosts' immune system.

Inactivation of genes

Careful comparisons of gene structure have also revealed a structural modification of DNA that occurs mostly in inactive genes. This modification involves the addition of a methyl group to cytosine bases in the DNA chain. It appears to have the role in vertebrate animals of inactivating genes that are not required for expression in a particular type of cell. An important feature of the methylation of cytosine lies in its ability to be copied, so that methyl groups in a dividing cell's DNA will result in methyl groups in the same positions in the DNA of both daughter cells.

From studies comparing the structure of DNA in different cells of the same organism there emerges a picture of remarkable consistency. Modifications and rearrangements of the nucleotide sequences in DNA are more exceptions than the rule, although they do cause significant changes in the structure and function of some cells. But it is in the transcription of the genetic code from DNA to RNA, and the translation of that code from RNA into protein, that the greatest modulation of genetic information occurs. This process, called genetic expression, takes place over several stages, and at each stage is the potential for further differentiation of cell types.

GENETIC EXPRESSION THROUGH RNA

As explained above, genetic information is encoded in the sequences of the four nucleotide bases making up a DNA molecule. One of the two DNA strands is transcribed exactly into RNA, with the exception that the thymine base of DNA is replaced by uracil. RNA also contains a slightly different sugar component (ribose) from that of DNA (deoxyribose) in its connecting sugar–phosphate chain. Unlike DNA, which is stable throughout the cell's life and individual strands of which are even passed on to many cell generations, RNA is unstable. It is continuously broken down and replaced, enabling the cell to change its patterns of protein synthesis.

Apart from mRNA, which encodes proteins, other classes of RNA are made by the nucleus. These include ribosomal RNA (rRNA), which forms part of the ribosomes and is also exported to the cytoplasm to help translate the information in mRNA into proteins. Ribosomal RNA is synthesized in a specialized region of the nucleus called the nucleolus, which appears as a dense area within the nucleus and contains the genes that encode rRNA (see Figure 8). This is also the site of assembly of ribosome subunits from rRNA and ribosomal proteins. Ribosomal proteins are synthesized in the cytoplasm and transported to the nucleus for subassembly in the nucleolus. The subunits are then returned to the cytoplasm for completion. Another class of RNA synthesized in the nucleus is transfer RNA (tRNA), which serves as an adaptor matching individual amino acids to the nucleotide triplets of mRNA during protein synthesis.

Three main RNA-synthesizing enzymes

RNA synthesis. The synthesis of RNA is performed by enzymes called RNA polymerases. There are three main RNA polymerases in higher organisms, designated I, II, and III (or sometimes A, B, and C). Each is a complex protein consisting of many subunits. RNA polymerase I synthesizes three of the four types of rRNA (called 18S, 28S, and 5.8S RNA); therefore it is active in the nucleolus, where the genes encoding these rRNA molecules reside. RNA polymerase II synthesizes mRNA, though its initial products are not mature RNA but larger precursors, called heterogeneous nuclear RNA, which are completed later (see below *Processing of mRNA*). The products of RNA polymerase III include tRNA and the fourth RNA component of the ribosome, which is called 5S RNA.

All three polymerases start RNA synthesis at specific sites on DNA and proceed along the molecule, linking selected nucleotides sequentially until they come to the end of the gene and, therefore, the end of the growing RNA chain. Energy for RNA synthesis comes from high-energy phosphate linkages contained in the nucleotide precursors of RNA. Each unit of the final RNA product is essentially a sugar, a base, and one phosphate, but the building material consists of a sugar, a base, and three phosphates. During synthesis two phosphates are cleaved and discarded for each nucleotide incorporated into RNA, and the energy released from the phosphate bonds is used to link the nucleotides. The crucial feature of RNA synthesis is that the sequence of nucleotides joined into a growing RNA chain is specified by the sequence of nucleotides in the DNA template: each adenine in DNA specifies uracil in RNA, each cytosine specifies guanine, each guanine specifies cytosine, and each thymine in DNA specifies adenine. In this way the information encoded in each gene is transcribed into RNA for translation by the protein-synthesizing machinery of the cytoplasm.

In addition to specifying the sequence of amino acids to be polymerized into proteins, the nucleotide sequence of DNA contains supplementary information. For example, short sequences of nucleotides determine the initiation site for each RNA polymerase, specifying where and when RNA synthesis should occur. In the case of RNA polymerases I and II, the sequences specifying initiation sites lie just ahead of the genes. In contrast, the equivalent information for RNA polymerase III lies within the gene, that is, within the region of DNA to be copied into RNA. The initiation site on a segment of DNA is called a promoter. The promoters of different genes have some nucleotide sequences in common, but they differ in others. The differences in sequence are recognized by specific proteins called transcription factors, which are necessary for the expression of particular types of genes and which contribute to differences in the gene expression of different types of cells.

Processing of mRNA. During and after synthesis, mRNA precursors undergo a complex series of changes before the mature molecules are released from the nucleus. First, a modified nucleotide is added to the start of the RNA molecule by a reaction called capping. This cap later binds to a ribosome in the cytoplasm. The synthesis of mRNA is not terminated simply by the RNA polymerase's detachment from DNA, as usually occurs, but by chemical cleavage of the RNA chain. Many (but not all) types of mRNA have a simple polymer of adenosine residues added to their cleaved ends.

In addition to these modifications of the termini, startling discoveries in 1977 revealed that portions of newly synthesized RNA molecules are cut out and discarded. In many genes, the regions coding for proteins are interrupted by intervening sequences of nucleotides called introns. These introns must be excised from the RNA copy before it can be released from the nucleus as a functional mRNA. The number and size of introns within a gene vary greatly, from no introns at all to more than 50. The sum of the lengths of these intervening sequences is sometimes longer than the sum of the regions coding for proteins.

RNA splicing

The removal of introns, called RNA splicing, appears to be mediated by small nuclear ribonucleoprotein particles (snRNP's). These particles have RNA sequences that are complementary to the junctions between introns and adjacent coding regions. By binding to the junction ends, an snRNP twists the intron into a loop. It then excises the loop and splices the coding regions.

REGULATION OF GENETIC EXPRESSION

Although all the cell nuclei of an organism generally carry the same genes, there are conspicuous differences between the specialized cell types of the body. The source of these differences lies not so much in the occasional modification of DNA, as outlined above, but in the selective expression of DNA through RNA; in particular, it can be traced to processes regulating the amounts and activities of mRNA both during and after its synthesis in the nucleus.

Regulation of RNA synthesis. The first level of regulation is mediated by variations in chromatin structure. In order to be transcribed, a gene must be assembled into a structurally distinct form of active chromatin. Although this is poorly characterized, it appears to correspond to the partial unfolding of chromatin. A second level of regulation is achieved by varying the frequency with which a gene in the active conformation is transcribed into RNA by an RNA polymerase. There is evidence for regulation of RNA synthesis at both of these levels—for example, in response to hormone induction. At both levels, protein factors are believed to perform the regulation, for example, by binding to special DNA regions flanking the transcribed gene.

Regulation of RNA after synthesis. After synthesis, RNA molecules undergo selective processing, which results in the export of only a subpopulation of RNA molecules to the cytoplasm. Furthermore, the stability in the cytoplasm of a particular type of mRNA can be regulated. There is more and more evidence for regulation of gene expression by prolonging or curtailing the life of a specific mRNA. For example, the hormone prolactin increases synthesis of milk proteins in tissue by causing a twofold rise in the rate of mRNA synthesis; but it also causes a 17-fold rise in mRNA lifetime, so that, in this case, the main cause of increased protein synthesis is the prolonged availability of mRNA. Conversely, there is evidence for selective destabilization of some mRNA—such as histone mRNA, which is rapidly broken down when DNA replication is interrupted. Finally, there are examples of selective regulation of the translation of mRNA into protein. This appears to be less generally used as a regulatory step than the other levels illustrated, but it is clear that it too can be used to regulate the expression of some genes. (R.A.La.)

The mitochondrion and the chloroplast

Mitochondria and chloroplasts are the powerhouses of the cell. Mitochondria appear in both plant and animal cells as elongated, cylindrical bodies, roughly one micrometre in length and closely packed in regions actively using metabolic energy. Oxidizing the products of cytoplasmic metabolism, they convert the energy so liberated into adenosine triphosphate (ATP), the energy currency of the cell. Chloroplasts are the photosynthetic organelles in plant and plantlike bacterial cells. They trap light energy and convert it partly into ATP but mainly into certain chemically reduced molecules that, together with ATP, are used in the first steps of carbohydrate production. Mitochondria and chloroplasts share a certain structural resemblance, and both have a somewhat independent existence within the cell, synthesizing some proteins and dividing according to their own genetic instructions.

MITOCHONDRIAL AND CHLOROPLASTIC STRUCTURE

Both organelles are bounded by an external porous membrane, which allows passage of small metabolites but which is an effective barrier, in general, to the movement of large cytoplasmic proteins. An inner membrane, concentric to the outer, is impermeable even to small ions, such as protons. The membranes of both organelles have a lipid bilayer construction, which has been shown to be a selective barrier against the passage of charged, water-soluble molecules and ions (see above *The plasma membrane: Chemical composition and structure of the membrane*). Between the inner and outer layers is the intermembrane space.

In mitochondria the inner membrane is thrown into a vast number of folds called cristae, enormously expanding the surface area of the membrane. In contrast, the inner membrane of chloroplasts is relatively smooth, but within this membrane is yet another series of membranes, also enormously folded, that form a set of flattened, disklike sacs called the thylakoids. The organellar space enclosed by the inner membrane is called the matrix in mitochondria and the stroma in chloroplasts. Both spaces are filled with a fluid containing a rich mixture of metabolic products, enzymes, and ions. Enclosed by the thylakoid membrane of the chloroplast is the thylakoid space. The extraordinary chemical capabilities of the two organelles lie in the cristae and the thylakoids. Both membranes are studded with enzymatic proteins either traversing the bilayer or dissolved in the lipid. These proteins contribute to the production of energy by transporting material across the membranes and by serving as electron carriers in the important oxidation–reduction reaction.

METABOLIC FUNCTIONS

The oxidation–reduction reaction

Crucial to the function of mitochondria and chloroplasts is the chemistry of the oxidation–reduction, or redox, reaction. This controlled burning of material comprises the transfer of electrons from one compound, called the donor, to another, called the acceptor. All compounds taking part in redox reactions are ranked in a descending scale according to their ability to act as electron donors. Those higher in the scale donate electrons to their fellows lower down, which have a lesser tendency to donate, but a correspondingly greater tendency to accept, electrons. Each acceptor in turn donates electrons to the next compound down the scale, forming a donor–acceptor chain extending from the greatest donating ability to the least.

At the top of the scale is hydrogen, the most abundant element in the universe. The nucleus of a hydrogen atom is composed of one positively charged proton; around the nucleus revolves one negatively charged electron. In the atmosphere, two hydrogen atoms join to form a hydrogen molecule (H_2). In solution, the two atoms pull apart, and in some chemical reactions the atoms are split into their constituent protons and electrons. In the redox reaction the electrons are passed from one reactant to another. The donation of electrons is called oxidation, and the acceptance is called reduction—hence the descriptive term oxidation–reduction, indicating that one action never takes place without the other.

A hydrogen atom has a great tendency to transfer an electron to an acceptor. An oxygen atom, in contrast, has a great tendency to accept an electron. The burning of hydrogen by oxygen is, chemically, the transfer of an electron from each of two hydrogen atoms to oxygen, so that hydrogen is oxidized and oxygen reduced. The reaction is extremely exergonic; *i.e.,* it liberates much free energy as heat. This is the reaction that takes place within mitochondria, but is so controlled that the heat is liberated not at once but in a series of steps. The free energy, harnessed by the organelle, is coupled to the synthesis of ATP from adenosine diphosphate (ADP) and inorganic phosphate (P_i).

An analogy can be drawn between this controlled reaction and the flow of river water down a lock system. Without the locks, water flow would be rapid and uncontrolled, and no ship could safely ply the river. The locks force water to flow in small, controlled steps conducive to safe navigation. But there is more to a lock system than this. The flow of water down the locks can also be harnessed to raise a ship from a lower to a higher level, with the water rather than the ship expending the energy. In mitochondria, the burning of hydrogen is broken into a series of small, indirect steps following the flow of electrons along a chain of donor-acceptors. Energy is funneled into the chemical bonding of ADP and P_i, raising the free energy of these two compounds to the high level of ATP.

The mitochondrion. *Formation of the electron donors NADH and FADH$_2$.* Through a series of metabolic reactions carried out in the matrix, the mitochondrion converts products of the cell's initial metabolism of fats, amino acids, and sugars into the compound acetyl coenzyme A. The acetate portion of this compound is then oxidized in a chain reaction called the tricarboxylic acid cycle. At the end of this cycle the carbon atoms yield carbon dioxide and the hydrogen atoms are transferred to the cell's

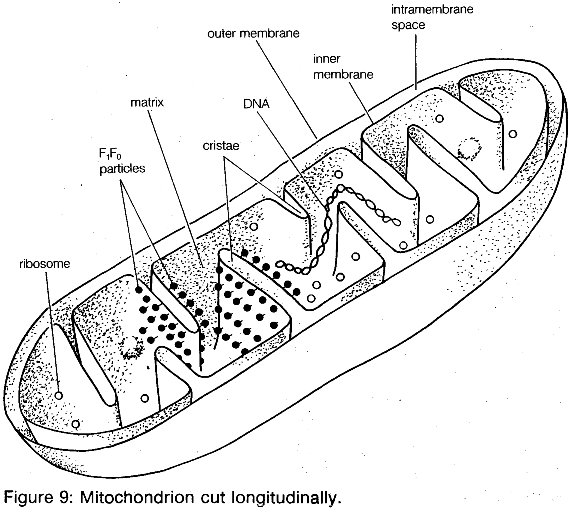

Figure 9: Mitochondrion cut longitudinally.

most important hydrogen acceptors, the coenzymes nicotinamide adenine dinucleotide (NAD$^+$) and flavin adenine dinucleotide (FAD), yielding NADH and FADH$_2$. It is the subsequent oxidation of these hydrogen acceptors that leads eventually to the production of ATP.

NADH and FADH$_2$ are compounds of high electron-donating capacity. Were they to transfer their electrons directly to oxygen, the resulting combustion would release a lethal burst of heat energy. Instead, the energy is released in a series of electron donor-acceptor reactions carried out, within the cristae of the mitochondrion, by a number of proteins and coenzymes that make up the electron-transport, or respiratory, chain.

Membrane proteins as electron carriers

The electron-transport chain. The proteins of this chain are embedded in the cristae membrane, actually traversing the lipid bilayer and protruding from the inner and outer surfaces. The coenzymes are dissolved in the lipid and diffuse through the membrane or across its surface. The proteins are arranged in three large complexes, each composed of a number of polypeptide chains. Each complex is, to continue the hydraulic analogy, a lock in the waterfall of the electron flow and the site at which energy from the overall redox reaction is tapped. The first complex, NADH dehydrogenase, accepts a pair of electrons from the primary electron donor NADH and is reduced in the process. It in turn donates these electrons to the coenzyme ubiquinone, a lipid-soluble molecule composed of a substituted benzene ring attached to a hydrocarbon tail. Ubiquinone, diffusing through the lipid of the cristae membrane, reaches the second large complex of the electron-transport chain, the b-c$_2$ complex, which accepts the electrons, oxidizing ubiquinone and being itself reduced. (This complex can also accept electrons from the second primary electron donor, FADH$_2$, a molecule below NADH in the electron-donating scale.) The b-c$_2$ complex transfers the pair of electrons to cytochrome c, a small protein situated on the outer surface of the cristae membrane. From cytochrome c, electrons pass (four at a time) to the third large complex, cytochrome oxidase, which, in the final step of the chain, transfers the four electrons to two oxygen atoms and two protons, generating two water molecules.

This transfer of electrons, from member to member of the electron-transport chain, provides energy for the synthesis of ATP through an indirect route. At the beginning of the electron-transport chain, NADH and FADH$_2$ split hydrogen atoms into protons and electrons, transferring the electrons to the next protein complex and releasing the protons into the mitochondrial matrix. When each protein complex in turn transfers the electrons down the chain, it uses the energy released in this process to pump protons across the inner membrane into the intermembrane space. (For the dynamics of this pumping action, see above *The plasma membrane: Transport across the membrane.*) This transport of positively charged protons into the intermembrane space, opposite the negatively charged electrons in the matrix, creates an electrical potential that tends to draw the protons back across the membrane. A high concentration of protons outside the membrane also creates the conditions for their diffusion back into the matrix. However, as is explained above, the inner membrane is extremely impermeable to protons. In order for the protons to flow back down the electrochemical gradient, they must traverse the membrane through transport molecules similar to the protein complexes of the electron-transfer chain. These molecules are the so-called F$_1$F$_0$ATPase, a complex protein that, transporting protons back into the matrix, uses the energy released to synthesize ATP. The protons then join the electrons and oxygen atoms to form water. (For further discussion of ATP production, see above *The nature and function of cells: The cell as a collection of self-replicating catalysts: Coupled chemical reactions.*)

This complex chain of events, the basis of the cell's ability to derive ATP from metabolic oxidation, was conceived in its entirety by the British biochemist Peter Mitchell in 1961. The years following the announcement of his chemiosmotic theory saw its ample substantiation and revealed its profound implications for cell biology.

The chemiosmotic theory. The chemiosmotic theory has four postulates:

(1) The inner mitochondrial membrane is impermeable to protons, hydroxide ions, and other cations and anions. This postulate was validated when it was shown that substances allowing protons to flow readily across mitochondrial membranes uncouple oxidative electron transport from ATP production.

(2) Transfer of electrons down the electron-transport chain brings about pumping of protons across the inner membrane, from matrix to intermembrane space. This was demonstrated in the laboratory by a reconstitution of components of the electron-transport chain in artificial membrane vesicles. The stimulation of electron transport caused a measurable buildup of protons within the vesicle.

ATP-synthesizing proteins

(3) The flow of protons down a built-up electrochemical gradient occurs through a proton-dependent ATPase, so that ATP is synthesized from ADP and P$_i$ whenever protons move through the enzyme. This hypothesis was confirmed by the discovery of what came to be known as the F$_1$F$_0$ATPase. Shaped like a knob attached to the membrane by a narrow stalk, F$_1$F$_0$ATPase covers the inner surface of the cristae. Its stalk (the F$_0$ portion) penetrates the lipid bilayer of the inner membrane and is capable of catalyzing the transport of protons. The knob (the F$_1$ portion) is capable of synthesizing as well as splitting, or hydrolyzing, ATP. F$_1$F$_0$ATPase is therefore reversible, either using the energy of proton diffusion to combine ADP and P$_i$ or using the energy of ATP hydrolysis to pump protons out of the matrix.

(4) The inner membrane of the mitochondrion possesses a complement of proteins that bring about the transport of essential metabolites. Numerous carrier systems have been demonstrated to transport into the mitochondrion the products of metabolism that are transformed into substrates for the electron-transport chain. Best known is the ATP–ADP exchange carrier of the inner membrane. Neither ATP nor ADP, being large, charged molecules, can cross the membrane unaided, but ADP must enter and ATP must leave the mitochondrial matrix in order for ATP synthesis to continue. A single protein conducts the counter-transport of ATP against ADP, the energy released by the flow of ATP down its concentration gradient being coupled to the pumping of ADP up its gradient and into the mitochondrion.

The chloroplast. *Trapping of light.* Light travels as packets of energy known as photons and is absorbed in this form by light-absorbing chlorophyll molecules embedded in the thylakoid membrane of the chloroplast. The chlorophyll molecules are grouped into clusters of several hundred, called antenna complexes, by specific proteins that hold them onto the thylakoid membrane and confer

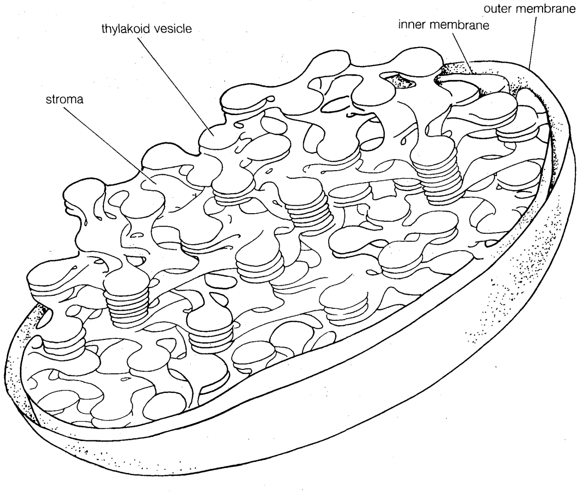

Figure 10: *The structure of a chloroplast.*
The internal (thylakoid) membrane vesicles are organized into stacks, which reside in a matrix called the stroma. All the chlorophyll in the chloroplast is contained in the membranes of the thylakoid vesicles.

upon one of them the special property of being a reaction centre. Into this centre are funneled photons absorbed by the other chlorophylls of the antenna. The energy of the photon is absorbed by an electron of the reaction centre molecule in sufficient quantity to enable its acceptance by a nearby coenzyme, which cannot accept electrons at low energy levels. This coenzyme has a high electron-donor capability; it initiates the transfer of the electron down an electron-transport chain similar to that of the mitochondrion. Meanwhile, the loss of the negatively charged electron leaves a positively charged "hole" in the reaction centre chlorophyll molecule. This hole is filled by the enzymatic splitting of water into molecular oxygen, protons, and electrons and the transfer of an electron to the chlorophyll. The oxygen is released by the chloroplast, making its way out of the plant and into the atmosphere. The protons, in a process similar to that in the mitochondrion, are pumped through the thylakoid membrane and into the thylakoid space. Their facilitated diffusion back into the stroma through proteins embedded in the membrane powers the synthesis of ATP.

Energizing of electrons

This part of the photosynthetic process is called photosystem II. At the end of the electron-transport chain of this system is another reaction centre molecule. The electron is again energized by photons and then transported down another chain, which makes up photosystem I. This system uses the energy released in electron transfer to join a proton to nicotinamide adenine dinucleotide phosphate ($NADP^+$), a phosphorylated derivative of NAD^+, forming NADPH. NADPH is a high-energy electron donor that, with ATP, fuels the conversion of carbon dioxide into the carbohydrate foods of the plant cell.

Fixation of carbon dioxide. NADPH remains within the stroma of the chloroplast for use in the fixation of carbon dioxide (CO_2). In a complex cycle of chemical reactions, CO_2 is bound to a five-carbon ribulose biphosphate compound. The six-carbon intermediate so formed is then split into three-carbon phosphoglycerate. With energy supplied by the breakdown of NADPH and ATP, this compound is eventually formed into glyceraldehyde 3-phosphate, an important sugar intermediate of metabolism. One glyceraldehyde molecule is exported from the chloroplast, for further conversion in the cytoplasm, for every five that undergo an ATP-powered re-formation into the five-carbon ribulose biphosphate. In this way three molecules of CO_2 yield one molecule of glyceraldehyde 3-phosphate, while the entire fixation cycle hydrolyzes nine molecules of ATP and oxidizes six molecules of NADPH.

EVOLUTIONARY ORIGINS

The mitochondrion and chloroplast as independent entities. In addition to their remarkable metabolic capabilities, both mitochondria and chloroplasts synthesize on their own a number of proteins and lipids necessary for their structure and activity. Not only do they contain the machinery necessary for this, but they also possess the genetic material to direct it. DNA within these organelles has a circular structure reminiscent of bacterial, not eukaryotic, DNA. Also as in bacteria, the DNA is not associated with histones. Along with the DNA are protein-synthesizing ribosomes, of bacterial rather than eukaryotic size, that are sensitive to bacteria-inhibiting antibiotics.

Similarities to bacteria

Only a small portion of the mitochondrion's total number of proteins is synthesized within the organelle. At least 90 proteins are encoded and made in the human cytoplasm specifically for export to the mitochondrion, while the mitochondrial DNA encode only 13 different proteins. The proteins that do contain components synthesized within the mitochondrion often possess, in addition, components synthesized in the cytoplasm. Mitochondrial and chloroplastic proteins synthesized in the cytoplasm have to enter the organelle by a complex process, crossing one or more membranes. Why this is possible for most, but not all, proteins is not known.

The endosymbiont hypothesis. Mitochondria and chloroplasts are self-dividing; they contain their own DNA and protein-synthesizing machinery, all of the bacterial type. Chloroplasts produce ATP and trap photons by mechanisms that are complex and yet similar to those of certain bacteria. These phenomena have led to the hypothesis that the two organelles are direct descendants of bacteria that entered primitive nucleated cells in a number of infections. Among billions of such infective events, a few could have led to the development of stable, symbiotic associations between nucleated hosts and bacterial parasites. The hosts would provide the parasites with a stable osmotic environment and easy access to nutrients, and the bacteria would repay by providing an effective oxidative ATP-producing system or a photosynthetic energy-producing reaction. The further development of genetic techniques may make it possible to identify the classes of bacteria that took part in these putative events. (W.D.S.)

The cytoskeleton

The cytoskeleton is the name given to a fibrous network formed by different types of long protein filaments present throughout the cytoplasm of eukaryotic cells (cells containing a nucleus). As the term cytoskeleton implies, these filaments create a scaffold or framework that organizes other cell constituents and maintains the shape of the cell. In addition, some filaments cause coherent movements, both of the cell itself and of its internal organelles. Prokaryotic (non-nucleated) cells, which are much smaller than eukaryotic cells, seem not to require an internal skeleton of this type.

Three major types of cytoskeletal filaments are commonly recognized: actin filaments, microtubules, and intermediate filaments. Actin filaments and microtubules are dynamic structures that continuously assemble and disassemble in most cells. Intermediate filaments are stabler and seem to be involved mainly in reinforcing cell structures. A wide variety of accessory proteins work in concert with each type of filament, linking filaments to one another and to the plasma membrane and helping to form the networks that endow the cytoskeleton with its unique functions. Many of these accessory proteins have not yet been characterized, limiting understanding of the cytoskeleton.

ACTIN FILAMENTS

Actin is a small globular protein molecule that polymerizes to form long filaments. Because each actin subunit faces in the same direction, the actin filament is polar, with different "plus" and "minus" ends. An abundant protein in all eukaryotic cells, actin is most easily studied in muscle cells, where it assembles into unusually stable filaments. In muscle the actin filaments are organized into regular arrays, and they interdigitate with a set of thicker filaments formed from a second protein called myosin. These two proteins create the force responsible for muscle contraction. When the signal to contract is sent along a nerve to the muscle, the myosin molecules are activated to hydrolyze adenosine triphosphate (ATP), releasing energy in such a way that a myosin filament moves along an actin filament, causing the two filaments to slide past each other. Large muscles are composed of bundles of many long muscle cells; when the actin–myosin assemblies slide, each of these giant muscle cells shortens, and the overall effect is the contraction of the entire muscle.

Muscle contraction

Actin is also present in non-muscle cells, where it forms less highly ordered arrays of filaments responsible for certain types of cellular movement. Actin is intimately involved in linking the plasma membrane to the underlying cytoplasm. In some cells, these filaments are stabilized by the binding of accessory proteins so as to form microvilli, stable protrusions of the plasma membrane that resemble tiny bristles. Microvilli on the surface of epithelial cells function to increase the cell's surface area, facilitating the absorption of vital molecules through the membrane. Other types of microvilli are involved in the detection of sound in the ear, where their movement, caused by sound waves, sends an electrical signal to the brain.

Many actin filaments in non-muscle cells have only a transient existence, polymerizing and depolymerizing in controlled ways that create movement. For example, many cells continually send out and retract tiny "microspikes," long, needlelike projections of the plasma membrane that are thought to enable cells to "taste" their environment. Like microvilli, microspikes are formed when actin filaments push out the membrane, but because these actin filaments are less organized and less stable, microspikes have only a brief existence. Another actin structure only transiently associated with the plasma membrane is the contractile ring, which is composed of actin filaments running around the circumference of the cell during cell division. As its name implies, this ring pulls in the plasma membrane by a myosin-dependent process, thereby pinching the cell in half. How actin is specifically organized into these different transient arrays is unknown, but actin-binding proteins on the plasma membrane probably play a central role.

MICROTUBULES

Movement of cilia and flagella

Microtubules are long filaments formed from 13 strands of a globular subunit called tubulin, with the strands arranged in the form of a hollow cylinder. Like actin filaments, microtubules are polar, having "plus" and "minus" ends. Most microtubules are constantly assembling and disassembling, but stable microtubules are found in cilia and flagella. Cilia are hairlike motile structures found on the surface of certain types of epithelial cells, where they act as little propellers to move fluid and particles over the cell surface. They are closely related in structure to flagella such as the sperm tail, the whiplike motion of which enables a sperm cell to propel itself rapidly through fluids. In all of these motile structures, a bundle of microtubules is connected in a regular array by various accessory proteins that act as links and spokes in the assembly. Movement of the cilia or flagella occurs when adjacent microtubules slide past one another, bending the structures. This motion is caused by the protein dynein, which uses the energy of ATP hydrolysis to move along the microtubules, in a manner resembling the movement of myosin along actin filaments.

In most cells, microtubules grow outward, from the cell centre to the plasma membrane, from a special region of the cytoplasm near the nuclear envelope called the centrosome. Experiments show that the "minus" ends of these microtubules are embedded in the centrosome and that the "plus" ends terminate near the plasma membrane. Just before cell division, the centrosome divides in two. The two halves move to opposite sides of the nuclear envelope, each carrying a starlike array of microtubules, and become the two poles of the mitotic spindle, which has a central role in partitioning the chromosomes and other cell components into two daughter cells during mitosis (see below *Cell division and growth*).

INTERMEDIATE FILAMENTS

Intermediate filaments have a larger diameter than actin filaments and a smaller diameter than microtubules. Unlike the other two types of filament, intermediate filaments are formed from elongated, ropelike subunits of a variety of different types. Their best-understood roles are as keratin filaments, strengthening cell sheets such as the skin, and as the nuclear lamina, a fibrous shell that underlies and supports the nuclear membrane.

STRUCTURAL RELATION OF THE FILAMENTS

Microtubules and actin filaments are thought to form the basic foundation of the cytoskeleton. The microtubules are believed to be the overall organizers of the cytoskeleton, affecting the position and function of both actin filaments and intermediate filaments. In addition, the movements of certain organelles depend on microtubules; specific proteins that bind to microtubules and hydrolyze ATP seem to be responsible for moving these organelles.

Difficulty of studying the cytoskeleton

An important unresolved issue in cell biology concerns the extent to which the many different soluble proteins in the cytoplasm are spatially organized into different regions. Such organization is presumably mediated in large part by the binding of metabolic enzymes and other proteins to a network of proteins linked in turn to different parts of the cytoskeleton. The dynamic nature of the cytoskeleton makes the nature of this organization difficult to clarify. (B.M.A.)

The cell matrix and cell-to-cell communication

The development of single cells into multicellular organisms involves a number of adaptations. The cells become specialized, acquiring distinct functions that contribute to the survival of the organism. The behaviour of individual cells is also integrated with that of similar cells, so that they act together in a regulated fashion. To achieve this integration, cells assemble into specialized tissues, each tissue being composed of cells and the spaces outside of the cells.

The surface of cells is important in coordinating their activities within tissues. Embedded in the plasma membrane of each cell are a number of proteins that interact with the surface or secretions of other cells. These proteins enable cells to "recognize" and adhere to the extracellular matrix and one another and to form populations distinct from surrounding cells. These interactions are keys to the organizational behaviour of cell populations. Each contributes to the formation of embryonic tissues, and each is necessary for normal tissue function in the adult organism.

THE EXTRACELLULAR MATRIX

A substantial part of tissues is the space outside of the cells, called the extracellular space. This is filled with a composite material, known as the extracellular matrix, composed of a gel in which are suspended a number of fibrous proteins. The gel consists of large polysaccharide (complex sugar) molecules in a water solution of inorganic salts, nutrients, and waste products known as the interstitial fluid. The major types of protein in the matrix are structural proteins and adhesive proteins.

Effects of matrix components on tissue properties

There are two general types of tissue distinct not only in their cellular organization but also in the composition of their extracellular matrix. The first type, mesenchymal tissue, is made up of clusters of cells grouped together but not closely adherent to one another. They synthesize a highly hydrated gel, rich in salts, fluid, and fibres, known as the interstitial matrix. Connective tissue is a mesenchyme that fastens together other more highly organized tissues. The solidity of various connective tissues varies according to the consistency of their extracellular matrix, which in turn depends on the water content of the gels, the amount and type of polysaccharides and structural proteins, and the presence of other salts. For example, bone is rich in calcium phosphate, giving this tissue its rigidity; tendons are mostly fibrous structural proteins, yielding a ropelike consistency; and joint spaces are filled with a lubricating fluid of mostly polysaccharide and interstitial fluid.

Epithelial tissues, the second type, are sheets of cells adhering at their side, or lateral, surfaces. They synthesize and deposit at their bottom, or basal, surfaces an organized complex of matrix materials known as the basal lamina or basement membrane. This thin layer serves as a boundary with connective tissue and as a substrate to which epithelial cells are attached (see Figure 11).

Matrix polysaccharides. The polysaccharides, or glycans, of the extracellular matrix are responsible for its gellike quality and for organizing its components. These large, acidic molecules exist alone (as glycosaminoglycans) or in combination with small proteins (as proteoglycans). They bind an extraordinarily large amount of water, thus forming massively swollen gels that fill the spaces between cells. Bound to proteins, they also organize other molecules in the extracellular matrix. The firmness and resiliency of cartilage, as at the surface of joints, is due to highly organized proteoglycans that bind water tightly.

Matrix proteins. Matrix proteins are large molecules tightly bound to form extensive networks of insoluble fibres. These fibres may even exceed the size of the cells themselves. The proteins are of two general types, structural and adhesive.

Properties of collagen and elastin

The structural proteins, collagen and elastin, are the dominant matrix proteins. At least 10 different types of collagen are present in various tissues. The most common, type I collagen, is the most abundant protein in vertebrate animals, accounting for nearly 25 percent of the total protein in the body. The various collagen types share structural features, all being composed of three in-

tertwined polypeptide chains. In some collagens the chains are linked together by covalent bonds, yielding a ropelike structure of great tensile strength. Indeed, the toughness of leather, chemically treated animal skin, is due to its content of collagen. Elastin is also a cross-linked protein, but instead of forming rigid coils, it imparts elasticity to tissues. Only one type of elastin is known; it varies in elasticity according to variations in its cross-linking.

The adhesive proteins of the extracellular matrix bind matrix molecules to one another and to cell surfaces. These proteins are modular, in that they contain several functional domains packaged together in a single molecule. Each domain binds to a specific matrix component or to a specific site on a cell. The major adhesive protein of the interstitial matrix is called fibronectin; that of the basal lamina is known as laminin.

Cell–matrix interactions. Molecules intimately associated with the plasma membrane link cells to the extracellular matrix. These molecules, called matrix receptors, bind selectively to specific matrix components and interact, directly or indirectly, with actin protein fibres that form the cytoskeleton inside the cell. This association of actin fibres with matrix components via receptors on the cell membrane can influence the organization of membrane molecules as well as matrix components and can modify the shape and function of the cytoskeleton. Changes in the cytoskeleton can lead to changes in cell shape, movement, metabolism, and development.

INTERCELLULAR RECOGNITION AND CELL ADHESION

The simplest examples of the ability of cells to recognize and adhere to one another come from studies of organisms that live much of their lives as single cells but form a multicellular aggregate for a specific purpose. For example, when starved, several types of single-cell organisms band together to develop the specialized cells needed for reproduction. In this process, certain cells at the centre of the developing aggregate secrete chemicals that cause the other cells to adhere tightly into a group. In the case of slime mold amoebas, starvation causes the secretion of a compound, cyclic adenosine monophosphate (cyclic AMP or CAMP), that induces the cells to stick together end-to-end. With further aggregation, the cells produce another cell-surface glycoprotein with which they stick to one another over their entire surfaces. The cellular aggregates then produce an extracellular matrix, which holds the cells together in a specific structural form.

Tissue and species recognition. Some multicellular animals or tissues can be dissociated into suspensions of single cells that show the same cellular recognition and adhesion as do aggregates of single-cell organisms. The marine sponge, for example, can be sieved through a mesh, yielding single cells and cells in clumps. When this cell suspension is rotated in culture, the cells reaggregate and in time reform a normal sponge. This reassociation shows selective cell recognition; that is, only cells of the same species reassociate. The ability of the cells to distinguish cells of their own species from those of others is mediated by proteoglycan molecules in the extracellular matrix. The proteoglycan binds to specific cell-surface receptor sites that are unique to a single species of sponge.

Spontaneous reassociation of dissolved tissue

Cells from tissues of vertebrate animals can, like sponge cells, be dissociated and allowed to reaggregate. These cells, however, show tissue specificity rather than species specificity. For example, when vertebrate embryonic cells from two different tissues are dissociated and then rotated together in culture, the cells form a multicellular aggregate within which they sort according to the type of tissue. This sorting occurs regardless of whether the cells are from the same or different species, indicating that tissue specificity is more important in adhesive recognition than species specificity. The specificity is due to a set of cell-surface glycoproteins called cell adhesion molecules (CAM). A portion of the CAM that extends from the surface of a cell adheres to identical molecules on the surface of adjacent cells. These CAM appear early in embryonic life, and their amounts in tissues change as the organs develop. The CAM, however, are not responsible for the stable adhesion of one cell to another; this more permanent adhesion is carried out by cell junctions.

Cell junctions. There are three functional categories of cell junction: adhering junctions, often called desmosomes; tight, or occluding, junctions; and gap, or permeable, junctions. Adhering junctions hold cells together mechanically and are associated with intracellular fibres of the cytoskeleton. Tight junctions also hold cells together, but they form a nearly leak-proof intercellular seal by fusion of adjacent plasma membranes. Both adhering junctions and tight junctions are present primarily in epithelial cells. On the other hand, all cell types possess gap junctions, which allow small molecules to pass from one cell to the next through a channel.

Adhering junctions. Cells subject to abrasion or other mechanical stress, such as those of the surface epithelia of the skin, have junctions that adhere cells to one another and to the extracellular matrix. These adhering junctions are called desmosomes when occurring between cells and hemidesmosomes (half-desmosomes) when linked to the matrix. Adhering junctions distribute mechanical shear force throughout the tissue and to the underlying matrix by virtue of their association with intermediate filaments crossing the interior of the cell. The linkage of these filaments, also called keratin filaments, to the desmosomes and, through these junctions, to adjacent cells provides a nearly continuous fibrous network throughout an epithelial sheet. Adhering junctions are also seen in other types of cells—for example, in the muscles of the heart and uterus—allowing these cells to remain anchored together despite the contractions of the muscles.

Tight junctions. Sheets of cells separate fluids within the organ from fluids outside, as in the epithelial layer lining the intestine. This separation requires leak-proof junctions between cells. Tight junctions form leak-proof seals by fusing the plasma membranes of adjacent cells, creating a continuous barrier through which molecules cannot pass. The membranes are fused by the melding of their lipid layers, which repel large, water-soluble molecules. In invertebrates, this function is provided by septate junctions, in which the proteins of the membrane rather than the lipids form the seal.

Gap junctions. These junctions allow communication between adjacent cells via the passage of small molecules directly from the cytoplasm of one cell to that of another. Molecules that can pass between cells coupled by gap junctions include inorganic salts, sugars, amino acids, nucleotides, and vitamins but not large molecules such as proteins or nucleic acids.

Passage of electrical current

Gap junctions are crucial to the integration of certain cellular activities. For example, muscle cells generate electrical current by the movement of inorganic salts. If the cells are coupled, they will share this electrical current, allowing the synchronous contraction of all the cells in the tissue. This coupling function requires the regulation of molecular traffic through the gaps. The junctions are not open pores but dynamic channels, which change their permeability with changes in cellular activity. They consist of proteins completely crossing the plasma membrane as six-sided columns with central pores. Under certain conditions the proteins change shape, causing the pores to become smaller or larger and thus changing the permeability of the junction.

Gap junctions are also found in tissues that are not electrically active. In these tissues, the junctions allow nutrients and waste products to travel throughout the tissue. Cells in such tissues are said to be metabolically coupled. During the formation of embryos, gap junctions are crucial to establishing differences between separate groups of cells, the coupled cells undergoing development together to become a specialized tissue.

CELL-TO-CELL COMMUNICATION VIA CHEMICAL SIGNALING

In addition to cell–matrix and cell–cell interactions, cell behaviour in multicellular organisms is coordinated by the passage of chemical or electrical signals between cells. The most common form of chemical signaling is via molecules secreted from the cells and moving through the extracellular space. Signaling molecules may also remain on cell surfaces, influencing other cells only after the cells make physical contact. Finally, as noted above, gap junctions allow small molecules to move between the cytoplasms of adjacent cells.

Types of chemical signaling. Chemical signals secreted by cells can act over varying distances. In the autocrine signaling process, molecules act on the same cells that produce them. In paracrine signaling, they act on nearby cells. Autocrine signals include extracellular matrix molecules and various factors that stimulate cell growth. An example of paracrine signals is the chemical transmitted from nerve to muscle that causes the muscle to contract. In this instance, the muscle cells have regions specialized to receive chemical signals from an adjacent nerve cell. In both autocrine and paracrine signaling, the chemical signal works in the immediate vicinity of the cell that produces it and is present at high concentrations. A chemical signal picked up by the bloodstream and taken to distant sites is called an endocrine signal. Most hormones produced in vertebrates are endocrine signals, such as the hormones produced in the pituitary gland at the base of the brain and carried by the bloodstream to act at low concentrations on the thyroid or adrenal glands.

Endocrine signaling system

The concentration at which a chemical signal acts has significance for its target cell. Chemical signals that act at high concentration act locally and rapidly. On the other hand, chemical signals that act at low concentrations act at distances and are generally slow.

Signal receptors. The ability of a cell to respond to an extracellular signal depends on the presence of specific proteins, called receptors, on its surface or in the cytoplasm. The receptors bind the chemical signals tightly, ultimately triggering a mechanism that modifies the behaviour of the target cell. Cells may contain an array of specific receptors allowing them to respond to a variety of chemical signals.

Signal molecules are either soluble or insoluble, this feature determining how they interact with the cell. Water-soluble molecules such as the polypeptide hormone insulin bind to receptors at cell surfaces. On the other hand, lipid-soluble molecules, such as the steroid hormones produced by the ovary or testis, pass through the lipid bilayer of the plasma membrane to reach receptors within the cell. Extracellular matrix molecules are chemical signals, but, because of their size and insolubility, they act only on cell surface receptors and are neither taken up by the cells nor rapidly destroyed.

Cellular response. The binding of chemical signals to their corresponding receptors induces events within the cell that ultimately change its behaviour. The nature of these intracellular events differs according to the type of receptor. Also, the same chemical signal causes different responses in different types of cell.

Cell surface receptors work in several ways when they are occupied. Some enter the cell still bound to the chemical signal. Others activate membrane enzymes, which produce certain intracellular chemical mediators. Still other receptors open membrane channels, allowing a flow of ions that causes either a change in the electrical properties of the membrane or a change in the ion concentration in the cytoplasm. This regulation of enzymes or membrane channels produces changes in the concentration of intracellular signaling molecules, which are often called second messengers (the first messenger being the extracellular chemical signal bound to the receptor).

Two common chemical signals

Two common intracellular signaling molecules are cyclic AMP and the calcium ion. Cyclic AMP is a derivative of adenosine triphosphate, the ubiquitous energy-carrying molecule of the cell. The intracellular concentrations of both cyclic AMP and calcium ions are normally very low. The binding of an extracellular chemical signal to a cell surface receptor may stimulate an enzyme complex in the membrane to produce cyclic AMP. This second messenger then diffuses into the cytoplasm and acts on intracellular enzymes that modify the behaviour of the cell—for example, by causing it to increase protein synthesis. The action of cyclic AMP is brief because it is rapidly degraded by specific enzymes.

Occupancy of other surface receptors causes a transient opening of membrane channels. This can allow calcium ions to enter the cytoplasm from the extracellular space, where its concentration is higher. The action of calcium ions is also brief because they are rapidly pumped out of the cell or bound to intracellular molecules, lowering the cytoplasmic concentration to the state existing before stimulation.

Some extracellular chemical signals enter the cell intact, still bound to the receptor, without generating a second messenger. In this mechanism, receptor occupancy causes individual receptors within the plasma membrane to aggregate spontaneously. That portion of the membrane containing the aggregated receptors is then taken into the cell, where it fuses with various membrane-bounded organelles in the cytoplasm. In some instances the chemical signal is released within the organelles, and in almost all instances the ingested membrane is rapidly returned to the plasma membrane along with the surface receptors.

(M.R.B.)

THE PLANT CELL WALL

The plant cell wall is a specialized form of extracellular matrix that surrounds every cell of a plant and is responsible for many of the characteristics distinguishing plant from animal cells. Although often perceived as an inactive product serving mainly mechanical and structural purposes, the cell wall actually has a multitude of functions upon which plant life depends. Such functions include: (1) providing the protoplast, or living cell, with mechanical protection and a chemically buffered environment; (2) providing a porous medium for the circulation and distribution of water, minerals, and other small nutrient molecules; (3) providing rigid building blocks from which stable structures of higher order, such as leaves and stems, can be produced; and (4) providing a storage site of regulatory molecules that sense the presence of pathogenic microbes and control the development of tissues.

Mechanical properties of wall layers. All cell walls contain two layers, the middle lamella and the primary cell wall, and many cells produce an additional layer, called the secondary wall. The middle lamella serves as a cementing layer between the primary walls of adjacent cells. The primary wall is the cellulose-containing layer laid down by cells that are dividing and growing. To allow for cell wall expansion during growth, primary walls are thinner and less rigid than those of cells that have stopped growing. A fully grown plant cell may retain its primary

From primary to secondary wall

cell wall (sometimes thickening it), or it may deposit an additional, rigidifying layer of different composition; this is the secondary wall. Secondary cell walls are responsible for most of the plant's mechanical support as well as the mechanical properties prized in wood. In contrast to the permanent stiffness and load-bearing capacity of thick secondary walls, the thin primary walls are capable of serving a structural, supportive role only when the vacuoles within the cell are filled with water to the point that they exert a turgor pressure against the cell wall. Turgor-induced stiffening of primary walls is analogous to the stiffening of the sides of a pneumatic tire by air pressure. The wilting of flowers and leaves is caused by a loss of turgor pressure, which results in turn from the loss of water from the plant cells.

Components of the cell wall. Although primary and secondary wall layers differ in detailed chemical composition and structural organization, their basic architecture is the same, consisting of cellulose fibres of great tensile strength embedded in a water-saturated matrix of polysaccharides and structural glycoproteins.

Cellulose. Cellulose consists of several thousand glucose molecules linked end to end. The chemical links between the individual glucose subunits give each cellulose molecule a flat, ribbonlike structure that allows adjacent molecules to band laterally together into microfibrils with lengths ranging from two to seven micrometres. Cellulose fibrils are synthesized by enzymes floating in the plasma membrane of the cell and arranged in a rosette configuration. Each rosette appears capable of "spinning" a microfibril into the cell wall. During this process, as new glucose subunits are added to the growing end of the fibril, the rosette is pushed around the cell on the surface of the plasma membrane and its cellulose fibril becomes wrapped around the protoplast. Thus, each plant cell can be viewed as making its own cellulose fibril cocoon.

Matrix polysaccharides. The two major classes of cell wall matrix polysaccharides are the hemicelluloses and the pectic polysaccharides, or pectins. Both are synthesized in the Golgi apparatus, brought to the cell surface in small vesicles, and secreted into the cell wall.

Hemicelluloses consist of glucose molecules arranged end to end as in cellulose, with short side chains of xylose and other uncharged sugars attached to one side of the ribbon. The other side of the ribbon binds tightly to the surface of cellulose fibrils, thereby coating the microfibrils with hemicellulose and preventing them from adhering together in an uncontrolled manner. Hemicellulose molecules have been shown to regulate the rate at which primary cell walls expand during growth.

Action of pectins

The heterogenous, branched, and highly hydrated pectic polysaccharides differ from hemicelluloses in important respects. Most notably, they are negatively charged owing to galacturonic acid residues, which, together with rhamnose sugar molecules, form the linear backbone of all pectic polysaccharides. The backbone contains stretches of pure galacturonic acid residues interrupted by segments in which galacturonic acid and rhamnose residues alternate; attached to these latter segments are complex, branched sugar side chains. Because of their negative charge, pectic polysaccharides bind tightly to positively charged ions, or cations. In cell walls, calcium ions cross-link the stretches of pure galacturonic acid residues tightly, while leaving the rhamnose-containing segments in a more open, porous configuration. This cross-linking creates the semirigid gel properties characteristic of the cell wall matrix—a process exploited in the preparation of jellied preserves.

Proteins. Although plant cell walls contain only small amounts of protein, they serve a number of important functions. The most prominent group are the hydroxyproline-rich glycoproteins, shaped like rods with connector sites, of which extensin is a prominent example. Extensin contains 45 percent hydroxyproline and 14 percent serine residues distributed along its length. Every hydroxyproline residue carries a short side chain of arabinose sugars, and most serine residues carry a galactose sugar; this gives rise to long molecules, resembling bottle brushes, that are secreted into the cell wall toward the end of primary-wall formation and become covalently cross-linked into a mesh at the time that cell growth stops. Plant cells apparently control their ultimate size by regulating the time at which this cross-linking of extensin molecules occurs.

In addition to the structural proteins, cell walls contain a variety of enzymes. Most notable are those that cross-link extensin, lignin, cutin, and suberin molecules into networks. Other enzymes help protect plants against fungal pathogens by breaking fragments off of the cell walls of the fungi. The fragments in turn induce defense responses in underlying cells. The softening and dropping of ripe fruit and of leaves in the autumn are brought about by cell wall-degrading enzymes.

Plastics. Cell wall plastics such as lignin, cutin, and suberin all contain a variety of organic compounds cross-linked into tight, three-dimensional networks that strengthen cell walls and make them more resistant to fungal and bacterial attack. Lignin is the general name for a diverse group of polymers of aromatic alcohols. Deposited mostly in secondary cell walls and providing the rigidity of terrestrial vascular plants, it accounts for up to 30 percent of a plant's dry weight. The diversity of cross-links between the polymers—and the resulting tightness—makes lignin a formidable barrier to the penetration of most microbes.

Cutin and suberin are complex biopolyesters composed of fatty acids and aromatic compounds. Cutin is the major component of the cuticle, the waxy, water-repelling surface layer of cell walls exposed to the environment above ground. By reducing the wetability of leaves and stems—and thereby affecting the ability of fungal spores to germinate—it plays an important part in the defense strategy of plants. Suberin serves with waxes as a surface barrier of underground parts. Its synthesis is also stimulated in cells close to wounds, thereby sealing off the wound surfaces and protecting underlying cells from dehydration.

Intercellular communication. *Plasmodesmata.* Similar to the gap junction of animal cells is the plasmodesma, a channel passing through the cell wall and allowing direct molecular communication between adjacent plant cells. Plasmodesmata are lined with plasma membrane, in effect uniting all connected cells with one continuous cell membrane. Running down the middle of each channel is a thin, membranous tube that connects the endoplasmic reticula (ER) of the two cells. This structure is a remnant of the ER of the original parent cell, which, as the parent cell divided, was caught in the developing cell plate.

Although the precise mechanisms are not fully understood, the plasmodesma is thought to regulate the passage of small molecules such as salts, sugars, and amino acids by constricting or dilating the openings at each end of the channel.

Stimulation of defense responses and cell growth

Oligosaccharides with regulatory functions. The discovery of cell wall fragments with regulatory functions opened a new era in plant research. For years scientists had been puzzled by the chemical complexity of cell wall polysaccharides, which far exceeds the structural requirements of plant cell walls. The answer came when it was found that specific fragments of cell wall polysaccharides, called oligosaccharins, are able to induce specific responses in plant cells and tissues. One such fragment, released by enzymes used by fungi to break down plant cell walls, consists of a linear polymer of 10 to 12 galacturonic acid residues. Exposure of plant cells to such fragments induces them to produce antibiotics known as phytoalexins. In other experiments it has been shown that exposing strips of tobacco stem cells to a different type of cell wall fragment leads to the growth of roots; other fragments lead to the formation of stems, and yet others to the production of flowers. In all instances the concentration of oligosaccharins required to bring about the observed responses is equal to that of hormones in animal cells; indeed, oligosaccharins may be viewed as the oligosaccharide hormones of plants. (L.A.St.)

Cell division and growth

In unicellular organisms, cell division is the means of reproduction; in multicellular organisms, it is the means of tissue growth and maintenance. Survival of the higher organisms depends upon interactions between many cell types, and it is essential that a balanced distribution of types be maintained. This is achieved by the highly regulated process of cell proliferation. The growth and division of different cell populations are regulated in different ways, but the basic mechanisms are similar throughout multicellular organisms.

Division of stem cells and mature cells

Most tissues of the body grow by increasing their cell number, but this growth is highly regulated to maintain a balance between different tissues. In adults most cell division is involved in tissue renewal rather than growth, many types of cells undergoing continuous replacement. Skin cells, for example, are constantly being sloughed off and replaced; in this case the mature differentiated cells do not divide, but their population is renewed by division of immature stem cells. In certain other tissues, such as those of the liver, mature cells remain capable of division to allow growth or regeneration after injury.

In contrast to these patterns, other classes of cell do not divide and are not renewable in the adult organism. These include heart muscle, nerve, and lens cells in mammals. Maintenance and repair of these cells is limited to replacing intracellular components rather than replacing entire cells.

DUPLICATION OF THE GENETIC MATERIAL

Before a cell can divide, it must accurately and completely duplicate the genetic information encoded in its DNA in order for its progeny cells to function and survive. This is a complex problem because of the great length of DNA molecules. Each human chromosome consists of a long double spiral, or helix, each strand of which consists of more than 100,000,000 nucleotides (see above *The nucleus*).

The duplication of DNA is called DNA replication, and it is initiated by complex enzymes called DNA polymerases. These progress along the molecule, reading the sequences of nucleotides that are linked together to make DNA chains. Each strand of the DNA double helix, therefore, acts as a template specifying the nucleotide structure of a new growing chain. After replication, each of the two daughter DNA double helices consists of one parental DNA strand wound around one newly synthesized DNA strand.

In order for DNA to replicate, the two strands must be unwound from each other. Enzymes called helicases unwind the two DNA strands, and additional proteins bind to the separated strands to stabilize them and prevent them from pairing again. In addition, a remarkable class of enzyme called DNA topoisomerase removes the helical twists by cutting either one or both strands and then resealing the cut. These enzymes can also untangle and unknot DNA when it is tightly coiled into a chromatin fibre.

Varying rates of replication

In the circular DNA of bacteria, replication starts at a unique site called the origin of replication, then proceeds in both directions around the molecule until the two processes meet, producing two daughter molecules. In rapidly growing bacteria, a second round of replication can start before the first has finished. The situation in higher organisms is more complicated, as replication moves more slowly than in bacteria. At 500 to 5,000 nucleotides per minute (versus 100,000 nucleotides per minute in bacteria), it would take a human chromosome about a month to replicate if started at a single site. Actually, replication begins at many sites on the long chromosomes of animals, plants, and fungi. Distances between adjacent initiation sites are not always the same; for example, they are closer in the rapidly dividing embryonic cells of frogs or flies than in adult cells of the same species. Less is known about the initiation sites of higher organisms than those of bacteria.

Accurate DNA replication is crucial to ensure that daughter cells have exact copies of the genetic information for synthesizing proteins. Accuracy is achieved by a "proofreading" ability of the DNA polymerase itself. It can erase its own errors and then synthesize anew. There are also repair systems that correct genetic damage to DNA. For example, the incorporation of an incorrect nucleotide, or damage caused by mutagenic agents, can be corrected by cutting out a section of the daughter strand and recopying the parental strand.

CELL DIVISION

Mitosis and cytokinesis. In higher organisms the processes of DNA replication and cell division occur at different times of the cell division cycle. During cell division, DNA condenses to form short, tightly coiled, rodlike chromosomes. Each chromosome then splits longitudinally, forming two identical chromatids. Each pair of chromatids is divided between the two daughter cells during mitosis, or division of the nucleus, a process in which the chromosomes are propelled by attachment to a bundle of microtubules called the mitotic spindle.

From B. Alberts *et al.*, *Molecular Biology of The Cell* (1983); Garland Publishing, Inc.

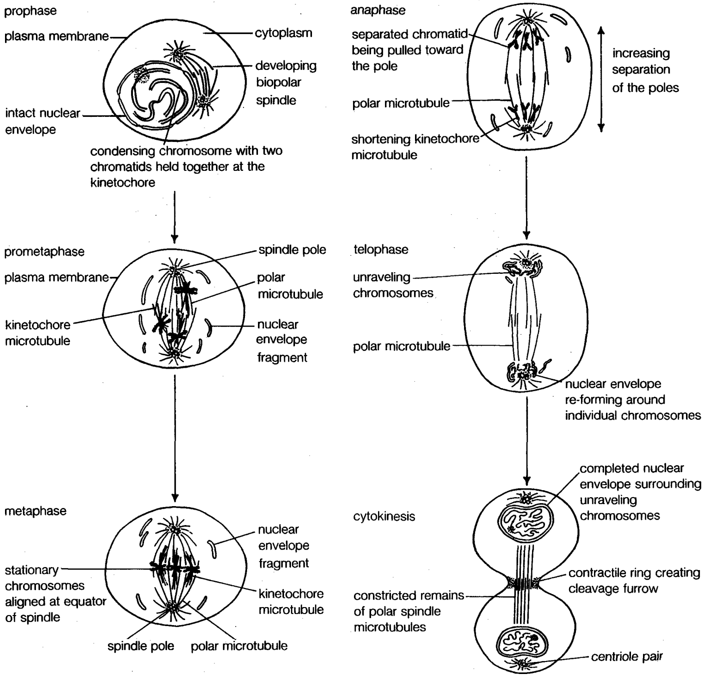

Figure 12: The events during cell division by mitosis.

Mitosis can be divided into five phases (see Figure 12). In prophase the mitotic spindle forms and the chromosomes condense. In prometaphase the nuclear envelope breaks down and the chromosomes attach to the mitotic spindle. Both chromatids of each chromosome attach to the spindle at a specialized chromosomal region called the kinetochore, or centromere. In metaphase the condensed chromosomes align in a plane across the equator of the mitotic spindle. Anaphase follows as the separated chromatids move abruptly toward opposite spindle poles. Finally in telophase a new nuclear envelope forms around each set of unraveling chromatids.

The mitotic spindle

An essential feature of mitosis is the attachment of the chromatids to opposite poles of the mitotic spindle. This ensures that each of the daughter cells will receive a complete set of chromosomes. The mitotic spindle is composed of microtubules, each of which is a tubular assembly of molecules of the protein tubulin (see above *The cytoskeleton*). Some microtubules extend from one spindle pole to the other, while a second class extends from one spindle pole to a chromatid. Microtubules can grow or shrink by the addition or removal of tubulin molecules. This change in length propels attached chromatids to the spindle poles, where they unravel to form new nuclei.

The two poles of the mitotic spindle are occupied by centrosomes, which appear to organize the microtubule arrays. In animal cells each centrosome contains a pair of cylindrical centrioles, which are themselves composed of complex arrays of microtubules. Centrioles duplicate at a precise time in the cell division cycle, usually close to the start of DNA replication. The exact significance of centrioles in cell division is clouded by their absence from plant cells that undergo mitosis. The microtubules in the

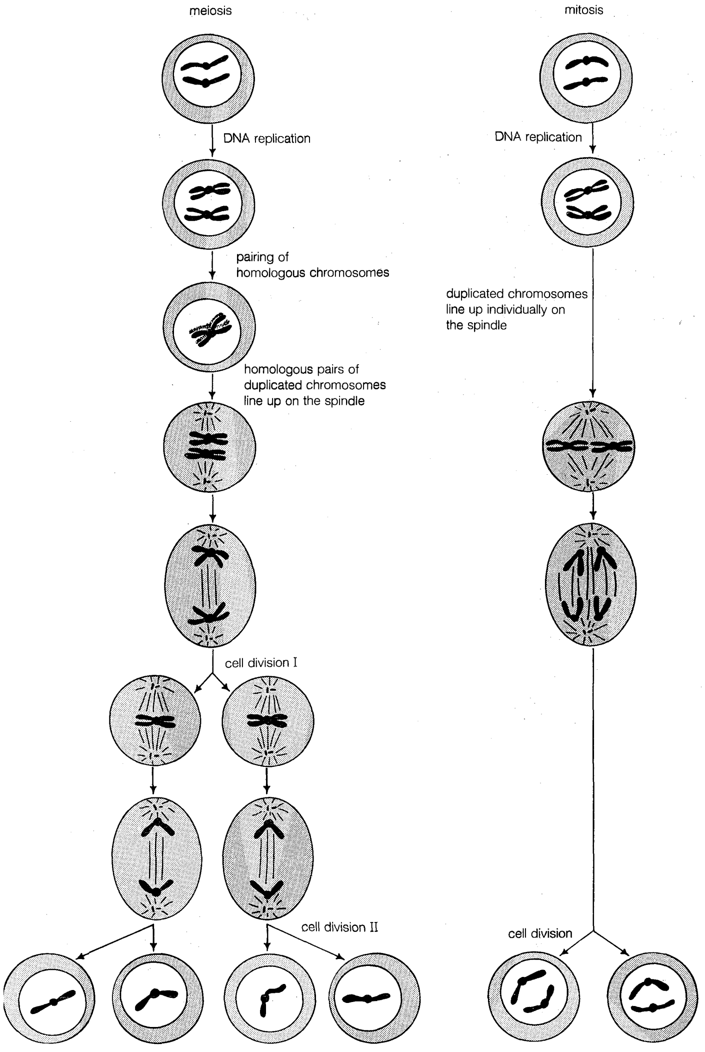

Figure 13: Meiosis compared with a normal mitosis.
From B. Alberts *et al.*, *Molecular Biology of The Cell* (1983); Garland Publishing, Inc.

mitotic spindles of plant cells are less tightly organized, suggesting an organizational role for the centriole.

After mitosis comes cytokinesis, the division of the cytoplasm. This is another process in which animal and plant cells differ. In animal cells cytokinesis is achieved through the constriction of the cell by a ring of contractile microfilaments consisting of actin and probably myosin, the proteins involved in muscle contraction and other forms of cell movement. In plant cells, the cytoplasm is divided by the formation of a new cell wall, called the cell plate, between the two daughter cells. The cell plate arises from small, Golgi-derived vesicles that coalesce in a plane across the equator of the late telophase spindle to form a disk-shaped structure. In this process, each vesicle contributes its membrane to the forming plasma membranes and its matrix contents to the forming cell wall. A second set of vesicles extends the edge of the cell plate until it reaches and fuses with the sides of the parent cell, thereby completely separating the two new daughter cells. At this point, cellulose synthesis commences, and the cell plate becomes a primary cell wall (see above *The cell matrix and cell-to-cell communication: The plant cell wall*).

Meiosis. A specialized division of chromosomes called meiosis occurs during the formation of the reproductive cells, or gametes, of sexually reproducing organisms. Gametes such as ova, sperm, and pollen begin as germ cells, which, like other types of cell, have two copies of each gene in their nuclei. The chromosomes composed of these matching genes are called homologs. During DNA replication, each chromosome duplicates into two attached chromatids. The homologous chromosomes are then separated to opposite poles of the meiotic spindle by tubulin fibres similar to those of the mitotic spindle. At this stage in the meiosis of germ cells, there is a crucial difference from the mitosis of other cells (see Figure 13). In meiosis the two chromatids making up each chromosome remain together, so that whole chromosomes are separated from their homologous partners. Cell division then occurs, followed by a second division that resembles mitosis more closely in that it separates the two chromatids of each remaining chromosome. In this way, when meiosis is complete, each mature gamete receives half of each parental chromosome and, thus, only one copy of each gene instead of the two copies present in other cells. (R.A.La.)

THE CELL DIVISION CYCLE

In bacteria, DNA synthesis can take place uninterrupted between cell divisions, and new cycles of DNA synthesis can begin before previous cycles have finished. In contrast, higher organisms duplicate their DNA exactly once during a discrete period between cell divisions. This period is called the S (for synthetic) phase. It is preceded by a period called G_1 (meaning "first gap") and followed by a period called G_2, during which nuclear DNA synthesis does not occur.

The four periods G_1, S, G_2, and M (for mitosis) make up the cell division cycle. The cell cycle characteristically lasts between 10 and 20 hours in rapidly proliferating adult cells, but it can be arrested for weeks or months in quiescent cells. Prolonged arrest of this type usually occurs during the G_1 phase and is sometimes referred to as G_0. In contrast, some embryonic cells, such as those of vinegar flies (also called fruit flies), can complete entire cycles and divide in only 11 minutes. In these exceptional cases, G_1 and G_2 are undetectable, and mitosis alternates with DNA synthesis. In addition, the duration of the S phase varies dramatically. The vinegar fly embryo takes only four minutes to replicate its DNA, compared with several hours in adult cells of the same species.

Controlled proliferation. Several studies have identified the transition from the G_1 to the S phase as a crucial control point of the cell cycle. Stimuli are known to cause resting cells to proliferate by inducing them to leave G_1 and begin DNA synthesis. These stimuli, called growth factors, are naturally occurring proteins specific to certain groups of cells in the body. They include nerve growth factor, epidermal growth factor, and platelet-derived growth factor. Such factors may have important roles in the healing of wounds as well as in the maintenance and growth of normal tissues. Many growth factors are known to act on the external membrane of the cell, usually by interacting with specialized protein receptor molecules. These respond by triggering further cellular changes, including an increase in calcium levels that makes the cell interior more alkaline and the addition of phosphate groups to the amino acid tyrosine in proteins. Although the complex response of cells to growth factors is not clearly understood, it is known to be of fundamental importance to the control of cell proliferation.

Failure of proliferation control. Cancer can arise when the controlling factors over cell growth fail and allow a cell and its descendants to keep dividing at the expense of the organism. Information on the development of malignant tumours has been obtained by studying viruses that transform cultured cells, leading to malignant behaviour. Transformed cells may differ from their normal progenitors by continuing to proliferate at very high densities, in the absence of growth factors, or in the absence of a solid substrate for support.

Major advances in the understanding of malignant transformation have come from studies of the viral genes that cause transformation. These viral oncogenes have led to the identification of related cellular oncogenes, whose activation can transform cells. Approximately 20 cellular oncogenes have been identified, and there is evidence that specific oncogenes are activated in particular human cancers. For example, an oncogene called ras is associated with many epithelial cancers, while another, called myc, is associated with leukemias.

An interesting feature of oncogenes is that they may act at different levels corresponding to the multiple steps seen in

Cancerous cell growth

the development of cancer. Some oncogenes immortalize cells, so that they divide indefinitely, whereas normal cells die after a limited number of generations. Other oncogenes transform cells so that they grow in the absence of growth factors. A combination of these two functions can make cells malignant, whereas each on its own cannot. The mode of action of oncogenes also provides important clues to the nature of growth control and cancer. At least some oncogenes are known to encode growth factors on the receptors of cells that may cause continuous proliferation in the absence of appropriate growth factors. Such studies identify the ways in which cancer cells differ from their normal counterparts, and they also emphasize how small and subtle those differences can be. (R.A.La.)

Cell differentiation

Adult organisms are composed of a number of distinct types of cell; in humans they number about 200. Cells are organized into tissues, each of which typically contains a small number of cell types and is devoted to a specific physiological function. For example, the epithelial tissue lining the stomach consists of three principal cell types: mucus-secreting columnar cells, acid-secreting parietal cells, and pepsin-secreting chief cells, together with smaller numbers of enteroendocrine cells secreting specific peptide hormones. The skeletal tissue of a long bone contains osteoblasts in the outer sheath; within the matrix are osteocytes, or mature bone cells, and osteoclasts, multinucleate cells involved in bone remodeling.

Invertebrate animals are also composed of differentiated cell types, many of which are similar to the cells of mammals; but, in general, the simpler the overall organization of the animal, the fewer the number of distinct cell types that they possess. Plants are also composed of differentiated cells, but they are quite different from the cells of animals. For example, a leaf in a higher plant is covered with a cuticle layer of epidermal cells. Among these are pores composed of two specialized cells, which regulate gaseous exchange across the epidermis. Within the leaf is the mesophyll, a spongy tissue responsible for photosynthetic activity. There are also veins composed of xylem elements, which transport water up from the soil, and phloem elements, which transport products of photosynthesis to the storage organs.

The various cell types have traditionally been recognized and classified according to their appearance in the light microscope following the process of fixing, processing, sectioning, and staining tissues that is known as histology. Classical histology has been augmented since the 1940s by electron microscopy, by histochemistry (methods of staining particular enzymes and other substances), and, since the 1960s, by immunohistochemistry (the use of specific antibodies to stain particular molecular species in situ). Immunohistochemistry has allowed the identification of many more cell types than could be visualized by classical histology, particularly in the immune system and among the scattered hormone-secreting cells of the endocrine system.

THE DIFFERENTIATED STATE

The biochemical basis of cell differentiation is the synthesis by the cell of a particular set of proteins, carbohydrates, and lipids. These syntheses are catalyzed by enzymes, all of them proteins, and each enzyme in turn is synthesized in accordance with a particular gene, or sequence of nucleotides in the DNA of the cell nucleus. A particular state of differentiation, then, corresponds to the set of genes that is expressed and the level to which it is expressed.

Genetic basis of differentiation

It is generally believed that all of an organism's genes are present in each cell nucleus, no matter what the cell type, and that differences between tissues are due not to the presence or absence of certain genes but to the expression of some and the repression of others. In animals the best evidence for retention of the entire set of genes comes from experiments in which the nucleus of a differentiated cell is substituted for the nucleus of a fertilized ovum, resulting in a small number of cases in the growth of a normal embryo. Such experiments show that any nucleus has the genetic information required for the growth of a developing organism, and they strongly suggest that, for most tissues, cell differentiation arises from the regulation of genetic activity rather than the removal or destruction of unwanted genes. The only known exception to this rule comes from the immune system, where segments of DNA in developing white blood cells are slightly rearranged, producing a wide variety of antibody and receptor molecules. (See above *The nucleus: Rearrangement and modification of DNA*.)

At the molecular level there are many ways in which the expression of a gene can be differentially regulated in different cell types. There may be differences in the copying, or transcription, of the gene into RNA, in the processing of the initial RNA transcript into messenger RNA (mRNA), in the control of mRNA movement to the cytoplasm, in the translation of mRNA to protein, or in the stability of mRNA. One of the best-understood cases is the differentiation of the red blood cell, of which hemoglobin is the major protein. In other tissues the globin genes are present but not transcribed at a high level, while, in the DNA of the developing red blood cell, nucleotide sequences called enhancers have been identified in and around the regions encoding hemoglobin. These enhancers, presumably upon interaction with regulatory proteins specific to red blood cells, allow the transcription of hemoglobin genes only in those cells.

Cells are normally sharply different from one another when they reach a state of terminal, or final, differentiation; intermediate forms found in an adult organism are in a process of maturation from a precursor cell type. States of terminal differentiation are stable and persistent, both in the lifetime of the cell and, in the case of differentiated types capable of continued cell division, through successive cell generations. The inherent stability of the differentiated state may be the result of a feedback mechanism, in which the products of active genes act on those genes to maintain their activity and on other genes to maintain their inactivity.

THE PROCESS OF DIFFERENTIATION

Differentiation from visibly undifferentiated precursor cells occurs during embryonic development from ova, during metamorphosis of larval forms, and following the separation of parts in asexual reproduction. It also takes place in the adult organism during the regeneration of missing parts and the growth of renewal tissues. Cell differentiation is, therefore, an essential and ongoing process at all stages of life.

Embryonic differentiation. The visible differentiation of cells is only the last of a progressive sequence of states, in each of which the cell becomes committed to a narrower range of types into which it can develop. Each committed state is probably based on differential gene activity, although this usually cannot be directly visualized. Different states of commitment can be investigated, however, by using the methods of experimental embryology. There are two basic procedures. First, the cell or group of cells is explanted and cultured in a neutral medium, and the types of cells into which it differentiates are recorded. This measures "specification," or the autonomous developmental capability of the cell. Second, the cell or group of cells is transplanted to other sites in the embryo in order to test its resistance to environmental stimuli. If it becomes the type of cell that it normally would regardless of position, it is said to be "determined" to form that particular tissue or cell type. Although states of specification and determination are thought to represent differential gene activity, the dynamic properties of embryonic cells are not necessarily the same as those of fully differentiated cells; in particular, they are often not stable over time.

Specification and determination of embryonic cells

Three mechanisms are thought to bring about altered commitments in the different regions of the early embryo: cytoplasmic localization, progressive chromosome modification, and induction. In the earliest stages of development it is usual for the ovum to divide without growth. The cells arising from these cleavage divisions are called blastomeres, and each blastomere inherits a certain region of the ovum. If a genetic regulatory molecule, called a cytoplasmic determinant, is localized to specific regions of the ovum, it will be inherited by only some of the blastomeres, providing a mechanism for the establishment of different states of commitment between blastomeres. Cytoplasmic determinants are thought to exist in most animal ova.

As mentioned above, chromosome modification as a mechanism of cell differentiation has been well established only in the immune system. However, it is thought to be a feature of early development in at least some animal types. The nematode *Caenorhabditis* has a cell lineage that does not vary between individual cells, but a number of mutations have been isolated in which the normal sequence of cell divisions and, hence, the resulting anatomy, are altered. The nature of these changes suggests that some form of chromosome modification is associated with particular blastomere cleavages, resulting in different determination of the daughter cells.

The role of induction in cellular commitment during embryonic development is very well established. In induction, a substance secreted by one group of cells alters the development of another group. In early development, induction is usually instructive; that is, the tissue assumes a different state of commitment in the presence of the signal than it would in the signal's absence. It is thought that inductive signals often take the form of concentration gradients of substances that evoke a number of different responses at different concentrations, leading to the formation of a sequence of groups of cells, each in a different state of specification.

In the early stages of vertebrate embryo development, the first induction, a signal from the endoderm acting on the cells of the ectoderm, leads to formation of the mesoderm. The second induction leads to a differentiation of mesoderm into somite (future vertebrae and muscle), lateral-plate, and blood-forming regions under the influence of the most dorsal region. During gastrulation, the third induction leads to the formation of the neural plate (the future brain and spinal cord) under the influence of the underlying mesoderm.

In later development, inductions may be merely permissive; that is, the signal allows completion of development along a certain pathway but does not increase cellular diversity. For example, in the development of the pancreas a factor from the mesenchymal tissue of the organ rudiment is known to be necessary for the proper differentiation of epithelial tissue.

Adult differentiation. In the adult mammal there are three classes of tissue. First, there are those that, like nerve and muscle tissue, are incapable of further cell division. Second, there are those that, like tissue of the liver or kidney, do not normally grow but may do so following removal of part of the tissue or after hormonal stimulation. Third, there are the renewal tissues, in which differentiated cells are constantly produced from an undifferentiated stem cell population.

Most renewal tissues are epithelia, such as the skin or the linings of the alimentary canal. But the renewal tissue whose differentiation is best understood is the blood. There are several different blood cell types: red blood cells, or erythrocytes, concerned with oxygen transport; granulocytes, mainly responsible for ingesting foreign particles; lymphocytes, concerned with antibody secretion and cell-mediated immune responses; and monocytes, responsible for removing cellular debris. There are also the platelets, fragments of giant cells called megakaryocytes, which are required for clotting. All of these types arise from a single type of stem cell, which is found in bone marrow together with larger numbers of mature cells and cells in intermediate stages of maturation.

Pluripotent stem cells

Evidence for a single, pluripotent stem cell (a stem cell from which many different types develop) comes mainly from experiments in which marrow cells are injected into mice whose blood cell production has been destroyed by irradiation. A small number of the injected cells grow in the spleen of the host, producing colonies, some of which contain more than one differentiated cell type. It can be shown that all the types in such colonies are descended from one stem cell. Experiments provide evidence about the events producing this differentiation: two cell types of restricted developmental potential arise immediately from the stem cell, one capable of forming granulocytes and monocytes and the other, erythrocytes and megakaryocytes. Each of these two types then segregates into two lines of unipotent cells (capable of producing only one type). Control over the number of terminal cell types occurs not at the level of cell commitment, which appears to be a random process, but by the action of growth-promoting substances on each of the lines at a precursor stage when they are committed but visibly undifferentiated and still capable of extensive cell division. Erythropoietin, for example, is required for the proliferation of erythroid precursors, and "granulocyte/macrophage colony-stimulating factor" is required for the proliferation of granulocyte/macrophage precursors.

Studies suggest that a similar situation obtains with epithelial renewal tissues but with an additional factor of spatial organization. For example, the small intestine is lined with crypts, each constituting one cell-proliferation unit. The crypts contain a small number of slowly cycling stem cells, which form all of the types of cells—absorptive, goblet, Paneth, and enteroendocrine—found in mucous membrane. These stem cells are located near the crypt base, and most of their progeny, destined to become absorptive and goblet cells, migrate upward into the villi. The intermediate forms between the stem cell and the differentiated cells go through several divisions, but little else is known about them. It is clear, however, that a proper balance between cell production and cell differentiation is necessary for the integrity and proper function of the tissue, for if the balance is disturbed, the tissue may become cancerous.

ERRORS IN DIFFERENTIATION

Two classes of abnormal cell differentiation are metaplasia and anaplasia. Metaplasia is the conversion of one cell type into another. In fact, it is not the differentiated cells themselves that change but rather the stem cell population from which they are derived. Metaplasia commonly occurs where chronic tissue damage is followed by extensive regeneration. Squamous metaplasia of the bronchi, for example, occurs when the ciliated respiratory epithelial cells of people who smoke develop into squamous, or flattened, cells. In intestinal metaplasia of the stomach, patches resembling intestinal tissue arise in the gastric mucosa, often in association with gastric ulcers.

Cancerous cells

Anaplasia is a loss of visible differentiation that can occur in advanced cancer. In general, early cancers resemble their tissue of origin, but as they develop they produce variants of more abnormal appearance and increased malignancy. Finally, a highly anaplastic growth can occur, in which the cancerous cells bear no visible relation to the parent tissue. The progression to anaplasia may represent a break in normal maturation, so that anaplastic cells resemble normal stem cells but do not respond to controls on growth and differentiation. (J.M.W.S.)

The evolution of cells

It is highly unlikely that scientists will ever re-create the crucial "experiment" that led to the origin of life. Billions of unsuccessful experiments must have been carried out in countless ponds and marshes before life first evolved, and these experiments lasted for hundreds of millions of years. During this period, conditions on Earth were different from those today. There was little oxygen in the atmosphere, and it is thought that the environment was rich in hydrogen, methane, and ammonia. Laboratory experiments show that, under these conditions, lightning charges could have created a large variety of small organic molecules, including the nucleotides, amino acids, and other raw materials of which cells are made. It is thought that life first arose after thick soups of such organic material had accumulated in local regions on Earth.

THE DEVELOPMENT OF GENETIC INFORMATION

Life could not exist until a collection of specific catalysts appeared that could promote the synthesis of more cat-

Primitive RNA

alysts of the same kind. Early stages in the evolutionary pathway presumably centred on RNA molecules, which not only present specific catalytic surfaces but also contain the potential for their own duplication through the formation of a complementary RNA molecule. It is assumed that a small RNA molecule eventually appeared that was able to catalyze its own duplication. Such an autocatalytic RNA molecule would have multiplied faster than its neighbours, usurping the RNA precursor molecules in the primeval soup.

Primitive RNA replication would have been imperfect, so that many variant autocatalytic RNA molecules would have arisen. Any variations that increased the speed or the fidelity of self-replication would have enabled those variant RNA molecules to outmultiply their neighbour RNA. Simultaneously, there would have been the natural selection of other small RNA molecules existing in symbiosis with autocatalytic RNA molecules, being replicated in return for catalyzing a useful secondary reaction such as the production of better precursor molecules. In this way, sophisticated families of RNA catalysts would eventually have evolved, in which cooperation between different molecules produced a system that was much more effective at self-replication than a collection of individual RNA catalysts.

The next major step in the evolution of the cell would have been the development, in one family of self-replicating RNA, of a primitive mechanism of protein synthesis. Protein molecules cannot provide the information for the synthesis of other protein molecules like themselves. This information must ultimately be derived from a nucleic acid sequence. Protein synthesis is much more complex than RNA synthesis, and it could not have arisen before a group of powerful RNA catalysts evolved. Each of these catalysts presumably has its counterpart among the RNA molecules that function in the current cell: (1) There was an information RNA molecule, much like messenger RNA (mRNA), whose nucleotide sequence was read to create an amino acid sequence; (2) there was a group of adaptor RNA molecules, much like transfer RNA (tRNA), that could bind to both mRNA and a specific activated amino acid; and (3) finally, there was an RNA catalyst, much like ribosomal RNA (rRNA), that facilitated the joining together of the amino acids aligned on the mRNA by the adaptor RNA.

Formation of cell membranes

At some point in the evolution of biologic catalysts the first cell was formed. This would have required the partitioning of the primitive soup of biologic catalysts into individual units, each surrounded by a membrane. Membrane formation might have occurred quite simply, since many amphiphilic molecules—half hydrophobic (water-hating) and half hydrophilic (water-loving)—aggregate to form bilayer sheets in which the hydrophobic portions of the molecules line up in rows to form the interior of the sheet and leave the hydrophilic portions to face the water. Such bilayer sheets can spontaneously close up to form the walls of small, spherical vesicles, as do the phospholipid bilayer membranes of present-day cells.

As soon as the biologic catalysts became compartmentalized into small individual units, or cells, the units would have begun to compete with one another for the same ingredients in the surrounding soup. Now the development of variant, but efficient, catalysts would have served only the cell itself and its progeny, rather than being dissipated throughout a much larger volume. The active competition that ensued must have greatly speeded up evolutionary change, serving as a powerful force for the development of more efficient cells. In this way, cells eventually arose that contained new catalysts, enabling them to use simpler, more abundant precursor molecules for their growth. Because these cells were no longer dependent on a rich soup of preformed ingredients for their survival, they were able to spread far beyond the limited environments where the first primitive cells arose.

It is often assumed that the first cells appeared only after the development of a primitive form of protein synthesis. However, it is by no means certain that cells cannot exist without proteins, and it has been suggested as an alternative that the first cells contained only RNA catalysts. In either case, protein molecules, with their chemically varied side chains, are more powerful catalysts than RNA molecules; therefore, as time passed, cells arose in which RNA served primarily as genetic material, being directly replicated in each generation and inherited by all progeny cells in order to specify proteins.

As cells became more complex, a need would have arisen for a stabler form of genetic information storage than that provided by RNA. DNA, related to RNA yet chemically stabler, probably appeared rather late in the evolutionary history of cells. Over a period of time, the genetic information in RNA sequences was transferred to DNA sequences, and the ability of RNA molecules to replicate directly was lost. It was only at this point that the central process of biology—the synthesis, one after the other, of DNA, RNA, and protein—appeared.

THE DEVELOPMENT OF METABOLISM

Transition from anaerobic to aerobic cells

The first cells presumably resembled prokaryotic cells in lacking nuclei and functional internal compartments, or organelles. These early cells were also anaerobic (not requiring oxygen), deriving their energy from the fermentation of organic molecules that had previously accumulated on the Earth over long periods of time. As these food sources became exhausted, more sophisticated cells evolved that could carry out primitive forms of photosynthesis, in which light energy was harnessed by membrane-bound proteins to form organic molecules with energy-rich chemical bonds. A major turning point in the evolution of life was the development of photosynthesizing bacteria requiring only water as an electron donor and producing molecular oxygen. The descendants of these bacteria, the cyanobacteria (also known misleadingly as blue-green algae), still exist as viable life forms. Their ancestors prospered to such an extent that the atmosphere became rich in the oxygen they produced. The free availability of this oxygen in turn enabled other bacteria to evolve aerobic forms of metabolism, a much more efficient use of organic molecules as a source of food.

The switch to predominantly aerobic metabolism is thought to have occurred in bacteria approximately 2,000,000,000 years ago, about 1,500,000,000 years after the first cells had formed. Aerobic eukaryotic cells (cells containing nuclei and all of the other organelles) probably appeared about 1,500,000,000 years ago, their lineage having branched off much earlier from that of the bacteria. Eukaryotic cells almost certainly became aerobic by engulfing aerobic bacteria, with which they lived in a symbiotic relationship. The mitochondria found in both animals and plants are the descendants of such bacteria. Later, in branches of the eukaryotic lineage leading to plants and algae, a cyanobacterium-like organism was engulfed to perform photosynthesis; in time, these bacteria became the chloroplasts.

The eukaryotic cell thus apparently arose as an amalgam of different cells, in the process becoming an efficient aerobic cell whose plasma membrane was freed from energy metabolism—one of the major functions of the plasma membrane of bacteria. The eukaryotic plasma membrane was therefore able to become specialized for cell-to-cell communication and cell signaling. It may be partly for this reason that eukaryotic cells were eventually more successful at forming complex multicellular organisms than their simpler prokaryotic relatives. (B.M.A.)

The history of cell theory

FORMULATION OF THE THEORY

Early observations. The history of cell theory is a history of the actual observation of cells, because early prediction and speculation about the nature of the cell were generally unsuccessful. The decisive event that allowed the observation of cells was the invention of the microscope in the 17th century, after which interest in the invisible world was stimulated. Robert Hooke, who described cork and other plant tissues in 1665, introduced the term cell because the cellulose walls of dead cork cells reminded him of the blocks of cells occupied by monks. Even after the publication in 1672 of excellent pictures of plant tis-

The role of microscopy

sues, no significance was attached to the contents within the cell walls. The magnifying powers of the microscope and the inadequacy of techniques for preparing cells for observation precluded a study of the intimate details of the cell contents. The inspired amateur of early microscopy Antonie van Leeuwenhoek, beginning in 1673, discovered blood cells, spermatozoa, and a lively world of "animalcules." A new world of unicellular organisms was opened up. Such discoveries extended the known variety of living things but did not bring insight into their basic uniformity. Moreover, when Leeuwenhoek observed the swarming of his animalcules but failed to observe their division, he could only reinforce the idea that they arose spontaneously.

Cell theory was not formulated for nearly 200 years after the introduction of microscopy. Explanations for this delay range from the poor quality of the microscopes to the persistence of ancient ideas concerning the definition of a fundamental living unit. Many observations of cells were made, but apparently none of the observers was able to assert forcefully that cells were the units of biologic structure and function.

Three critical discoveries made during the 1830s, when improved microscopes with suitable lenses, higher powers of magnification without aberration, and more satisfactory illumination became available, were decisive events in the early development of cell theory. First, the nucleus was observed by Robert Brown in 1833 as a constant component of plant cells. Next, nuclei were also observed and recognized as such in some animal cells. Finally, a living substance called protoplasm was recognized within cells, its vitality made evident by its active streaming, or flowing, movements, especially in plant cells. After these three discoveries, cells, previously considered as mere pores in plant tissue, could no longer be thought of as empty, because they contained living material.

Two German biologists, Theodore Schwann and Matthias Schleiden, clearly stated in 1839 that cells are the "elementary particles of organisms" in both plants and animals and recognized that some organisms are unicellular and others multicellular. This statement was made in Schwann's *Mikroskopische Untersuchungen über die Übereinstimmung in der Struktur und dem Wachstume der Tiere und Pflanzen* (1839; *Microscopical Researches into the Accordance in the Structure and Growth of Animals and Plants*). Schleiden's contributions on plants were acknowledged by Schwann as the basis for his comparison of animal and plant structure.

Schleiden and Schwann's descriptive statements concerning the cellular basis of biologic structure are straightforward and acceptable to modern thought. They recognized the common features of cells to be membrane, nucleus, and cell body and described them in comparisons of various animal and plant tissues. A statement by Schleiden pointed toward the future direction of cell studies:

> Each cell leads a double life: an independent one, pertaining to its own development alone; and another incidental, insofar as it has become an integral part of a plant. It is, however, easy to perceive that the vital process of the individual cells must form the first, absolutely indispensable fundamental basis, both as regards vegetable physiology and comparative physiology in general. . . .

The problem of the origin of cells. Schwann and Schleiden were not alone in contributing to this great generalization of natural science, for strong intimations of the cell theory occur in the work of their predecessors. Recognizing that the basic problem was the origin of cells, these early investigators invented a hypothesis of "free cell formation," according to which cells developed *de novo* out of an unformed substance, a "cytoblastema," by a sequence of events in which first the nucleolus develops, followed by the nucleus, the cell body, and finally the cell membrane. The best physical model of the generation of formed bodies then available was crystallization, and their theory was inspired by that model. In retrospect, the hypothesis of free cell formation would not seem to have been justified, however, since cell division, a feature not characteristic of crystallization processes, had frequently been observed by earlier microscopists, especially among single-celled organisms. Even though cell division was observed repeatedly in the following decades, the theory of free cell formation lingered throughout most of the 19th century; however, it came to be thought of more and more as a possible exception to the general principle of the reproduction of cells by division. The correct general principle was affirmed in 1855 by a German biologist of great prestige, Rudolph Virchow, who asserted that "omnis cellula e cellula" ("all cells come from cells"). Doubt remained, however.

The hypothesis of "free cell formation"

The inherently complex events of cell division prevented a quick resolution of the complete sequence of changes that occur during the process. First, it was noted that a cell with a nucleus divides into two cells, each having a nucleus; hence, it was concluded that the nucleus must divide, and direct division of nuclei was duly described by some. Better techniques served to create perplexity, because it was found that, during cell division, the nucleus as such disappears. Moreover, at the time of division, dimly discerned masses, now recognized as chromosomes, were seen to appear temporarily. Observations in the 1870s culminated in the highly accurate description and interpretation of cell division by Walther Flemming in 1882. His advanced techniques of fixing and staining cells enabled him to see that cell reproduction involves the transmission of chromosomes from the parent to daughter cells by the process of mitosis and that the division of the cell body is the terminal event of that reproduction.

The discovery that the number of chromosomes remains constant from one generation to the next resulted in the full description of the process of meiosis. The description of meiosis, combined with the observation that fertilization is fundamentally the union of maternal and paternal sets of chromosomes, culminated in the understanding of the physical basis of reproduction and heredity. Meiosis and fertilization therefore came to be understood as the complementary events in the life cycle of organisms: meiosis halves the number of chromosomes in the formation of spores (plants) or gametes (animals), while fertilization restores the number through the union of gametes. By the 1890s "life" in all of its manifestations could be thought of as an expression of cells.

Protoplasm as the living substance of the cell

The protoplasm concept. As the concept of the cell as the elementary particle of life developed during the 19th century, it was paralleled by the "protoplasm" concept—the idea that the protoplasm within the cell is responsible for life. Protoplasm had been defined in 1835 as the ground substance of living material and hence responsible for all living processes. That life is an activity of an elementary particle, the cell, can be contrasted with the view that it is the expression of a living complex substance—even a supermolecule—called a protoplasm. The protoplasm concept was supported by observations of the streaming movements of the apparently slimy contents of living cells.

Advocates of the protoplasm concept implied that cells were either fragments or containers of protoplasm. Suspicious and often contemptuous of information obtained from dead and stained cells, such researchers discovered most of the basic information on the physical properties—mechanical, optical, electrical, and contractile—of the living cell.

An assessment of the usefulness of the concept of protoplasm is difficult. It was not wholly false; on the one hand, it encouraged the study of the chemical and mechanical properties of cell contents, but it also generated a resistance, evident as late as the 1930s, to the development of biochemical techniques for cell fractionation and to the realization that very large molecules (macromolecules) are important cellular constituents. As the cell has become fractionated into its component parts, protoplasm, as a term, no longer has meaning. The word protoplasm is still used, however, in describing the phenomenon of protoplasmic streaming—the phenomenon from which the concept of protoplasm originally emerged.

CONTRIBUTION OF OTHER SCIENCES

Appreciation of the cell as the unit of life has accrued from important sources other than microscopy; perhaps

The role of microbiology

the most important is microbiology. Even though the small size of microorganisms prohibited much observation of their detailed structure until the advent of electron microscopy, they could be grown easily and rapidly. Thus it was that the studies of microbes by Louis Pasteur, published in 1861, helped to establish the principle of biogenesis, namely, that organisms arise only by the reproduction of other organisms. Fundamental ideas regarding the metabolic attributes of cells—that is, their ability to transform simple nutritional substances into cell substance and utilizable energy—came from microbiology. Pasteur perhaps overplayed the relation between catalysis and the living state of cells in considering enzymatic action to be an attribute of the living cell rather than of the catalytic molecules (enzymes) contained in the cell; it is a fact, however, that much of cell chemistry is enzyme chemistry—and that enzymes are one defining attribute of cells. The techniques of microbiology eventually opened the way for microbial genetics, which, in turn, provided the means for solving the fundamental problems of molecular biology that were inaccessible at first to direct attack by biochemical methods.

The science of molecular biology would be most capable of overthrowing the cell theory if the latter were an exaggerated generalization. On the contrary, molecular biology has become the foundation of cell science, for it has demonstrated not only that basic processes such as the genetic code and protein synthesis are similar in all living systems but also that they are made possible by the same cell components—*e.g.,* chromosomes, ribosomes, and membranes.

In the overlapping histories of cell biology and medicine, two events are especially important. One, the identification in 1827 by Karl Ernst von Baer of the ovum (unfertilized egg) as a cell, was important considering the many ways it often differs from other cells. Baer not only laid the foundations for reproductive biology but also provided important evidence for the cell theory at a critical time. The second important event was the promotion in 1855 of the concept of "cellular pathology" by Rudolph Virchow. His idea that human diseases are diseases of cells and can be identified and understood as such gave an authority to cell theory.

Although biochemistry might have made considerable progress without cell theory, each influenced the other almost from the start. When it was established that most biochemical phenomena are shared by all cells, the cell could be defined by its metabolism as well as by its structure. Cytochemistry, or histochemistry, made a brilliant start in 1869, when a Swiss biochemist, Friedrich Miescher, postulated that the nucleus must have a characteristic chemistry and then went on to discover nucleic acids, which have since been shown to be the crucial molecules of inheritance and metabolism.

The cell as part of an organism

Cell theory by itself cannot explain the development and unity of the multicellular organism. A cell is not necessarily an independently functioning unit, and a plant or an animal is not merely a congeries of individual cells. Fortunately, however, the long controversy centring upon the individuality and separateness of cells has ended. Cell biology now focuses on the interactions and communication among cells as well as on the analysis of the single cell. The influence of the environment on the cell has always been considered important; now it has been recognized that one important part of the environment of a cell is other cells.

Cell theory thus is not so comprehensive as to eliminate the concept of the organism as more than the sum of its parts. But the study of a particular organism requires the investigation of cells as both individuals and groups. The problem of cancer is an example: a plant or animal governs the division of its own cells; the right cells must divide, be differentiated, and then integrated into the proper organ system at the right time and place. Breakdown results in a variety of abnormalities, one of which is cancer. When the cell biologist studies the problem of the regulation of cell division, the ultimate objective is to understand the effect of the whole organism on an individual cell.

Celtic Literature

This article gives a historical account of Celtic literature, a term commonly applied to writings in Irish Gaelic, Scottish Gaelic, Manx, Welsh, Cornish, and Breton, in the so-called Insular Celtic languages. For writings in English by Irish, Scottish, and Welsh authors, see ENGLISH LITERATURE. French-language works by Breton authors are covered in FRENCH LITERATURE.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* section 621, and the *Index.*

The article is divided into the following sections:

IRISH GAELIC

The introduction of Celtic into Ireland has not been authoritatively dated, but it cannot be later than the arrival there of the first settlers of the La Tène culture in the 3rd century BC. The language is often described in its earliest form as Goídelic, named after the Celts (Goídil; singular, Goídel) who spoke it. The modern form, known in English as Gaelic (in Gaelic called Gaedhilge or Gaeilge), is derived from the Scottish Gàidhlig.

The earliest evidence of Irish Gaelic consists of archaic sepulchral inscriptions in the ogham alphabet based on a system of strokes and notches cut on the edges of stone or wood usually ascribed to the 4th and 5th centuries AD. Writings in the Roman alphabet date from 8th-century glosses in Old Irish, but 7th- and even 6th-century compositions are preserved in much later manuscripts.

Four distinct periods are recognizable in Irish Gaelic literature. The early literature (linguistically Archaic, Old, and Early Middle Irish), was composed by a professional class, the fili (singular, fili), and by churchmen. The medieval literature (linguistically late Middle and Classical Modern Irish) was dominated by the lay and hereditary bardic orders. In the late literature (17th century to the end of the 19th) authorship passed into the hands of individuals among the peasants, the class to which most Irish speakers had been reduced, using the dialects into which the language had been broken up. The subsequent revival has continued to the present day.

The functions of the fili

Early period. Irish literature was originally aristocratic and was cultivated by the fili, who seem to have inherited the role of the learned priestly order represented in Caesar's Gaul by the Druids, *vates* ("seers"), and bards and to have been judges, historians, and official poets responsible for all traditional lore and the performance of all rites and ceremonies. The arrival of Christianity and the gradual disappearance of paganism led to the abandonment of their specifically priestly functions. Nevertheless, the fili seem to have retained responsibility for the oral transmission of native lore or learning, which was in marked contrast to the new book or manuscript learning of the Christian Church. Fortunately, the ecclesiastical scholars were not as hostile to the native lore as were their counterparts abroad, and they appear to have been eager to commit it to writing. As a result, Ireland's oral culture was extensively recorded in writing long before it could have evolved that art itself. The record consisted mainly of history, legendary and factual; laws; genealogies; and poems, but prose was the predominant vehicle.

The fili were powerful in early Irish society and were often arrogant, enforcing their demands by the threat of a lampoon (*áer*), a poet's curse that could ruin reputations and, so it was thought, even kill. The laws set out penalties for abuse of the *áer,* and belief in its powers continued up to modern times. The official work of the fili has been preserved in fragments of annals and treatises.

Rhyme and metre

Verse. The earliest verse has been preserved mainly in passages incorporated into later documents, both literary and legal; most have suffered in transmission and are very obscure. One of the earliest poems is a eulogy on St. Columba (*c.* 521–597) in rhetorical short sentences linked by alliteration, ascribed to Dallán Forgaill, chief poet of Ireland. This device of alliterative rhythmical prose was used again in the sagas. Probably the oldest actual metre was that in which two half lines were linked by alliteration—a system reminiscent of early Germanic verse. Rhyme was used from the 7th century; the requirement was only that there should be identity of vowel and syllabic length and that consonants should belong to the same phonetic class—a system also found in early Welsh. The quatrain (seven or eight syllables to a line and rhyme between second and fourth lines) was derived from Latin hymn metres. The quatrains of the later popular metre, the *debide* (literally "cut in two"), consisted of two couplets with the two lines of each couplet rhyming.

Much early verse was of an official nature, but that of the church was hardly more lively than that of the fili, who often affected a deliberately obscure style. More interesting was the 10th-century *Psalter,* a biblical history in 150 poems. But the real glory of Irish verse lay in anonymous poets who composed poems such as the famous address to Pangur, a white cat. They avoided complicated metres and used a language that had been cultivated for centuries, with a freshness of insight denied to the fili. That the fili could, however, adapt their technique was shown by an 11th-century poem on the sea, where preface, choice of theme, and metaphorical expressions all suggest Scandinavian influence. This and other nature poetry carried on a tradition of native lyrics, sagas, and seasonal songs that showed remarkable sensitivity. The monastic and eremitic movement in the Irish Church also provided a strong impetus to nature poetry. This almost Franciscan poetry had an especial appeal to monastic scribes, so that much of it has been preserved.

Historical verse arose partly because recording of the past was an important part of the work of the fili; some of the earliest poems were metrical genealogy. As time went on the necessity for compendiums of information grew, and these were again often in metrical form. In a long poem, *Fianna bátar in Emain* ("The Warriors Who Were in Emain"), Cináed ua Artacáin summed up the saga material, while Fland Mainistrech collected the work of generations of fili who had laboured to synchronize Ireland's history with that of the outside world. Equally important is a great collection, in prose and verse, called the *Dindshenchas,* which gave appropriate legends to famous sites of Ireland between the 9th and 11th centuries. Indeed, the development of a loose *debide* form, making rhyming easy, facilitated mnemonic verse on numerous subjects.

The early Irish epic

Prose. The early Irish epic was a prose narrative that usually contained non-narrative poetic passages, often in dialogue form. The resemblance between this and the type of epic found in early Sanskrit suggests that the tradition went back to Indo-European times. The oldest sagas probably were first written down in the 7th and 8th centuries, from an oral tradition. These were imperfectly preserved, since Scandinavian invasions in the 9th and 10th centuries disrupted literary studies. Not until the 11th century did life become sufficiently settled for works to be collected in monasteries, and even then the collecting seems to have been haphazard. The great codex *Lebor Na Huidre* (*The Book of the Dun Cow*), written early in the 12th century, showed older treatments of saga material than are found in *The Book of Leinster,* written years later. The material has preserved a picture of primitive society—fighting from chariots, taking heads as trophies, the position of the Druids, the force of taboos—for which there is little or no evidence from strictly historical sources.

The Ulster cycle

The most important cycle was that of the Ulaid, a people who gave their name to Ulster. Conchobar (king of the Ulaid), Cú Chulainn (a boy warrior), Medb (queen of Connaught), and Noísi and Deirdre, doomed lovers, were outstanding figures in early Irish literature, and it was on elements from the sagas of the Ulaid that the nearest approach to an Irish epic was built—*Táin Bó Cuailnge* (*The Cattle Raid of Cooley*). First put together in the 7th or 8th century, it is striking chiefly for its terse vividness. The finest section is that in which Fergus, an exile from Ulster, recalls the deeds of Cú Chulainn's youth. But the value of the *Táin* generally lies in that, as it was being continually worked over, it provides a record of the degeneration of Irish style. The *Táin* collected around itself a number of ancillary stories, including that of its revelation to the fili in the 7th century by the ghost of Fergus and that of the tragedy of Noísi and Deirdre.

In this period stories with an origin outside the recognized tradition began to appear. An exotic element was represented by *The Taking of Troy* and *The Story of Alexander,* which appeared in the oldest saga lists, but classical learning had comparatively little effect until the next period. Stories of Finn, whose traditions went back to an early period, only really developed when the fili were no longer in control. The "wild-man-of-the-woods" cycle associated with Suibne Geilt had its origins in Strathclyde, where Irish and Brythonic literature must have been in contact at an early date; this mixture of hagiography, saga, and nature material was one of the most attractive stories of the later period.

The earliest didactic writings, Irish in language but in content mostly of Latin origin, comprised monastic rules, homilies, and hagiography. The lives of the saints were mainly works of fantasy, increasingly incorporating elements from folklore and saga material. The emphasis was always on the miraculous, but they are valuable as social documents. Another important genre of religious work was the vision, exemplified in *Fís Adamnáin* (*The Vision of Adamnan*), whose soul is represented as leaving his body for a time to visit heaven and hell under the guidance of an angel. Both the saints' lives and the visions tended to degenerate into extravagance, so that parodies were composed, notably *Aislinge Meic Con Glinne* (*The Vision of MacConglinne*).

Theory has always been important in Irish cultural life, and the fili built up a considerable body of academic speculation. A few surviving fragments discuss the nature of inspiration and the origin of language, with practical instruction on matters of metrics and style. Early on, a technical vocabulary was built up to deal with Latin, as well as Irish, grammar. In several ancient texts discussion of the art of the poet was mixed with questions relating to his legal status.

The rise of the bards

Middle period. The 12th century was a period of contradictions. While the oldest surviving codices were being written in monasteries, fairly faithfully preserving the much earlier literature, a new literary order elaborated verse forms to a far greater extent than before and used a language close to the vernacular of the day. After the 12th century the hereditary bardic families became custodians of Irish literature and continued in that function until the collapse of the Gaelic polity. At first completely divorced from ecclesiastical influence, they soon were sending their sons into the recently introduced orders, above all to the Franciscans, who were to become by the end of this period the greatest custodians of the tradition.

Bardic verse. The bardic reform of verse was sweeping. The language was modernized, the large number of metres used by the fili was greatly reduced, and greater rhythmic control and ornamentation were required. The scope of the verse narrowed; the bulk was poetry praising the poet's patron or God. No longer associated with monastic foundations, the bards, who trained for six or seven years, confidently looked to patrons to secure their living. One of the earliest poets of the great bardic family of Ó Dálaigh, Muireadhach Albanach, left a fine elegy on the death of his wife, as well as a stirring defense of his action in killing a tax collector. The courtly love themes, introduced into Irish literature by the Norman invaders, were used with native bardic wit and felicitous style to produce the enchanting poems called *dánta grádha.* A different departure from praise poetry was the *crosánacht,* in which verse was frequently interspersed with humorous or satirical prose passages.

The Fenian cycle. Most native prose of this period was concerned with the hero Finn and his war band (*fian*). Stories about Finn, Oisín, Caoilte, and the rest must have existed among the people for many centuries. The outstanding work was *Agallamh na Seanórach* ("The Interrogation of the Old Men"), written in the 12th century, in which Caoilte is represented as surviving the Battle of Gabhra and living on to accompany Patrick through Ireland. The Fenian stories never received such careful literary treatment as did those of the Ulster cycle, and the old form was soon abandoned for prose tales and ballads, which may be regarded as the beginnings of popular, as opposed to professional, literature in Irish. The metres represented a drastic simplification of the bardic technique, and a distinct change in theme occurred as this literature passed into the hands of the people.

Other prose. Stories popular with the fili steadily dropped out of favour. Sometimes they were combined with folktale elements, as was the case with the very old saga of Fergus mac Léti, which was rewritten, perhaps in the 14th century, to include a story of a people of tiny stature—the leprechauns. Most important of all, a flood of translations from Latin and English began. The stories of Marco Polo, Sir John Mandeville, Prester John, and Guy of Warwick, as well as classical and Arthurian stories in their medieval adaptations, became well known in Ireland. The new religious orders translated many spiritual and devotional works, and the churchmen made the experiment, remarkable for the time, of handling philosophical material in the vernacular. There was also much technical writing, especially on grammar and metrics. Continental teaching seems to have superseded the native tradition during this period.

The influence of other literatures

The spread of printing

By the end of the 15th century the printing press began to make literature available to larger numbers in most European countries. In Ireland, however, literature remained for some time the preserve of those who could afford to maintain the writers and supply their costly vellum.

Late period. The dispossession of the Irish and the old Anglo-Irish nobility during the late 16th and early 17th centuries entailed the practical disappearance of the professional bards, who were the nobility's dependents and propagandists. With their elimination the old order was doomed, and the Irish language itself began its long process of decay.

Hardly any correct bardic verse was written in Ireland after 1650, but new poets took over from the bards. And just as the bardic measures had been in preparation for centuries before they established themselves as canonical, so the song metres that replaced them had existed for centuries among the people. The new poets abandoned the syllable-measured lines for lines with a fixed number of stresses; the stressed vowels rhymed in patterns that might be very simple or, later, bewilderingly intricate, but simple vocalic assonance took the place of earlier rhyme. The language of poetry moved toward that of the people. While poets had little patronage, there was at least an increasing supply of paper, so that their works, still barred from the printing press, were able to circulate. The tone of verse throughout the 17th century was passionately defiant of the new regime. In it is found the first coherent expression of patriotism conceived as devotion to an abstract ideal rather than as loyalty to an individual, but much of the verse represents a mere nostalgia for the past.

The greatest poets of the song metres were Dáibhidh Ó Bruadair, one of the last poets to enjoy some patronage, and Aodhagán Ó Rathoille whose aisling (vision) poems made the genre popular. After them the poetic tradition was maintained into the 19th century by peasant poets who, although not lacking in subtlety of craftsmanship, and occasionally vigorous in satire, had none of the advantages and only a few of the virtues of their predecessors.

During the 17th century valuable antiquarian prose was produced. The most important is *Annála Ríoghachta Éireann* (completed 1636; "Annals of the Kingdom of Ireland"; Eng. trans., *Annals of the Four Masters*), a compilation of all available material on the history of Ireland to 1616, directed by Michael O'Clery. Geoffrey Keating produced the first historical (as opposed to annalistic) work in his *Foras Feasa ar Éirinn* (written *c.* 1640; *History of Ireland*) as well as some fine verse in both old and new metres and two spiritual treatises.

Prose developments

An interesting development in prose style was the satire *Páirliment Chloinne Tomáis* ("Parliament of Clan Thomas"). It appears to be by a representative of the bardic order, for it attacked with equal savagery the new ruling class and the native peasantry, using a style close to that of the earlier *crosánacht* but with prose predominating over verse. It found several imitators, but the old tradition was by this time too attenuated for so aristocratic an attitude to be maintained. Imaginative prose was more popular; it consisted of developments of Fenian or romance themes from Irish and foreign medieval literature mingled with elements of folklore and of the fabliau (a short metrical tale). As in the case of the song metres, these romances had a considerable tradition before they appeared in writing. But as the public for Irish became smaller, there was little hope for much prose production.

The 18th century is a low point in Irish Gaelic literature. The last great flowering of the poetic tradition in Munster was *Cúirt an Mheadhon Oidhche* (written 1780, published 1904; *The Midnight Court*) by Brian Merriman, a Clare schoolmaster. After it, Irish poetry became a matter of folk songs.

During the 18th and early 19th centuries the only books in Irish prose were catechisms and devotional tracts. The manuscript tradition was carried on by a few scribes into the first half of the 19th century, when it all but died out. By the mid-19th century there was little literary activity in Irish, and almost all Irish speakers were illiterate.

The Gaelic revival. Ironically, it was English-speaking antiquarians and nationalists from the small educated class, rather than the Irish-speaking minority, who led the 19th-century revival, which in turn was stimulated by the Romantic movement's interest in Celtic subjects.

The rich vocabulary and idiomatic expressions and the wealth of folklore and folktales of the Irish-speaking districts (*gaeltachts*) gradually were acknowledged. Folklore collectors such as Douglas Hyde were able to restore some sense of pride in the language. The revivalists even succeeded in securing for Irish a modest place in the country's educational system.

But the revivalists were faced with a language of diverse dialects, and standardization was only effected in the mid-20th century with the help of new grammars, adequate dictionaries, and government support and direction. Writers whose Irish was rich and vigorous were persuaded that the reading public needed not more folklore but a literature that could compete internationally. Among the pioneers in this field were Patrick Pearse and Pádraic Ó Conaire, who introduced the modern short story into Irish. The short story flourished in the hands of Liam O'Flaherty and Máirtín O Cadhain, who also produced an outstanding novel, *Cré na Cille* (1953; "Churchyard Dust"). In verse the work of Máire Mhac an tSaoi, Máirtín Ó Direáin, and Seán Ó Ríordáin is impressive, and in their shadow a new generation of young poets, some of considerable talent, has grown up. Indeed, there is no lack of literary activity, as the two literary periodicals, *Comhar* ("Cooperation") and *Feasta* ("Henceforth"), eloquently testify.

In drama Brendan Behan's *An Giall* (1957; *The Hostage*) stands out, but Seán Ó Tuama, Eoghan Ó Tuairisc, Diarmaid Ó Súilleabháin, and Criostóir Ó Floinn also have written fine plays and have contributed in other genres. However, the drama in Irish cannot be said to have created for itself the following attracted by the Anglo-Irish theatre in its heyday under the influence of Yeats and Synge.

Literary criticism of distinction has developed also, and Seán Ó Tuama, Tomás Ó Floinn, and Breandán Ó Doibhlin have produced essays of high standard.

The most valuable contribution made by the *gaeltachts* has been a series of personal reminiscences describing local life. One of the best is Tomás Ó Criomhthain's *An tOileánach* (1929; *The Islandman*). At one time the *gaeltacht* memoirs threatened to become a vogue and inspired the brilliant satirical piece *An Béal Bocht* (1941; *The Poor Mouth*) by Flann O'Brien (pseudonym of Brian Ó Nualláin). Less characteristic but perhaps no less valuable have been the autobiographies written in Irish. Together with the spate of scholarly biographies in Irish, some on literary or semiliterary figures, they show how the revival has increased its range and depth.

SCOTTISH GAELIC

The Lismore compilation

Writings of the medieval period. The earliest extant Scottish Gaelic writing consists of marginalia added in the 12th century to the Latin Gospels contained in the 9th-century *Book of Deer.* The most important early Gaelic literary manuscript is *The Book of the Dean of Lismore,* an anthology of verse compiled between 1512 and 1526 by Sir James MacGregor, dean of Lismore (Argyllshire), and his brother Duncan. Its poems fall into three main groups: those by Scottish authors, those by Irish authors, and ballads concerned with Ossian, the mythical warrior and bard. This is the earliest extensive anthology of heroic Gaelic ballads in either Scotland or Ireland. The Scottish Gaelic poems date from about 1310 to 1520. The bard best represented is Fionnlagh Ruadh, bard to John, chief of clan Gregor (died 1519). There are three poems by Giolla Coluim mac an Ollaimh, a professional poet at the court of the Lord of the Isles and almost certainly a member of the MacMhuirich bardic family, the famous line of hereditary bards whose work spans nearly 500 years from the 13th to the 18th century. Perhaps the most notable of the other poets is Giolla Críost Brúilingeach and two women, Aithbhreac Inghean Coirceadail and Isabella, countess of Argyll.

Continuation of the oral tradition. Some 16th-century Gaelic poetry survived in oral tradition until the mid-18th century, when it was written down. Examples are *An Duanag Ullamh* ("The Finished Poem"), composed in honour of Archibald Campbell, 4th earl of Argyll, and the lovely lament *Griogal Cridhe* ("Teasing Heart"; *c.* 1570). It is certain that the poetry recorded in *The Book of the Dean of Lismore* was not an isolated outburst; much professional and popular poetry must have been lost. Songs in the nonsyllabic, accented measures survived, again orally, from the early 17th century. This was the tradition that produced the work songs—*e.g.,* waulking songs used when fulling cloth.

In 1567 appeared the first book printed in Gaelic in Scotland: Bishop John Carswell's *Foirm na Nurrnuidheadh,* a translation of John Knox's liturgy, in Classical Common Gaelic.

The 17th century. This period was the high point of Scottish Gaelic literature. The political, ecclesiastical, and social structures of Scotland were changing as was the relationship between the central government and the Gaelic area. Enough Gaelic poetry survives to show that there were many poets of great talent, and the diffusion of artistic talent is scarcely matched in any other period in Scottish Gaelic history. It was the great age of the work songs and of the classical bagpipe music. Some of the poetry and prose was contained in three 17th-century manuscripts. The first two were the *Black Book of Clanranald* and the *Red Book of Clanranald,* written by members of the MacMhuirich family, who were latterly hereditary bards to the MacDonalds of Clanranald. They were probably written for the most part in the 17th century but contained poems by earlier representatives of the family. The other important document was the Fernaig manuscript, compiled between 1688 and 1693, containing about 4,200 lines of verse, mostly political and religious.

Mary MacLeod and Iain Lom

The two best known poets of the 17th century were Mary MacLeod and Iain Lom. The former, known as Màiri Nighean Alasdair Ruaidh, was closely associated with the MacLeods of Harris and Dunvegan. Her poems show deep personal emotion, and her style is fresh and natural. She inherited the imagery of the bardic poets but placed it in a new setting, and her metres were strophic (having repeating patterns of lines) rather than strictly syllabic. John Macdonald, known as Iain Lom, took an active part in the events of his time. His life spanned an eventful period in Highland history, and his poetry reflected this. He composed poems about the battles of Inverlochy and Killiecrankie, a lament for the Marquess of Montrose, a poem on the Restoration of Charles II in 1660, several poems dealing with the Keppoch murder of 1663, and a song bitterly opposing the union of the Parliaments in 1707. His versification had a compression and concentration not often found in later Gaelic poetry.

Other noteworthy 17th-century poets include Donnchadh MacRaoiridh, whose best-known poem consists of four calm, resigned verses composed on the day of his death; Alasdair MacKenzie and his son Murdo Mackenzie; and Roderick Morison, known as An Clarsair Dall (the Blind Harper), who became harper to Iain Breac MacLeod of Dunvegan. The strong texture and poetic intensity of Morison's *Oran do Iain Breac MacLeòid* ("Song to Iain MacLeod") and his *Creach na Ciadaoin* ("Wednesday's Bereavement") are remarkable. Dorothy Brown and Sìleas na Ceapaich were women poets of great talent.

Four other poets mark the transition from the poetry of the 17th century to that of the 18th: Lachlan MacKinnon (Lachlann Mac Thearlaich Oig); John Mackay (Am Pìobaire Dall), whose *Coire an Easa* ("The Waterfall Corrie") was significant in the development of Gaelic nature poetry; John Macdonald (Iain Dubh Mac Iain 'Ic Ailein), who wrote popular jingles; and John Maclean (Iain Mac Ailein), who showed an interest in early Gaelic legend. Finally, bardic poetry continued to be composed into the 18th century by Niall and Domhnall MacMhuirich.

Developments of the 18th century. Almost no secular poetry in Gaelic was printed before 1751, and most earlier verse was recovered from oral tradition after that date.

The influence of Alexander Macdonald

Much of the inspiration of Gaelic printing in the 18th century can be traced to Alexander Macdonald (Alasdair Mac Mhaighstir Alasdair), who published a Gaelic vocabulary in 1741 and the first Scottish Gaelic book of secular poetry, *Ais-eiridh na Sean Chánain Albannaich* ("Resurrection of the Ancient Scottish Tongue"), in 1751. He rallied his fellow Highlanders to Prince Charles Edward's cause in the '45 rising with *Brosnachadh nam Fineachan Gaidhealach* ("Incitement to the Highland Clans") and a song of welcome to the Prince. His masterpiece, *Birlinn Chlann Raghnaill* ("The Galley of Clanranald"), is an extravaganza, ostensibly a description of a voyage from South Uist in the Hebrides Isles to Carrickfergus in County Antrim, Northern Ireland. He also composed nature poems, love poems, drinking songs, and satires.

Duncan Ban Macintyre (Donnchadh Bàn Mac an t-Saoir), who was influenced by Macdonald, had his poems published in 1768. He fought on the Hanoverian side at the Battle of Falkirk and later praised George III in *Oran do'n Rìgh* ("Song to the King"), but he had been a forester on the Perthshire–Argyllshire borders in early manhood, and this is the setting of his greatest poems, *Moladh Beinn Dóbhrainn* (*The Praise of Ben Dorain*) and *Oran Coire a Cheathaich* ("Song of the Misty Corrie"). His most famous love song is addressed to his wife, Màiri.

Other poets of note in the 18th century included John MacCodrum, author of much humorous and satirical poetry; Robert (called Rob Donn) Mackay, who wrote social satire with a wealth of shrewd and humorous understanding of human nature; and William Ross, the Romantic poet of the group, several of whose best poems, such as *Feasgar Luain* ("Monday Evening") and *Oran Eile* ("Another Song"), were occasioned by an unhappy love affair.

The greatest composer of Gaelic religious verse in the 18th century was Dugald Buchanan, who assisted the Rev. James Stewart of Killin in preparing his Gaelic translation of the New Testament (1767). His *Latha à Bhreitheanis* ("Day of Judgment") and *An Claigeann* ("The Skull") are impressive and sombre and show considerable imaginative power.

Modern trends and works. Short stories and essays appeared in 19th- and 20th-century periodicals. Alongside these were numerous religious translations from the 17th century onward, including Calvin's catechism of 1631, Gaelic translations of the Old and New Testaments, Kirk's Psalter and his Irish version of the Bible, and the 1807 Gaelic Bible. Other translations included works by John Bunyan, Richard Baxter, Thomas Boston, and Philip Doddridge. Among original prose writers were the Rev. Donald Lamont, Donald Mackechnie, and Angus Robertson. The most notable modern short stories have been written by Colin Mackenzie, John Murray, and Iain Crichton Smith.

Little vital poetry appeared in the 19th century, and a 20th-century movement to free Gaelic poetry from its traditional shackles began with Sorley Maclean, George Campbell Hay, and Derick Thomson. This has been continued by Donald MacAulay and Iain Crichton Smith.

MANX

Although they succeeded in establishing their language on the Isle of Man, the Gaels lost their hegemony over the island to the Norse in the 9th century and recovered it only from 1266 to 1333, when they lost it again to the English. They were consequently unable to provide there, as they did in Ireland and Scotland, the aristocratic support needed by the bardic institution. This, and the fact that Manx and Scottish Gaelic did not deviate significantly from Irish until the 16th century, explains why no medieval literature specifically identifiable with the island survives, and why such modern literature as exists, apart from translation literature, is predominantly folklore.

The Reformation's slow progress on the island is reflected in the comparatively late appearance of a Manx translation of the Bible and the Book of Common Prayer. The latter was completed about 1610 by a Welshman, John Phillips, bishop of Sodor and Man, but it remained unpublished until it was printed in 1893–94 side by side with the 1765 version made by the Manx clergy.

Translating the Bible into Manx was indeed a formidable task because the clergy on whom it fell had but few scholars among them and no literary tradition to draw upon. A start was made in 1748 with the appearance of a Manx version of the Gospel According to St. Matthew. A revision of Matthew and a translation of the other Gospels and of the Acts appeared in 1763, and the remainder of the New Testament in 1767. The translation of the Old Testament was published in two parts: Genesis to Esther in 1771, Job to Malachi with two books of the Apocrypha in 1773.

The Holy Scriptures were not the only religious books to be translated. Bishop Thomas Wilson's *Principles and Duties of Christianity* appeared in English and Manx in 1699, and 22 of his sermons appeared in a Manx translation in 1783. More interesting are *Pargys Caillit,* the paraphrase translation of Milton's *Paradise Lost,* which was published in 1794 and reprinted in 1872, and *Coontey ghiare yeh Ellan Vannin* ("The Short Account of the Isle of Man"), written in Manx by Joseph Bridson and printed as the 20th volume of the Publications of the Manx Language Society. As late as 1901 there appeared from the press *Skeealyn Æsop,* a selection of Aesop's fables.

More characteristic of Manx folk culture were the ballads and carols, or *carvels.* Among the most notable of the former are an Ossianic ballad describing the fate of Finn's enemy, Orree; the Manx Traditionary Ballad, a history of the island to the year 1507 made up of a mixture of fact and fiction; and the ballad on the death of Brown William; *i.e.,* William Christian, shot as a traitor in 1663. The *carvels* differ from English carols because they take as their subject not so much the Nativity as the life of Jesus, his crucifixion, and the Last Judgment. They were sung by individuals in church on Christmas Eve. With the spread of Nonconformity on the island, Manx translations of some of the popular hymns of the Methodist Revival were published.

WELSH

Taliesin and Aneirin

Literature of the Middle Ages. *Poetry.* Welsh literature has extended in an unbroken tradition from about the middle of the 6th century to the present day, but, except for two or three short pieces, all pre-Norman poetry has survived only in 12th- to 15th-century manuscripts. Welsh had developed from the older Brythonic by the middle of the 6th century. In the *Historia Brittonum* (*c.* 800) references are made to Welsh poets who, if the synchronism is correct, sang in the 6th century. Works by two of them, Taliesin and Aneirin, have survived. Taliesin wrote odes, or *awdlau,* in praise of the warlike deeds of his lord, Urien of Rheged, a kingdom in present-day southwest Scotland and northwest England. To Aneirin is attributed a long poem, *Y Gododdin,* commemorating in elegies an ill-starred expedition sent from Gododdin, the region where Edinburgh stands today, to take Catraeth (Catterick, North Yorkshire) from the invading Saxons. The background, inspiration, and social conventions of the poems of Taliesin and Aneirin are typically heroic, the language is direct and simple, and the expression terse and vigorous. These poems, and others that have not been preserved, set standards for later ages. The alliterative verse and internal rhyme found here were developed by the 13th century into the intricate system of consonant and vowel correspondence, or consonant correspondence and internal rhyme, called cynghanedd.

The heroic tradition of poetry existed also in Wales proper and was continued after the break with North Britain in the mid-7th century. The earliest surviving example is a poem in praise of Cynan Garwyn of Powys, whose son Selyf was slain in battle. This poem struck a note that remained constant in all Welsh eulogies and elegies down to the fall of the Welsh bardic system: Cynan is the bravest in the field, the most generous in his home, all others are thrall to him and sing his praises.

The period between the 7th and 10th centuries is represented by a few scattered poems, most of them in the heroic tradition, including *Moliant Cadwallon* ("The Eulogy of Cadwallon"), by Afan Ferddig, the elegy on Cynddylan ap Cyndrwyn of Powys in the first half of the 7th century, and *Edmyg Dinbych* ("The Eulogy of Tenby"), by an unknown South Wales poet. Poetry claiming to foretell the future is represented by *Armes Prydain Fawr* ("The Great Prophecy of Britain"), a stirring appeal to the Welsh to unite with other Britons, with the Irish, and with the Norse of Dublin to oppose the Saxons and to refuse the unjust demands of their "great king," probably Athelstan of Wessex. Poetry outside the main bardic tradition is preserved in englyns (stanzas of three of four lines), a dialogue between Myrddin and Taliesin, and in *Kanu y Gwynt* ("The Song of the Wind"), a riddle poem that contains the germ of the later convention known as *dyfaliad* (kenning).

The poems of Llywarch Hen

The poems associated with the name Llywarch Hen are the verse remains of at least two sagas composed toward the middle of the 9th century by an unknown storyteller of Powys, whose basic material was the traditions associated with the historical Llywarch and Heledd, sister to Cynddylan ap Cyndrwyn. In these, it seems that prose (now lost) was used for narrative and description and verse for dialogue and soliloquy. The metrical form was embellished by alliteration, internal rhyme, and incipient cynghanedd. The theme of both sagas was lamentation for the glory that once had been. The background was the heroic struggle of the Welsh of Powys against the Saxons of Mercia. Some fragments of poetry preserved in the *Black Book of Carmarthen* (12th century) were parts of soliloquies or dialogues from other lost sagas. Examples are a conversation between Arthur and the doorkeeper Glewlwyd Mightygrasp; a monologue of Ysgolan the Cleric; verses in praise of Geraint, son of Erbin; and a fragment of what may be an early native version of the Trystan and Esyllt (Tristan and Iseult) story. The manuscript shows that there once existed a legend of Myrddin Wyllt, a wild man of the woods who went mad at the sight of a battle, a legend associated with Suibne Geilt in Ireland and with Lailoken in Scotland. This Myrddin (later better known as Merlin) had the gift of prophecy. The historical poet Taliesin also became the central prophetic figure in a folk tale that was given literary form in the 9th or 10th century, but that has survived only in certain monologues preserved in *The Book of Taliesin* and in garbled versions in late texts of *Hanes Taliesin* ("Story of Taliesin").

Nature, a source of similes in the heroic poetry and of symbolism in verse fragments of the sagas, was sometimes a subject of song in its own right. Generally, treatment of the subject was remarkable for its sensitive objectivity, its awareness of form, colour, and sound, and its concise, often epigrammatic, expression. In mood, matter, and form (that of the englyn) it often overlapped with gnomic poetry, which consisted of sententious sayings about man and nature. Most gnomic and nature poems were probably produced in the 10th and 11th centuries by poets other than professional bards. Toward the end of the pre-Norman period a few poems on religious, biblical, and other subjects showed acquaintance with nonnative legends. Saga poetry gradually gave way to prose.

The poets of the princes

With the consolidation of the principality of Gwynedd under Gruffudd ap Cynan (1054–1137) and his descendants, court poetry flourished in the country, composed by the *gogynfeirdd,* or poets of the princes, who continued and developed the tradition of their predecessors, the *cynfeirdd.* The bardic order seems to have been reorganized, although no clear picture of it emerges from references in the poetry and law texts, and it seems to have been less schematized in practice than in theory. At the top of the order was the *pencerdd* ("chief of song or craft"), the ruler's chief poet, whose duty was to sing the praise of God, the ruler, and his family. Next came the *bardd teulu,* who was the poet of the ruler's war band although he seems to have been poet to the ruler's family as well. There were other, less exalted grades, with less exalted duties and the license probably to engage in satire and ribaldry.

The bardic hierarchy

Bards were also graded according to proficiency. This classification led, under Henry IV, to the holding of an eisteddfod, or a session of bards to confer certificates of proficiency and to prevent the lower orders from proliferating and drifting into mendicancy. One of the results of a bardic system of this type was a remarkable conservatism in literature. Most of the 13th-century bards used a conventional diction that was consciously archaic in its vocabulary, grammar, and idiom and incomprehensible to anyone uneducated in poetry.

Bardism often went by families, and among the first court poets were Meilyr, his son Gwalchmai, and his grandson Meilyr ap Gwalchmai, who were attached to the court of Gwynedd at Aberffraw. Gwalchmai in his *Arwyrain Owain* ("Exaltation of Owain") displayed one characteristic of all the *gogynfeirdd,* description of water, whether of river or sea. Bardic poetry, highly conventional in form, was now marked not by profundity but by adornment and linguistic virtuosity. Two poet-princes, Owain Cyfeiliog of Powys and Hywel ab Owain of Gwynedd, however, stand out from contemporary bards. Cyfeiliog's most famous work, the *Hirlas Owain* ("Owain's Long Blue Drinking Horn"), celebrates a victorious raid; Hywel ab Owain's departure from convention was more striking; for the first time in Welsh literature love of country and of beauty in the modern sense appeared: land and sea and women and the

Welsh language spoken in cultured accent by his ladylove awoke in him feelings of awe and wonder. The *gogynfeirdd* poetry alternated throughout this period between *marwnad* ("elegy") and *moliant* ("eulogy"), and the period closed with the most famous of all elegies, Gruffudd ab yr Ynad Coch's elegy after the death in 1282 of Llywelyn ap Gruffudd, last native prince of Wales.

The religious verse of the *gogynfeirdd* was generally simpler in style than the eulogies and elegies. A set type was the *marwysgafn* ("deathbed song"), in which the poet, sensing the approach of death, confessed his sins and prayed for forgiveness. Other religious poems were in praise of God and the Trinity, in honour of saints, on the torments of hell, and on the birth of Christ. They illustrate the gradual widening of the bardic horizon.

With the passing of princes and their pageantry, the poets were forced to find patrons among the new aristocracy. These patrons had more limited means and less restricted interests, with the result that the bardic system and its educational basis were gradually changed and a new kind of poetry was produced. The language became less esoteric, less specialized. Poets in the years between the English conquest (1282) and the appearance of Dafydd ap Gwilym (flourished *c.* 1340–70) seem to have returned to an earlier poetic fashion or to have been influenced by new ideas from other lands. Famous in this period of transition were Gruffudd ap Maredudd, Gruffudd ap Dafydd, and Casnodyn.

The golden age of the cywydd

The conquest of Wales by Edward I transferred the patronage of court poetry at Gwynedd and Powys from prince to landed aristocracy. The *pencerdd* lost his superiority over the lower bardic ranks, who were no longer restricted in choice of content and style, and who, especially in South Wales (where the Norman Conquest had been established for a whole century before the conquest of Gwynedd), became more vocal as the older bardic song began to decline. The new poets of the south were well established before their works began to be preserved. The most important of them was Dafydd ap Gwilym (a contemporary of Chaucer), who in his early period wrote according to two distinct traditions. He wrote *awdlau,* or odes, in the manner of the later *gogynfeirdd.* (Originally an *awdl* was a poem with a single end rhyme throughout; later it contained sequences of lines with such end rhymes. In both cases the lines were embellished with alliteration, a correspondence of consonants or internal rhyme; *i.e.,* "free" or incipient cynghanedd.) In the manner of a more popular and perhaps lower class of poets, Dafydd ap Gwilym wrote cywyddau, composed of couplets of seven-syllable lines rhyming in alternately stressed and unstressed final syllables. Each line was embellished by a stricter form of cynghanedd, the *cynghanedd gaeth.* Dafydd established, if he did not invent, the cywydd, but his main achievement was the simplicity of diction he cultivated in it. His successors followed his lead; the old diction became obsolete, and he thus established the standards of modern Welsh. The substance of his poetry was also new, for he seems to have borrowed many of his themes from the wandering minstrels and trouvères of France. He wrote love poetry but perhaps is best known for his descriptions of nature.

Dafydd ap Gwilym's influence

Dafydd's influence was twofold: the cywydd was established as the leading form, and the new subjects were recognized as fit themes for poetry. One contemporary, Gruffudd ab Adda, went much further toward a modern conception of nature; another, Iolo Goch, in his poem to the husbandman shows traces of English ideas, as seen in *Piers Plowman.* Llywelyn Goch Amheurug Hen wrote some early poems in the *gogynfeirdd* tradition, but his "Elegy to Lleucu Llwyd" successfully combined the Welsh elegy tradition with the imported serenade form.

In the 15th century the cywydd was refined. Although Dafydd Nanmor was inferior to most of Dafydd ap Gwilym's contemporaries in treatment of his subject and in imagination, in his mastery of the cywydd form he had no equal. Further advances in the cywydd metre were made by Lewis Glyn Cothi and Guto'r Glyn, in whose work a real consciousness of Welsh nationhood is seen.

Prose. The earliest examples of Welsh prose were utilitarian: notes on Latin texts dealing with weights and measures, an agreement, a list of church dues, and an astronomical commentary. Shortly before the middle of the 10th century Howel (Hywel) Dda, according to tradition, had the Welsh laws codified. Although the earliest Welsh law manuscripts belong to the first half of the 13th century, some of the texts probably derive from 12th-century and earlier exemplars.

The *Mabinogion* collection of tales

The stylistic merits of the legal texts were reflected in a more conscious literary use of prose by storytellers (*cyfarwyddiaid*), who recited oral tales made up of a medley of mythology, folklore, and heroic elements. Some of these were recorded in writing; the most famous collection is the *Mabinogion,* preserved in *The White Book of Rhydderch* (*c.* 1300–25) and *The Red Book of Hergest* (*c.* 1375–1425). The *Mabinogion* are composed of 11 anonymous tales, based on older oral material. The greatest are the four related stories "The Four Branches of the *Mabinogi,*" redacted in the second half of the 11th century by a writer from Dyfed. The author of "Culhwch and Olwen" (*c.* 1100), drawing on material akin to that of the "Four Branches," appears to have kept closer to the oral tale, but his inferior stylistics presaged the later decadent *areithiau* ("rhetorics"), which were in part parodies of the *Mabinogion.* Three of the *Mabinogion* tales, "Owain and Luned" (or "The Lady of the Fountain"), "Geraint and Enid," and "Peredur Son of Efrawg," represented a transition from purely native tales to those composed under Norman influence. These romances correspond to the *Yvain, Erec,* and *Perceval* of Chrêtien de Troyes, and the exact relationship between the Welsh and French texts has long been debated. Although more sophisticated, they show a decline from the directness and restraint of the native tales.

Many translations from Latin and French helped to create a prose that could express aspects of life rarely touched on in the tales. Most of them dated from the 13th and 14th centuries and were probably made by monks. Notable among them were translations from the Latin of Geoffrey of Monmouth's *Historia regum Britanniae* and the French of the *Queste del Saint Graal* and *Perlesvaux.* Their prose was largely experimental and influenced in varying degrees by the language and style of the originals, but at its best it was a not unworthy development of the prose of the law tracts and native tales.

The development of medieval prose was hampered by a gap between Welsh literary tradition and the wider learning of western Europe. The inspiration for the fashioning of a prose able to express all facets of thought and activity arose toward the middle of the 16th century out of the Reformation and the Renaissance, from foundations laid by humanists, both Protestant and Catholic.

The Reformation and the Renaissance. After the outstanding period of Dafydd ap Gwilym and his followers in the cywydd, there arose for a short time a school of literary formalists. The chief of these was Dafydd ab Edmwnd, whose poetic heirs were Tudur Aled (died 1526) and Gutun Owain (flourished *c.* 1460–1500).

Effects of the Reformation and the accession of the Tudors

The Reformation broke the hold of the Roman Catholic religion on Welsh life without establishing at the same time a similar hold of its own. The Tudor policy of encouraging the spread of English at the expense of Welsh and of inducing the Welsh aristocracy to emigrate to England almost destroyed the old Welsh culture, completely bound up as it was with the language. Yet fine poetry was written by the satirists Siôn Tudur and Edmwnd Prys. Other masters of the cywydd were William Llŷn and Siôn Phylip.

The rise of modern prose. When printing began in Wales in the 16th century, traditional prose was abandoned by the Renaissance humanists. The new prose they fashioned was based on bardic language and classical authors, enriched by new formations and borrowings. The first Welsh printed book, *Yn y lhyvyr hwnn* (1547; "In This Book"), consisted of extracts from the Scriptures and the prayer book: from this time modern Welsh prose began to assume definite form.

The Reformation. The most important figure of the Reformation was William Salesbury, who translated most of the New Testament of 1567. Despite some eccentricities, it was a fine piece of translation. In the same year was published the Welsh Prayer Book, also translated mainly by Salesbury in collaboration with Richard Davies, bishop of St. David's. The Welsh Bible translated by William Morgan, bishop of St. Asaph, aided by Edmwnd Prys, was published in 1588. The revised version, published in 1620, is still used. It would be difficult to exaggerate the importance of these three translations in the development of Welsh prose. They started a steady, if not large, stream of Welsh prose books. The first were translations from English and Latin aimed at grounding the Welsh nation in the principles of the Reformation.

The Counter-Reformation. While the reformed religion was being established in Wales, Welsh society and the Welsh language were at their lowest ebb. The Roman Catholic writers of the Counter-Reformation regarded the new religion as an English import and struggled to preserve old Roman Catholic culture. As a result there appeared *Dosparth Byrr* ("A Short Rationale"), the earliest printed Welsh primer, the work of Gruffydd Robert (*c.* 1522–*c.* 1610), and several religious works, many of which were published on the Continent.

The Welsh Renaissance. Just as Italy and other European countries during the Renaissance turned to the Latin and Greek classics, so Wales turned to its own classical tradition of bardism. In addition to Gruffydd Robert's primer mentioned above, there appeared a set of rules for bardic poetry and principles of the Welsh language compiled by Siôn Dafydd Rhys and a dictionary and a grammar by John Davies of Mallwyd.

Religious emphasis in Welsh writing

Welsh literature in the 17th century. *Prose.* So far, writers of Welsh prose had contented themselves with translation, until Morgan Llwyd produced his religious works. A Puritan, he made an original contribution to Welsh religious thought, chiefly in *Llyfr y Tri Aderyn* (1653; "The Book of the Three Birds"), a disquisition on government and religious liberty, and *Llythur ir Cymru Cariadus* (*c.* 1653; "Letter to the Beloved Welsh"), which expounded a mystical gospel. Among the clergy who produced some of the many translations, mostly of religious originals, during this period were Edward Samuel; Moses Williams, a diligent searcher into manuscripts; Griffith Jones, the father of Welsh popular education; and Theophilus Evans, author of *Drych y Prif Oesoedd* (1716; *A View of the Primitive Ages*). Ellis Wynne o Lasynys is often regarded as the greatest of Welsh prose writers. His two great works were *Rheol Buchedd Sanctaidd* (1701), a translation of Jeremy Taylor's *Rule and Exercises of Holy Living,* and *Gweledigaetheu y Bardd Cwsc* (1703; *The Visions of the Sleeping Bard*), an adaptation of a translation of the *Sueños* of the Spanish poet Quevedo.

Poetry. When Henry VII came to the throne, the old Welsh gentry turned toward England for preferment. Soon, poets of the older school had no audience, and only the rich gentlemen farmers kept up the old tradition. A new school, however, was rising that combined a vast store of folk song, previously despised and unrecorded, with imitation of contemporary English popular poetry and sophisticated lyrics. Landmarks of this new development were Edmwnd Prys's metrical version of the Psalms and Rhys Prichard's *Canwyll y Cymry* (1646–72; "The Welshman's Candle"), both written in so-called free metres. Prys's Psalter contained the first Welsh metrical hymns. Prichard's work consisted of moral verses in the metres of the old folk songs (*penillion telyn*). Many other poets wrote in these metres, but they were generally crude until handled by the greatest poet of the period, Huw Morus, who was particularly famous for his love poems. Later came Lewis Morris, the inspirer and patron of Goronwy Owen and thus a strong link with the next extremely productive period.

Owen's poetic reforms

The 18th century: the first revival. The mid-18th century was, after the 14th, the most fruitful period of Welsh literature. Goronwy Owen, inspired by English Augustanism, reintroduced and improved the strict metres of the cywydd and *awdl* (by this time a long poem written in a number of the classical cynghanedd metres). He also introduced a wide range of subject content, and thus founded a new classical school of Welsh poetry. The more important poets of this school were William Wynn of Llangynhafal, Edward Richard, and Evan Evans (Ieuan Fardd). Much of their activity was associated with the Welsh community in London and the Cymmrodorion Society and led to the establishment of local eisteddfods in Wales, which perpetuated the classical forms of Welsh poetry.

Chief among Owen's successors was David Thomas (Dafydd Ddu Eryri), who, however, like other eisteddfodic bards of this period, soon departed from classical strictness.

The classicists of the 18th century stood aloof from the Methodist Revival, but religious fervour brought a new articulateness and inspired poets in free metre, especially hymn writers like the preeminent William Williams of Pant-y-celyn and the mystical Ann Griffiths.

For a long time after 1750, Welsh prose was mainly concerned with religious subjects. The French Revolution, however, gave impetus to political writing, and among those it influenced was John Jones (Jac Glan-y-gors). It was only after a periodical press had been established that politics began to compete with religion as a subject for comment.

19th-century literary trends. *Poetry.* Strict metre poetry declined in the 19th century. Although the volume produced was enormous, the quality was poor. Eben Fardd was probably the last of the eisteddfodic poets to make any real contribution. The influence of the hymn writers of the 18th century was seen in the development of the lyric. In fact, all the poetry of the 19th century betrays a religious origin. The influence of contemporary English songs was also seen, as in the work of John Blackwell (Alun). More originality was shown by Evan Evans (Ieuan Glan Geirionydd), who founded the Eryri school of poetry, inspired by the scenery of Snowdonia. The earlier lyricists were followed by a more bohemian group—Talhaiarn (John Jones), Mynyddog (Richard Davies), and Ceiriog (John Hughes), the latter the greatest lyrical writer of the century. Only one poet, Islwyn (William Thomas), made a success of the long poem: his *Y Storm* is a series of meditations on life and art.

Prose. This was the most prolific period of Welsh prose, though much of it was of poor quality, partly because it was produced by a people who had had little formal education in their own language and who had lost touch with their own literary past. Much of it was marred also by the pretentious style of the followers of William Owen Pughe, who tried to "restore" literary standards. A tremendous volume of prose was produced—periodicals, religious books and tracts, biographies, sermons, letters, and monumental works such as *Y Gwyddoniadur* ("The Encyclopaedia") and *Hanes y Brytaniaid a'r Cymry* ("History of the Britons and the Welsh"). Political writings became an important part of Welsh literature, the two great political writers of the century being Samuel Roberts and Gwilym Hiraethog (William Rees). Lewis Edwards, founder and editor of *Y Traethodydd* ("The Essayist"), tried to introduce a wider, European standard of literary criticism. There were some interesting attempts at creative writing, but the only great novelist was Daniel Owen, whose work portrays the extraordinary influence of religion on contemporary society.

Welsh literary renaissance

The second revival. The most important event for the second revival in Welsh literature was the establishment of the University of Wales (1872–93). The immediate result was a great widening of literary horizons, accompanied by a strong reaction toward the old Welsh classical ideas. Sir Owen M. Edwards, Sir John Morris-Jones, Emrys ap Iwan (Robert Ambrose Jones), and others made the Welsh conscious of their literary identity and set new standards for correctness of language and integrity of thought. The great literary renaissance that followed was marked by T. Gwynn Jones's masterly use of the old strict metres to express modern thought and W.J. Gruffydd's lyrical use of the free metres to express his rebellion against society and his love for the countryside of his youth. R. Williams Parry showed a superb gift of poetic observation, while Sir Thomas Parry-Williams combined a mystical love for his native Gwynedd with an almost scientific analysis of his own metaphysical preoccupations. Older poets, such as Cynan (A. Evans-Jones), William Morris, and Wil Ifan (William Evans), clung to earlier lyrical models, although many others, like D. Gwenallt Jones and Saunders Lewis, drew increasingly on the rhythms and vocabulary of colloquial speech. Waldo Williams, Gwilym R. Jones, the younger Bobi Jones, and particularly Euros Bowen experimented with form and subject. Their work has been followed and developed by writers of the younger generation, the most distinctive and prolific being Gwyn Thomas. Interest in the use of the strict metres of cynghanedd has revived, as reflected in the publication of the popular periodical *Barddas* ("Bardism"). Most poets, old and young, reflect a varying involvement in contemporary Welsh political activity.

The high standard of the periodical *Y Llenor* ("The Litterateur"; 1922–51) indicated the advances made in prose. Contributors were generally involved in a wide range of activities: its editor, W.J. Gruffydd, was both poet and essayist; Saunders Lewis was a poet, dramatist, and politician; Sir Thomas Parry-Williams a poet and essayist; and R.T. Jenkins an essayist and historian. Together with novelists and short-story writers like Tegla Davies, T. Rowland Hughes, Kate Roberts, and D.J. Williams, they effectively mirrored contemporary Wales. John Gwilym Jones and Islwyn Ffowc Ellis were innovators in form and subject matter, and they were followed by an enthusiastic younger generation. Literary criticism has also benefited. The standard set by *Y Llenor* has been maintained in *Ysgrifau Beirniadol* ("Critical Essays"). In this field as in others the establishment of the Welsh Academy (Yr Academi Gymreig) in 1959 and the publication of its review *Taliesin* have made an outstanding contribution.

Drama in Wales was first written in the 20th century. At first realistic, it developed into poetic, symbolic drama, often based on historical and mythological themes but dealing with moral, social, and psychological contemporary problems. The outstanding names are Saunders Lewis, John Gwilym Jones, Emyr Humphreys, and Gwenlyn Parry.

CORNISH

The oldest remains of Cornish are proper names in the Bodmin Gospels and in the Domesday Book, 10th-century glosses on Latin texts, and a 12th-century vocabulary based on Aelfric's Latin–Anglo-Saxon glossary. The earliest literary text in Middle Cornish is a 41-line fragment of a drama, written about 1400, in which a girl is offered as wife, praised for her virtues, and counseled on her behaviour. The other plays that have survived complete or in part are related to the medieval miracle and morality plays.

Of these the most important is the *Ordinalia,* a trilogy written in Middle Cornish (probably late 14th century) and designed to be acted on three consecutive days, perhaps in a *plen-an-gwary* ("play-field"). The first play, the *Origo Mundi* ("Origin of the World"), is based on the Old Testament and serves as a prologue to the other two, the *Passio Domini Nostri Ihesu Christi;* and the *Resurrexio Domini Nostri Ihesu Christi.* Lacking a treatment of the Nativity and of the ministry of Jesus, the scheme underlying the *Ordinalia* is more like that of the great French Passions than that of the English Corpus Christi cycle.

The *Pascon Agan Arluth* ("Passion of Our Lord"), of which 259 stanzas have survived, has passages common to the *Ordinalia* and must have been composed about the same time.

Beunans Meriasek ("The Life of Meriasek [or Meriadoc]"), on the patron saint of Camborne, is held to be considerably later: the manuscript in which it is found was completed in 1504 by one Dominus Hadton, thought to have been a canon of the Collegiate Church of Glasney. *Gwreans an Bys* ("The Creation of the World"), surviving in a text written in 1611, was intended to be the first of three plays and seems to be an extended and reworked version of the *Origo Mundi.* Written in Late Cornish, it is the latest of the Cornish religious plays.

The Protestant Reformation destroyed the mentality that had created and enjoyed these plays, although there is evidence that the destruction was slow. Unfortunately the Reformation provided no work in the Cornish language that could take the place of the plays. A few people recognized that the Bible and the Book of Common Prayer should be made accessible to the monoglot Cornishmen, but little was done to that end. John Tregear translated into Cornish 12 of Bishop Edmund Bonner's sermons and a 13th sermon from an unidentified source, and it is probably significant that this translation was lost and not rediscovered until 1949.

Attempts have been made to revive the use of Cornish as a spoken and written language. Among the societies and movements that have worked to this end are the Cornish-Celtic Society, The Old Cornwall Society, Land and Language, The Sons of Cornwall, and The Cornish Language Board; and among the papers or periodicals these have promoted, *Kernow* ("Cornwall"), *An Lef* ("The Voice"), *An Lef Kernewek* ("The Cornish Voice"), and *Hedhyu* ("Today") have been notable for the attention they have given to compositions in Cornish—mostly poems, short stories, and short plays. Among the Cornish language revivalists are Henry Jenner, R. Morton Nance, and A.S.D. Smith.

BRETON

The three major periods of Breton literature. Old Breton (8th to 11th century) is found only in lists and glosses in documents or as names in Latin books and charters. From the Middle Breton period (11th to 17th century) the 11th- to 15th-century compositions were mainly oral, and little except a few scraps of verse is extant until the late 15th century, when there appeared the *Catholicon* of Jean Lagadeuc, a Breton–Latin–French dictionary printed in 1499, and Quiquer de Roscoff's French–Breton dictionary and conversations (printed 1616).

A 17th-century collection, *Cantiques bretons* (1642), names several Breton airs. All the remaining works of the middle period were religious and mostly in verse. Three mystery plays were probably the most significant products of the period: *Buez santez Nonn* ("Life of St. Nonn"), *Burzud bras Jesuz* ("The Great Mystery of Jesus"), and *Buhez santes Barba* ("Life of St. Barbara"). Three long poems, "Tremenvan an itron gwerches Maria" ("The Passion of the Virgin Mary"), "Pemzec levenez Maria" ("The Fifteen Joys of Mary"), and "Buhez mabden" ("The Life of Man"), were all probably based on French versions. A book of hours in verse, a prose extract from the Leon missal, and a prose catechism belong to this period, as does the prose *Buhez an itron sanctes Cathell, guerches ha merzeres* ("Life of St. Catherine, Virgin and Martyr"). *Am Mirouer a Confession* ("The Mirror of Confession") and *Doctrin an Christenien* ("Christian's Doctrine") are translated from the French. A collection of carols, *An Nouelou ancient ha devot* ("Ancient and Devout Songs"), appeared in 1650, and a book of metrical meditations in 1651. In general, Middle Breton literature lacked originality, and the indigenous culture of Brittany seems to have been entirely neglected by the educated classes, who introduced an enormous number of French words into the vocabulary.

Modern Breton is said to have begun in 1659, when Julien Maunoir introduced a more phonetic orthography, but works of the Middle Breton type appeared until the 19th century. The bulk of Breton literature in this period consisted of mystery and miracle plays treating subjects from the Old and New Testaments, saints' lives, and stories of chivalry derived from French or Latin. Even plays depicting Breton saints evinced little originality. In the 18th century many Breton dictionaries were published but little of literary significance was produced. One name survives: Claude-Marie Le Laë, who wrote satiric poems.

The revival of Breton literature. Interest in Breton, which revived at a time when France's central government was trying to impose French on Brittany and destroy the regional language, was particularly stimulated with the publication of the celebrated *Barzaz Breiz* (originally *Barzas-Breiz,* 1839; "Breton Bardic Poems"). This collection of poems was compiled by Théodore Hersart de La Villemarqué, who declared that they had survived unchanged as part of Breton folklore. Breton-speaking scholars doubted the collection's authenticity, and attacks reached their height when R.-F. Le Men, in a reprinting

Barzaz Breiz

in about 1870 of *Catholicon,* and François-Marie Luzel, in a paper delivered in 1872, showed that *Barzaz Breiz* was not authentic (though scholars during the period often edited such collected material). *Barzaz Breiz* led to a renaissance of Breton writing and stimulated Luzel to collect authentic folk songs and publish *Gwerziou Breiz-Izel* (2 vol., 1868–74; "Ballads of Lower Brittany") and, in collaboration with Anatole Le Braz, *Soniou Breiz-Izel* (2 vol., 1890; "Folk Songs of Lower Brittany"). In the 1980s Donatien Laurent, the first to have had access to Villemarqué's papers, demonstrated that some of the poems were authentic.

Prose. Luzel also collected folktales and legends, publishing many in Breton as well as in French translation. His collaborator, Le Braz, published stories concerning *an ankou* ("death"), as *La Légende de la mort* (1893; *Dealings with the Dead*). Traditional and literary elements combined indistinguishably in many stories. When Breton writers did not depend on folk legends for material, they fictionalized their own life stories. The many improving religious works published were not at all original; yet many Bretons who have read only one book in their own language have read *Buez ar Zent* ("Lives of the Saints").

Most playwrights were concerned to teach moral and religious lessons, such as Toussaint Le Garrec and Abbé J. Le Bayon, who revived several great mystery plays—*Nicolazig, Boeh er goed* ("The Voice of the Blood"), *Ar hent en Hadour* ("In the Steps of the Sower"), and *Ar en hent de Vethleem* ("On the Way to Bethlehem").

Poetry. For 200 years Bretons expressed their feelings in poems that were published as pamphlets—either as *soniou* (love songs, satires, carols, marriage lays) or *gwerziou* (ballads or broadsides describing recent events in Brittany and elsewhere). Their authors were people of every social class, and the poems were hawked at fairs. Dozens of poets published collections after the appearance of *Barzaz Breiz.*

20th-century Breton writers

Developments of the 20th century. Collections of folklore continued to appear, but there was an ever-increasing realization that the reading public needed a literature reflecting contemporary life. Literary periodicals attempted to satisfy the need. Worthy of special mention are *Dihunamb* (1905; "Let Us Wake Up"), *Gwalarn* (1925–44; "North West"), and *Al Liamm* (1946; "The Bond"). Tangi Malemanche was a prolific playwright but gained little recognition. Per-Jakez Helias as poet, playwright, and radio script writer has been both prolific and popular. The reminiscences of Yeun ar Go in *E Skeud Tour Bras Sant Jermen* (1955; "In the Shadow of the Great Tower of Saint-Germain") and continued in *Al Liamm* have great charm. But the three writers who can claim to have done most to give Brittany a 20th-century Breton literature have been Jakez Riou and Youenn Drezen, authors of short stories and novellas, and Roparz Hemon, who has enriched every genre. Maodez Glanndour has given of his best to poetry. As one would expect in a literature in which little prose was written until the 20th century, verse continues to attract the attention and the skill of young and old writers. One of its recurring themes is the fear that the Breton language will die.

(D.Gr./D.S.T./T.Jo./J.E.C.W.)

BIBLIOGRAPHY

General works: For a survey of modern Celtic literatures, see J.E. CAERWYN WILLIAMS (ed.), *Literature in Celtic Countries* (1971). Other works on Celtic literatures include H. MUNRO CHADWICK and N. KERSHAW CHADWICK, *The Growth of Literature,* vol. 1, *The Ancient Literatures of Europe* (1932, reprinted 1968); KENNETH JACKSON, *Studies in Early Celtic Nature Poetry* (1935, reprinted 1977), and *A Celtic Miscellany: Translations from the Celtic Literatures,* rev. ed. (1971); PIERRE-YVES LAMBERT, *Les Littératures celtiques* (1981); MAGNUS MACLEAN, *The Literatures of the Celts* (1902, reprinted 1970); and ALWYN REES and BRINLEY REES, *Celtic Heritage: Ancient Tradition in Ireland and Wales* (1961, reprinted 1978). See also RACHEL BROMWICH, *Medieval Celtic Literature: A Select Bibliography* (1974).

Irish Gaelic: General works include AODH DE BLÁCAM, *Gaelic Literature Surveyed* (1929, reprinted 1974), a popular account; MYLES DILLON, *Early Irish Literature* (1948); PROINSIAS MAC CANA, *Literature in Irish* (1980); FRANK O'CONNOR, *A Short History of Irish Literature: A Backward Look* (U.K. title, *The Backward Look: A Survey of Irish Literature,* 1967); JAMES CARNEY, *Studies in Irish Literature and History* (1955, reissued 1979); ROBIN FLOWER, *The Irish Tradition* (1947, reprinted 1979); DOUGLAS HYDE, *A Literary History of Ireland from Earliest Times to the Present Day,* new ed. (1967, reprinted 1980); ELEANOR KNOTT and GERARD MURPHY, *Early Irish Literature* (1966); BRIAN Ó CUÍV (ed.), *Seven Centuries of Irish Learning: 1000–1700,* 2nd ed. (1971); PATRICK C. POWER, *A Literary History of Ireland* (1969); and J.E. CAERWYN WILLIAMS and MÁIRÍN NÍ MHUIRÍOSA, *Traidisiún Liteartha na nGael* (1979).

Studies of Irish Gaelic poetry include DAVID GREENE and FRANK O'CONNOR (eds.), *A Golden Treasury of Irish Poetry A.D. 600 to 1200* (1967), with excellent translations; TADHG DALL Ó HUIGINN, *A bhfuil aguinn dár chum Tadhg Dall Ó Huiginn (1550–1591),* ed. and trans. by ELEANOR KNOTT, 2 vol. (1922–26), one of the best studies of the bardic system and technique, with English translations of Ó Huiginn's poems (vol. 2); OSBORN BERGIN, *Irish Bardic Poetry* (1970); ELEANOR KNOTT, *Irish Classical Poetry,* rev. ed. (1966, reprinted 1974); SEÁN MAC RÉAMOINN, *The Pleasures of Gaelic Poetry* (1982); GERARD MURPHY, *Early Irish Lyrics, Eighth to Twelfth Century* (1956, reprinted 1970); and SEÁN Ó TUAMA, *An Duanaire: An Irish Anthology: 1600–1900, Poems of the Dispossessed,* trans. by THOMAS KINSELLA (1981).

(1867, reprinted 1981); F.M. LUZEL (ed.), *Gwerziou Breiz-Izel: chants populaires de la Basse-Bretagne,* 2 vol. (1868–74), and *Soniou Breiz-Izel: chansons populaires de la Basse-Bretagne,* 2 vol. (1890), both studies reprinted as *Chants et chansons populaires de la Basse-Bretagne,* 4 vol. (1971); FRANCIS GOURVIL, *Langue et littérature bretonnes* (1952, reissued 1976), and *Théodore-Claude-Henri Hersart de La Villemarqué (1815–1895) et le "Barzaz-Breiz" (1839–1845–1867)* (1960), a study critical to the understanding of 19th-century Breton literature and Breton literary movements; JOSEPH ROUSEE, *La Poésie bretonne au XIX^{e} siècle* (1895); YVES MARIE RUDEL, *Panorama de la littérature bretonne, des origines à nos jours* (1950).

(J.E.C.W.)

Censorship

To censor is to act so as to change or suppress speech or writing that is condemned as subversive of the common good. This article discusses censorship and its relation to government and the rule of law.

The article is divided into the following sections:

Concerns relevant to censorship

THE STATUS OF "INDIVIDUALITY"

Censorship, as a term in English, goes back to the office of censor established in Rome in 443 BC. That officer, who conducted the census, regulated the morals of the citizens counted and classified. But, however honourable the origins of its name, censorship itself is today generally regarded as a relic of an unenlightened and much more oppressive age.

Illustrative of this change in opinion is how a community responds to such a sentiment as that with which Protagoras (*c.* 485–410 BC) opened his work *Concerning the Gods:*

> About the gods I am not able to know either that they are, or that they are not, or what they are like in shape, the things preventing knowledge being many, such as the obscurity of the subject and that the life of man is short.

This public admission of agnosticism scandalized Protagoras' fellow Greeks. Such statements would no doubt have been received with hostility, and probably with social if not even criminal sanctions, throughout the ancient world. There are few places in the modern world, on the other hand, where such a statement cannot be made without the prospect of having to endure a pained and painful community response. This change reflects, among other things, a profound shift in opinion as to what is and is not a legitimate concern of government.

Whereas it could once be maintained that the law forbids whatever it does not permit, it is now generally accepted—at least wherever Western liberalism is in the ascendancy—that one may do whatever is not forbidden by law. Furthermore, it is now believed that what may be properly forbidden by law is quite limited. Much is made of permitting people to do with their lives (including their opinions) as they please, so long as they do no immediate and evident (usually physical) harm to others. Thus, Leo Strauss has observed, "The quarrel between the ancients and the moderns concerns eventually, and perhaps even from the beginning, the status of 'individuality.' "

All this is to say that individualism is made much of in modernity. The status, then, of censorship very much depends on the standing of government itself and of legitimate authority, revealing still another aspect of the complicated relation between "the individual and the state."

REQUIREMENTS OF SELF-GOVERNMENT

One critical source of the contemporary repudiation of censorship in the West depends on something that may be distinctive to modernity, an emphasis upon the dignity of the individual. This respect for individuality has its roots both in Christian doctrines and in the (not unrelated) sovereignty of the self reflected in state-of-nature theories about the foundations of social organization. Vital to this approach is the general opinion about the nature and sanctity of the human soul. This general opinion provides the foundation of a predominantly new, or modern, argument against censorship—against anything, in fact, that interferes with self-development, and especially such self-development (or, better still, "self-fulfillment") as a person happens to want and to choose for himself. This can be put in terms of liberty—the liberty to become and to do what one pleases.

The old, or traditional, argument against censorship was much less individualistic and much more political in its orientation, making more of another sense of liberty. According to that sense, if a people is to be self-governing, it must have access to all information and arguments that may be relevant to its ability to discuss public affairs fully and to assess in a competent manner the conduct of the officials it chooses. Thus, "freedom of speech," which is constitutionally guaranteed to the people of the United States, first comes to view in Anglo-American legal history as a guarantee for the members of the British Parliament assembled to discuss the affairs of the kingdom.

Origin of freedom of speech

In the circumstances of a people actually governing itself, it is obvious that there is no substitute for freedom of speech and of the press, particularly as that freedom permits an informed access to information and opinions about political matters. Even the more repressive regimes today recognize this underlying principle, in that their ruling bodies try to make certain that they themselves become and remain informed about what is "really" going on in their countries and abroad, however repressive they may be in not permitting their own people to learn about and openly to discuss public affairs. Whether anyone who thus rules unjustly, or otherwise improperly, can be regarded as truly understanding and hence truly controlling his situation is a question not limited to these circumstances.

"FREEDOM OF EXPRESSION"

The shift from the more political to the more individualistic view of liberty may be seen in how the constitutional guarantees with respect to speech and the press are typically spoken of in the United States today. Restraints upon speaking and publishing, and indeed upon action generally, are fewer than at any time in the history of the country. This absence of restraints is reflected as well in the very terms in which these rights and privileges are described. What would once have been referred to as "freedom of speech and of the press" (drawing upon the language of the First Amendment to the Constitution of the United States) is now often referred to as "freedom of expression."

To make much of freedom of expression is to encourage a liberation of the self from the constraints of the community. It may even be to assume that the self has, intrinsic to it or somehow available to it independent of any social guidance, intimations of what it is and what it wants. Thus, liberation may be seen in the currently fashionable insistence upon "doing one's own thing"—which can include a reliance upon standards and objectives that are solely one's own. It is difficult, in such circumstances, to avoid a radical subjectivism that tends to result in a thoroughgoing relativism with respect to moral and political judgments. One consequence of this approach is to identify an ever-expanding array of forms of expression that are believed to be entitled to immunity from government regulation.

On the other hand, if the emphasis is placed upon the more traditional language, "freedom of speech and of the press," the requirements and prerogatives of a self-governing people are apt to be made more of. This means, among other things, that a people must be prepared and equipped to make effective use of its considerable political power. (Even those rulers who act without the authority of the people must take care to shape their people in accordance with the needs and circumstances of their regime. This kind of effort need not be altogether selfish on the part of such rulers, since all regimes do have an interest in law and order, in common decency, and in a routine reliability or loyalty.) It should be evident that a people entrusted with the power of self-government must be able to exercise a disciplined judgment: not everything goes, and there are better and worse things awaiting the community and its citizens.

True freedom

What is particularly difficult to argue for, and to maintain, is an arrangement that, while it leaves a people clearly free politically to discuss fully all matters of public interest with a view toward governing itself, routinely disciplines and otherwise prepares that same people for an effective exercise of its considerable freedom. In such circumstances, it is tempting for a people to take the case for, and the rhetoric of, liberty one step further—and thus to insist that no one should try to tell anyone else what kind of human being he should be. Yet, cannot it be said that only they are truly free who know what they are doing and who choose to do what is right? All others are, in varying degrees, prisoners of illusions and appetites, however much they may believe themselves to be freely expressing themselves.

There are, then, two related sets of concerns evident in any consideration today of the forms and uses of censorship. One set of concerns has to do with the everyday governance of the community; the other, with the permanent shaping of the character of the people. The former is more political in its methods, the latter is more educational.

History of censorship

It should be instructive to consider how the problem of censorship has been dealt with in the ancient world, in premodern times, and in the modern world. Care must be taken here not to assume that the modern democratic regime, of a self-governing people, is the only legitimate regime. Rather, it is prudent to assume that most of those who have, in other times and places, thought about and acted upon such matters have been at least as humane and as sensible in their circumstances as modern democrats are apt to be in theirs.

ANCIENT GREECE AND ROME

It was taken for granted in the Greek communities of antiquity, as well as in Rome, that citizens would be formed in accordance with the character and needs of the regime. This did not preclude the emergence of strong-minded men and women, as may be seen in the stories of Homer, of Plutarch, of Tacitus, and of the Greek playwrights. But it was evident, for example, that a citizen of Sparta was much more apt to be tough and unreflective (and certainly uncommunicative) than a citizen of Corinth (with its notorious openness to pleasure and luxury).

Power of religious opinion

The scope of a city's concern was exhibited in the provisions it made for the establishment and promotion of religious worship. That "the gods of the city" were to be respected by every citizen was usually taken for granted. Presiding over religious observances was generally regarded as a privilege of citizenship: thus, in some cities it was an office in which the elderly in good standing could be expected to serve. A refusal to conform, at least outwardly, to the recognized worship of the community subjected one to hardships. And there could be difficulties, backed up by legal sanctions, for those who spoke improperly about such matters. The force of religious opinions could be seen not only in prosecutions for refusals to acknowledge the gods of the city but perhaps even more in the frequent unwillingness of a city (no matter what its obvious political or military interests) to conduct public business at a time when the religious calendar, auspices, or other such signs forbade civic activities. Indicative of respect for the proprieties was the secrecy with which the religious mysteries, such as those into which many Greek and Roman men were initiated, were evidently practiced—so much so that there does not seem to be any record from antiquity of precisely what constituted the various mysteries. Respect for the proprieties may be seen as well in the outrage provoked in Sparta by a poem by Archilochus (7th century BC) in which he celebrated his lifesaving cowardice.

Athens, it can be said, was much more liberal than the typical Greek city. This is not to suggest that the rulers of the other cities did not, among themselves, freely discuss the public business. But in Athens the rulers included much more of the population than in most cities of antiquity—and freedom of speech (for political purposes) spilled over there into the private lives of citizens. This may be seen, perhaps best of all, in the famous funeral address given by Pericles in 431 BC. Athenians, he pointed out, did not consider public discussion merely something to be put up with; rather, they believed that the best interests of the city could not be served without a full discussion of the issues before the assembly. There may be seen in the plays of an Aristophanes the kind of uninhibited discussions of politics that the Athenians were evidently accustomed to, discussions that could (in the license accorded to comedy) be couched in licentious terms not permitted in everyday discourse.

The limits of Athenian openness may be seen, of course, in the trial, conviction, and execution of Socrates in 399 BC on charges that he corrupted the youth and that he did not acknowledge the gods that the city did but other new divinities of his own. One may see, as well, in the *Republic* of Plato an account of a system of censorship, particularly of the arts, that is comprehensive. Not only are various opinions (particularly misconceptions about the gods and about the supposed terrors of death) to be discouraged, but various salutary opinions are to be encouraged and protected without having to be demonstrated to be true. Much of what is said in the *Republic* and elsewhere reflects the belief that the vital opinions of the community could be shaped by law and that men could be penalized for saying things that offended public sensibilities, undermined common morality, or subverted the institutions of the community.

The circumstances justifying the system of comprehensive "thought control" described in Plato's *Republic* are obviously rarely to be found. Thus, Socrates himself is recorded in the same dialogue (and in Plato's *Apology*) as recognizing that cities with bad regimes do not permit their misconduct to be questioned and corrected. Such regimes should be compared with those in the age of the good Roman emperors, the period from Nerva (*c.* AD 30–98) to Marcus Aurelius (121–180), the golden times, said Tacitus, when everyone could hold and defend whatever opinions he wished.

ANCIENT ISRAEL AND EARLY CHRISTIANITY

Much of what can be said about ancient Greece and Rome could be applied, with appropriate adaptations, to ancient Israel. The stories of the difficulties encountered by Jesus, and the offenses he came to be accused of, indicate the kinds of restrictions to which the Jews were subjected with respect to religious observances and with respect to what could and could not be said about divine matters. (The inhibitions so established were later reflected in the manner in which Moses Maimonides [1135–1204] proceeded in his publications, often relying upon "hints" rather than upon explicit discussion of sensitive topics.) The prevailing watchfulness, lest someone say or do what he should not, can be said to be anticipated by the commandment "You shall not take the name of the Lord your God in vain; for the Lord will not hold him guiltless who takes his name in vain" (Ex. 20:7). It may be seen as well in the ancient opinion that there is a name for God that must not be uttered.

It should be evident that this way of life—directing both opinions and actions and extending down to minute daily routines—could not help but shape a people for centuries, if not for millennia, to come. But it should also be evident that those in the position to know, and with a duty

Nathan the Prophet

to act, were expected to speak out and were, in effect, licensed to do so, however cautiously they were obliged to proceed on occasion. Thus, the prophet Nathan dared to challenge King David himself for what he had done to secure Bathsheba for his wife (II Sam. 12:1–24). On an earlier, perhaps even more striking, occasion, the patriarch Abraham dared to question God about the terms on which Sodom and Gomorrah might be saved from destruction (Gen. 18:16–33). God made concessions to Abraham, and David crumbled before Nathan's authority. But such presumptuousness on the part of mere mortals is possible, and likely to bear fruit, only in communities that have been trained to share and to respect certain moral principles grounded in thoughtfulness.

The thoughtfulness to which the Old Testament aspires is suggested by the following counsel by Moses to the people of Israel (Deut. 4:5–6):

> Behold, I have taught you statutes and ordinances, as the Lord my God commanded me, that you should do them in the land which you are entering to take possession of it. Keep them and do them; for that will be your wisdom and your understanding in the sight of the peoples, who, when they hear all these statutes, will say, "Surely this great nation is a wise and understanding people."

This approach can be considered to provide the foundation for the assurance that has been so critical to modern arguments against censorship (John 8:32): ". . . and you will know the truth, and the truth will make you free." Further biblical authority against censorship may be found in such "free speech" dramas as that described in Acts 4:13–21.

It should be remembered that to say everything one thought or believed was regarded by pre-Christian writers as occasionally irresponsible or licentious: social consequences dictated a need for restraint. Christian writers, however, called for just such saying of everything as the indispensable witness of faith: transitory social considerations were not to impede, to the extent that they formerly had, the exercise of such a liberty, indeed of such a duty, so intimately related to the eternal welfare of the soul. Thus we see an encouragement of the private—of an individuality that turned eventually against organized religion itself and legitimated a radical self-indulgence.

ANCIENT CHINA

Perhaps no people has ever been so thoroughly trained, on such a large scale and for so long, as the Chinese. Critical to that training was a system of education that culminated in a rigorous selection, by examination, of candidates for administrative posts. Particularly influential was the thought of Confucius (551–479 BC), with its considerable emphasis upon deference to authority and to family elders and upon respect for ritual observances and propriety. Cautiousness in speech was encouraged, licentious expressions were discouraged, and long-established teachings were relied upon for shaping character. All in all, it was contrary to Chinese good taste to speak openly of the faults of one's government or of one's rulers. And so it could be counselled by Confucius, "He who is not in any particular office has nothing to do with plans for the administration of its duties" (*Analects* [*Lun yü*], 7:14). It has been suggested that such sentiments have operated to prevent the spread in China of opinions supportive of political liberty.

Confucius

Still, it could be recognized by Confucius that "oppressive government is fiercer than a tiger." He could counsel that if a ruler's words are not good, and if people are discouraged from opposing them, the ruin of the country can be expected (*Analects,* 13:5). Blatant oppressiveness, and an attempt to stamp out the influence of Confucius and of other sages, could be seen in the wholesale destruction of books in China in 231 BC. But the Confucian mode was revived thereafter, to become the dominant influence for almost two millennia. Its pervasiveness may well be judged oppressive by contemporary Western standards, since so much depended, it seems, on mastering the orthodox texts and discipline.

Whether or not the typical Chinese government was indeed oppressive, effective control of information was lodged in the authorities, since access to the evidently vital public archives of earlier administrations was limited to a relative few. In addition, decisive control of what was thought, and how, depended in large part on a determination of what the authoritative texts were—something that has been critical in the West, as well, in the establishment of useful canons, both sacred and secular. Thus, Richard McKeon has suggested, "Censorship may be the enforcement of judgments based on power, passion, corruption, or prejudice—political, popular, elite, or sectarian. It may also be based on scholarship and the use of critical methods in the interest of advancing a taste for literature, art, learning, and science."

MEDIEVAL CHRISTENDOM

Among the heirs of Greece and Rome and of Israel were the Christians of varying professions. Perhaps the most dramatic form of censorship in Christendom was that displayed in the development by the Roman Catholic Church of the *Index Librorum Prohibitorum,* a list of proscribed books, the origins of which go back (in a primitive form) to the 5th century AD and which continued to have official sanction well into the 20th century. The most spectacular instance of the silencing of a thinker of note may well have been the restrictions placed upon Galileo in 1633.

The orthodoxy protected by an institution such as the *Index* probably had to be a system of thought in which much was made of certain books, particularly if other publications should seem to challenge in significant respects the teachings of the canonical texts. This must have appeared even more acute a problem when means became available, especially after the invention of printing, to produce and distribute books in large quantities.

The establishment of a fairly precise orthodoxy led to a perhaps unprecedented recourse to creeds. Thus, for example, the Nicene Creed was promulgated in AD 325. It was devised to fend off a heretical threat to Christian doctrine—and it led, partly because of a unilateral change in wording made by the Western church, to a schism that has continued since 1054 between Eastern Orthodoxy and Roman Catholicism.

Thus, it very much mattered which doctrines people were taught and what came to be believed—and this was largely determined, as it usually is, by the action of some authority, ecclesiastical or temporal. Similar developments can be seen in the Islāmic world down to this day, as well as among contemporary Marxists.

It is difficult to distinguish religious and nonreligious elements in some of the more celebrated controversies of the medieval Christian world, just as it is today among Islāmic peoples. The persecutions of witches—which ranged across much of Europe from the 14th to the 18th century and cost hundreds of thousands, if not millions, of lives—can be understood as due to various political, social, and psychic disturbances as well as to strictly religious differences.

The trials of Joan of Arc in France (1431) and of Thomas More in England (1535) are notorious illustrations of the difficulty in distinguishing religious from political differences. Indeed, it has been common, because of the experiences of the Middle Ages and of the Renaissance, to see the cause of political liberty as intimately related to the cause of religious liberty (and especially the liberty to do without religion).

Joan of Arc and Thomas More

The Enlightenment, beginning in the 17th century, attempted to purge Europe of the censorship that found political despotism allied with religious traditionalism. Alexis de Tocqueville was astonished to find in the United States, in the 1830s, that it was possible for ordinary men who stood for political freedom to be, and to remain, religiously devout. This was not the typical combination in the Europe of his day.

Even so, it should be recognized that the rigorous medieval theological–political regime against which moderns have rebelled did have at its core a principle that subjected the exercise of will (or sovereignty) to the test of wisdom. This principle, upon which the contemporary dedication to freedom of speech may ultimately depend, is reflected in Thomas Aquinas' insistence in *De veritate* (Q. 23), ". . . to say that justice depends simply upon the will is to say that the divine will does not proceed according to the order of wisdom, and that is blasphemous."

THE 17TH AND 18TH CENTURIES

The struggle against censorship in the Anglo-American world in the 17th and 18th centuries took two principal forms. There was the effort to keep government from reviewing, before publication, any manuscript, and there was the effort to keep government from penalizing, after publication, any text that expressed forbidden sentiments. (There were throughout the Western world developments with respect to these matters similar to those in Great Britain and the United States, but they usually occurred later.)

The effort to eliminate "previous restraints" (also known as prior restraints) in Great Britain and in America had its roots in English constitutional experience. Previous restraint (or licensing) came to be regarded as an inheritance of Roman Catholic practices. And so, when the Anglican successor to the Roman Catholic Church was disestablished by the Puritans, it was evidently something of a shock to John Milton to find Parliament reinstating licensing in 1643.

Milton's
"Areopagi-
ica"

Milton's "Areopagitica" (1644) has remained the classic statement of the arguments against censorship, particularly in the form of previous restraint. Milton conceded that criminal prosecutions might, perhaps even should, follow upon the publication of certain writings. He insisted, however, that such works must not be suppressed before publication.

Critical to Milton's position in support of freedom of the press is something that may not have been implicit in the traditional pre-Miltonian position against censorship—his confidence that truth, "in a free and open encounter," will be able to overcome error. Related to this opinion is the assurance that it is a positive good for mankind to be exposed to error; only in this way may virtue be tested, strengthened, and made adequate to the trials of earthly life. Milton cannot praise "a fugitive and cloister'd vertue." All this seems to rest upon a Christian view of the world: truth may indeed win out in its encounter with error, if the struggle continues long enough and if divine aid is thrown into the balance, as Milton seems to assume it will be; a man must not only act virtuously, but he must also personally choose to do so; he must be prepared to be exposed to alternatives, as inevitably he will be, and he must choose rightly if he is to merit and secure eternal salvation.

A reliance upon due process of law (which Milton in effect calls for) is the vital concession that the community can be led to make to reason: it provides a safeguard that must be so well established in times of calm and reflection that it is held to firmly, as a tenet of a common political faith, when the community is almost beside itself with passion. And, Milton might add if he were to use modern terminology, due process provides the ground rules for that free and open encounter in which truth may indeed prevail over error.

Black-
tone's
Commen-
aries

Thus, it is against the polemical background provided by Milton's "Areopagitica" that the abandonment of prepublication censorship in England in 1695 could be properly seen as a great victory for liberty of the press in Anglo-American constitutional history. And so, in 1765–69, William Blackstone could say about the English common law with respect to liberty of the press in his *Commentaries on the Laws of England:*

> The liberty of the press . . . consists in laying no *previous* restraints upon publications, and not in freedom from censure for criminal matter when published. Every freeman has an undoubted right to lay what sentiments he pleases before the public; to forbid this, is to destroy the freedom of the press: but if he publishes what is improper, mischievous, or illegal, he must take the consequence of his own temerity.

The next major step in the Anglo-American response to censorship problems may be seen in the First Amendment to the Constitution of the United States. That amendment, ratified in 1791, provides:

> Congress shall make no law respecting an establishment of religion, or prohibiting the free exercise thereof; or abridging the freedom of speech, or of the press; or the right of the people peaceably to assemble, and to petition the Government for a redress of grievances.

Similar provisions may be found in most of the state constitutions in the United States, although the connection between political and religious liberty is not always recognized to be as intimate as it is in the First Amendment.

Freedom
of speech

Such a guarantee of freedom of the press as is found in U.S. constitutional documents has long been understood to foreclose the possibility of previous restraints, thereby confirming the definition of "liberty of the press" found in Blackstone's *Commentaries.* A few scholars and jurists have gone so far as to suggest that the First Amendment and the state constitutional provisions do no more than limit restraints prior to publication, but it is difficult to bring the "freedom of speech" language (often found in the same guarantees) within this suggestion, since there never had been (and, in the nature of things, could never easily be) previous restraints upon what might be spoken (as distinguished from what might be printed). Rather, as indicated above, "freedom of speech" is modelled upon the British parliamentary privilege, a privilege that should be generally available when a people becomes sovereign in the fashion of the American people. (In addition, the celebrated case of John Peter Zenger [1735] had already established for Americans the principle that truth was a defense in seditious libel prosecutions, thus going beyond Blackstone's position in still another respect.)

The traditional parliamentary privilege—which is still guaranteed in the United States to members of Congress and to state legislators—can be considered virtually absolute in the protection it provides legislators against being held accountable "in any other place" for what they utter in a legislative body. The question remains, of course, as to precisely what kinds of matters may be discussed freely, and without fear of sanction, by citizens entitled to such protection as is provided by the First Amendment.

The old-fashioned answer was that the kind of discussion primarily protected by the First Amendment is that of citizens engaged in investigating and assessing the public business. Such protected discussion may be found in art, in moral and scientific inquiry, and in advertising, as well as in obvious political discourse. Thus, whatever is suppressed *because* of political differences is likely, in the circumstances, to be "political." Another way of putting this is to say that the crime of seditious libel is not consistent with the First Amendment. Particularly influential spokesmen for this position in the 20th century have been Alexander Meiklejohn (1872–1964), Hugo L. Black (1886–1971), Harry Kalven, Jr. (1914–74), and Malcolm P. Sharp (1897–1980). It is a position epitomized by its questioning of the constitutionality of the Sedition Act enacted by Congress in 1798.

The Sedition Act made criminal the publication of "any false, scandalous and malicious writing . . . against the government of the United States, or either House of Congress . . . or the President . . . with intent to defame [them] or to bring them . . . into contempt or disrepute." This act, which was allowed to lapse after two years, has been generally repudiated by American jurists and scholars. The U.S. credo in these matters may well be found in Thomas Jefferson's First Inaugural Address (1801), in which he said, "If there be any among us who would wish to dissolve this Union or to change its republican form, let them stand undisturbed as monuments of the safety with which error of opinion may be tolerated where reason is left free to combat it."

The First Amendment guarantee of freedom of speech and of the press was anticipated, in effect, by the provision of the Constitution (drafted in 1787) that "Treason against the United States shall consist only in levying War against them, or in adhering to their Enemies, giving them Aid and Comfort." This, too, has made it difficult to prosecute citizens for their criticism of government, something that had been much easier to do under an expansive definition of treason. The First Amendment guarantee was anticipated as well by the assumption evident in the Declaration of Independence that a people is always entitled to examine and to assess the doings of its governments, all with a view to being able to replace any government deemed upon due consideration to be unsatisfactory.

There can be no doubt that the extensive freedom of Americans to discuss political matters can lead to serious abuses. But it is generally recognized that the abuses resulting from censorship of such discussion—whether in the form of previous restraints or in the form of postpublication sanctions—are apt to be even more serious for a community.

Perhaps not as generally recognized is that considerable self-restraint is required, especially on the part of intellectuals, if the best possible use is to be made of free discussion in the circumstances of a people. A call for such restraint (or self-censorship), as well as for both public enlightenment and respect for organized religion, may be seen in George Washington's Farewell Address (1796). Similarly, Lord Macaulay could say of the 19th-century British press, "Foreigners who dare not print a word reflecting on the government under which they live, are at a loss to understand how it happens that the freest press in Europe is the most prudish."

MODERN PRACTICES

The Soviet system. The *Index,* which was abolished by the Roman Catholic Church in 1966, may be seen in another form in the Soviet Union, where there is a comprehensive system of supervision of manuscripts before publication. (Similar control, in varying degrees, is exercised in other countries with Marxist governments.) Such supervision, in the light of official Communist Party doctrines, is not limited to political discussions or to books and newspapers but seems to cover all kinds of subjects and all forms of publication, including broadcasts. This leads, in effect, to considerable self-censorship by authors seeking to be published in some form. Of course, the more "unreliable" authors are simply refused publication in the conventional places.

The comprehensive Soviet system has led to the development of a sophisticated mode of guarded expression in print, which is designed to conform with official proprieties even as signals are given to the more perceptive about impending political shifts. It has, as well, led to (or perhaps permitted the perpetuation of) such expedients as the transformation of the circus clown into a tolerated means for exhibiting and venting public exasperation with the regime. All in all, in such circumstances, the bearing of persecution on the art of writing can be seen.

There have been, in recent decades, periodic relaxations of control in the Soviet Union, but a pervasive and shameless control by the Communist Party oligarchy remains. A limited uncensored circulation is effected by privately copied manuscripts; a few authors have had their manuscripts published abroad. And then there are materials that are smuggled into the Soviet Union, as well as foreign radio broadcasts, which are "jammed" from time to time. But these exceptional modes provide uncensored information and discussion only to a very small number of Soviet citizens. The large body of citizens knows, by and large, only what the government has chosen to reveal, often being ignorant of critical conditions and developments in its own country (such as the serious illness of a Soviet leader) that are well known abroad.

This sort of control is justified as necessary for the protection of the state and the welfare of its citizenry. Some of the restrictions are designed to permit retention of information that is considered vital to national security; others are designed to keep citizens from being "misled," especially since a proper understanding of "dialectical materialism" is said to be necessary to determine what is relevant and what contributes to the health of the community and the well-being and moral soundness of citizens. Variations of the arguments used in the Soviet Union today may be found in medieval apologetics, in Confucian doctrines, in Plato's *Republic,* and in UNESCO proposals for "a new world information and communication order."

Orwell's *Nineteen Eighty-four*

How seriously such arguments are to be taken depends, in part, on whose interest the rulers exercising this control truly serve. George Orwell, in his novel *Nineteen Eighty-four* (1949), displayed a ruling class that was evidently drawn in large part from his study of the practices of the ruling party in the Soviet Union. The rulers in *Nineteen Eighty-four,* when they speak most frankly, disavow serving any interest but their own, whatever they may say publicly about national security and social progress. Such ruthless self-centredness on the part of rulers fits the traditional definition of tyranny. (It is not necessary to be concerned here with whether or not such a completely self-centred tyranny, which must be rare, would be likely to withstand determined opposition by men and women willing to sacrifice themselves.)

The portrayal in *Nineteen Eighty-four* is particularly gripping because it suggests how extensive the modern control of ideas can be. (Developments with respect to computers and information banks subsequent to the publication of Orwell's novel make the prospects of comprehensive control seem even more ominous.) The ultimate in censorship may be seen, in the novel, in a technology and an ideology that permit government to edit not only what is being said today and tomorrow but also what is recorded or remembered to have been said yesterday. The Western reader of *Nineteen Eighty-four* is likely to be offended not only by its government's efforts to control political discussion but also by the official assumption that the individual has no standing worthy of serious consideration.

It is unlikely that any system of censorship in the world today, with the possible exception of that in the People's Republic of China, is as effective as that in the Soviet Union. But official secrecy, as well as tyranny, is something to which Russians have long been accustomed. (In the late 19th century, the Russians had perhaps the only extensive censorship system in the world.) It is instructive, therefore, to consider how censorship works today in countries with somewhat more experience in self-government.

Censorship in Greece, 1967–74

Censorship under a military government. Particularly revealing in this respect was what happened in Greece between 1967 and 1974, when a conspiracy of junior army officers seized control of the government. The dependence of Greece upon foreign trade and tourism made it difficult to keep out the foreign press and foreign broadcasts. This meant, among other things, that the more educated citizens in the country were always fairly well informed about what was going on in the world at large. But information about domestic affairs (especially economic data) was hard to come by, since much of that kind of information depends in modern times (as in ancient China) upon official sources. (Thus, there is the better known example of the chronic complaint about the unreliability of official Soviet statistics. Thus, also, the strict censorship in Poland during the 1970s evidently kept the Communist government there from becoming aware of how serious the country's economic problems were, leading to considerable domestic turmoil. Such regimes depend, in effect, upon free peoples to do their thinking for them about the most serious matters.)

The limits of government censorship in a country such as Greece, where the press (unlike the broadcast media) is not owned by the government, are in part determined by the fact that much of the business of daily life depends on fairly reliable newspaper operations. All kinds of information—about goods for sale, about schedules and timetables, about innumerable activities upon which an efficient daily life depends—must be published regularly and reliably in the press, whoever may be in power. This means that newspapers must not be unduly delayed in their appearance; it also means that if they are to continue to appear they must be profitable.

The censor who is too slow (that is, careful) in reviewing everything that is to appear in a forthcoming daily newspaper jams up the works. And if he is too restrictive in what he does permit, the paper is apt to become so dull that readers do not buy it. Either way, sales suffer and newspapers go out of business.

What happens in practice is that a rough accommodation develops between an editor and his censor. Each can make the duties of the other a constant aggravation. The accommodation worked out is rather like that which guards and inmates arrive at in their collaborative governance of a prison. One critical problem in maintaining indefinitely a system of censorship is, as Milton pointed out, that it is dull, unrewarding work for the typical censor—and so the quality of people drawn to it tends to deteriorate.

Of course, one way of avoiding much of the difficulty, expense, and inefficiency of a system of prepublication censorship is simply to allow each editor to publish as he chooses, subject to the risk of prosecution for whatever is published contrary to the standards laid down by the regime. But it is far from easy, even in a dictatorial regime, to prosecute effectively so long as some semblance of due process remains. It appears simpler for dictators to refuse to permit a particular newspaper report to be published than it is to explain in open court what was wrong with the report once published. Whether it is indeed simpler can be doubted, however, considering the mammoth effort required to supervise the many innocuous reports that make up the bulk of any newspaper.

Two meanings of "censorship"

It should be evident from these observations that "censorship" is used today in two senses. The more limited, perhaps more rigorous, sense refers to a system of prepublication control; the broader sense includes, in addition, sanctions visited upon a publisher after publication (whether or not the publication has previously been "approved"). Something analogous to prepublication censorship is often said, by contemporary psychologists, to operate in the human psyche to prevent the conscious awareness of any unacceptable desires harboured in the unconscious. Comparable suppression, as well as intimidation, may be seen in the political world, when prosecution and persecution for various kinds of associations and actions can render certain opinions virtually unthinkable.

Postpublication censorship does tend to be moderated to the extent that there is the rule of law in the community (including trials that are conducted more or less in public). The Greek military government of 1967–74 was repeatedly embarrassed by the trials it dared to conduct in public. The same could be said of the South African government since World War II, so long as an independent judiciary was trying sedition cases. (One result of this was that certain cases involving "national security" were removed, by act of the South African Parliament, from the ordinary jurisdiction of the courts. Or, to put this in terms familiar in Anglo-American law, nothing comparable to a habeas corpus hearing is permitted in South Africa today in certain categories of cases.) In the Soviet Union, on the other hand, the judicial proceeding in a political case seems, by and large, to be but another tool of government policy: in such circumstances, there may not be much to choose from between prior restraint and postpublication sanctions if an efficient allocation of resources is not a concern.

The *Pentagon Papers*

Censorship in the United States. *Freedom of the press.* One of the most dramatic attempts by the government of the United States to exercise prepublication restraint occurred in connection with the *Pentagon Papers* (1971), a "top secret" multivolume report on the Vietnam War that was surreptitiously supplied to various newspapers, which then began to publish it in installments. Each newspaper that managed to secure and thereupon to publish the report was enjoined in turn, at the request of the U.S. Department of Justice. The Supreme Court of the United States, after hearing arguments, lifted the injunctions and publication proceeded.

This case points up how difficult it is, in the United States today, to prevent publication, whatever recourse there may be to criminal sanctions or to damage suits after unauthorized or improper publication. Of course, it cannot be known whether the Supreme Court would have acted differently if the *Pentagon Papers* documents had been more current or if they had dealt with even more sensitive materials.

By the very nature of things, prepublication restraint is, in the United States, a rare occurrence. Thus, if each newspaper that began to publish the *Pentagon Papers* had published in one issue everything it had, that would have been the end of the previous-restraint case. And it should be obvious that that is the typical situation in the United States: the first the government usually knows about any publication is when the newspaper comes out—and by that time, of course, prepublication restraint is out of the question.

Thus, the U.S. government, in order to keep certain information out of the press, has to depend upon its ability to select those to whom sensitive information may be entrusted. Otherwise, the judgment of editors must be relied upon. There is nothing in the United States comparable to the Official Secrets Act and the "D" notice system in Great Britain, which, it seems, effectively restrain editors from publishing materials bearing certain restrictive designations. An attempt was made in 1983–84 by the U.S. government to require thousands of officials handling classified matter to pledge that they would submit any future writings for prepublication review by government censors. Opposition in Congress kept the new code from taking effect, except perhaps to a limited degree.

Private property and censorship

Contributing massively to the absence of censorship in any country is the existence there of considerable private property. Not only do personal resources provide a cushion against government unfriendliness, but they also provide independent access to the means of publication, if only in the form of a private printing with private circulation or of paid advertisements in the press. The attempts at censorship encountered in the United States today testify, in effect, to the importance of private property for freedom of the press. The instances of censorship that have been widely publicized generally have to do with public libraries, textbook selections, and government employment contracts. But in these instances, as with most of the repressive measures of the 1940s and 1950s, public funding, government authority, or a critical dependence upon public opinion—as in the case of the motion-picture and broadcast industries—is involved. Otherwise, there would be no effective way for either the government or public opinion to control what is published—certainly not when anyone with private means is determined to make his opinions known.

Parallel to the immunity provided by the institution of private property is that provided in the United States by academic freedom in colleges and universities. This freedom, which encourages scholars and teachers to traffic in unpopular truths, rests in part on the private property of tenured appointments. On the other hand, libel suits on behalf of another kind of private property—the interest everyone has in his reputation—are seen by some as a growing danger to freedom of the press. That is, concern has been expressed lest the protection provided by *New York Times Co.* v. *Sullivan* (1964) be eroded. In that case, the U.S. Supreme Court required that any public official who sues for damages because of an alleged falsehood prove that the falsehood had been issued with knowledge that it was false or in reckless disregard of whether it was false or not. The court was determined to protect the press from the prospects of large damage awards in libel cases that would intimidate it into drastic self-censorship. The court also saw itself as confirming the settled U.S. opinion condemning the Sedition Act of 1798.

A different kind of "protection" for the press, less welcome to journalists, was the decision by the U.S. government not to permit reporters to accompany the troops invading Grenada in 1983. Critical to the controversy on that occasion was a general concern that too much of the information necessary for adequate discussion of public affairs remains within the exclusive control of government. Thus, it is sometimes said, neither previous restraints nor postpublication sanctions need be resorted to by a government able to shape public opinion simply by regulating the flow of vital information as it pleases. This, too, can be considered a form of censorship, the more insidious in that it is obviously sensible in some cases to restrict public access to information for the sake of legitimate defense, diplomatic and administrative efficiency, or confidential professional relations.

Still another form of censorship may take the form of the preferences government bodies exhibit through the financial and other support they distribute to artistic, scientific, and educational applicants. And yet it is generally recognized that such distribution can be helpful, perhaps even necessary, and that it has to be done on the basis of standards that must rely on the good-faith judgment of public officials for their application. Here, as elsewhere, an informed and vigilant citizenry may be the best guarantor of both quality and fairness.

Freedom and truth. Postpublication sanctions were used in the courts, between 1948 and 1961, against leaders of the Communist Party in the United States. Even so, the indictments in those cases were put in terms of a conspiracy to overthrow the government. That is, despite the unpopularity of Communism in a time of considerable international tension, no U.S. government could rely merely on the fact that people found the defendants' opinions to be offensive. An effort had to be made to connect what the defendants were saying to what they (and others elsewhere) were likely to do.

Still, such prosecutions were confronted by the prohibition in the First Amendment that "Congress shall make no law . . . abridging the freedom of speech, or of the press." But the apparent absoluteness of that prohibition had long been subverted by the ill-conceived, yet all too influential, statement by Justice Oliver Wendell Holmes in *United States* v. *Schenck* (1919):

> . . . the character of every act depends upon the circumstances in which it is done. The most stringent protection of free speech would not protect a man in falsely shouting fire in a theatre and causing a panic. [The] question in every case is whether the words used are used in such circumstances and are of such a nature as to create a clear and present danger that they will bring about the substantive evils that Congress has a right to prevent.

Dennis v. *United States*

There does not seem to be much doubt that the man who causes a panic in a theatre should be dealt with firmly. But it is far from clear that this sensible conclusion has justified punishing men and women whose principal offense seems to have been that of raising fundamental (however ill-conceived) objections to the established political, economic, and social arrangements in the United States. Justice Holmes's constitutional flexibility in the Schenck case can be considered to have culminated in the later assurance by Chief Justice Fred M. Vinson in *Dennis* v. *United States* (1951), in which the convictions of a dozen Communist Party leaders were upheld:

> Nothing is more certain in modern society than the principle that there are no absolutes, that a name, a phrase, a standard has meaning only when associated with the considerations which gave birth to the nomenclature. . . . To those who would paralyze our government in the face of impending threats by encasing it in a semantic straitjacket we must reply that all concepts are relative.

This is hardly in the spirit of Milton's high confidence in the power of an enduring truth to prevail. Nor is it in the spirit of the Declaration of Independence, with its informed reliance upon natural rights, upon self-evident truths, and hence upon the right of revolution.

Be that as it may, it is unlikely that any of the prosecutions from the Schenck to the Dennis case and beyond for what was, in effect, sedition would succeed under present conditions. The sorts of things those defendants said are no longer considered dangerous by the community at large. Rather, the much more vexing question is whether any kind of speech is not entitled to First Amendment protection. That protection is now said to extend far beyond political discussion. Thus, advertising (or commercial speech) is said to be protected as is much (if not virtually all) obscenity, although reservations are heard about child pornography and about inducements to violence and the worst depravity. (Whether any particular utterance or action should be regulated has itself always been a political question open to free discussion.)

Much is made today of an asserted right of self-expression and of the related right to privacy. The arguments drawn upon in their support seem to be variations of those developed in John Stuart Mill's *On Liberty* (1859). Mill's arguments are invoked today not only in opposition to government censorship but in opposition as well to those suppressive efforts by private organizations that are sometimes more effective than government can be in a liberal democracy. Particularly susceptible to the influence of private censors are the broadcasting media, especially since they are still subject in the United States to some government regulation. A different kind of private suppression has been usefully described in this fashion by Jamie Kalven: "Being badly edited is as close as most American writers ever come to being censored. It thus offers a vehicle for imagining the *experience* of censorship, for getting at what it *feels* like. My strongest impression is that the abuse of one's prose feels like an assault on one's mind." Similarly, Lord Radcliffe (in his *Censors*) could speak of "the real licensors of thought today, the editors, the publishers, the producers, the controllers of radio and television."

Character and freedom

Lord Radcliffe could speak as well about "the apparent indifference of censors of all kinds to the depiction or portrayal of mindless violence and brutality, that witless rejection of civility that threatens to be the Black Death of the twentieth century." Thus, it is not usually noticed today that Mill recognized that a people has to be trained properly to make use of the considerable liberty he advocates. If, for example, a community should recognize that television is corrupting the young, distorting the political process, and generally playing havoc with education and the public character, is it really helpless to do anything about it? Would it be censorship to abolish altogether such a baleful influence? And if abolition of television should be considered censorship, may not that suggest that censorship is not altogether bad? What, in short, is the popular character presupposed for effective self-government, and how is that character properly to be developed and maintained?

Such questions reflect the fact that censorship and freedom of the press problems depend for their sensible resolution upon more general considerations of liberty, of the common good, and of the rights, virtues, and duties of citizens entrusted with self-government. Thus, Tocqueville could observe in *Democracy in America* (1835–40):

> It cannot be repeated too often: nothing is more fertile in marvels than the art of being free, but nothing is harder than freedom's apprenticeship. The same is not true of despotism. Despotism often presents itself as the repairer of all the ills suffered, the support of just rights, defender of the oppressed, and founder of order. People are lulled to sleep by the temporary prosperity it engenders, and when they do wake up, they are wretched. But liberty is generally born in stormy weather, growing with difficulty amid civil discords, and only when it is already old does one see the blessings it has brought.

Among the blessings of liberty may be found the philosophical pursuits that have sometimes appeared so threatening to public order. Laurence Berns has reformulated the ancient dilemma posed by the trial of Socrates, "the greatest hero of freedom of thought"—a dilemma that exposes one of the roots of the perennial censorship controversy:

> Is philosophy, the intransigent quest for truth (including the truth about politics and religion), inherently subversive? Does it necessarily undermine political society and conventional morality, or, on the contrary, is a good society impossible without freedom to philosophize?

(G.An.)

Central Africa

Although merely a conventional designation, the term central Africa corresponds with an undeniable physiographic whole, consisting of the interior bowl of the Congo River basin and the intervening spaces that lie between it and the Atlantic Ocean. Stretching across the African continent from latitude 11° N to 13° S and from longitude 8° 43′ E (at Cape Lopez) to 31° 30′ E (at Lake Albert), central Africa comprises Burundi, the Central African Republic, Congo, Gabon, Rwanda, and Zaire; it also includes the islands of São Tomé and Príncipe off the coast of Gabon. This is the least populated part of tropical Africa, with the exception of Rwanda and Burundi, which are the most densely populated countries on the continent. Rwanda and Burundi's human geography resembles that of eastern Africa, but they are here linked with central Africa because, before independence, they were administered by Belgium, as was neighbouring Zaire.

This article is divided into the following sections:

THE REGION

Physical and human geography

THE LAND

Geology. Central Africa is underlain by a basement complex of Precambrian rock, which is partially covered by a thin sedimentary layer. This complex consists of a varied lithology, including migmatites and other metamorphic rocks, granito-gneissic complexes, and partially metamorphosed sedimentary rocks (among which are limestones, sandstones, and conglomerates of glacial origin).

Orogeny

Several orogenic phases occurred more than 600 million years ago. Though long subjected to weathering and erosion, the folds produced by these orogenies are still obvious in some reliefs: ridges lie parallel to the coast in western Congo and coastal Zaire; linear and curvilinear ridges of quartzitic sandstones are found in Rwanda and Burundi; and an arc-shaped range extends through the copper belt of southeastern Zaire. This Precambrian complex contains a wealth of mineral resources: gold and manganese are found in the very ancient parts (northeastern and southern Zaire, southeastern Gabon) and tin in Middle Precambrian strata (southeastern Zaire, Rwanda, Burundi), and in Late Precambrian strata (western Congo, southeastern Zaire) there is copper, often linked with lead and zinc or, as in southern Zaire, with cobalt and uranium. Iron ore abounds in central Africa's crust, but it is still relatively unexploited. During the Cretaceous Period (144 to 66.4 million years ago), kimberlitic pipes, a major source of diamonds, intruded through the basement rocks to the surface in central Zaire.

In the west the basement sinks under a sedimentary coastal basin formed during the Cretaceous Period—*i.e.,* after Africa and South America were separated. Narrow in Zaire, the basin widens in Gabon. Petroleum (most often tapped offshore), some phosphate, and potash are found there.

Since the end of the Precambrian, the basement complex has undergone deformations of major amplitude, in addition to local upliftings and fractures. Raised and emerging at the periphery, the basement sags in the centre into a shallow basin (maximum depth about 5,000 to 6,500 feet [1,500 to 2,000 metres]), buried beneath sediments—often of continental origin—deposited from the Late Precambrian to the Quaternary. The sediments also extend toward the south, between the coastal rim and the Kasai region in western Zaire. Sand deposits cover the surface of some plateaus in southern Zaire, and other small sedimentary basins may be found in the Central African Republic (*e.g.,* sandstone plateaus near Carnot in the west and between Ouadda and Mouka in the east, the latter containing alluvial diamonds). The far north of the Central African Republic is part of the interior-draining Chad sedimentary basin.

The eastern part of central Africa is interrupted by the western branch of the East African Rift System, which marks the progressive separation of the continental African plate in the west from the Somalian plate in the east. Transform faults disconnect the valley axis. Two of these dislocations are the centre of volcanic activity (old volcanism in the south, present Virunga volcanism north of Lake Kivu).

The islands in the Gulf of Guinea are of volcanic origin, jutting out of the sea along an extension of the western Cameroon fault axis.

Relief. The landscapes of central Africa are most often wide plateau surfaces (often terraced planed surfaces), which are smooth in the central part and etched at the periphery.

The interior basin of the Congo (Zaire) River, the lowest part of which (Malebo [Stanley] Pool) lies about 1,000 feet above sea level, is joined to the Atlantic Ocean by a narrow neck traversing ridges parallel to the coast. The basin comprises some marshy surfaces in the region where the Congo, Ubangi (Oubangui), Likouala, and Sangha rivers converge and where Lakes Mai-Ndombe (formerly Lake Léopold II) and Tumba are found. Its major part, however, consists of drier surfaces (low plateaus or alluvial terraces).

Plateau formations

Higher plateaus extend through older sedimentary strata around the central part of the Congo basin. Those crossed by the Congo above Malebo Pool—the Batéké Plateaus—reach an elevation of 2,600 to 3,000 feet north of Brazzaville and stretch southeastward to the Kwango Plateaus, which exceed 3,000 feet near the Angolan border. Beyond this sedimentary aureole the plateaus frequently show outcroppings of Precambrian basement rock. In the north a low divide (2,000–2,300 feet) separates the Congo River and its tributaries from the Chad basin. The landscape beyond the divide descends by steps toward Lake Chad. In the west the rim of the Congo basin is well demarcated. The Chaillu Massif (3,000–3,300 feet), in Gabon and Congo, is a granitic elliptical buttress surrounded by a crown of ancient erosion surfaces. Southwest and south of the massif, from west to east, are ridges ranging from 2,600 to 3,000 feet, which are traversed through deep and narrow gorges by the Kouilou and Congo rivers; a shale-limestone depression; and a sandstone plateau. East of this complex the Congo River has eroded a broad basin, known as Malebo Pool, into the upper sedimentary strata before cutting rapids farther downstream. In the southeast, the plateaus often exceed 3,300 feet. Some parts, uplifted more than 5,000 feet (*e.g.,* Kibara, Kundelungu), surround depressions (*e.g.,* Lake Upemba, Lufira River plain).

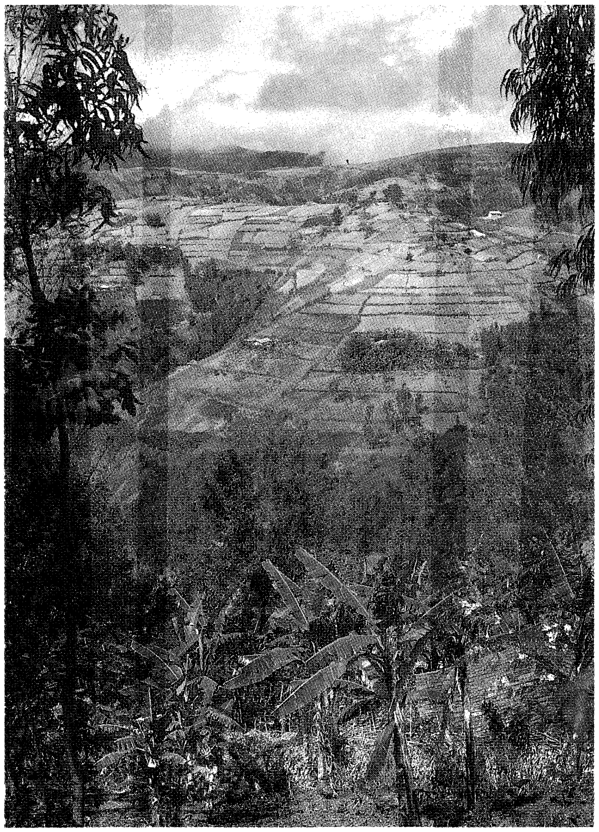
The most rugged terrain is seen on the eastern fringe of the Congo basin, where the Precambrian bedrock has been uplifted above the Western Rift Valley and is more than 8,000 feet high. A ravined slope abruptly drops to the floor of the rift valley. The level of Lake Albert (Mobutu) lies at 2,034 feet, that of Lake Edward at 2,995 feet, and that of Lake Tanganyika at 2,543 feet. In its southern part, the bottom of Lake Tanganyika is 2,165 feet below sea level, making the lake more than 4,700 feet deep. In Rwanda and Burundi, which lie east of the Western Rift Valley, the eastern edge of the valley mirrors that of the west: a vigorous slope on the fault side and an etched surface with a gentler slope dipping toward the east. North of Lake Kivu and of Rwanda, the Virunga volcanoes form an east–west-trending range whose main peaks exceed 9,800 feet (14,557 feet [4,437 metres] for Mikeno, 14,787 feet [4,507 metres] for Karisimbi). The highest point in central Africa, Margherita Peak (16,795 feet [5,119 metres]), is located on an uplifted portion of the Precambrian basement on the eastern fringe of the Rift Valley. Its summit bears residual features of glaciation.

The western sedimentary basin (a maritime plain with low hills) has a coastline broken up by estuaries (that of the Congo, downstream from Boma, Zaire, extends into a deep submarine canyon), lagoons, and rias. In Congo and southern Gabon offshore sandbars, stretched toward the north by the coastal current, alternate with small sea cliffs or rocky capes.

Drainage. Central Africa encompasses the Congo River basin. The immense size of the basin (1,334,700 square miles [3,457,000 square kilometres]) and its extension into regions with heavy rainfall make this river second only to the Amazon for rate of flow, which averages 1,421,400 cubic feet per second (40,250 cubic metres per second) at Kinshasa.

The Congo's flow fluctuations during the year, important in absolute value, are moderate in relative value: the low water average is 1,094,610 cubic feet per second, and the high water average is 1,977,360 cubic feet per second. Because the Congo straddles the equator, with its contrasting north-south precipitation regimes, the low waters of affluents originating in one hemisphere are matched by simultaneous high waters coming from affluents in the opposite hemisphere; a near constant flow is fed by the affluents of the central part. As the basin extends mostly south rather than north of the equator, the lowest waters occur in July and August—the Southern Hemisphere dry season—the highest waters in December. The tributaries in the peripheral regions have more varied regimes. As is true of the Amazon, the rivers rising in the forest are black, laden with humic acids (the name of the Mai-Ndombe, for example, means "black water"), whereas the rivers rising in the basin periphery are of brown or reddish brown waters.

In the central part of the basin the fan of quiet rivers constitutes one of the most attractive networks of navigable waters in the world, but this network is cut off from



Small farms line the slopes in the highlands of Burundi, one of the most densely populated regions in central Africa.

Dr. Nigel Smith/The Hutchison Library

the Atlantic by a succession of rapids between Kinshasa and Matadi, Zaire. Downstream from Matadi the river becomes navigable again before entering its estuary. All the rivers in the region flow down through rapids or waterfalls from the peripheral plateaus to the central basin. The rivers of the western region are only navigable for a few miles from their estuaries, though the Ogooué, in Gabon, which lies in a wider sedimentary coastal basin, is navigable for more than 100 miles.

Navigable rivers

Some parts of central Africa lie within the Chad basin (northern Central African Republic) or the Nile basin (eastern Rwanda and northeastern Burundi, the Rift Valley north of the Virunga Mountains). Lava fields from the Virungas have blocked the outlet of an ancient hydrographic network previously oriented to the north. This created Lake Kivu; its waters discharge to the south, through the Ruzizi (Rusizi) River gorge into Lake Tanganyika, one outlet of which links the lake with the Lualaba River, and thus the Congo. The volcanic dam also caused a river course reversal in northern Rwanda, generating lakes and marshes.

Climate. Central Africa is characterized by hot and wet climates, which are disposed in a symmetrical manner on both sides of the equator. The equatorial strip that extends from the Atlantic Ocean to the Western Rift Valley is influenced throughout the year by the intertropical convergence zone (ITCZ), resulting in intense, heavy precipitation. The mean annual temperatures in the region vary from 77° to 82° F (25° to 28° C), and monthly means vary only a few degrees throughout the year. The diurnal range of about 20° F (11° C) always exceeds the range of monthly means. Annual rainfall exceeds 80 inches (2,000 millimetres) in coastal Gabon, in the centre of the Congo basin, and on the mountain summits bordering the Western Rift Valley. There is no serious dry season, but in the extreme east and west there are two months (July and August) of lower rainfall.

Also, north and south of the equatorial strip the dry season increases in severity with latitude. It is centred in the Northern Hemisphere in January (when the area receives dry Saharan air masses) and in the Southern Hemisphere in July; the season lasts nearly seven months in the far northern part of the Central African Republic and in far southern Zaire. Notwithstanding its low latitude and proximity to humid air masses, the coastal region of southwestern central Africa has an abnormally long dry season with a low annual rainfall; at Banana, Zaire, at the mouth of the Congo River, it lasts five months. This abnormality is due to the presence of a cold marine current (the Benguela Current) along the coast, which stabilizes the lower strata of the atmosphere and curtails the development of rain clouds but allows the formation of mists. The current reaches as far north as Cape Lopez during the southern winter.

Effect of the Benguela Current

North of the equator, rains are mainly of Atlantic origin. In the south, rains are linked to humid air masses penetrating from the Atlantic Ocean (those not cooled by the Benguela Current during the southern summer and thus holding little moisture), to the humid southern trade winds penetrating from the Indian Ocean, or to the front between these two systems. Throughout central Africa during the rainy season, squalls move from east to west and release "tornadoes" (violent stormy downpours).

Orographic factors greatly modify both rainfall amounts and temperatures; highland areas tend to be wetter and cooler. The slopes and elevated topography, for example, that surround the Western Rift Valley are rainy in comparison with the relatively dry valley bottom (which receives less than 40 inches of rain per year). The western part of Rwanda and Burundi is wetter than the eastern part (*e.g.,* Akagera plain in northeastern Rwanda), which is situated at a lower elevation.

Plant and animal life. Vegetation roughly corresponds to the regional climate, relief, and geology. Equatorial central Africa is covered by an evergreen forest of almost 400,000 square miles. This rain forest—an exuberant world of high trees, rich in epiphytes and lianas—has three main forms: permanently wet marshy forests at the confluence of the Ubangi and Congo rivers; gallery forests, which are subject to periodic flooding, along banks and river floodplains; and, most extensive, forests of dry land, either featuring a single dominant species or, more often, a variety of species (sometimes several hundred per acre). This last type of forest is also found on the eastern slopes of the Congo basin, but it changes to high-altitude lifeforms on the highlands of the Western Rift Valley.

The rain forest is surrounded by a patchwork of savannas and other forests. Savannas of poor, permeable sandy soils unevenly strewn with small trees cover the plateau surfaces, whereas subequatorial forests fill the valleys. Large areas of the savanna probably were created by slash-and-burn agricultural techniques, through which the original forest was cleared and the resulting grasslands maintained by periodic bushfires. Savannas also border the cooler and drier Atlantic coast of Congo and Zaire, while mangrove thickets stretch along the banks of nearby estuaries, lagoons, and deltas.

Beyond this savanna forest region the most distinctive vegetal formation is the dry tropical forest (called miombo in the southeast). Its trees are smaller and less dense than in the equatorial forest, and they are deciduous, losing their leaves during the dry season. The dry tropical forest covers the southern Kwango and Shaba plateaus in Zaire but exists only in shreds north of the equator, in the Central African Republic. More often than not it has made room for wooded savannas. In the far north the thorny steppe is a typical Sahelian landscape.

With its steep gradients over short distances, rainy highlands, and relatively dry bottoms, the Western Rift Valley region is characterized by sharp vegetation contrasts. Central Africa's most famous national park, Zaire's Virunga National Park (formerly Albert Park), is located there. Among its animals are elephants, lions, hippopotamuses, warthogs, forest hogs, okapis, and mountain gorillas on the volcano slopes. Also in the same region is the Kahuzi-Biega National Park, which features mountain gorillas. Other parks are located in savanna or wooded savanna regions: for example, Garamba National Park in northeastern Zaire, which is well known for its white rhinoceroses,

National parks

Upemba National Park in southern Zaire, parks in the northern part of the Central African Republic, and Akagera National Park in northeastern Rwanda. Other parks and reserves are also located in the equatorial forest in Zaire, such as Maiko and Salonga national parks.

Settlement patterns. The most uniformly rainy part of tropical Africa is the least densely populated. In the late 20th century, with the exception of Burundi and Rwanda, the population density in each state was low: the number of persons per square mile was about 10 in Gabon and the Central African Republic, 15 in Congo, and 36 in Zaire. The population is not uniformly distributed, however. Immense areas of the equatorial forest are nearly empty. The obstacle that the forest poses to the African agriculturalist does not explain this situation, for large sections of the more easily cultivated savannas in the north, south, and southeast are also sparsely populated. More heavily inhabited cores are located on the northern fringe of the great forest and at some distance outside its southern fringe. The most densely inhabited region includes the interior slope of the Western Rift Valley and the Burundi and Rwanda highlands, where the density reaches several hundred persons per square mile.

A major transformation of the region has been the development of cities, which as late as the 19th century were limited to a few European coastal settlements. Urbanization was at first slow, but it gathered momentum at the end of the colonial era, especially immediately after independence, which provoked large-scale internal migrations from the countryside to the growing cities.

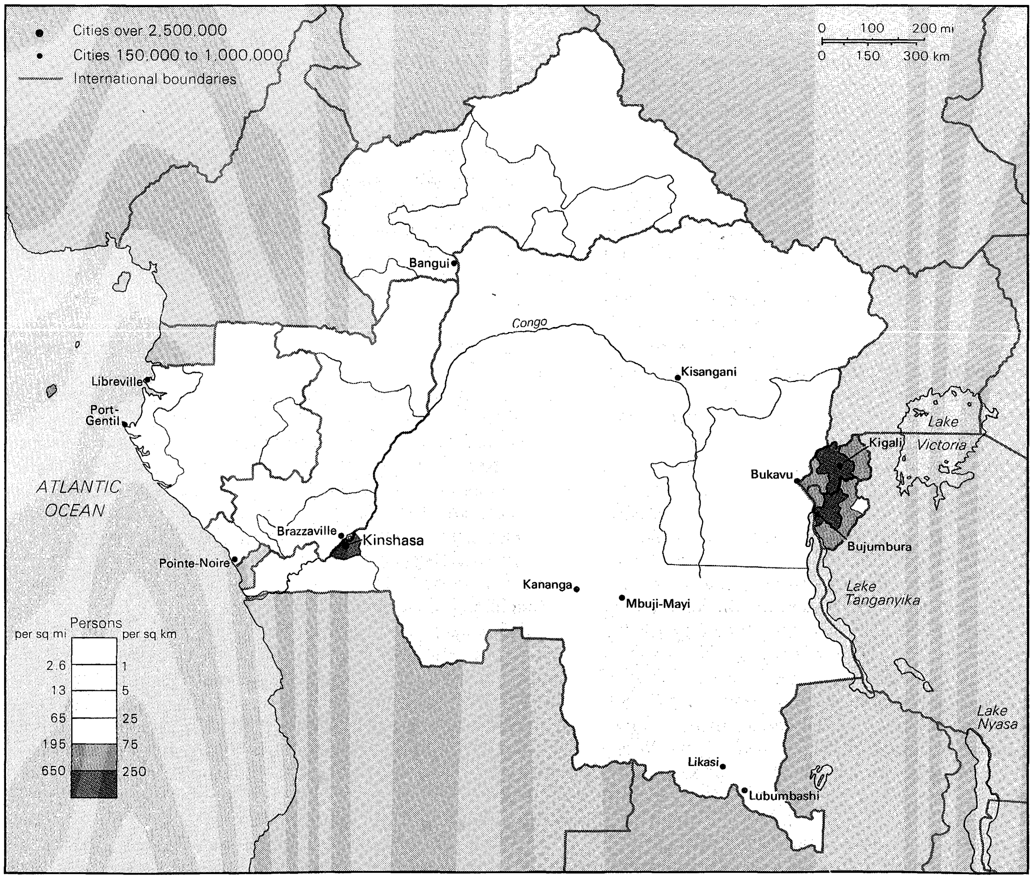
In the late 20th century about 40 percent of the population was urban in most central African countries, with heavy concentrations in the national capitals, provincial administrative centres (*e.g.,* Kananga, Zaire), mining cities (Lubumbashi, Kolwezi, and Mbuji-Mayi, Zaire), and major ports (Port-Gentil, Gabon; Pointe-Noire, Congo; and Matadi, Zaire). Paradoxically, Rwanda and Burundi—the most densely populated countries—have urbanization ratios (6 and 8 percent, respectively) that are among the lowest in the world.

THE PEOPLE

Ethnic composition. National borders have split the territory of many ethnic groups. Pygmies are scattered in the forests from Cameroon to the Kivu and Rwanda mountains. The Fang of Gabon also occupy Equatorial Guinea and southern Cameroon. The Teke are spread throughout Congo, Gabon, and Zaire. The Kongo inhabit western Zaire, western Congo, and Angola; the Chokwe (Tshokwe) and the Lunda occupy Zaire and Angola. In each country some major groups enjoy a numerically dominant position—for example, the Fang in Gabon and the Mboshi, Teke, and Kongo in Congo. Burundi and Rwanda comprise a Hutu majority (agriculturists), a Tutsi minority (pastoralists), and some Twa (Pygmies). In Zaire the major groups are the Kongo (southwest), Mongo (central basin), Luba (south-central), Zande and Mangbetu (northeast), and Ngbaka (northwest). In the Central African Republic, the Baya (Gbaya), in the west, are the most numerous, but the Banda, in the centre, occupy the largest territory. The islands of the Gulf of Guinea, owing to their history of slave plantations and, later, of plantations with a more or less enforced recruitment, have a mixed population originating from Angola as well as from western and central Africa.

Vehicular languages

Linguistic composition. Most languages spoken in central Africa belong to the Bantu group of the Niger-Congo language family. In northern central Africa, Adamawa-Eastern and Sudanic languages are also spoken. The area's rich linguistic diversity includes the use of vehicular languages (*i.e.,* lingua francas) born of local languages, pidgin-creoles (in the islands of the Gulf of Guinea), and European languages, which are the official languages of the various countries (Portuguese in São Tomé and Príncipe, French elsewhere). The vehicular languages often overlap the borders. Lingala, which is important in Zaire, is also spoken in Congo, as are Kongo and Sango, which, in turn, is the main language in the Central African Republic. Swahili, the eastern Africa language, is the lingua franca in eastern Zaire and among the merchants of Burundi and Rwanda. In the latter countries, Rundi (more prop-



Population density of central Africa.

erly, Kirundi) and Rwanda (Kinyarwanda) are (along with French) the official languages.

Demographic trends. As a whole, central Africa has undergone extensive population growth in the latter half of the 20th century. During the 1980s annual growth rates equaled or exceeded 2.5 percent. This rapid growth is a relatively recent historical phenomenon, however. At the turn of the century great epidemics (especially of sleeping sickness)—perhaps worsened by the colonial occupation, which ended ancient isolation—added their effects to those of the other major tropical endemic diseases (malaria, leprosy, and various parasitoses such as filariasis and bilharzia). The population then diminished tangibly. After the 1930s vigorous medical action and a noticeable improvement in hygiene stopped this process and even enabled rapid population growth—except for groups such as the Fang of Gabon, the Nzakara and Zande of the Central African Republic and Zaire, and the Mongo of the Congo basin, whose fertility rates were abnormally low, but which have recently approached those of other groups.

Traditional societies. The Pygmies are hunter-gatherers. Physical characteristics (small stature, thinner lips, clearer skin) distinguish them from their Bantu neighbours, whose language they generally speak. The Pygmies live in symbiosis with their neighbours, supplying them with meat in exchange for agricultural products and iron weapons. They move their campsites frequently throughout the forest regions.

The major part of central Africa's population, however, lives in rural societies with a strong traditional character. These societies are usually organized on a kinship basis of either patrilineal or matrilineal consanguinity (in this case the head of the family is often the maternal uncle). The group that receives a bride must pay compensation in the form of matrimonial possessions to the group which supplied her. Polygyny, in varying degrees, is common almost everywhere.

Land is in principle the collective property of the clan. The headman of the lineage (branch of the clan) is the ruler of the land and divides its use. The rural population most often lives in villages with houses built of local vegetal materials and mud. In contrast to village life, in eastern Zaire, Burundi, and Rwanda the population is dispersed. Each family dwells in an enclosure in the middle of its fields and banana trees.

Religious beliefs

The majority of these populations believe in a creator-god associated with nature spirits. Ancestors, especially the next of kin, are worshiped. A large part of the population is, in principle, Christian, but in many regions the number is lower than 30 percent. Roman Catholicism dominates but is closely followed by Protestantism. The Roman Catholic church is the strongest in Rwanda. Local African Christian churches with a messianic character are of great importance in Congo (Matsouanists, Mpadists) and Zaire (Kimbanguism). Islām has some devotees in the eastern regions—where it was spread during the 19th century by Swahili traders from the Indian Ocean coast—as well as in the north of the Central African Republic. Small Muslim merchant groups also live in the cities.

Traditional political life does not reach above the village level in most forest-dwelling groups. In the savanna, however, there are chiefdoms, varying in size and often with sacral power. Some of these have brought together thousands of individuals, as, for example, the former Kongo, Lunda, Luba, and Kuba kingdoms. Some groups in eastern Zaire, the Rwandese, and the Burundese were organized into kingdoms under a king or mwami. The Zande and the Mangbetu of northeastern Zaire and the Central African Republic built their kingdoms by conquest.

THE ECONOMY

Agriculture, forestry, and fishing. *Traditional agriculture.* Farming societies practice a subsistence agriculture intended to ensure family nutrition. Its rhythm is linked to the rain cycle. Fields are cleared or reclaimed by cutting and burning the forest or the savanna during the dry season and are left fallow after one or more crops. Tools are rudimentary, and there is little, if any, use of manure, which a small stock-farming operation—limited to a few goats or sheep and some chickens (rarely a pig)—cannot in any case supply. No other equipment is used for growing, processing, or transporting the produce. The tasks are distributed between men and women, but the women's participation is substantially greater than the men's. The wife carries nearly the whole burden of the family nutritional subsistence, though the husband participates a little more actively in the trading cultures. Yields are low owing to the general poverty of soils, the absence of fertilizer, and the poor quality of seeds. Heavily populated regions (*e.g.,* parts of Zaire, Rwanda, and Burundi) use more intensive forms of agriculture.

Plantains are the staple food crop in the equatorial forest region; yam and taro are of secondary importance. Since the 19th century, cassava has become more important. Fats are furnished by oil palm trees that often grow wild in the bush. In the savanna regions, in the north as well as in the south, cereal plants such as sorghum and millet dominated in the past, but they have been partially replaced by cassava and corn (maize). Peanuts (groundnuts) are also grown. In the north, sesame is traditionally included in crop rotation. In the highlands (eastern Zaire, Rwanda, Burundi), sorghum, traditional cereals, bananas (used to brew beer), kidney beans, sweet potatoes, and corn are grown.

Stock raising

There is traditionally no cattle raising in most of central Africa, either because this technique was never known by its inhabitants or because of the widespread presence of the tsetse fly, carrier of trypanosomiasis, a disease that attacks both humans (sleeping sickness) and domestic animals (nagana), especially cattle and horses. Stock farming exists in the east and northeast, mainly in the highlands of eastern Zaire, Burundi, and Rwanda, where the tsetse fly is not found. Bororo nomadic stockbreeders, originally from Cameroon, began migrating to the Central African Republic in the 1920s. Pastoralist groups also live in the eastern and northeastern part of this country, into which herds from The Sudan frequently move.

Fishing, an important source of animal protein, is practiced in the interior rivers and lakes and supplies an important trade. There is a small amount of sea fishing in the cool coastal waters.

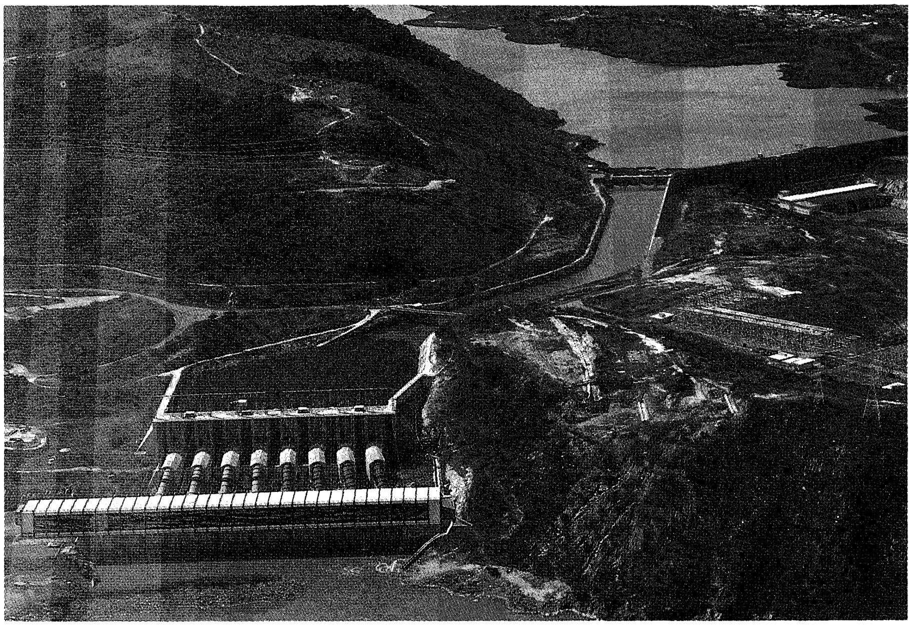
Commercial agriculture. Since the colonial period, agriculture has been part of a monetary economy. From that time, a part of the vegetable production has been intended for the urban markets. Cash crops were often introduced by the colonial authorities: cotton, urena fibres, tobacco, peanuts, robusta coffee in the low regions and arabica coffee in high-altitude regions, cacao, and hevea.

During the colonial era large oil palm, sugarcane, coffee, cacao, and hevea plantations and smaller estates were established by European companies and settlers. Timber was cut in the coastal region forests (especially the limba tree in Zaire and the okoume tree in Gabon) and in the internal forests of northern Congo, southern Central African Republic, and the Lake Mai-Ndombe region in Zaire. Wood was the most important export for Gabon and Congo until the start of petroleum exploitation. Stock-farming ranches were established to supply the cities and, especially, the mining camps.

Agro-industrial models

Most of these estates were returned to nationals after 1960. Several governments have since founded (or helped to found) large agro-industrial companies, for example, in Congo, which adopted a socialist political model with general consolidation of small producer holdings together with centralized planning. But some multinational companies have preserved a dominance in the related area of agribusiness. Unlike most of central Africa, the islands of the Gulf of Guinea continue to be dominated by the plantation system, where cacao plantations followed the 19th-century sugarcane plantations.

Industry. *Resources and mining.* The exploitation of mineral resources contributes substantially to the economy of central Africa. In Zaire, ore fields located in the central and southern regions of the country produce copper, cobalt, manganese, zinc, and tin; quantities of tin are also mined in Rwanda. After independence Gabon was transformed into a mining state, with manganese, uranium, and, especially, petroleum forming the basis of its



The hydroelectric dam on the Congo River at Inga Falls, near Matadi, Zaire.
COMSTOCK INC./Georg Gerster

economy. Gabon was the first petroleum-producing country in central Africa; in Congo, the second largest producer in the region, petroleum accounts for about 90 percent of all exports. There is a modest amount of petroleum production in Zaire. Precious minerals are mined in several countries. Gold washing in some of the region's rivers has developed since 1960, and diamonds are mined in Zaire and the Central African Republic.

Zaire began to tap the hydroelectric potential of the Congo River in the early 1970s through an installation at Inga Falls, about 25 miles (40 kilometres) upstream from the port of Matadi. One of the largest hydroelectric dam projects in the world, the Inga Falls complex provides power mainly for Zaire's mineral processing industries. Other hydroelectric sites in Zaire and Congo have also been developed, mainly in the mining regions.

Manufacturing. Industrial activity remains on a small scale. In the mid-1980s, except for Zaire, Gabon, and Congo, the manufacturing sector accounted for less than 20 percent of the gross domestic product. The main industry consists of the processing of mining products. Major processing centres in Zaire are Lubumbashi, Kolwezi, and Likasi. Sugar mills, sawmills, plywood factories, palm-oil works, cotton ginneries, rubber processing plants, and coffee-dehusking factories are scattered around the countryside. Cement plants are located in western Congo and western and southeastern Zaire.

Other industrial activities are concentrated in the capital cities and the ports of Pointe-Noire, Congo, and Libreville and Port-Gentil, Gabon. These locations primarily manufacture consumer goods such as cotton textiles, shoes, beverages (mainly breweries), tobacco products, soap, and some import substitutes. The low overall standard of living, however, has narrowed the market for consumer goods, hampering the growth of such industries.

Rail systems

Transportation. The 19th-century explorers Henry Morton Stanley and Pierre Savorgnan de Brazza both stressed that without a railway it was impossible to take advantage of the resources of the interior Congo basin, which is insulated from the Atlantic Ocean by rapids and waterfalls. The Matadi-Kinshasa railway began operation in 1898, and the Congo-Ocean Railway between Pointe-Noire and Brazzaville began in 1934. The copper belt of southern Zaire was opened by a web of railways leading to South Africa and Mozambique, to Matadi (by a mixed route of railway to Kasai and then waterway to Kinshasa, where it met the Matadi-Kinshasa line), and to the Angolan port of Lobito (via the Benguela Railway). This web is linked with the Chemins de Fer des Grands Lacs leading to Lake Tanganyika. Rail lines were also laid to bypass the Lualaba rapids upstream of Kisangani, Zaire, thus providing a link between the Lualaba and Congo waterways. In the mid-1950s the Comilog railway was built in west-central Congo to transport manganese ore from Moanda, Gabon, to the port of Pointe-Noire for export. It runs 180 miles south from the Congo-Gabon border (where it is linked to Moanda by a 47-mile cable car system) to join the Congo-Ocean line. The Transgabon Railroad has linked the port of Libreville with Franceville in the eastern interior since 1987; it passes through the important manganese-producing fields near Moanda.

In general the railway, road, and domestic waterway networks have greatly declined in quality since the 1960s. This situation has not been sufficiently matched by the increase of domestic air transport. The Central African Republic continues to suffer from its landlocked location. No rapid transport links give it access to coastal ports; the most direct connections are by road through Cameroon and via the Ubangi and Congo waterway to Brazzaville and then by railway to Pointe-Noire. Rwanda and Burundi send their products through eastern Africa, by road through Uganda or northern Tanzania and then by rail to Mombasa, or, from Burundi, to Dar es Salaam.

Finance and trade. Nearly all industry in central Africa—except for some state-owned companies and a few businesses of mixed public and private ownership—is the product of overseas investment. Before 1960 this came mainly from the colonial power. Some states have nationalized or transferred these assets to their own citizens since independence. These measures have promoted the growth of a middle class that is linked with the political and governmental circles. As a result of poor management, some capital assets in Zaire have been returned to the original investors. Because there is little market for consumer goods, most investment is directed toward export commodities.

Exports and imports

The Central African Republic (cotton), Burundi and Rwanda (coffee), and São Tomé and Príncipe (cocoa) primarily export agricultural products, whereas the main exports of Zaire, Congo, and Gabon are mineral products. Since 1960 the share taken by mining products in these countries has risen as farm exports have fallen owing to inadequate transportation, weak administrative and agronomic management, and the setting of price limits on farm produce. The countries of the European Economic Community and the United States are the leading trading partners. Major imports include petroleum (except in Congo and Gabon) and manufactured products.

Regional cooperation. Difficulties encountered since the accession to independence (disruption of transportation systems, adverse effects of political ideologies and domestic political troubles, drop in prices for agricultural products and sudden fluctuation in bullion quotations, exaggerated growth of the civil service, monetary inflation, and management inadequacy) have led most countries (except Rwanda) to run huge debts. These have been increased, moreover, by the launching of major development projects, some yielding insufficient results (projects linked with the Inga hydroelectric facility or the Transgabon Railroad, for example). For most countries this has resulted in intervention by the International Monetary Fund. Attempts at cooperation in the economic sector remain weak and often link countries that were previously dependent on the same colonial power. Since 1976 Gabon, Congo, and the Central African Republic have been members of the Franc Zone and, with Cameroon, Equatorial Guinea, and Chad, of the Customs and Economic Union of Central Africa (UDEAC). Since 1976, Zaire, Burundi, and Rwanda have belonged to the Economic Community of the Great Lakes Countries (CEPGL). These countries, except Zaire, have also joined the Preferential Trade Area (ZEP). All the central African states are members of the Economic Community of the Central African States (CEEAC), founded in 1983. (He.Ni.)

History

Central Africa consists of three parallel belts of tropical terrain that follow the equator from the Atlantic to the mountains and lakes of the East African borderlands. The northern and southern belts are predominantly orchard woodland with areas of savanna grassland that are either man-made or occur naturally where altitude and soil are appropriate. The middle belt has at most times in the Earth's history been thickly forested, but an increased population dedicated to farming and timber exploitation led to extensive deforestation in the 20th century. One unifying feature of the region is the great Congo (Zaire) River, which rises in the far southeast, crosses the savanna and the forest, captures tributaries from the northern savanna, and recrosses the forest to enter the Atlantic in the southwestern corner of the region. The river has been a source of food and a means of communication over hundreds of generations, but it has also provided an environment in which human and animal diseases have endangered life.

Three historical stages

The population of central Africa has evolved in three broad time zones. During the earliest, which covered a million years, early humans sought food and shelter throughout the savanna regions and probably in the forest as well, though the forest may have been much thinner in the great dry phases of Africa's climatic history. In the second phase *Homo sapiens,* modern man and woman, came to the region and absorbed or eclipsed the thinly scattered original inhabitants over a 100,000-year stretch. The third phase covered less than 10,000 years and brought the development of the societies that have become familiar to modern history. These societies arose from a blend of old populations familiar with the ecological environment and new immigrants with fresh skills to impart.

EARLY SOCIETY AND ECONOMY

Early toolmakers. The oldest population is known almost exclusively from the evidence of its tools. Humankind had made a great intellectual step beyond its fellow primates by learning how to fashion and use tools of a regular form for a specific purpose. The most famous of the Paleolithic tools are the Acheulian knives, oddly known to scientists as "hand axes," used to skin animals and cut meat into chunks that could be chewed raw. Those used in central Africa bear an uncanny resemblance to those used in many other parts of the Old World, suggesting that learning was an intercontinental phenomenon, however slow the transfer of technology may have been. Some of the tools used in central Africa bear marks of local specialization and adaptation, but broadly central Africa was integrated into the culture of the Paleolithic period.

The middle phase of central Africa's prehistory saw significant change, but again the changes suggest that the region was linked to development in other parts of the world. The use of fire to roast vegetable foods as well as meats increased the range of diet and probably resulted in greater human health and fertility. The expanding population may have benefited from new skills in communication. The first use of language enabled societies to become more organized and efficient in their command of natural resources. Mobility in search of food was still the norm, but speech allowed the coordination of effort on a scale that hunting animals could not achieve despite their powers of instinct. The use of tools became ever more varied, though the great majority were probably made of wood or vegetable and animal fibre and so have not survived in the archaeological record. The stone weapons, on the other hand, have survived and show a growing inventiveness among the scattered little bands of central African peoples who survived for millennia in competition with their much fiercer and stronger animal neighbours.

The agricultural revolution. About 10,000 years ago central Africa began to undergo an economic revolution. It started in the north, where a new dry phase in the world's history forced people to make better use of a more limited part of their environment as the desert spread southward once more. Hunters who had roamed the savanna settled beside the rivers and perfected their skills as fishermen. Gatherers who had harvested wild grain on the plains settled beside lakes, where they could sow some of their gleanings as seed in the moist and fertile soils left by the waters that withdrew at the end of each wet season. The northern border of central Africa became one of the cradles of the world's food-producing revolution.

Appearance of vegeculture

The first features of the new way of life in northern central Africa were vegeculture and agriculture. Vegeculture enabled people to collect wild plants on a more systematic basis and to protect the regions where wild tubers grew most plentifully. The regular harvesting of wild roots led to the perfection of specialized digging tools. Stone hoes were ground to a finer polish than the chipped cutting tools of an earlier age. Gradually women and men learned how to clear plots of fertile land and deliberately plant a piece of each root or tuber they ate to allow it to regenerate. They began to select the plant types that most readily lent themselves to domestication, to the ennoblement of regular crops, and to the development of agriculture. The white Guinea yam, *Dioscorea rotundata,* was the basis of the new root farming, which enabled the population to grow in the northern savanna from about 5000 BC.

The second phase of the local agricultural revolution was even more important and had an impact over a wide area of the tropical world. A type of cereal farming based on wild seed of the millet and sorghum families was first developed in the northern savanna. Millet farming became particularly successful in the tropics because, unlike wheat and barley, it did not require the long daylight hours of summer that occur in the temperate climes. Tropical cereals spread from central Africa not only into West Africa but also eastward to India and eventually southward to southern Africa.

The third phase of the food-producing revolution brought an increase in the scale of food production and in its quality. The tending of trees and the gathering of fruit was probably as old as any other form of vegeculture. One of the most valuable of the tree crops was the oil palm, *Elaeis guineensis.* The preparation of palm fruits to make cooking oil enhanced the nutritional quality of the diet with both proteins and vitamins, further enhancing health and leading to population growth and the search for new land to be colonized and cultivated. The tending of trees also enhanced the quality of life in another dimension: some palm trees could be tapped for their sap, and the juice became the basis of a widespread wine industry, adding a festivity to communal life.

A fourth and last aspect of early farming in central Africa was the arrival of a new family of plants. This was the banana family (Musaceae), originally domesticated in the islands of Southeast Asia. Banana plants, like yam tubers, were propagated by cuttings and roots rather than by seeds, but they gradually spread from neighbour to neighbour until the crop had become a dominant one in many parts of central Africa. Banana plants supplied edible roots and textile fibres, but the two fundamental contributions were vegetable bananas (plantains) for cooking and sweet bananas for brewing. The banana flourished particularly well in the wetter areas—in the forest, along the rivers, and in the mountains—and to many societies it became the essential crop. Steamed, baked, fried, or boiled, the banana became the staple carbohydrate of many central African peoples, and they washed it down with a banana beer rich in nutrients.

The agricultural revolution in central Africa was paralleled by another nutritional change as people became more skilled at catching fish. Fishermen—like farmers but unlike hunters—could settle in more permanent village communities. Their diet was richer and more varied. They could own more possessions than simply the weapons and clothes they carried with them. They could make rafts and canoes to transport people and goods on the numerous rivers and lakes. The most important technical innovation was the use of clay for making pots for cooking, brewing, and storing food or drink. A whole "fish-stew revolution" occurred when cooking could be done in earthenware vessels. Pottery also gives the earliest clues about the artistic styles of central Africa; dotted and waved patterns were drawn on pot rims.

The "fish-stew revolution"

The growth of settled communities of hamlets and villages to which food was brought by carriers and canoes led to changes in architecture, social organization, land law and property rights, and warfare and the defense of territory. Although most families probably remained self-sufficient and did their own building, thatching, net making, and pot throwing, some skills may have been concentrated in the hands of a few people of authority or experience. Little evidence survives of Neolithic religion and ritual, but societies surely would have had priests to mediate between the gods and the mortals and to assist with the search for security in an age when the natural forces of fire or flood, plague or famine, were subject only to the most limited human control.

One important change that entered into the Neolithic world of central Africa in the last millennium BC was the spread of new languages. These were spoken in the relatively prosperous and thickly peopled savanna and plateau regions of the Cameroon-Nigeria borderland and came to be known as the Bantu languages, meaning simply the languages of the people, the *bantu*. Languages spread along lines of communication: they followed trade as specialists offered their finest pots or their best axes for sale to their neighbours. They became the vernacular of the clustered villages. They were picked up by countryfolk who came to market. They were carried into new frontier lands by pioneers seeking less crowded spaces. Within 1,000 to 2,000 years the eastern Bantu languages had spread across the northern border of central Africa to reach the highlands of East Africa. Meanwhile, the speakers of the western Bantu languages had found new niches in the great forest and established rapport with the old hunting and foraging communities of both the coast and the river basins.

Development of Bantu languages

Not all the peoples of central Africa were converted to Bantu speech and to the economic way of life of their new neighbours in the first flush of contact. Some hunting societies, commonly known as Pygmies, retained much of their own culture and life-style for another 2,000 years. Some intermarriage occurred with the Bantu speakers of the new villages, and the exchange of hunted meat for grown produce fostered a fairly close symbiotic relationship. Eventually even the Pygmy groups spoke the language of the new majority, which came to outnumber them in nearly all parts of the region. In the deepest forest, however, the hunting societies were able to protect traditional values to a marked degree. Even the great social and political upheavals that accompanied the advent of the Iron Age did not unduly disturb their long-standing and highly specialized relationship with the tropical environment.

The Iron Age. The Iron Age reached central Africa more or less at the same time it reached western Europe, slightly more than 2,000 years ago. The hallmark of the new era was technological innovation, but the social and economic changes that metalworking brought about were fundamental to the agricultural communities—if not to the hunting communities—of the tropics. Ironworking, unlike agriculture, was not a local invention but was a skill that spread from community to community as the superiority of metal tools and weapons came to be recognized. Iron smelting came into central Africa from two directions. In the northwest the oldest source of the new knowledge was on the Nigerian plateau. The skill necessary to dig pit furnaces and surround them with ranks of bellows spread among the Bantu-speaking peoples of the western forest. Gradually the polished stone tools that they had perfected were replaced by much more expensive but effective iron ones. Initially iron was probably used mainly for small and valuable objects such as razors, needles, and knives; later, as the smelting technique became more commonplace, iron came to be used for cutlasses, axes, and, eventually, hoes, which replaced the old wooden digging sticks.

The second source of technical information in central Africa was probably the middle valley of the Nile, where the city of Meroe had been an early industrial site with a huge charcoal industry and great piles of iron slag surrounding its furnaces. The eastern tradition of smelting used furnaces as well as bellows to create the necessary draft with which to turn charcoal and ironstone into wrought iron and molten waste. The iron masters became revered craftsmen and were accorded a quasi-religious status. They lived in some seclusion and often commanded a degree of political authority over their neighbours. Legends of blacksmith-princes became commonplace in the historical folklore of central Africa. Iron became important not only in the immediate locality but also in a developing interregional trade. Although ironstone and charcoal wood were relatively common in most areas, the best smiths could nevertheless command a premium for their wares, and in some regions of deep blown sand or wide alluvial soils, where ores were not available, iron tools and weapons had to be bought from itinerant tinkers.

Iron was a valuable commodity, both raw in wrought bars and worked into spears or machetes. Even more valuable, however, was copper. Unlike northern Africa, central Africa had no Copper or Bronze Age in the last millennium BC, and it was in the Iron Age that the value of copper came to be recognized. Copper was particularly appreciated for its colour and lustre and was used for personal jewelry, rings, bangles, chains, necklaces, and hair ornaments—all made with great craftsmanship and given to persons loved or revered. Copper was also used in the ornamenting of personal belongings, the inlaying of decorations on knife handles, the binding of spear hafts with fine copper wire, and the embellishing of shields with burnished copper nails. Much of the copper mined in central Africa was used to furnish the graves of important people with beautiful objects. The demand for fresh copper rose with each new generation. In particular, the development of new political authorities in the Iron Age led to the need for court regalia for chiefs and kings. Copper was used not only for its visual brilliance but also for the musical quality of the copper instruments that accompanied the nobility on their progress around their domains.

Copper smithing

The three main zones of copper working in central Africa were the Nile watershed, the eastern savanna, and the southwestern forest. Each industrial complex was a thousand miles from the next, and trade intensified as the demand for copper increased. The oldest and largest mines were those of the east. By the end of the first millennium AD, the mines of the Shaba (or "Copper") province of Zaire were casting copper ingots into molds of standard sizes for the international traffic. The region remained one of the world's greatest copper-mining areas for the next thousand years. In the north the copper was used to enhance the wealth and prestige of the local population, but it also fed into the long-distance trade networks of the southern Sahara, particularly after these had been strengthened and organized by Muslim merchants and entrepreneurs in the later Middle Ages. The third copper complex, on the lower Congo River, remained an important but localized industry until a later date. At the end of the 16th century, however, the miners discovered a new outlet for their copper in Europe and sold large quantities to sea merchants from the Netherlands in exchange for Indian textiles, Chinese porcelain, South American tobacco, and stone jars of Dutch gin.

Growth of trade. The development of the copper industry caused many of the peoples of central Africa to look to their own resources for produce that could be sold in order to buy the prestigious new metal and other exotic goods. The salt industry developed out of the needs of long-distance trade. The salt lagoons of the west coast became particularly important, and salt tracks ran far into the interior to agricultural communities without salt of their own to season the cereal dishes which millet growing had made the staple food. Away from the coast, communities that had access to salt mines, or to dried salt lakes, organized exploitation and marketing, sometimes going far afield to the salt mines of East Africa. Where salt was not available, or where the costs of transport made it prohibitively expensive, people had to make do with salt substitutes such as the ash of marsh plants. Where real salt was produced, however, the industry became a focus for political power, and early states were formed, as on the Loango coast of modern Congo.

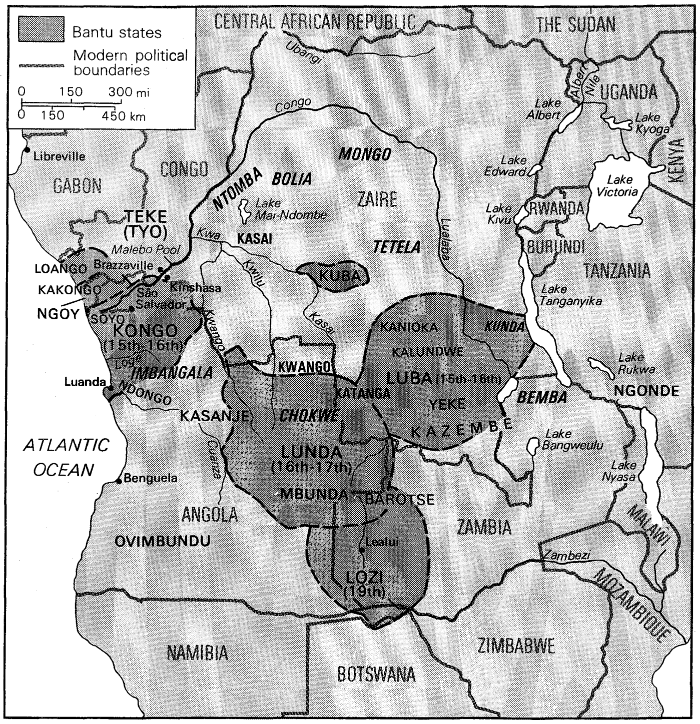
Of comparable importance to copper and salt was the textile industry. This also led to long-distance trade as specialized cloths were made for export to neighbouring regions. Like the salt industry, the textile industry sometimes was controlled by princes who dominated the markets and supplied protection to the caravanners who carried the bales of cloth. In western central Africa the textile industry was based on fibre drawn from the raffia palm. The quality of the finished product, which sometimes had a velvetlike pile and a rich range of natural colours, was much admired by the first foreign visitors to the region. Indeed, raffia squares became the basis of colonial currency in the 17th century. Before that, raffia trading to and from the forest palm groves became one of the sources of wealth among kings in the Kongo kingdom.

Social importance of textiles

Textile weaving in central Africa was important not only to kings and colonial governors but also in regulating social relations. Cloth provided one of the more durable and valuable possessions in every household. It therefore became the preferred item for social payments. In particular, bride wealth—which in other societies might be paid in gold or cattle—was commonly paid in cloth. The control of weaving was in the hands of old men. They no longer had the strength of young men to go hunting or to raid their neighbours, but they did control social wealth by monopolizing the weaving of raffia cloth. Young men had no access to the cloth and thus could not get married and set up a household; they remained dependent on the elders. The old men controlled cloth, and thus marriage, and could in the last years of their lives marry several young wives and ensure that their own line would be dominant in the next generation. In small and scattered societies across central Africa marriage was an important link between communities. Marrying into one's own clan or lineage was not always desirable, and maintaining contacts with neighbours in order to exchange brides was necessary. Permanent overarching political systems were not common, but the regular patterns of social communication went beyond merely commercial ones.

Another source of wealth that became important throughout the history of central Africa was the trade in dried fish. The management of fish ponds became one way in which the scale of political power increased from village size to state size. The lakes of the eastern savanna provide one example of early state formation. The medieval ancestors of the Luba became wealthy and powerful by controlling the fishing industry, building canoes and drying ovens, and setting up networks of trade paths along which porters carried tightly packed headloads of dried fish. In tropical conditions many foods were perishable, but dried fish could be preserved for months and carried to regions deficient in protein, where it was sold for high prices. The fish trade of the great rivers remained important, and fishermen were among the wealthier of the river dwellers. In the 20th century they were able to motorize their canoes, refrigerate their catches, and use steamers for long-distance transport.

In most of central Africa the scale of political management remained small; the power brokers were men who gained influence in local communities. Kingdoms were not the norm. In a few places, however, administration was organized on a scale that went beyond a single day's march from the central homestead. The most striking of the early kingdoms was that of the Kuba peoples, at the heart of the southern forest. Kuba kings controlled the resources of a diverse ecological environment. They built up trade networks that enabled them to obtain copper from far afield and, later, even to buy such valuable ornamental assets as cowrie shells from the Indian Ocean, which were traded from community to community across Africa. The kings of the Kuba based their claim to power on a mystical exotic origin, far away down the rivers to the west, though such an alien pedigree bore no historical justification. Power had more to do with membership in influential local groups than with migration. Wealth, the ownership of livestock, the control of land, the mobilization of militias—these were the features of state formation in those rare areas where kingship could flourish. The Kuba knew government on a scale comparable to the early fish-trading states of the Luba and the raffia-weaving principalities of the Kongo kings.



Bantu states of central Africa from the 15th to the 19th century.

From J. Fage, *An Atlas of African History;* Edward Arnold (Publishers) Ltd.

CENTRAL AFRICA AND THE OUTER WORLD

Development of the slave trade. In the 15th century central Africa came into regular contact with the outer world for the first time. Hitherto all external contact had been indirect and slow. Language, technology, and precious objects had spread to affect peoples' lives, but no regular contact was maintained. In the 15th century central Africa opened direct relations both with the Mediterranean world of Islām and with the Atlantic world of Christendom. The Islāmic contacts remained limited until the 19th century, though the great Spanish Muslim Leo Africanus visited the northern states of central Africa in the early 16th century and described them in Latin for the benefit of the Vatican, where he worked for a time.

The Atlantic opening had an earlier and more direct impact on central Africa than the Mediterranean opening. In the 1470s a colony of Portuguese was settled on the offshore island of São Tomé. The Portuguese had been experimenting with colonial plantations for more than a century and already had settlements on Cape Verde and the Canary and Madeira islands. On São Tomé they es-

Plantations on São Tomé

tablished fields of sugarcane and built sugar mills. This prototype industry, which was later taken to Brazil and the Caribbean, became the richest branch of Europe's colonial enterprise and had a lasting impact on the history of the African mainland. Settlers were unable to build plantations unaided and so recruited local support. European immigrants—predominantly if not exclusively male—sought out African consorts from the adjacent communities and established creole families of plantation owners and managers. They also bought mainland slaves to work the estates. São Tomé became the first bridgehead for the great Atlantic slave trade, which was to have a deep and scarring influence on most of central Africa.

Central African slaves brought to the island slave market were sold to three destinations. The strongest were sold to the Akan miners of the Gold Coast in West Africa, where royal Portuguese agents were able to buy up to half a ton of gold a year in exchange for imported commodities and slave workers from other parts of the continent. A second category of central African slave was shipped to Europe and used both for domestic service in the town and for farm labour on the sparsely peopled estates that Portuguese Christians had conquered from Portuguese Muslims in the late Middle Ages. The third class of slave was put to work locally on the island.

The fortunes of the São Tomé plantations fluctuated over the next five centuries. Sugar gave way to coffee as the mainstay, and coffee in turn was replaced by cocoa in the 19th century. In the 20th century the island was at the centre of a humanitarian storm over the continued use of slaves on the plantations. Cocoa manufacturers boycotted the island, and the planters tried to improve the working conditions of their employees. In the meantime, however, central Africa's premier colony had been eclipsed by other European ventures on the mainland.

The second attempt to build a European colony in central Africa occurred in the medieval kingdom of Kongo surrounding the mouth of the Congo River. Portuguese traders exploited a division in the ruling class to gain a foothold at the court and the support of a royal claimant, who adopted Christianity and assumed the title of Afonso I. The Portuguese had hoped to find precious metals, as they had done in West Africa and were later to do in southeastern Africa, but the only source of profit they could realize was the buying of slaves for the São Tomé market. The king was under increasing pressure to use his army to raid his neighbours for captives. Even the Roman Catholic priests attached to the colonial mission found that they had to finance their activities by trading in slaves. The increasing profitability of slaving, and the lack of alternative sources of exportable wealth, placed growing pressures on the kingdom. Eventually, after the death of Afonso, popular rebellion broke out on a virulent scale. In order to preserve their foothold the Portuguese equipped the governor of São Tomé with an army of 600 musketeers with which to reconquer their mainland base and install a pliant king in the Kongo capital. The Latin American tradition of the Iberian conquistador was thus introduced into central Africa.

The great slaving campaigns of the conquistadores began in the 1570s after the Kongo wars had been quelled. The Portuguese harbour of Luanda was taken over by the Spanish Habsburgs in 1580, when the two crowns were united, and a series of armed assaults was launched on the states of the Mbundu peoples of the interior. The basis of the invasion was the rising demand for slaves to colonize the huge but sparsely peopled provinces of Brazil. Many slaves were captured direct or obtained as ransom for important chiefs. Many more were obtained from long-distance trade networks that penetrated ever deeper into the heart of central Africa both by river and by footpath. The primary imports of the traders were textiles from India, England, North Africa, or Portugal itself. But Portugal, even with the backing of Spain, was not economically strong enough to maintain its monopoly over the foreign trade in central Africa. By the end of the 16th century competitors were frequenting the coast.

Growth of Dutch power

The Dutch were the second colonial power to influence the history of central Africa. Their impact was felt in ways rather different from that of the Portuguese. They were more interested in commodities than in slaves and so opened up the market for ivory. The old hunting skills gained a new value as the market for tusks blossomed and commercial entrepreneurs organized caravans over long distances. Even the shiest of the Pygmy forest dwellers were able to benefit from the hunting of elephants. By the mid-17th century, however, the Dutch had established their own American colonies and so joined in the scramble for slaves. They began to sell guns to their trading partners to facilitate the destruction of old communities and the capture of fugitives. The supply and sale of powder, lead, and muskets became profitable to the coastal brokers but devastating to the inland victims.

The geographic scale of the central African slave trade was enormous. By the 18th century, the supply routes to the Atlantic reached the middle of the continent and began to intersect with the long-distance trade to the Indian Ocean. As the trade spread so did the search for political systems that could manage the traffic. The largest and most successful of the new merchant empires was the empire of the Lunda at the heart of the southern savanna. The Lunda people seem to have become aware of the slave trade as early as the 16th century. Wandering Lunda hunters and salt prospectors, known as Imbangala (or Jaga), entered Angola and recruited local followers into heavily armed bands that raided the countryside, sold their captives to European sailors, and eventually formed an alliance with the Portuguese conquistadores, who allowed them to set up their own kingdom in the Kasanje plain on the borders between Lunda and the European coastal enclaves. At first the kingdom of Kasanje acted solely as merchant brokers to the Portuguese, but with the rise of rival European buyers on the northern Congo coast its network spread farther afield. As the market expanded so did the sources of supply. In the Lunda hinterland a powerful ruler adopting the title of Mwata Yamvo became chief supplier to the Kasanje intermediaries. The Lunda empire spread its commercial network not only to the west but also eastward until it had outlets to the lower Zambezi and the Indian Ocean. The Mwata Yamvo of the west and his viceroy, the Mwata Kazembe of the east, effectively monopolized the slave trade of the heartland. As the Atlantic market grew, Lunda influence spread both north toward the forest and south into the dry plain of the upper Zambezi. In the early 19th century the court began to receive ambassadorial visits from representatives of the king of Portugal, and some years later echoes of the Mwata's greatness reached the Protestant explorer-missionaries of the far south, such as David Livingstone.

In the 18th century the Dutch were replaced by the French as the leading slave merchants on the north coast of the Congo region. The scale of the trade grew rapidly. Forced Congo migrants became the dominant population in Saint Domingue, later called Haiti, which rose to be the richest of all the world's colonies and the largest supplier of sugar. The slaves were carried in crowded, disease-ridden sailing vessels, packed in 500 at a time. Those that survived weeks of suffocation, thirst, and sparse rations on the Middle Passage were sold to rich owners and put to work under cruel bailiffs. The slaves brought some of their cultural values and tried to reconstruct their communities under the shadow of the great plantation houses. Bantu vocabulary and personal names were added to the Creole speech of the Caribbean. Kongo religious practices were preserved in a nominally Christian colonial society when attempts were made to minimize the insecurity and suffering by worship and ritual. But however much the forced migrants tried to reconstruct central African society in the New World, their departure left a serious mark on the old world. The scale of the French trade rose to about 10,000 men, women, and children each year. The demographic hemorrhage was felt in spreading ripples, and the already frail population of central Africa was further weakened. Not until the outbreak of revolution in France, and later in Haiti, did the French trade begin to decline.

Long-term consequences of the slave trade

The long-term consequences of central Africa's involuntary participation in the slave trade affected more than emigration, warfare, and political organization. It also affected agriculture, the occupation of the large majority of the population. In particular, two new crops introduced to the region from the Americas enhanced the productive capacity of the land. The first was corn (maize), which required the same agricultural skills as millet and so could be easily adopted. Corn had the advantage over millet that its grain was wrapped in an envelope of leaves that protected the crop from predatory birds. Corn also had higher yields than millet where soil and water were sufficient, which increased food production and partly compensated for the loss of field hands to the slavers. The second new crop that helped central Africans to recover from the ravages of slaving was cassava, or manioc, a root crop easily adopted by tuber farmers but more difficult for grain farmers to accept. It, too, was better protected from rodents—and even from marauders—than traditional crops. Cassava could be left in the ground when farmers had to flee in war and then recovered whole and edible on their return. To those unfamiliar with cassava, however, it could be dangerous, because the protective poisons in the plant, which made it inedible to vermin, had to be washed out before it was cooked for human consumption.

New crops brought some small benefit to the region from outside, but new diseases had the opposite effect. The growth of long-distance communication led to the spread of smallpox along the slave trails. It was a disease much feared both in the villages and on the slave ships. During serious periods of warfare and raiding, populations were weakened by famine and so easily fell prey to measles and pneumonia. Central Africa was also a malarial zone, and not until late in the 19th century were even the most informed and affluent of traders aware that quinine could protect them. Equally dangerous was sleeping sickness, which periodically spread through the region in great pandemics. As though this were not enough, central Africa was attacked in the early 20th century by the world influenza pandemic. The already weakened population became thinner still and did not recover until well into the middle of the century.

The 19th century did not see the end of the central African slave trade. The Portuguese moved back into northern central Africa when the French trade declined, and Brazil bought more slaves than ever from central Africa in the first half of the century, continuing to use slaves until the 1880s. Spain also came into the market to buy slaves for its surviving American colony in Cuba, where the tobacco industry combined the modernization of the railway age with the old plantation use of slaves. Some of the last slaves also found their way illicitly to the United States, where slaves continued to be employed long after it was illegal to buy and carry them from Africa. Moral condemnation, and the arguments in favour of wage incentives for a more effective labour force, eventually led to the suppression of slave exports by the early 20th century. The end of four centuries of international slaving might have been expected to lead to a new era of freedom and opportunity in central Africa. It did not happen, and instead a whole new set of foreign forces began to penetrate the area. The first of these came from the long-delayed growth of international commerce on the northern border of the region.

Exploitation of ivory. In the second half of the 19th century the northern border of central Africa was suddenly opened up to the impact of a virulent new trade in ivory. The rise of Victorian prosperity in both Europe and North America had led to a rapid increase in demand for ivory to make piano keys, billiard balls, knife handles, and ornamental carvings. Traders from Egypt and the old Ottoman Empire of North Africa came across the Sahara and up the Nile to cross into the upper reaches of the Congo basin, where elephants were still plentiful. In so doing, they severely disrupted local societies, kidnapping local peoples as bearers, servants, and concubines in much the same way that Europeans had done on the Atlantic front. The victims of the trading and hunting razzias not only were used in the heavily armed and fortified ivory camps but also were taken away to be sold as exotic slave girls in the harems of Constantinople or as water carriers in the streets of Cairo.

The second mobile frontier to intrude on central Africa in the 19th century was in the east, and eventually it became as disruptive as the northern incursion. The first immigrants were long-distance traders from the Nyamwezi country in Tanzania who came in search of copper. They set up their own trading kingdom under Msiri and developed a large army of followers equipped with lances and bows. Msiri also trained a military elite of 2,000 men, whom he armed with guns bought on the east coast in exchange for ivory. Msiri's kingdom became one of the largest conquest states to be carved out in central Africa. He adopted the administrative methods of the old Lunda kings, whose provinces he captured and whose governors he reappointed as his own agents and consuls. He also gained control of the old empire's eastern slave trade. In this field, however, Msiri had a powerful rival in the Swahili trade community, which had reached central Africa from Zanzibar.

Trading kingdoms

The Swahili traders and their Arab allies were concerned with both the slave trade and the ivory trade. Their slaves were put to work on the spice plantations of Zanzibar or sold as pearl divers and domestic servants in the Arabian and Persian gulfs. The ivory went to the United States to buy calico, which was in great demand in eastern Zaire. One of the traders took the nickname "Americani" because his American calico was so famed. An even better-known Swahili merchant prince was Tippu Tib, who became the effective ruler of the Swahili towns on the upper reaches of the Congo River. His methods of trade were brutal. Villagers were forcibly rounded up into camps, often with great loss of life—as witnessed by Livingstone on his visit—and then ransomed by their relatives, who were sent out on hazardous elephant-trapping expeditions. The ivory trade thus disrupted the east as effectively as it disrupted the north. Worse still, the pattern of exploitation was one that was soon adopted by the first Europeans to enter the region. They also used capture and ransom to extract wealth from their victims. The first European ruler of the Congo, the Belgian king Leopold, appointed Tippu Tib as his governor and gave him command of the east in recognition of his military and commercial achievements rather than in recognition of his civilizing mission.

The great 19th-century scramble for ivory also brought disruption to central Africa from the south in the years immediately preceding the colonial partition. The agents in the south were Chokwe (Cokwe) hunters from Angola. They had been successful collectors of beeswax, and their trade had enabled them to build up armories of guns, which they eventually turned on their neighbours. They penetrated the heartland of the Lunda empire in the 1880s and destroyed the court. Their victims were sold on the Atlantic coast to be the last European-owned slaves on the old plantations of São Tomé. Their ivory went to the Portuguese after the crown had abandoned its restrictive monopoly on tusks and allowed private entrepreneurs to benefit from market forces. But when ivory became scarce and slaves were frowned upon, the Chokwe pioneered a new branch of trade that was to bring even greater horrors to the peoples of central Africa. This was the search for red rubber, the sap of the wild rubber vine that grew throughout the forest and savanna galleries of the Congo basin. As the price of rubber rose with the development of the electrical and motor industries, so the rubber traders penetrated further into the communities of refugees who had sought to escape the disruptions of the last phase of the slave trade. It was the rubber trade that financed the first stage of formal colonial rule in central Africa.

COLONIALISM

Establishment of European colonies. The pioneer colonizer in central Africa was Leopold II, king of the Belgians. The early attempts of his father, Leopold I, to found colonies in remnants of the Spanish empire in the Pacific or America had failed, and he therefore turned his attention to the heart of Africa, which was still little known to European geographers and therefore less heartily coveted than western or southern Africa. He set up his colony as a private humanitarian venture aimed at limiting the devastation of slaving and the liquor trade.

To finance the venture, however, he rented out nation-size fiefs to commercial companies that were licensed to make a profit and pay tax and tribute to the colonizer-king. Companies such as the Anglo-Belgian India Rubber Company, the Antwerp Company, and the king's own Crown Domain took over the extraction of rubber from the Chokwe. Since the profits on rubber were low compared to ivory or slaves, great pressure had to be brought to bear to encourage newly subjected villagers to forsake their agricultural livelihoods and risk their lives in the forest to gather the vine sap. Military force was used, rubber-collecting became compulsory, and defaulters were barbarically punished by having their hands amputated. The rubber regime in the western Congo was no more benign than the ivory regime that Leopold adopted from the Swahili in the east. The civilizing mission of the first colonizer turned sour very quickly.

Leopold's Congo domain

The humanitarian protest against the rule of Leopold was led by traders who had lost access to their former sphere of interest, by missionaries who deplored the savage denial of human rights, and by a British diplomat who believed in political freedom. Roger (later Sir Roger) Casement publicized the atrocities in the Congo to such good effect that in 1908 the Belgian government confiscated the colony from its own king in an attempt to put an end to the misrule of exploitation. Casement himself went on to a diplomatic career that led to the English gallows when he supported the liberation of Ireland in the same way he had advocated the liberation of the peoples of the Congo, but his humanitarianism did not take root in central Africa. However much other nations might condemn Leopold's rule, rival colonizers were also keen to make their colonies profitable and did so by farming out concessions to private enterprise and turning a blind eye to the large-scale use of forced labour in place of slavery.

The most immediate rival to Leopold in creating instant new colonies was Otto von Bismarck, chancellor of the new German Empire. Most of the colonies he created were outside of central Africa, but he did succeed in laying claim to one tiny but richly populated corner on the mountainous border of East Africa. The old kingdoms of Rwanda and Burundi had thrived for centuries. The ruling class grew tall on the milk of its cattle and governed its farming subjects with imperious superiority. In the forest the old inhabitants continued to maintain their hunting values and, where possible, to escape the attentions of their neighbours. In the late 19th century Burundi underwent severe dislocation, with conflicts over the monarchy and rivalry between chiefs and kings. The Germans moved in from Tanganyika and tried to impose order. They also took over the more stable kingdom of Rwanda, though not for long. In the middle of World War I, the Belgians effectively annexed both kingdoms to their Congo colony and gradually incorporated them into a central colonial administration. The League of Nations maintained watch over the Belgian mandate to care for the interests of former German colonial subjects. The responsibility did not lead to interference, and after World War II the United Nations confirmed Belgian authority and allowed it to continue for nearly another 20 years before the two kingdoms were again separated from one another and given internationally recognized independence.

The French in central Africa

Although the German intrusion into central Africa from the east was slight and short-lived, a comparable French intrusion in the west led to the creation of a much bigger and more lasting equatorial empire. It was the work of the explorer-turned-governor Pierre Savorgnan de Brazza. The roots of the French presence consisted of disused slaving beaches on the Congo coast and a haven for freed slaves called Libreville on the Gabon Estuary. Brazza aspired to join these coastal enclaves to the middle stretch of the Congo River, where the colonial capital was named Brazzaville in his honour. He also aspired to claim territory for France as far east as the upper regions of the Nile. Such an enterprise brought France into competition not only with Leopold, on the far bank of the river, but also with Britain, which had laid claim to the lower Nile in Egypt and wanted to protect the headwaters by conquering the upper Nile as well. The French were narrowly defeated in the race to the Nile but nevertheless gained imperial dominion over a huge stretch of northern central Africa, which they called Ubangi-Shari and which later became the diamond-rich Central African Republic.

The problems that France faced in central Africa were not materially different from those faced by Leopold. The territories were huge, thinly peopled, and poorly endowed with resources that could finance colonial administration and make a profit for the colonizing power. Transport was the greatest difficulty. Leopold went so far as to claim that the essence of colonization was the creation of a transport system. Both France and Leopold were handicapped by the rapids on the lower Congo River and so each had, at huge cost in money and men, to build a railway to reach the navigable middle river. Leopold used a Welshman, Henry Morton Stanley, the Breaker of Rocks (Bula Mutari), to mobilize the necessary forced labour to gain access to his territory. The French tried importing Chinese workers, who could be hired in Asia even more cheaply than local labour could be conscripted in Africa.

The French imitated Leopold—and also the British and Portuguese in south-central Africa—by awarding concessions to colonial companies on the condition that they take responsibility for their own administration and infrastructure in return for the right to extract profits from subject peoples and conquered lands. The most notorious of the French colonial entrepreneurs made their money out of timber concessions. Only toward the end of the colonial period and after did French Equatorial Africa discover that it was rich in iron ore, petroleum, and uranium.

Economic organization. The violent phase of central African colonialism, involving the forced extraction of rubber, ivory, and timber, was followed by a more systematic phase of economic organization. One facet was the establishment of formal plantations on which to grow oil palms and rubber trees. These plantations required capital, machinery, and expensive foreign management. As a result, there was little margin left for adequate wages for workers. The recruitment of labour became the duty of the colonial state or its licensed agents. Some workers accepted the incentive of a cash wage to buy material goods or to accumulate the necessary social payments for marriage. Others were driven into the wage sector by the imposition of cash taxes, which could only be met by working for colonial enterprises. But some were recruited on a compulsory basis—not as convicts deserving of punishment but as subjects who needed to be "civilized" by submitting to a work regime imposed by the state.

Where plantations did not develop, the colonial state found a means of extracting wealth from free peasants. They introduced compulsory crops, most notably cotton—"le coton du gouverneur." Forced cotton imposed severe hardships on farmers, who could not grow family food but instead had to clear land to sow cotton seed for the state. When the crop succeeded, they received a small payment. But much of the cotton regime was applied to marginal lands, where it often failed. The risk was borne by the victim, and famine resulted. The planting of cotton led to frequent protests and to harsh repression in central Africa, as it did in German East Africa and Portuguese West Africa.

The largest industrial complex to develop in central Africa was the mining industry of the copper belt in far southeastern Zaire. Leopold had won a race with the British empire builder Cecil Rhodes to reach the copper mines and had conquered the kingdom of Msiri, killing the king in the process. The next challenge was to build a transport system that could carry machinery into the mining zone and export finished ingots. The politics of transport were the key to development in the high colonial period, as they had been in the early phase. Two railway lines ran to the Indian Ocean coast: one was built across German Africa to the port of Dar es Salaam and another through British Zambesia to the Portuguese port of Beira; a third railroad crossed Angola to the harbour of Lobito on the Atlantic. None of these, however, was under the control of the Belgians, who planned to create a national route to their own port of Matadi on the Congo estuary. To do so, they had to use an expensive and complex mixture of rail and river steamers, and so the copper mines remained integrated in an international network of finance and transport. They also depended on neighbouring regions for their supply of coal and electricity. The industry was dominated by a concession company, the Union Minière du Haut-Katanga, which became almost as powerful as the colonial state itself. The two were interlocked in rivalry and mutual dependence, and the Belgian Congo was described as the "portfolio state" for its reliance on copper shares.

Social consequences of the colonial economy

Two other mining zones added to the wealth of the colonial Congo: diamonds in the west and gold in the east. Between them the three mining zones were large-scale employers of unskilled labour. Some workers were temporary migrants who worked on contract and whose families subsisted on peasants' incomes during their absence. Much of the burden of colonialism fell on women, who became heads of household and managers of family farms when the men were taken to the mines. Part of the mine labour was supplied by migrants who moved permanently to the towns and became proletarian workers exclusively dependent on their wages. Among the townsmen, education and technical training became the road to economic advancement. The Belgian colonial system maintained a rigorous paternal structure, however, and although more subjects in Congo became literate than in other colonies, few could aspire to higher skills or managerial posts. These positions were reserved for the white expatriate population.

One distinctive feature of the colonial era in central Africa was the role of the church. The state provided so few services that missions moved in to make up the deficit. The most famous of all missionaries was Albert Schweitzer, the Alsatian musician and theologian who became a physician and set up a hospital in the heart of French Equatorial Africa. British Baptists also played a major role in converting the people of the lower Congo area to Protestantism and providing them with basic education and minimal welfare services. When turmoil again hit the region at the end of the colonial period, it was the Baptists who brought services to the mass refugee camps. In the Belgian sphere, the Roman Catholic church took a high profile and eventually established a Catholic university through which to train not only colonial whites but also a small elite of black Africans. The rival to the state church was an independent black church, built in honour of the martyred preacher Simon Kimbangu, who spent most of his life in a Belgian colonial prison. Later still, central Africa became a prime zone of evangelism for the fundamentalist groups that sprang up in the United States in the last decades of the 20th century. When the postcolonial state withered, the churches took on greater formal and informal responsibilities for health and education and for communications and financial services in remote areas.

CENTRAL AFRICA SINCE INDEPENDENCE

Continuity and change in politics and economics. The colonial period in central Africa came to an abrupt end in 1960. At a constitutional level dramatic changes occurred. Both France and Belgium decided that they could not resist the winds of change with armed force. Once the black nationalists of West Africa had won the right to self-determination from Britain, it was not deemed possible to deny the same rights in central Africa. New constitutions were therefore agreed, parliaments were elected, and flags were flown and anthems played. General Charles de Gaulle of France, whose path to power had led him to Brazzaville during World War II, became the hero of the new equatorial republics to which he granted independence. King Baudouin of the Belgians visited the Congo for its independence celebrations but managed to orchestrate his reception with less finesse. It soon became clear that "flag independence" in central Africa did not bring any real transformation to satisfy the high aspirations of former colonial subjects.

The continuities of colonial structure after independence could be perceived in a number of different ways. The first president of the former French Congo was a Catholic priest well integrated into French society and culture. Power in the Central African Republic fell into the hands of Jean-Bedel Bokassa (later Bokassa I), a junior army officer who had served the French in a series of colonial wars in defense of the empire; his hero was Napoleon, and his patron was the president of the French Republic. In Gabon power passed to the mining companies, and political influence was orchestrated by officials who worked in the back rooms of the French embassy. When the country tried to change to a nationalist ruler, Paris sent in the French army to restore its chosen neocolonial partner to presidential office. French influence was felt not only through the church, the army, and the corporations, but, most significantly, through the control of the financial system. None of the "independent" French republics had their own currency but were tied instead to the CFA (Communauté Financière Africaine) franc, a former colonial currency managed by France. France also continued to dominate the external trade of the ex-colonies, monopolizing the supply of manufactures and giving itself preferential access to resources, often with a subsidy financed by the European Economic Community.

Instability in Zaire

In the former Belgian Congo (later rechristened Zaire), the colonial continuities were less obvious and the role of Belgium in postcolonial management more volatile. The army, which had been the backbone of order under the police-style administration of the colonial period, reemerged as the single most powerful institution in the country, and its self-appointed leader, General Joseph-Désiré Mobutu (later Mobutu Sese Seko), became the national president after five years of political turmoil in the early 1960s. In the financial sphere Belgium continued to control the copper-mining complex, but the currency was unstable and had to be reformed on several occasions. The Roman Catholic church grew in power after independence and was occasionally seen as a threat to the new elite because of its monolithic and structured capacity to survive in times of social and political decay. In the 1970s many of the expatriate-owned small businesses and plantations were nationalized and given to soldiers, civil servants, and business people, who expected rewards from the state for their loyalty. The result was economic disruption, and expatriates were once again restored to favour. Immigrants from Greece, Portugal, and India continued to play the entrepreneurial role they had exercised in colonial times.

In both the early 1960s and the late '70s the integrity of Zaire was challenged by regional rebellions that threatened the existence of the state. The rebellions were fueled by ideological confrontations over the direction that the postcolonial state should follow. The first rebellion, in Katanga, was backed by investors in Europe and white settlers in southern Africa. They sought to create a mining republic that would not need to share its wealth with the rest of the country and whose black leaders would be amenable to pressure from white neighbours and patrons. Katanga was seen from the south as a buffer that would stop the flow of black nationalist independence movements from reaching British, Portuguese, and Afrikaner territory. The Katanga rebellion failed because the United States decided that a fragmentation of Zaire might give an entrée to the Soviet Union in tropical Africa. Presidents Dwight D. Eisenhower and John F. Kennedy therefore commissioned the United Nations to crush the rebellion by force in a three-year war (1960–63).

A second threat to the survival of Zaire came from the opposite end of the ideological spectrum. Followers of Patrice Lumumba, the murdered prime minister who had gained national independence, and other more radical politicians rose up in a series of rural rebellions. After independence, the breakdown of communications and services led to a serious loss of earnings in the rural areas. Bands of frustrated youths took up arms and attacked the provincial towns. Political leaders who were unwilling to accept the authority of the central government tried to gain help from abroad, in Egypt or eastern Europe. The disorder verged on civil war, and the central government recruited bands of white mercenaries to protect the towns and attempt to restore minimal civil order. In 1964 the United States intervened once again, this time with a direct and controversial parachute drop designed to save

American lives as well as to support the government. By the late 1960s the army government of Mobutu was in control of the whole country.

The third threat to the unity of Zaire occurred in the 1970s. The 1973 revolution in oil prices hit the economy hard since Zaire, unlike Congo and Gabon, produced no petroleum of its own. Once again popular expectations outran economic performance. Worse still, the neighbouring colony of Portuguese Angola threatened to achieve independence under a left-wing government that advocated the economic rights of peasants and workers. Mobutu, probably in collusion with the United States and South Africa, decided to lend part of his army to the conservative party in Angola to ensure that a right-wing regime would be installed, rather than one which might encourage renewed rebellion among the dispossessed of Zaire. The venture failed—in spite of the support of a South African armed column and the U.S. financing of renewed mercenary involvement in central Africa—and Mobutu temporarily lost his credibility as a strongman. Katanga, renamed Shaba, rebelled twice more, and foreign troops were flown in to maintain the authority of the government. This time the initiative was taken by France, and the soldiers came from Morocco in exchange for political concessions in North Africa. Mobutu was again restored to preeminence and went on to celebrate 25 years of power in 1990.

In the 1980s central Africa managed on the whole to avoid the world's limelight. Economies developed at a modest pace. Engineers made increasing use of the hydroelectric power of the Congo River and carried it over greater distances to maintain the industrial complexes inherited from the colonial era. In Gabon a new railway was built to transport logs from one of the world's last great forests and to reach new mining complexes of the far interior. The world price of iron ore dropped, undermining the extractive plans of the various governments.

Role of petroleum in developing economies

The most serious difficulty for central Africa was the decline in the price of petroleum. The price rises of 1973 and 1979 had been hard on petroleum-importing Zaire but had benefited petroleum-exporting Congo and Gabon. The decline in price in the 1980s had the reverse effect. Gabon had become particularly dependent on its oil revenue. The city of Libreville had attracted about half the country's population; the oil boom also brought 60,000 migrants from Equatorial Guinea. So close did relations with the former Spanish colony become that it adopted the CFA currency of Gabon as its own. The intensive urbanization of Gabon was partially matched elsewhere in the region. Nowhere did agricultural production meet the rising demand for foodstuffs in the towns. Cities had to be fed with imported staples paid for with foreign exchange. Gabon saw an influx of petty traders from Nigeria as well as the expansion of the import-export businesses controlled by Lebanese and Senegalese entrepreneurs. The countryside was denuded, and farming fell into abeyance.

One corner of central Africa that did occasionally catch the eye of the media was Burundi. The lack of satisfaction brought by independence was particularly acute in the overpopulated highlands. Demographic pressure led to increased competition over land resources. The conflict took on class and ethnic dimensions, and spasmodic fighting broke out between the aristocratic Tutsi and the farming Hutu. They vied with one another to gain influence on government—the largest employer, the purveyor of educational opportunity, and the source of all power. The relatively fertile and healthy highlands remained overpopulated, and the children remained undernourished. In the 1980s a new plague, already endemic in neighbouring Uganda, added AIDS to the existing catalog of diseases. Throughout central Africa the human immunodeficiency virus (HIV) spread rapidly in a society where traditional family norms had been disrupted and sexual partnerships were often casual or financial. Urbanization grew apace and with it a loss of moral control by village elders, making it impossible to predict what the health record of central Africa was likely to become.

Postindependence culture. One of the most lasting legacies of the colonial period was language and culture. In the French territories an assimilated elite spoke French, married into French society, adopted French styles of clothing and eating, created French universities with French syllabi, and wrote French prose and poetry in praise of their blackness while rejoicing also in their Frenchness. French was the language of high society in Zaire as well, but two other languages that had been used for colonial command survived alongside the local vernaculars. In the east, Swahili had been the language of the military and became a widely used lingua franca. In the west the language of the missionaries, Lingala, served to bridge the communications gap between town and country and between the numerous tiny ethnic groups. But in other ways European culture took root. Musical instruments in particular were adapted to the powerfully evolving local musical tradition. Zaire became the home of the most famous African bands. Although the country could not itself mass-produce records and discs, its musicians became a part of world culture and their music spread out from the great studios of Europe that bought up the recordings. Zairian dance music became one of the best-known and happiest of the exports from central Africa.

Influence of central African art

A second export from central Africa that has greatly enriched the culture of the world is its art. In the late 19th and early 20th centuries several great explorers—including Henrique de Carvalho from Portugal, Oskar Baumann from Austria, Émil Torday from Belgium, and Percy H.G. Powell-Cotton from England—brought back chests of beautiful objects with which to fill enthnographic museums. The plastic arts of central Africa excited particular curiosity, and wooden statues of great originality were bought from the Kuba and the Chokwe and eventually came to be auctioned as objets d'art of great price. The influence of central African art was particularly felt by the Spanish artist Pablo Picasso and European painters of his school. Artistic influence was a two-way process, however, and societies in which decoration and ornamentation were important also adopted European motifs and artistic materials. Pottery designs long remained traditional, but the burned pictures drawn on gourd vessels began to show the material objects of the new age. Art was also a therapeutic means of coming to terms with the new wave of potentially threatening invaders brought by colonialism. In a more peaceful vein, a colonial school of art developed, with distinctive pictures of hunting and fishing scenes painted in brilliant colours on black paper. In central Africa art remained a vital part of modern culture as well as of deep history. (D.Bi.)

THE COUNTRIES OF CENTRAL AFRICA

Burundi

Landlocked, beset by population pressure and meagre economic resources, the Republic of Burundi (French: République du Burundi; Rundi: Republika y'u Burundi) is one of the poorest and most conflict-ridden countries in Africa. Shaped in the form of a broad arrowhead, it is bounded on the north by Rwanda and by the converging boundaries of Tanzania to the east and Zaire and Lake Tanganyika to the west. Its small size (10,747 square miles [27,834 square kilometres]) belies the magnitude of the problems it faces in seeking to reconcile the supremacist claims of the ruling Tutsi minority with the growing demands for political participation of the Hutu majority.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief and drainage.* Topographically, Burundi is the prolongation of a chain of mountains and

Burundi highlands

high plateaus forming the eastern flank of the Western Rift Valley. In the northwest the narrow Imbo valley extends southward from Rwanda to Lake Tanganyika and includes the Rusizi (Ruzizi) River, which separates Burundi from Zaire. Farther south, along the shores of Lake Tanganyika, the land rises steeply to form part of the Congo-Nile divide, which in places reaches altitudes of 8,500 feet (2,600 metres).

Soils. Light, forest-derived soils predominate, forming a thin layer of humus over lateritic subsoils. Because of the steep slopes and frequency of rainfall, soil erosion is a serious problem. The leaching away of the fertile topsoil is a major constraint on agriculture. The best soils are formed from alluvium, but their extent is confined primarily to the lower portions of larger river valleys.

Climate. Altitude is a major factor in Burundi's climate, greatly moderating its tropical character. The country's high average elevation produces relatively cool temperatures, which average only about 70° F (21° C) throughout the year in the central plateau area and usually drop to below 60° F (15° C) at night. At lower elevations the annual average is only slightly higher—73° F (23° C), for example, at Bujumbura in the Imbo valley. Annual rainfall averages 60 to 70 inches (1,500 to 1,800 millimetres) in the highest-lying areas but only 40 inches on the shores of Lake Tanganyika. Except for a short summer dry season, rainfall is evenly distributed throughout the year.

Plant and animal life. The natural forest vegetation has almost entirely disappeared from the landscape and is limited now primarily to higher mountain slopes. On the plateau, wooded savanna is found at higher elevations, giving way to more open savanna on the lower slopes. Poaching has dealt a severe blow to the country's wildlife. The elephant population has virtually disappeared, leaving only waterbuck, warthogs, baboons, and antelope among the less endangered species.

Hutu family compound, Burundi.

Dispersed pattern of settlement

Settlement patterns. The standard pattern of settlement is one of family compounds, with characteristic beehive huts rising above the hedges of individual enclosures. Villages are almost nonexistent; dispersal rather than concentration is the key characteristic of settlement patterns. The population density is one of the highest on the continent. Bujumbura, the capital, sprawled along the northern tip of Lake Tanganyika, is the largest city.

The people. *Ethnic composition.* As in Rwanda, Tutsi and Hutu are the principal ethnic communities, representing respectively nearly 15 percent and more than 80 percent of the total population. Other groups include the pygmoid Twa (representing less than 1 percent of the population), the descendants of the princely families (*ganwa*), and a sprinkling of Swahili-speaking peoples from Tanzania and Zaire. Popular images of Tutsi as uniformly tall and graceful, and Hutu as short and stocky, do not fit the reality of physical variations. A more meaningful distinction refers to ethnoregional identities, as between Tutsi-Hima, in the southern province of Bururi, and Tutsi-Banyaruguru, found primarily in the north. The former constitute the bulk of the armed forces.

Linguistic composition. Rundi (Kirundi), the standard medium of communication throughout the country, has joined French as an official language. Swahili, the language of trade, is, along with French, widely spoken in the capital city.

Position of the Roman Catholic church

Religion. The country claims a large Christian population, of whom about 90 percent are Roman Catholic. In recent times church-state relations have become the focal point of renewed ethnic tension. Under the Second Republic (1976–87) a variety of sanctions were taken against the Roman Catholic church in an attempt to curtail its social and educational activities, as these were thought to favour the Hutu against the Tutsi. After the coup d'état of 1987, the issue was temporarily defused, yet the church continues to be seen by many Tutsi as a dangerously subversive institution.

Demographic trends. Although infant and child mortality rates are high, Burundi's birth rate is above average for central Africa, and its population is growing at about the same high rate as Africa as a whole. More than 40 percent of the population is under the age of 15, assuring a continued high growth rate. Less than 8 percent of the population is urban, most of whom live in Bujumbura, the only city with a population of more than 100,000. Life expectancy at 49 years is below average for the continent.

The economy. Agriculture is the lifeblood of the country, with industrial activities accounting for less than 10 percent of the gross national product (GNP). Coffee, chiefly arabica, is the principal export crop and source of foreign exchange. Cash crops of lesser importance include cotton, tobacco, tea, and pyrethrum (a flower used in making some insecticides). Rural poverty is evidenced by the predominance of traditional subsistence agriculture, the persistence of low income levels, chronic deficits in the balance of trade, and heavy dependence on foreign aid.

Resources. Unexploited mineral resources include huge nickel deposits in the eastern region, as well as significant vanadium and phosphate deposits. Geologic assessments also indicate possible major petroleum reserves beneath Lake Tanganyika and in the Rusizi valley. Mineral production, however, is limited to small quantities of gold, tin, and wolfram. Peat and firewood are the two major local sources of fuel.

Coffee cultivation

Agriculture, forestry, and fishing. Approximately 50 percent of Burundi's land area is considered cultivable, and 35 percent is suitable for pasture. Staple food crops include beans and corn (maize), grown in the wet season (September to December), and cassava and sorghum, grown in the drier part of the year (January to July). Arabica coffee is grown by many farmers, reaching an average output of 30,000 to 35,000 metric tons per annum. Large areas of cotton are cultivated, mainly in the Imbo valley. While the density of livestock results in overgrazing, the commercial value of livestock production is virtually nil: on the average a cow yields only 40 gallons (150 litres) of milk per annum, and the dressed weight of cattle is only about 250 pounds (110 kilograms). Despite efforts at reforestation, the country's forested area has shrunk to less than 3 percent of the total area. Fishing activities are conducted on Lake Tanganyika and in the smaller lakes and rivers of the interior, both rich in tilapia. About 13,000 tons of fish are caught annually.

Industry and finance. Industry is limited to small-scale processing and manufacturing plants, concentrated mostly in Bujumbura. The government-owned BRARUDI brewery and COTEBU textile company are the two largest industrial enterprises. BRARUDI produces some 23 million gallons of beer annually, providing the government with about one-third of its tax revenue. With the sharp drop in coffee prices, tax revenue declined drastically in the 1980s, in turn causing huge annual budget deficits.

Trade. The trend in the 1980s was in the direction of a growing trade deficit and heavy dependence on foreign aid. On the average, export earnings are only 50 percent of the import bill, reflecting a steady growth of consumption and investment coupled with a sharp decline in the international price of coffee and rising import prices. Approximately 90 percent of Burundi's export earnings come from coffee, with cotton and tea accounting for most of the remaining exports.

Transportation. In the absence of railroads, only three major routes are available: the northern route by road from Bujumbura to Mombasa, Kenya, via Rwanda; the central route by barge down the Rusizi River to Lake Tanganyika, then to Kigoma, Tanz.; and the southern route across Lake Tanganyika to Kalemi, Zaire. A secondary road network connects Bujumbura to various provincial capitals. In addition to Bujumbura's international airport there are five smaller airstrips for domestic flights.

The Third Republic

Administration and social conditions. *Government.* Since the advent of the Third Republic, on Sept. 3, 1987, Burundi has been ruled by a 30-member military junta, the Military Committee for National Salvation (Comité Militaire de Salut National; CMSN), headed by President Pierre Buyoya, a Tutsi-Hima. Despite the appointment of a Cabinet consisting of an equal number of Hutu and Tutsi, headed by Prime Minister Adrien Sibomana (a Hutu), the CMSN is the key decision-making organ. Pending the adoption of a new constitution, the ruling party, the Unity for National Progress (Unité pour le Progrès National; UPRONA), acts as the principal counterweight to the army. Burundi is divided into *provinces, districts,* and *communes.* Power at the local level rests in the hands of centrally appointed authorities, virtually all of whom are of Tutsi origins.

Education. Primary education begins at age seven and is compulsory for six years; secondary education, divided into programs of four and then three years, is not compulsory. The distribution of the school-age population shows a striking disproportion in enrollment figures between primary and secondary schools, the former accounting for about 90 percent of total enrollments. Only a small fraction of primary school students are admitted to the secondary level, and fewer still are able to gain admission to the University of Burundi, at Bujumbura, the country's only university. Ethnic discrimination in schools remains a politically explosive issue. The overrepresentation of Tutsi at the secondary and university levels translates into the absence of significant avenues of upward mobility for Hutu, resulting ultimately in a virtual monopoly of civil service positions by representatives of the Tutsi minority.

Health and welfare. The most common health problems stem from communicable diseases and nutritional deficiencies, a situation that accounts for 70 percent of infant and child mortality. Malaria, measles, influenza, and diarrhea account for 80 percent of reported cases of communicable diseases. While sleeping sickness is widespread in the lakeshore areas, pulmonary diseases are common in the central highlands.

Cultural life. *The arts.* Much of Burundi's rich cultural heritage, most notably folk songs and dances, was intended to extol the virtues of kingship; since the fall of the monarchy in 1966, however (and particularly after the bloodbath of 1972), cultural life has entered a period of prolonged lethargy. The annual sorghum festival (*umuganuro*) was once the occasion for a magnificent display of traditional dances by court dancers (*intore*), with the Karyenda drum, emblem of the monarchy, intended to give both musical and symbolic resonance to the ceremony.

Cultural institutions. Despite the efforts of the government to promote interethnic harmony through displays of a shared cultural heritage, the latter assumes modest proportions. Arts and crafts, including basketry and beadwork, are prominently displayed, however, in the country's only cultural centre.

Press and broadcasting. Radio and television are under strict government control, and so is the press. The only existing daily, *Le Renouveau du Burundi,* is also the official mouthpiece of the government. Because of the strict censorship exercised by the government, tracts are the primary medium through which members of the opposition (both Hutu and Tutsi) make their views known to the public.

For statistical data on the land and people of Burundi, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL.

HISTORY

Origins of the monarchy

The origins of the Burundi monarchy are shrouded in legend. According to one set of traditions, Ntare Rushatsi, the founder of the original dynasty, came from Rwanda in the 17th century; a more reliable source suggests that Ntare must have come from Buha, in the southeast, and laid the foundation of the original nuclear kingdom in the neighbouring Nkoma region.

Until its overthrow in 1966, the kingship was the linchpin of the political system and the most obvious element of continuity with the past. Yet the type of monarchy that emerged from the debris of the Belgian trusteeship at the time of independence in 1962 had little in common with the weakly structured and highly decentralized archaic kingdom in existence at the time of the German conquest in 1903.

Although Belgian rule did little to mitigate factional competition between the two rival dynasties—the Bezi and the Batare—the legislative elections of 1961 resulted in a landslide victory for the representatives of the ruling Bezi dynasty, identified with the Union and National Progress Party (Parti de l'Union et Progrès National; UPRONA), whose leader at the time was Prince Rwagasore, the eldest son of Mwami (King) Mwambutsa. Rwagasore stood as the embodiment of populist aspirations and the strongest supporter of the monarchy. His assassination on Oct. 13, 1961, ushered in a crisis of legitimacy from which the country has yet to recover.

The turning point came on Oct. 18, 1965, when a group of Hutu officers unsuccessfully tried to overthrow the monarchy, yet came close enough to realizing their objective to cause the panic-stricken Mwambutsa to flee the country. By then the inability of the crown to handle the competing claims of Hutu and Tutsi had become palpably clear. The assassination of the Hutu prime minister Pierre Ngendandumwe, on Jan. 15, 1965, by a Tutsi gunman, provided dramatic evidence of the spillover of ethnic hostilities from the party into the government. The critical factor behind the abortive coup, however, was Mwambutsa's decision to ignore the verdict of the May 1965 elections, which gave the Hutu 23 seats in the National Assembly out of a total of 33. By appointing his private secretary, Léopold Biha, as prime minister, Mwambutsa made it unequivocally clear that power would continue to rest with the crown.

Mwambutsa's abdication

In the complicated sequence of events that followed the abortive coup, the execution of some 34 Hutu officers was the first in a series of steps intended to give Tutsi elements unfettered control over the institutions of the state. The second came in July 1966 with the appointment of Michel Micombero as prime minister. A Tutsi-Hima from Bururi province, Micombero had played a key role in thwarting the 1965 coup and in organizing anti-Hutu pogroms in the countryside. Finally, with the formal overthrow of the monarchy in November 1966—less than three months after the official transfer of the crown from Mwambutsa to his younger son, Prince Charles Ndizeye—and the formal proclamation of the First Republic, the last obstacle in the path of Tutsi hegemony was removed.

No other event has cast greater discredit on the First Republic than the genocidal killings perpetrated against the Hutu community in April and May 1972. The carnage took the lives of approximately 5 percent of the population and virtually wiped out the educated stratum of the Hutu population. Anywhere from 100,000 to 150,000 Hutu were killed in the course of the repression triggered by the outbreak of Hutu-instigated uprisings.

Besides creating deep and lasting hatreds on both sides of the ethnic divide, the events of 1972 became the source of considerable tension within the Tutsi minority, thus paving the way for the overthrow of Micombero in 1976 and the advent of the Second Republic under the presidency of Jean-Baptiste Bagaza. Though himself a Tutsi-Hima from Bururi, like Micombero, Bagaza set out to reinvigorate the UPRONA on a scale that Micombero had never contemplated. At the same time every effort was made to bring the Roman Catholic church firmly under the control of the state.

The crisis in church-state relations was the critical factor behind Major Pierre Buyoya's decision to overthrow the Second Republic on Sept. 3, 1987, and proclaim the advent of the Third Republic. The 1987 coup did more than replace one group of Tutsi oligarchs by another; it signaled an important shift of policy on the issue of church-state relations, and, by implication, on the Hutu-Tutsi problem. Ironically, Buyoya's call for liberalization, while significantly raising the expectations of the Hutu masses, did little to alter the rigidly discriminatory posture of Tutsi civil servants in the provinces. The gap between Hutu expectations and the realities of Tutsi hegemony lies at the root of the killings of August 1988.

Informed estimates put at 20,000 the number of people killed in the northern communes of Ntega and Marangara between Aug. 15 and 25, 1988, the overwhelming majority of Hutu origins. As in 1972 the initial outburst of violence—in the wake of countless provocations by local Tutsi officials—came from Hutu elements. Unlike his predecessor in 1972, however, President Buyoya responded to the crisis in a surprisingly conciliatory fashion. For one thing, the existence of a Hutu-Tutsi problem had been explicitly recognized by the Bujumbura authorities, along with the need for appropriate solutions. Moreover, a conscious effort had been made to achieve parity of ethnic representation within the government. Finally, and most importantly, a National Commission in Charge of Studying the Problem of National Unity was entrusted with the task of making specific recommendations to the government to "protect and strengthen the unity of the people of Burundi."

Search for national unity

Whether as a result of these recommendations significant changes will take place in the distribution of rank and privilege remains unclear. Although the formal institutions of government are no longer a monopoly of the Tutsi minority, the army and the police remain firmly in Tutsi hands. What is beyond doubt is that memories of the 1972 and 1988 slaughters will persist for generations and so will the mutual fears and hatreds they have instilled in the minds of both Hutu and Tutsi. (Re.L.)

For later developments in the history of Burundi, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

Central African Republic

The Central African Republic (République Centrafricaine) is an independent state located in the centre of Africa. It has an area of 240,324 square miles (622,436 square kilometres) and is bordered by Chad to the north, The Sudan to the east, Zaire and Congo to the south, and Cameroon to the west. The capital, Bangui, is situated on the southern boundary, formed by the Ubangi (Oubangui) River, a tributary of the Congo (Zaire) River.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief, drainage, and soils.* The Central African Republic occupies a vast rolling plateau that rises to an altitude of between 2,000 and 2,500 feet (610 and 760 metres) above sea level and that forms, along a southwest to northeast trending crest, the drainage divide between the Lake Chad and Congo River basins.

Topography

The vast central plains rise gradually to the Bongos (Mongos) Massif (4,600 feet) to the northeast and to the Tondou Massif in the east and southeast. In the west, the Karre Mountains (4,000 feet) form a high granite range that declines eastward into sandstone plateaus. In the north, the most important mountains are those of the Dar Challa range, which rise to 4,423 feet (1,348 metres) at Mount Tinga on the border with The Sudan. In the southeast is a plain cut by a number of rivers.

Climate. The climate is tropical. The Central African Republic lies in a transitional climatic zone between the sub-Saharan zones to the north and the equatorial zone to the south. During the wet season (from March to October or November) heavy rainstorms occur almost daily, and early morning fog is typical. Maximum annual rainfall occurs during August and September, especially in the upper Ubangi region (71 inches [1,800 millimetres]) and in the Karre Mountains (59 inches). During this season of southwestern monsoon (rain-bearing) winds, the daily temperature ranges between 66° and 86° F (19° and 30° C).

The dry season—brought by the northeastern trade winds, or harmattan—generally begins in October and ends in February or March. The air is dry, and temperatures range between 64° and 104° F (18° and 40° C); it is warm during the day but considerably cooler at night. The skies are clear and seldom cloudy, although some dry fog can be observed. Sandstorms or dust storms also occur in the extreme north.

Plant and animal life. The country lies largely in the savanna zone of Africa. While the north is treeless, dense rain forests follow the southern rivers and stretch far into the savanna country. Bushfires in the dry season are a constant threat to the republic's extensive timberland, which is densest in the far southwestern regions.

Animal life

Antelope, buffalo, and elephants are found on the savanna. Along the rivers, which are abundant with fish, groups of hippopotamuses, crocodiles, and rhinoceroses are to be found. A rich and varied birdlife—in addition to many varieties of snakes, bats, and insects, including many colourful butterflies and moths—makes the territory zoologically one of the most interesting in Africa.

Settlement patterns. More than 60 percent of the total population is rural, living along limited zones of the Ubangi River and along the Chad border. The eastern and northeastern sections of the country are thinly populated. With more than 40 percent of the people under 15 years of age, the rapidly growing population will approach four million by the end of the century. Much of this growing population gravitates toward urban areas, the largest of which is Bangui, the capital city on the Ubangi River. Other major towns are Berbérati, Bossangoa, and Bouar, in the west; Bambari and Bria, in the central plains; and Bangassou and Mobaye, on the Ubangi.

The people. *Ethnic and linguistic composition.* The people of the Central African Republic compose an interesting ethnic mosaic. Ranging from the most simple hunting-and-gathering groups of Aka to state-forming groups such as the Zande (Azande) and Nzakara, most Central Africans had developed a relatively homogeneous culture through centuries of interaction by the time of the European conquest.

Shifting ethnic identities

The attempts by colonial administrators and ethnographers to fix Central Africans into hard and fast ethnic groups no longer seem viable. Central African ethnic groups are and have been historically open. Their membership and identity shift constantly. In this heterogeneous and environmentally diverse area, ethnic groups have come together, changed, and disappeared continuously throughout the past and continue to do so.

Beginning under the French colonial regime, a small bureaucratic elite drawn largely from riverine people, who—as slavers, fishermen, and traders—had served other groups as middlemen, emerged as an indigenous ruling group for the whole country. Since independence this elite group of Ubangi region ethnics, such as the Mbaka and Yakoma, has held most positions of political power. Other Central Africans, far more numerous, have tended to resent this situation and have occasionally rallied to nonriverine leadership, reflecting latent ethnic hostilities.

A handful of Greek, Portuguese, and Yemeni traders are scattered around the country. A small European minority, largely French, living in Bangui, as well as small numbers of more recent political refugees from the southern Sudan and Zaire complete the population of the country.

The national language, Sango, is a lingua franca that developed during the course of the 19th century; it has many dialects. A written form is used in mission publications and in some schools. The official written language is French, which is taught in the schools. Other ethnic languages, such as Baya (Gbaya) and Mandjia, are widely spoken. The oral history tradition is not strong in this often-disrupted country.

Religion. The vast majority of Central Africans are roughly equally divided among putative adherents of Roman Catholicism, various Protestant denominations, and traditional African religious practices. There is a small Muslim minority and an undetermined but large and growing minority of Central Africans with little if any religious affiliation.

Demographic trends. As is the norm in Africa, the Central African Republic is underpopulated. Its inhabitants are increasing at a rather rapid rate, yet, given the country's low population density, relative lack of immigration, and high infant death rate, this growth rate does not seem to pose a problem in the short run. Much of the population is under the age of 15 and is poorly nourished. Life expectancy is only 44 years for men and 47 years for women. Far too much of the available land in the Central African Republic is given over to the cultivation of crops, such as cotton, that are destructive in tropical areas. As a result, a growing number of Central Africans suffer from malnutrition. Cases of kwashiorkor, marasmus, and other malnutrition-induced diseases are becoming the norm in urban and more densely populated areas.

The economy. Agriculture is the basis of the Central African economy and provides the livelihood for most people. A large percentage of the population are subsistence agriculturalists producing cassava (manioc), millet, sorghum, and peanuts (groundnuts) for their own consumption. International (mostly French) capital dominates the economy. The Central African Republic is a classic neocolonial situation: the national economy is controlled by both private and public investment from the former colonial power, and a small minority of local elites live on the proceeds from international aid and taxes.

Resources. With some of the most fertile land in tropical Africa and sufficient water resources, the Central African Republic has considerable agricultural potential. Diamond deposits produce more than one quarter of the country's total export earnings, and gold, uranium, iron ore, copper, and other minerals show promise.

Tropical rain forest covers large areas in the southwest of the country, and timber exports are a vital source of foreign exchange. The country's waterfalls are sources of hydroelectric power. The only major dams, located on the Mbali Lim River northwest of Bangui, produce most of the country's electricity.

Agriculture. Cultivation is largely the work of women, who grow a little cassava, some leafy vegetables, and a few bananas around their houses. In the savanna, peanuts, corn (maize), and some millet are still grown for family consumption. The main cash crops of coffee, cotton, and tobacco were introduced by French plantation owners, but, faced with political instability since independence, many Central African producers have returned to subsistence production. Newer cash crops being developed largely for import substitution purposes include oil palm and sugarcane.

The livestock population includes cattle, sheep, goats, pigs, and chickens, most of which are kept for domestic consumption. Pond-raised tilapia and river fish contribute substantial amounts of protein to the diet. The tsetse fly reduces the ranching possibilities for the Central African Republic, but development programs aimed at improving herds and migrations from Chad and The Sudan continue to increase the number of domestic animals.

Diamond mining

Industry. Diamonds are the main mineral product, but diamond mining activity has fluctuated as a result of disputes between the governing elite and a succession of foreign companies and because of smuggling. A small amount of gold is produced each year, but promised development of uranium, limestone, and other mineral resources has yet to be realized.

In comparison with neighbouring Cameroon, the Central African Republic's manufacturing sector is small; it is concentrated almost entirely in or near Bangui. Many sizable firms that once were the personal property of Emperor Bokassa were nationalized after his overthrow in 1979 and later sold to private owners.

The lack of space and poor service in Bangui hotels precludes mass tourism. Relatively exclusive tours to big game reserves in the far north are under foreign management; some passing trans-African expeditions are the only other major activities in the tourist sector.

Finance and trade. The government has experienced sizable budgetary deficits since the early 1980s. Supported by stand-by programs from the International Monetary Fund, direct budgetary aid from France, and assistance from other donors, the Central African government continues to struggle with the burden of a bloated and inefficient public sector. Foreign investment is theoretically welcomed and encouraged by liberal conditions for foreign investors and assistance to the private sector. Since import licenses are required for imports from outside the Franc Zone and payments for imports from countries outside the Franc Zone are subject to exchange control regulations, few non-French companies have sought to invest in the Central African Republic.

Three banks in the Central African Republic have more than 30 percent French ownership. The two commercial banks have expanding networks of provincial banks, and the Banque de Credit Agricole et de Développement supplies most of the nation's farm credit. The Central African Republic is a member of the African Financial Community (Communauté Financière Africaine; CFA); the currency is the CFA franc. The country is also an active member of the Central African Customs and Economic Union (UDEAC).

The Central African Republic relies heavily on its exports. The main exports—coffee, diamonds, timber, and cotton—have not produced enough revenue to achieve a positive trade balance since the mid-1970s. France is the country's leading trading partner, purchasing most of the coffee and tobacco produced. Belgium is also an important trading partner, purchasing most of the nation's diamond exports.

Transportation. With no direct access to the sea, no railways, and only about 300 miles (500 kilometres) of hard-surfaced roads, the country relies on its waterways for communication and commerce. More than 70 percent of the international trade is shipped by river. There are about 4,400 miles of inland waterways, though only some 750 miles are navigable year-round. The Ubangi-middle Congo route is the normal international transportation link with the outside world. This course is navigable most

Superstock

Boats moored along the banks of the Chari River, Central African Republic.

of the year from Bangui to Brazzaville, Congo, and from there goods are shipped by rail to the Atlantic port of Pointe-Noire.

Only the international airport, at Bangui-Mpoko, can take wide-bodied aircraft. There are several regional airports and many other airstrips, although internal services are irregular, depending on an unreliable supply of aviation fuel. The country has several international air links, including Air Afrique.

Administration and social conditions. *Government.* The territory known as the Central African Republic was granted political independence from France in August 1960; the current government is the result of a military coup in September 1981. This regime began to be somewhat liberalized after September 1985, when the military committee that had ruled under the direct guidance of General André Kolingba for four years was dissolved. At that time, Kolingba appointed a Cabinet with a number of civilian members. On Nov. 21, 1986, a new constitution creating a strong executive presidential form of government was adopted by referendum; on the same day, Kolingba was elected president. After the creation of a single-party state in February 1987, on July 31, 1987, for the first time in 20 years, members of a national assembly were elected for five-year terms by universal suffrage. In the spring of 1988, municipal elections for a slate of candidates presented by Kolingba's Central African Democratic Assembly were held. Since only candidates allowed by Kolingba may run for office, there is little opposition to executive decisions.

The country is divided into *préfectures, sous-préfectures* (subprefectures), and *communes.* Bangui is an autonomous commune.

Judiciary

Besides the Supreme Court, a court of appeals, and a criminal court, there are several lower tribunals and a military tribunal. Judges are appointed by the president. The judicial system is loosely based on that of France, with some vestigial traditional courts still operating on the local (subprefecture) level.

Education. In the late 1980s there were about 780 primary schools and 20 secondary schools in the country. The University of Bangui, founded by Jean-Bedel Bokassa in 1969, has operated fitfully since October 1970, offering courses in law, science, and medicine. In addition, the École Normale Supérieure, the National School of Administration, the National School of Arts, the Central School of Agriculture, and a number of other religious and technical schools offer students an education that is increasingly irrelevant for the needs of the desperately poor country. The best students, and especially those with the best political connections, continue to go to France for their education.

Health and welfare. For all practical purposes, no modern health care facilities exist outside of Bangui and a few other towns. A number of missionary-staffed and -run hospitals and clinics give relatively good care to those who can reach them. For the majority of Central Africans, however, the poorly equipped and poorly staffed maternity clinics, dispensaries, and first-aid posts theoretically available to them in the countryside are of little practical value. Even the Bangui hospital is far below minimal care standards; some private clinics are available to the wealthy in the capital. Sleeping sickness, malaria, leprosy, tuberculosis, and venereal diseases, including AIDS, are rampant. Data on the AIDS/HIV infection problem are not readily available, but the problem is growing and poses a major threat to the health of Central Africans.

Welfare benefits, including unemployment and maternity benefits, child-care allowances, and social security, are available to a small number of government and private-sector employees in the urban centres, but most people rely on their families and traditional village support systems for what little help they can get. The growing number of homeless youths in Bangui and in the other larger urban areas is a major social problem facing the nation.

Cultural life. The actual living situation of the majority of Central Africans has not been systematically studied. Neither the impact of the French colonial regime nor the unsettled state of affairs since independence has seriously altered the rural life patterns that have been evolving for centuries. In most Central African families women continue to play a crucial role in the gathering, production, conservation, distribution, and preparation of food. Hunting and fishing—male occupations by custom—remain important for the subsistence of many Central Africans, and the production of such commercial crops as coffee, cotton, and tobacco tends to be chiefly a male activity, but women are the principal food producers for household consumption.

Traditional crafts

Until the 19th century, craftspersons in the region produced many fine handmade items. The slave trade and the early years of colonization disrupted the expansion of crafts, however, and most of them disappeared. Today roughly woven mats and baskets, simple wooden utensils, and plain pottery are all that remain of traditional local handiwork. In recent years handicraft workers have begun producing unique designs and pictures made from butterfly wings glued to paper and some rather interesting ebony carvings.

Central African musicians form dance bands in Bangui and in some regional towns. These bands use electronic equipment to play popular music from around the world. Many groups also perform original Central African music, characterized by sad, haunting vocals and a strong, rhythmic beat.

Few works of literature from Central Africa have been published, although collectors are slowly gathering the traditional oral legends and folk stories from older villagers who remember them. Makombo Bamboté is the relatively well-known author of the novel *Princesse Mandupa* (1972) and *Coup d'état Nègre* (1987).

Central African artists have produced both watercolour and oil paintings. The murals and canvases of Jerome Ramedane depict scenes of African animal life, hunting parties, and daily village life. Similar works are often found on the walls of restaurants, bars, and other gathering places in Bangui and other towns. The Musée National Ethnologique Centrafricain (Musée Barthélemy Boganda) in Bangui contains exhibits of traditional musical instruments, implements of warfare, village architecture, hunting tools, pottery, and religious objects.

Football (soccer) and dancing are the major recreational pastimes of young Central Africans. Basketball and some rugby are also played, especially in Bangui, and those who can afford it may take in films in Bangui or one of the larger towns. Religious functions and traditional folksinging and dancing are also part of the yearly cycle for many Central Africans.

The national radio system broadcasts widely, but the national television system is limited mainly to the Bangui district. The local press is comparatively undeveloped, being based until 1986 on government news bulletins. The main publications are *Centrafric Presse,* a daily information bulletin; *Terre Africaine,* a weekly; and *Le Courrier Rural,* a regular publication from the Chamber of Agriculture. There is one government-controlled press agency, the Agence Centrafricaine de Presse. In 1986 the nation's first daily newspaper, *E le Songo,* began publication; it is also government-controlled. (J.v.H./T.E.O'T.)

For statistical data on the land and people of the Central African Republic, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL.

HISTORY

Early history. Diamond prospectors in the Central African Republic have found polished flint and quartz tools at least 8,000 years old. About 2,500 years ago local farming people set up megaliths weighing several tons near Bouar. The cooperation necessary to make and position these monuments suggests that they were built by fairly large social units. By the 15th century AD, ethnic groups speaking languages related to those spoken by present-day Central Africans were living in the area. These ethnic groups lived in relatively isolated small settlements. They used iron tools and cleared land by the slash-and-burn method.

Emergence of ethnic groups

Until the 17th century, the region of the Central African Republic was not directly connected to external commercial routes. At that time, Arabic-speaking slave traders extended the trans-Saharan and Nile River trade routes into the region. Until the mid-19th century, Arabic-speaking and local African traders captured people and sent them as slaves to North Africa or down the Ubangi and Congo rivers to the Atlantic coast. From these points, slave ships transported the captives to the Americas.

By the mid-19th century, the Bobangi people from the Ubangi River area had become major slave traders themselves and raided for captives among the nearby Baya and Mandjia peoples. Many ethnic groups in Central Africa still harbour resentment against the ruling elite, who tend to come from riverine groups akin to the Bobangi. The disruption caused by the slave trade hampered the development of strong social organization among the region's ethnic groups.

The colonial era. Toward the end of the 19th century, faster ships, more powerful weapons, and the use of quinine against malaria made it possible for Europeans to gain control of vast areas of Africa. The Industrial Revolution in Europe had created the need for more markets and for new sources of raw materials. During the last two decades of the 19th century, Belgium, Great Britain, Germany, and France competed for control of what became the Central African Republic. By the beginning of the 20th century, frontiers had been established for the Ubangi-Shari (Oubangui-Chari) colony by the European powers. Many Africans resisted French control. Several military expeditions in the first decade of the 20th century were needed to crush their resistance.

To squeeze a profit from the colony, the French government leased large tracts of land to private European companies. Once leases were granted, firms had almost complete power to administer the land as they desired. Company overseers forced men to gather wild rubber and to work on plantations and public projects. At the same time, famine, disease, and the absorption of village lands into European plantations further disrupted the lives of Central Africans.

In the late 1920s, the French began to create a mobile health system in the colony to fight disease, especially sleeping sickness. Roman Catholic and Protestant missionaries set up a few schools and medical clinics. Through the use of forced labour, cotton cultivation was increased and a good network of roads was established. By the late 1930s, gradual increases in gold and diamond production began to produce a profit for French investors.

During World War II General Charles de Gaulle called on residents of French territories to help fight the Germans, and 3,000 Central Africans responded. After the war these troops returned to their homeland with a new sense of national, rather than simply ethnic, identity. After the war de Gaulle organized the French Union. He created new local assemblies, and French colonists and a few Africans became regional political representatives. On Nov. 10, 1946, Barthélemy Boganda became the first Central African elected to the French National Assembly.

Government of Barthélemy Boganda

Independence. A Roman Catholic priest, Boganda left the priesthood and formed the Social Evolution Movement of Black Africa (Mouvement pour l'Evolution Sociale de l'Afrique Noire; MESAN). In 1957 MESAN gained control of the Territorial Assembly, and Boganda became president of the Grand Council of French Equatorial Africa. Boganda hoped that the former French territories of Chad, Gabon, Congo, and Ubangi-Shari could form a single nation. When the others rejected the unification plan, Boganda reluctantly agreed to accept the new constitution offered to Ubangi-Shari by France.

After Boganda's death on March 29, 1959, David Dacko, a former teacher, became president. The Central African Republic was granted independence on Aug. 13, 1960. Dacko allowed France broad authority in trade, defense, and foreign relations. To reward his ethnic supporters, Dacko multiplied government positions, and the increased number of salaries drained the national budget.

In 1962 Dacko made MESAN the only legal national political party. In the elections of early 1964 Dacko ran unopposed and was, for the first time, formally elected as president. The economy declined and the national debt soared. On Dec. 31, 1965—amid impending bankruptcy and a threatened nationwide strike—the commander of the army, Jean-Bedel Bokassa, replaced Dacko in a rather uneventful coup d'état.

Bokassa abolished the constitution, dissolved the legislature, and turned over administrative duties to his appointed Cabinet. Bokassa allowed no opposition. Despite his increasingly dictatorial rule, France continued to support him and the country's faltering economy. The French wanted to retain control of the diamond—and potential uranium—output of the country. French paratroopers helped bolster Bokassa's rule in the mid-1970s.

Creation of the Central African Empire

In 1972 Bokassa declared himself president for life, and on Dec. 4, 1977, he renamed the country the Central African Empire and crowned himself Emperor Bokassa I with lavish ceremonies largely financed and organized with French government support. Under Bokassa's rule, the government went further into debt while the emperor personally administered the nation's diamond trade, keeping most of the profits. Finally, in September 1979 the French government removed Bokassa and restored Dacko as their client ruler.

Dacko's second turn at governmental control was not received with enthusiasm. To maintain his power, Dacko relied on French paratroops and on administrative officials who had served in Bokassa's government. As opposition grew, labour strikes and bomb attacks undermined Dacko's control. He increasingly relied on the army to retain power. On Sept. 1, 1981, General André Kolingba, a member of another riverine ethnic group, the Yakoma, removed Dacko from office in a relatively bloodless coup and established a military government.

The government stayed almost entirely in military hands until 1985. In that year Kolingba dissolved the military committee that had ruled the country since 1981 and named a new 25-member Cabinet with a few civilians. In early 1986, under pressure from the World Bank and other international organizations, Kolingba had a new constitution approved by the national assembly; it was adopted following a referendum later that year. Legislative elections were held in July 1987, but the government continued to operate under the direct control of Kolingba, who was elected in a 1986 referendum to six more years as head of state. As president, he effectively held all executive and legislative power in the nation. (T.E.O'T.)

For later developments in the history of the Central African Republic, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

Congo

The People's Republic of the Congo (République Populaire du Congo)—commonly known as the Congo—lies astride the equator in west-central Africa. It is bordered to the west by Gabon, to the northwest by Cameroon, to the north by the Central African Republic, and to the east and south by Zaire. To the southwest it shares a border with the Angolan enclave of Cabinda; the republic also has a coastline 100 miles (160 kilometres) long on the Atlantic Ocean. The Congo has an area of 132,047 square miles (342,000 square kilometres), but the country as a whole is sparsely inhabited, with somewhat more than half of its population concentrated in the towns. The national capital of Brazzaville is an important inland port on the Congo River.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* The country is fringed by a narrow coastal plain 40 miles (64 kilometres) wide, which stretches for about 100 miles between Gabon and Cabinda. The plain rises gradually from the sea to the Mayombé Massif, a low mountain range that parallels the coast. The Mayombé peaks are quite sharp and are separated by deep river gorges. At the southern end of the range, Mount Foungouti attains 3,051 feet (930 metres). The northern peaks are lower; among them, Mount Moguindou rises to 2,132 feet (650 metres).

East of the Mayombé Massif lies the Niari valley, a 125-mile-wide depression. Toward the north the terrain rises gradually to the Chaillu Massif, which reaches elevations between 1,600 and 2,300 feet on the Gabon border; toward the south the depression rises to the Cataractes Plateau. The valley is an important passage route between the inland plateaus and the coast.

Beyond the Niari valley is a series of plateaus about 1,600 feet above sea level, separated by the deeply eroded valleys of tributaries of the Congo River. The Bembe Plateau lies between the Niari valley and the Chaillu Massif, while the Batéké Plateau stretches northward along the Congo River from Brazzaville to Mpouya.

The Congo basin

The northeast is composed of the western reaches of the Congo basin; from the western mountains and plateaus a vast 60,000-square-mile plain slopes eastward to the Congo River. Cut by numerous Congo tributaries, the plain is swampy and floods annually.

Drainage and soils. The country's drainage system is dominated by the Congo (Zaire) River. The Congo's main tributary, the Ubangi (Oubangui) River, flows southward from the Central African Republic and forms the country's eastern border until it reaches the town of Liranga, where it joins the Congo proper. The main river continues southward to Malebo (Stanley) Pool, a shallow 300-square-mile lake, and on to Livingstone Falls before turning southwest through Zaire to enter the Atlantic Ocean. The major right-bank tributaries of the Congo, all within the republic, include the Sangha, Likouala, Alima, Nkéni, Léfini, Djoué, and Foulakari rivers.

The coastal watershed is formed by the Kouilou River, which flows southwestward for about 450 miles from its source in the plateau region to Kayes, where it empties into the Atlantic. Through the Niari valley to Makabana, where it joins the Louessé River to form the Kouilou proper, it is called the Niari River. The stream is broken by numerous waterfalls, and the banks are irregular. The mouth is blocked to navigation by sandspits formed by the strong Benguela Current.

About two-thirds of the country is covered with coarse-grained soils that contain sand and gravel. Lateritic soils, with a high proportion of iron and aluminum sesquioxides, characterize low-lying areas. Because of the hot and humid climate, organic matter is decomposed by rapid bacterial action before it can accumulate into humus; moreover, topsoil is washed away by the heavy rains. In the savanna regions, the fertile alluvial soils are threatened with erosion by wind as well as rain. A diverse pattern of coarse- and fine-grained soils covers the plateaus and hills.

Climate. The tropical climate is characterized by heavy rainfall and high temperatures and humidity. The equator passes across the country just north of Liranga. In the north the dry season extends from November through March and the rainy season from April through October, whereas in the south the contrary is true. On both sides of the equator, however, local climates with two dry and two wet seasons may be found.

Annual rainfall is abundant throughout the country, but seasonal and regional variations are important. Precipitation averages more than 48 inches (1,200 millimetres) annually and often surpasses 80 inches.

Temperature range

Temperatures are relatively stable with little variation between seasons. Much greater variation occurs between day and night, when the difference between the high and low readings averages about 27° F (15° C). Over most of the country, annual average temperatures range between 68° and 81° F (20° and 27° C), although in the south the cooling effect of the Benguela Current may produce readings as low as 54° F (12° C). The average daily humidity is about 80 percent.

Plant and animal life. Nearly two-thirds of the Congo is covered with tropical rain forest. The dense growth of African oak, red cedar, walnut, softwood okoume, or gaboon mahogany, and hardwood limba (*Terminalia superba*) provides an evergreen canopy over the sparse undergrowth of leafy plants and vines. The coast and the swampy areas contain coconut palms, mangrove forests, and tall grasses and reeds. The plateau areas and the Niari valley are covered with grasses and widely spaced broad-leaved trees.

The forests contain several varieties of monkey, chimpanzee, gorilla, elephant, okapi, wild boar, and buffalo. Wildlife in the savanna regions includes several varieties of antelope, jackal, wild dog, hyena, and cheetah. On the plateaus, rhinoceroses and giraffes are numerous, but lions are scarce. Birdlife includes the predatory eagle, hawk, and owl, the scavenging vulture, and the wading heron.

Freshwater fish include perch, catfish, sunfish, and mudskippers. Crocodiles live throughout the Congo River. The numerous snakes include poisonous varieties: cobra, python, green mamba, and puff adder. Among the insects, the most dangerous are the tsetse fly, which causes sleeping sickness in human beings and a similar disease, called nagana, in cattle, and the mosquito, which carries malaria and yellow fever.

Settlement patterns. The country's four main regions developed around the historical concentrations of the main ethnic clusters. The southern region between Brazzaville and the coast is inhabited by the Kongo peoples. Also in the south, the Teke inhabit the Batéké Plateau region. In the north, the Ubangi groups inhabit the Congo River basin to the west of Mossaka, while the Binga Pygmies and the Sanga are scattered through the northern Congo basin. Precolonial trade between north and south stimulated both cooperation and competition, while French favouritism toward the peoples of the southwest enhanced interregional rivalries. Massive internal migration and urbanization following independence has, however, attenuated such conflicts.

Settlement of the Congo landscape is very uneven. The southwestern quarter of the country is home to 70 percent of the population. In the north and northeast, population is sparse. Congo is also highly urbanized by African standards; a majority of the population lives in cities, and because the urban growth rate far exceeds that of the country as a whole, urbanization continues to intensify. Since this growth has been chiefly the result of internal migration, most rural communities have ties to the larger national community and economy of the cities.

Urban centres

The major cities are Brazzaville, Pointe-Noire on the Atlantic coast, Nkayi (formerly Jacob) in the Niari valley, and Loubomo (formerly Dolisie) in the Mayombé region. Colonial creations by and large, the cities reflect French influence: a central administrative and commercial core is surrounded by residential areas. Before independence there was a marked difference between the spacious, planned European neighbourhoods and the less regimented, more populous African parts of town. Since 1960, however, greater social and economic mobility in the African population, attempts at urban renewal, and massive rural-to-urban migration have blurred these distinctions.

The people. *Ethnic and linguistic composition.* About half of the Congo's inhabitants belong to the Kongo peoples, whose major subgroups include the Sundi, Kongo, Lali, Kougni, Bembe, Kamba, Dondo, Vili, and Yombe. The Ubangi people include the Makoua, Kouyou, Mboshi, Likouala, Ngala, and Bonga. The Teke and the Sanga, or Gabonese Bantu, are also divided into various subgroups. The Binga Pygmies live in small bands, usually as clients of surrounding peoples. Most of the Europeans in the Congo are French who live in the main cities. There are also small populations of foreign Africans, Portuguese, and Chinese.

Except for the Pygmies, all the indigenous peoples speak their own Bantu languages. Intergroup communication and trade fostered the development of two trade languages, Lingala and Monokutuba. Lingala is spoken north of Brazzaville, and Monokutuba is common in the area between the capital and the coast. French is the official language and the medium of school instruction at all levels, as well as the language of the African upper class and the European community.

Independent churches

Religion. About half of the population practices classical African religions. The Christian community is composed of about two-thirds Roman Catholics and one-third Protestants, including members of the Evangelical Church of the Congo. There are also independent African churches: the Church of Jesus Christ on Earth by the Prophet Simon Kimbangu, the largest independent church in Africa, is a member of the World Council of Churches. Other independent churches include the Matsouana Church and the Bougist Church. Most of the small Muslim community is made up of foreigners who reside in Brazzaville or Pointe-Noire.

Demographic trends. Like many African countries, Congo has a fast-growing, relatively young population. Earlier in the 20th century, however, the country was part of the low fertility belt, a region stretching from Gabon to Uganda where many societies experienced little or no population growth. Life expectancy, among the lowest on the continent prior to 1950, has improved steadily in the last half of the 20th century and is now about average for mainland sub-Saharan Africa. Urban in-migration has long been an important demographic trend. During the colonial era, the new colonial cities, and Brazzaville in particular, attracted African migrants. Congo is today among the most urban countries of sub-Saharan Africa.

The economy. Petroleum and mining are the major export industries, followed by forestry and commercial agriculture. Light manufacturing (mostly shoes), sugar processing, and assembly industries also assumed greater importance in the 1980s. These activities, however, employed only a small fraction of the labour force, most of which was engaged in agriculture and the non-salaried informal urban economy.

In the late 1980s, following the fall in world oil prices, Congo experienced a major financial crisis. Negotiations for aid from the International Monetary Fund and the World Bank produced agreements to privatize portions of the national economy and to reduce the national bureaucracy. Such agreements may have improved the ability of Congo to compete in the international economy; at the same time, they did little to ameliorate the poverty of much of the population.

Resources. Important resources include petroleum and natural gas. Large reserves of potash (potassium chloride) are found at Tchitondi (Holle), 30 miles northeast of Pointe-Noire. Iron ore is found in the south and in the western Sangha basin. Minor deposits of gold and diamonds are located in the Kouilou valley, and there are copper and lead deposits west of Brazzaville. Oil reserves are found in the coastal zone. There are also deposits of zinc, tin, uranium, bauxite, and titanium (a metallic element used in alloys).

Forests of both softwoods and hardwoods cover nearly two-thirds of the country. The rivers and lakes are home to important fish resources. Power resources consist of petroleum, wood, charcoal, and the hydroelectric potential of Congo's rivers, which generate nearly all of the country's electricity.

Agriculture, forestry, and fishing. For the most part, agriculture is subsistence in nature and occupies about three-fifths of the work force. Poor soil and the lack of fertilizers produce low yields; the country is not self-sufficient in food production. Most of the cultivated land is in family holdings that are too small for mechanized farming; international development strategies, which are shaped by reliance on large-scale production, have yet to devise plans to reach such small-scale cultivators. In the savanna, land is cleared by burning, and women work the fields with hand tools. Cassava (manioc) is the basic food crop everywhere but in the south, where bananas and plantains are prevalent. Rice is grown in the Niari valley and in the north around Djambala. The diet is supplemented with yams, taros, sweet potatoes, corn (maize), peanuts (groundnuts), and fruit. Livestock consists of sheep, goats, pigs, and poultry. The government has sponsored the raising of cattle since the introduction in the 1960s of *n'dama* cattle—a breed resistant to the tsetse fly.

Commercial agriculture

The major cash crops are cacao, coffee, peanuts, palm kernels, tobacco, and sugarcane. All are grown in modest amounts. Other cash crops include rice, bananas, and cotton. Commercial agriculture, including cattle ranching, is concentrated in the Niari valley.

Forestry products accounted for more than 60 percent of the total exports in the late 1960s. Twenty years later, petroleum made up more than 90 percent of exports. Although forest reserves are extensive, inadequate transportation and flood conditions limit exploitation in the north; hence forestry operations are concentrated in the south. The Congo is the world's largest producer of limba and (after Gabon) the second largest producer of okoume. Products include logs, sawn wood, and veneers. Forestry was largely under French control until the 1960s, when African participation began to increase.

Commercial marine fishing is conducted off Pointe-Noire. The catch includes tuna, bass, soles, and sardines. Freshwater fishing on the rivers, lakes, and swamps is largely a subsistence activity.

Industry. Potash is mined, and petroleum is the most important export. Copper, zinc, lead, and iron ore are also extracted on a small scale.

The small manufacturing sector is hampered by limited domestic markets, dependence upon foreign investment, and the lack of skilled labour. Most factories are located in Brazzaville, Pointe-Noire, Kayes, Loubomo, and cities in the Niari valley. Products include processed foods, beverages, cigarettes, textiles and clothing, footwear, processed wood and paper, chemicals, cement and bricks, glassware, and metal goods such as nails and metal furniture. The first petroleum refinery went into operation in 1976 at Pointe-Noire. Handicrafts produced by individual artisans include carvings, pottery, needlework, tiles, and bricks.

Transportation. The road system is most developed in the south. Major routes link Brazzaville with Pointe-Noire and Loubomo with the Gabon border. Many roads are impassable during the rainy season.

Railways are also concentrated in the south. The major Congo-Ocean Railway line runs for about 320 miles from Brazzaville west through Nkayi and Loubomo to Pointe-Noire. There is also a 175-mile branch line from Favre north to Mbinda on the Gabon border. These railways offer important transshipment services for neighbouring countries, contributing significant revenues. They are also important to mining and industrial development, for most industrial towns are located along them.

Water transportation has long linked Congo, Chad, and the Central African Republic. The rivers, however, are often broken by rapids and are subject to seasonal variations in flow. Brazzaville is the most important inland port. Linked to Kinshasa, Zaire, by ferry, it is there also that passengers and freight traveling downriver from Bangui, in the Central African Republic, are transshipped overland by rail to the ocean port of Pointe-Noire. This seaport is the major transshipment centre for these three countries as well as western Cameroon.

Administration and social conditions. *Government.* Congo is a single-party people's republic led by the Congolese Labour Party (Parti Congolais du Travail; PCT). The party's 75-member Central Committee may initiate revision of the constitution (adopted in 1979 and amended in 1984), and it appoints members of the Revolutionary Court of Justice, which heads the judicial system. The Central Committee's chairman is the president of the republic, who is head of state and of government and who is elected by the party congress to serve a five-year term. The 133 members of the People's National Assembly (Assemblée Nationale Populaire) are elected by direct universal suffrage from a list of candidates chosen by the PCT; they also serve five-year terms. The judicial system consists of a Supreme Court, a court of appeals, and criminal, labour, and common law courts.

Role of the PCT

Congo is divided into nine *régions* and the capital district of Brazzaville, each headed by appointed district leaders and an elected council; it is further subdivided into *communes* and villages. In addition to Brazzaville, there are five other *communes*—Pointe-Noire, Loubomo, Mossendjo, Nkayi, and Ouesso—and eight administrative control posts subordinate to their regions. The village remains the primary administrative and political unit outside the cities.

Education. Education is free and compulsory for students between the ages of 6 and 16. The six-year primary education course includes instruction in agriculture, manual skills, and domestic science. On the secondary level courses are offered in vocational training, academic and technical training, general education, and teacher training. Institutions of higher learning include the Marien

Ngouabi University in Brazzaville and colleges and centres for specialized and technical learning. Congo enjoys a literacy rate much higher than most countries in sub-Saharan Africa.

Health and welfare. The most common health problems are respiratory diseases, malaria, tuberculosis, and intestinal parasites—all preventable maladies. Other diseases include trypanosomiasis (sleeping sickness), yellow fever, leprosy, yaws, and AIDS. Disease control is difficult because most water sources are polluted and sanitation is poor, even in the cities. The country's two largest hospitals are in Brazzaville and Pointe-Noire. Other health facilities include regional health centres, infirmaries, dispensaries, maternal and child-care centres, and private clinics. Mobile health units combat communicable diseases in remote areas.

Welfare services provided by the government, the labour union, and employers are largely limited to wage earners in the formal sector and their families. Benefits include old-age pensions, life insurance, worker's compensation, and family-allowance payments. Government-sponsored social workers operate among the poor.

Cultural life. Precolonial artistic expression emphasized ceremonial music, dance, sculpture, and oral literature. Christianity and colonialism had a great impact on these art forms. The carving of ritual objects became commercialized, and music and dance altered as a result of the introduction of Western instruments and musical styles. In the 1980s the Brazzaville region, along with Kinshasa, across the river in Zaire, became a vital centre of contemporary African music. There are two libraries in Brazzaville, and a national museum contains collections of prehistoric objects as well as precolonial and contemporary art. (A.Fu./D.D.C.)

For statistical data on the land and the people of Congo, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL.

HISTORY

Early history. Human habitation of Congo came relatively late in the Sangoan era (100,000 to 40,000 BP), perhaps because of the dense forest. The people who used the large-core, bifacial Sangoan tools probably subsisted by food gathering and digging up roots; they were not hunters. Refined versions of this tradition continued through the Lupemban (40,000 to 25,000 BP) and Tshitolian eras. Only late in the first millennium did agriculture emerge in the savanna adjacent to the lower Congo River.

The early inhabitants were farmer-trappers, fishing peoples, and Pygmy hunters. People lived in households including kin and unrelated individuals; at the centre of the household was a "big man," who represented the group. Mobility—of individuals, groups, goods, and ideas—figured prominently and created a common social environment. Such intercommunication is evident from the closely related Bantu languages of the region. Speakers of the Eastern (Ubangian) languages lived in the north but maintained ties with their forest neighbours.

Emergence of three kingdoms

Larger-scale societies emerged between AD 1000 and 1500; they were based on clans whose members lived in different villages, village clusters with chiefs, and small forest principalities. Chiefdoms on the southern fringes became more complex; three kingdoms eventually developed: Loango, at the mouth of the Kouilou River on the Atlantic coast; Kongo, which had its beginnings in the first millennium, in the far southwest; and Tio, which grew out of small chiefdoms on the plains north of Malebo Pool. Rulers derived power from control over spirit cults, but trade eventually became a second pillar of power.

In 1483 the Portuguese landed in Kongo. Initially, relations between the Kongolese and Portuguese rulers were good. Characterized by the exchange of representatives and the sojourn of Kongolese students in Portugal, this period was a harbinger of late 20th-century technical assistance. Unfortunately, the need of Portuguese planters on São Tomé for slaves undermined this amicable arrangement by the 1530s.

Between 1600 and 1800, the slave trade expanded. Local leaders challenged state control. Among the Tio the western chiefs became more autonomous. Contact with Europeans also introduced new American food crops. Corn and cassava allowed greater population densities. This, along with the emergence of a "market" for foodstuffs, led to greater use of slaves, intensified women's work, and changed the sexual division of labour.

Role of Brazza

The colonial era. By the early 19th century the Congo River had become a major avenue of commerce between the coast and the interior. Henry Morton Stanley, a British journalist, explored the river in 1877, but France acquired jurisdiction in 1880 when Pierre Savorgnan de Brazza signed a treaty with the Tio ruler. The formal proclamation of the colony of French Congo came in 1891. Early French efforts to exploit their possession led to ruthless treatment of the local people, and Brazza returned in 1905 to lead an inquiry. In 1910 the French joined Congo with neighbouring colonies as the federation of French Equatorial Africa, with its capital at Brazzaville.

The French were preoccupied with acquiring labour. Forced labour, head taxes, compulsory production of cash crops, and draconian labour contracts forced Africans to build infrastructure and to participate in the colonial economy. No project was more costly in African lives than the Congo-Ocean Railway, built between 1921 and 1934 from Pointe-Noire to Brazzaville; between 15,000 and 20,000 Africans died.

In 1940 Congo rallied to the Free French forces. Charles de Gaulle, Governor-General Félix Eboué, and African leaders held a conference in Brazzaville in 1944 to announce more liberal policies. In 1946 Congo became an overseas territory of France with representatives in the French Parliament and an elected Territorial Assembly. Ten years later, the *loi cadre* (enabling act) endowed the colony with an elected government. Congo became a republic within the French Community in 1958 and acquired complete political independence in August 1960.

Congo since independence. Two major parties existed at independence: the African Socialist Movement (Mouvement Socialiste Africain; MSA) and the Democratic Union for the Defense of African Interests (Union Démocratique pour la Défense des Intérêts Africains; UDDIA). The two parties pitted the north against the south, an opposition that stemmed from the privileged place occupied by the southern Kongo and Vili in the colonial era. The two parties also had different political philosophies. The MSA favoured a powerful state and a partially publicly owned economy; the UDDIA advocated private ownership and close ties with France. UDDIA leader Fulbert Youlou formed the first parliamentary government in 1958; in 1959 he became premier and president.

Corruption, incompetence, mass disapproval, general strikes, and lack of French support led to Youlou's ouster in 1963. His successor, Alphonse Massamba-Débat, shifted policies to the left, notably by founding the National Revolutionary Movement (Mouvement National de la Révolution; MNR) as the sole party. The country sought assistance from the Soviet Union and the People's Republic of China and voted with the more radical African states in world forums. Regionally, Congo extended concrete support and offered a geographic base for the Popular Movement for the Liberation of Angola (MPLA), the Marxist movement that won independence for that country. Congo also offered asylum to the Patrice Lumumba followers who fled neighbouring Zaire and plotted for a return to power there.

Creation of the People's Republic

Regionalism and policy failures led the military to replace Massamba-Débat with Major Marien Ngouabi in 1968. Ngouabi maintained a socialist line, renaming the country the People's Republic of the Congo on Dec. 31, 1969; the Congolese Labour Party (PCT) replaced the MNR at the same time. Ngouabi was a northerner, and his regime shifted control of the country away from the south. Such moves created opposition among workers and students in the highly politicized environment of Brazzaville and other southern urban centres. Ngouabi was assassinated in March 1977. His successor, the more conservative Colonel Joachim Yhombi-Opango, soon clashed with the PCT, and Colonel Denis Sassou-Nguesso replaced Yhombi-Opango in 1979.

Although Sassou-Nguesso represented the more militant wing of the PCT—and immediately introduced a new constitution intended as a first step toward building a Marxist-Leninist society—he improved relations with the Western nations and with France. The regime's political language became more moderate, but the inefficient state enterprises created by earlier socialist policies remained in place in the early 1980s. They had been subsidized by petroleum production, but the drop in oil and other raw material prices led to economic crisis. The external debt surpassed $1.5 billion in 1985, and debt service consumed 45 percent of state revenue. Negotiations with the International Monetary Fund the following year led to an agreement to help the national economy in exchange for cuts in public spending and the state bureaucracy. At the end of the 1980s, however, the debt had tripled in size and the economic crisis continued. (D.D.C.)

For later developments in the history of Congo, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

Gabon

The Gabonese Republic (République Gabonaise), on the west coast of Africa, lies astride the equator, with a total area estimated at 103,347 square miles (267,667 square kilometres). The republic is bordered by Equatorial Guinea and Cameroon to the north, the People's Republic of the Congo to the east and south, and the Atlantic Ocean to the west; the island state of São Tomé and Príncipe is situated off the coast. Gabon's capital is Libreville. Gabon remains strongly attached to France, its former colonizer, and to the French language and culture.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief and drainage.* The narrow coastal plain—often no more than 20 miles (32 kilometres) wide in the south—is formed of sandstone and alluvium; northward it broadens to a width of 100 miles, with outcrops of chalk, limestone, and Cretaceous sandstone. North of the most westerly point, Cape Lopez, the contour of the coast becomes more jagged. The Atlantic's northward-flowing Benguela Current, which softens the southern coastline by creating sandbars, is no longer effective here. Inland, the relief is characterized by a series of granite plateaus, extending generally northwest to southeast and rising to heights of from 1,000 to 2,000 feet (300 to 600 metres). Farther to the west and north, the Cristal Mountains have been dissected by the river system from the western plateau escarpment into a distinct upland area. To the south, the Ogooué River drains through a sandstone saddleback before descending to the lowlands through the granite formations of the Lambaréné region. Granite also forms the Chaillu Massif, Gabon's central watershed, south of the Ogooué, which rises to an elevation of approximately 3,000 feet, except where topped by the 3,215-foot (980-metre) elevation of Mount Iboundji.

Climate. Gabon has an equatorial climate, with year-round high temperatures and humidity. Rainfall varies from an annual average of 120 inches (3,050 millimetres) at Libreville to 150 inches on the northwest coast, with almost all of it falling between October and May. In the period from June to September there is little, if any, rainfall, but humidity remains high. Temperature shows little seasonal variation, the daily average being about 81° F (27° C).

Plant and animal life. About 75 percent of the country is covered by a dense equatorial rain forest containing more than 3,000 species of vegetation, including the okoume, a hardwood tree that forms the backbone of Gabon's wood industry. The rain forest is inhabited by antelope, monkeys, gorillas, numerous tropical birds, and several varieties of elephants. (J.v.H./D.E.G.)

The towns

Settlement patterns. Gabon's major towns—Libreville, Port-Gentil, Lambaréné, Moanda, Mouila, Oyem, Franceville, and Bitam—contain nearly two-fifths of the total population. The remainder is scattered widely among some 4,000 rural villages, which are concentrated along the rivers and roads, often with a population of no more than a few families. Port-Gentil is the centre of the wood and petroleum industries, and Libreville is the administrative capital and commercial centre.

The people. *Ethnic and linguistic composition.* All of Gabon's 40 or so ethnic groups, except the few thousand Pygmies, speak Bantu languages and, on that basis, can be classified into 10 larger groups. The Myene group (including the Mpongwe and Orungu), though only a small part of the population today, has played an important role in the history of the country as a result of its location along the northern coasts. The Fang, who belong to the larger Ewondo or Pahouin group also found in southern Cameroon and Equatorial Guinea, account for one-third of the population; they live north of the Ogooué River. The largest groups south of the Ogooué are the Sira (including the Eshira and Punu), the Nzebi (Njabi), and the Mbete; these groups together form close to half the population. Less numerous peoples include the Benga and Seke (Sheke) in the far northwest, the Kota and Teke in the east, and the Vili along the far southern coast.

Many of the Bantu languages do not have written forms. During the 19th century Christian missionaries transliterated several of them in the Latin alphabet and prepared Bible translations and catechisms for their followers. But the French policy of limiting the use of indigenous languages solely to religious instruction inhibited the growth of other types of literature. Because of the extensive efforts to teach French, at least one-third of the Gabonese can speak the language, and more than one-quarter can read it.

Religion. A large majority of Gabon's population is Christian, with about three times as many Roman Catholics as Protestants. Though Gabonese serve as Roman Catholic bishops, they rely heavily upon foreign clergy, particularly the French Holy Ghost Fathers. The largest Protestant body, the Evangelical Church of Gabon, has Gabonese pastors in its parishes throughout the north. There also exist a small but growing Christian Alliance Church in the southwest and the tiny Evangelical Pentecostal Church (Assembly of God) in the estuary and far northern regions. A syncretic religion called Bwiti (based on an earlier secret society of the same name) came into being in the early 20th century and later played a role in promoting Fang solidarity. Most of the few thousand Muslims are immigrants from other African countries.

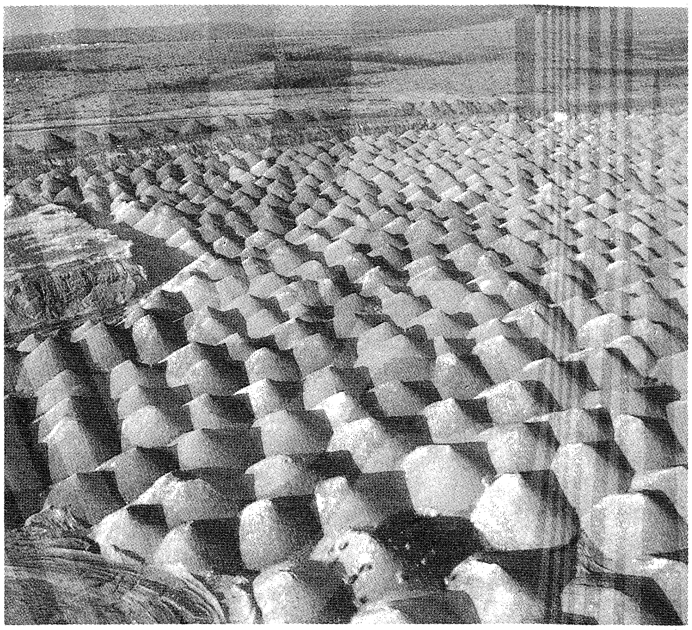
Demographic trends. Gabon, like its central African neighbours, has a very low population density. Since 1970, as a result of increased urbanization, the low rate of natural increase of the previous half-century appears to have given way to a relatively high growth rate. The extent to which the heavy immigration of foreign workers and Equatorial Guinean refugees has contributed to this growth is unclear. The population is relatively young—half are below age 22. Life expectancy, at 50 years for men and 53 years for women, is about average for the continent.

Labour shortage

The economy. Gabon's economy has more links with European and American markets than with those in neighbouring states (with the exception of Cameroon) or elsewhere in Africa. The economy shares some of the characteristics of those of other tropical African states: strong links with the former colonial ruler, a large degree of foreign investment and control, dependence on foreign technicians, and the decline of agriculture. Gabon differs from these states in its reliance on thousands of wage earners from other African countries to supplement its own sparse supply of workers in retailing, artisanship, and domestic transport.

Resources. Gabon possesses important resources in woods and minerals and much hydroelectric potential. But its poor transportation infrastructure and lack of financing, as well as unfavourable world market conditions, hinder the development of some of these resources.

Agriculture, forestry, and fishing. Although agriculture (mainly subsistence farming) occupies about two-thirds of the population, it plays but a small part in the economy of the country as a whole. Moreover, its appeal as a way of life has declined. Better educational and employment opportunities in the towns and cities have emptied the countryside of young people. Despite government efforts during the 1970s to promote development that would



A manganese mine in Moanda, Gabon.
Bernard Regent/The Hutchison Library

stem the rural exodus and raise foodstuffs for urban markets, by 1980 Gabon was producing only enough food to satisfy 10 to 15 percent of its needs. During the 1980s the government turned to expensive capital-intensive projects for market gardening to supply Libreville and Franceville. Efforts to revive cocoa and coffee production brought only modest results, but new projects for sugar refining at Franceville and palm oil processing at Lambaréné have worked out well. The prevalence of the tsetse fly has defeated attempts to raise beef and dairy cattle, though chicken raising has succeeded. Commercial fishing, though having considerable potential, is little developed.

For many years Gabon's forests, covering 75 to 85 percent of its territory, were its principal natural resource. Newly discovered and exploited mineral wealth had by the early 1970s forced raw wood and forest products into second place, and by the early 1980s, wood accounted for less than 10 percent of Gabon's exports. The principal forest districts have been at Kango, Booué, Fougamou, Ndjolé, Mitzic, and Mouila. The forest resources near the coast and rivers have been largely depleted. Exploitation of the forests of the interior began in the late 1970s with the construction of the first section of the Transgabon Railroad.

Industry. Gabon is the world's fourth largest producer of manganese; it possesses an estimated 25 percent of the world's known reserves outside the Soviet Union. Expansion of production at Moanda has been possible since the completion of the railroad to nearby Franceville in December 1986 and by the completion of improved ore handling facilities at the rail terminus at the deepwater port of Owendo in 1988. The exploitation and processing of uranium, which began in 1961 16 miles north of Moanda, mainly serves the needs of the French Atomic Energy Commission. Reserves estimated at 35,000 tons will last until about 2030 at present production levels. Reserves of nearly one billion tons of high-quality iron ore (60–65 percent iron content) discovered in the northeast at Mékambo in the 1950s have not been exploited because of the lack of transportation facilities. Plans to run a section of the Transgabon Railroad from Booué to this area were postponed because of lack of financing and depressed world market prices.

Mining industries

Since the late 1960s, revenues from petroleum have brought the government of Gabon unprecedented income, which it has used to construct infrastructure and to fund the expansion of education and health services. National budgets multiplied 15 times between the late 1960s and late '70s, when petroleum came to represent 70 percent of the country's exports. Despite slumping prices and the resulting drops in production, revenues from petroleum still provided 65 percent of national budgets during the late 1980s. More than 80 percent of production is from offshore fields, which are the most productive near Port-Gentil. The major onshore production sites are at Sette Cama and Rabi-Kounga. Gabon exports 85 percent of its petroleum production outside Africa, with the bulk of the crude oil going to France, the United States, Brazil, and Argentina. Natural gas from the fields at Port-Gentil is used largely to generate electricity.

Light industry has been expanding and diversifying since the opening in 1967 of a petroleum refinery at Port-Gentil. The refinery and its support operations (a shipyard and metalworking facilities) overshadow other manufacturing enterprises, which include lumber processing, cement and cigarette factories, a sugar refinery, breweries, light electronics, palm oil and flour mills, and textile-printing factories.

Finance and trade. Membership in the Franc Zone gives Gabon considerable stability. The CFA (Communauté Financière Africaine) franc is automatically convertible to French francs, giving trading partners confidence in Gabonese currency. The government has also encouraged foreign investors with its policy of economic liberalism, although there is governmental direction and planning.

France is Gabon's most important trading partner, receiving more than a third of its exports and providing half of its imports. Other important partners are other European Common Market nations, the United States, and Japan. These same countries provide the bulk of investment funds and foreign assistance; France alone is the source of more than one-half of the total. Saudi Arabia has also given financial help. Gabon belongs to a customs union with five other central African states and a common market with four others.

Transportation. The lack of good transportation facilities has long hindered Gabon's development. The Ogooué River is navigable from the Atlantic to Ndjolé, 150 miles upstream. The Ogooué and such rivers as the Abanga and the Nyanga can be used to float logs downstream from the interior.

Infrastructure development

The difficulty of building and maintaining all-weather roads led to an expansion of air transport after World War II. Gabon acquired a network of airfields served by light planes as well as international airports at Libreville, Port-Gentil, and Franceville. But air transport could not move such bulk goods as timber and minerals. Thus in the 1970s petroleum revenues were used to construct the Transgabon Railroad, or Transgabonais, to move such products and to prepare for the time when petroleum reserves would be depleted. With loans and aid from France, West Germany, and international organizations, work began in 1974. The first section, from Owendo to Ndjolé, opened in 1979; the second section, to Booué, in 1983; and the third, to Franceville, at the end of 1986.

Administration and social conditions. *Government.* Under the frequently revised constitution of 1961, Gabon is a republic under the executive direction of a president elected by direct universal suffrage for a period of seven years and a Council of Ministers appointed by the president. Provision is also made for a prime minister (appointed by the president) and a National Assembly (elected by direct suffrage) to assume legislative responsibilities and for an independent Supreme Court. After the French intervention of 1964, power became concentrated in the presidency. In 1968 the president's party, the Gabon Democratic Party (Parti Démocratique Gabonais; PDG) was declared the only one legally permitted. But in May 1990 transitional constitutional arrangements reestablished a multiparty system. A committee was appointed to formulate a new constitution.

The judicial system consists of a series of customary law courts at the lowest level, above which are a criminal court, a court of appeals, and the Supreme Court (all located in Libreville). The High Court, which is composed of members elected from the National Assembly, has the power to try the president and members of government. An audit office (*cour des comptes*) was created in 1977 to oversee the government's finances.

Administratively, Gabon is divided into nine *provinces,* which are further divided into *préfectures* and *sous-préfectures* (subprefectures). The provincial governors, the prefects, and the subprefects are all appointed by the president.

Education. The educational system continues to be modeled closely after that of France. French remains the sole medium of instruction; Bantu languages are studied as electives at the secondary and higher levels. While education is officially mandatory from the ages of 6 to 16, the bulk of children do not attend long enough to achieve literacy or numeracy. The Omar Bongo University, founded in 1970, has two- and three-year programs in most fields and some advanced studies. The University of Science and Technology of Masuku, near Franceville, opened in 1986. Many Gabonese study abroad, particularly in France, at the university and graduate levels.

Health and welfare. Health facilities remain inadequate, particularly outside the Libreville area, despite improvements during the 1970s and '80s. The government provides nearly all health care services. The internationally known hospital operated by Albert Schweitzer at Lambaréné from 1924 to 1965 receives government assistance. Malaria, sleeping sickness, tuberculosis, syphilis, and other infectious diseases are widespread problems.

Influence of French culture

Cultural life. A great deal of the cultural life of Gabon continues to be derived from or influenced by France. Gabon's contemporary writers express themselves almost exclusively in French. At the same time, there has been continued interest in the precolonial history and traditions of Gabon's peoples. Examples are the research on the Fang epic (*mvet*) and the art of the Mpongwe, Fang, and Kota. In 1983 the International Centre for Bantu Civilizations (Centre International des Civilisations Bantu; CICIBA) was created, with its headquarters at Libreville.

Gabon has newspapers in French, national and provincial radio stations broadcasting in French and local languages, and television broadcasting from Libreville that can be received as far away as Lambaréné. French publications circulate extensively, and television programs are relayed from France. (B.Wn./D.E.G.)

For statistical data on the land and people of Gabon, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL.

HISTORY

Early colonization. Little is known about the history of the Gabon region prior to the arrival of the first Portuguese navigators in the Gabon Estuary in 1472, for the Bantu-speaking peoples inhabiting the region lacked writing. At that time portions of southern Gabon were loosely linked to the state of Loango, which in turn formed a province of the vast Kongo kingdom. From the offshore islands of São Tomé and Príncipe, where the Portuguese established sugar plantations, they developed trade with the mainland. From the late 1500s, Dutch, French, Spanish, and English competitors also exchanged cloth, iron goods, firearms, and alcoholic beverages for hardwoods, ivory, and a few slaves.

The slave trade

The slave trade achieved extensive development only between the 1760s and 1840s, as a result of heightened demand from Brazil and Cuba. Interior peoples sent undesirables from their own societies and captives from warfare down the waterways to the coast where they were collected in barracoons (temporary enclosures) to await the arrival of European ships. The Orungu clans at Cape Lopez organized a kingdom whose power rested on control of the slave trade through the mouths of the Ogooué River. The Mpongwe clans of the estuary, who were already important traders, also profited from the slave trade, as did the Vili of Loango, whose activities extended throughout southern Gabon. Only the Fang, who were migrating southward from Cameroon into the forests north of the Ogooué, ordinarily refused to hold slaves or engage in warfare to obtain them. The coastward migrations of the numerous and often warlike Fang nevertheless contributed to the further decimation and dispersion of many interior peoples, particularly during the 19th century.

French control. By 1800 the British were becoming the leading traders in manufactures throughout the Gulf of Guinea. After 1815 the French sought to compete more actively in the commercial sphere and to join Britain in combating the slave trade. To these ends, Captain Édouard Bouët-Willaumez negotiated treaties with the heads of two Mpongwe clans, King Denis (Antchouwe Kowe Rapontchombo) on the southern bank of the estuary in 1839 and King Louis (Anguile Dowe) on the northern bank in 1841. They agreed to end the slave trade and to accept French sovereignty over their lands. The arrival of American Protestant missionaries on the northern bank in May 1842 to open a school in the lands of King Glass (R'Ogouarowe)—the centre of British, American, and German commercial activity—spurred the French to establish Fort d'Aumale within the territory of King Louis in 1843. In 1844 France brought in Roman Catholic missionaries to promote French cultural influence among the Mpongwe and neighbouring peoples. French agents obtained a treaty from King Glass recognizing French sovereignty. In 1849 Bouët-Willaumez organized a small settlement of mainly Vili freed slaves called Libreville ("free town"), which with the fort formed the nucleus of the capital.

During the 1850s and '60s the French gradually extended their control along the adjacent coast and sent explorers into the interior. The expeditions of Pierre Savorgnan de Brazza between 1875 and 1885 established French authority on the upper Ogooué, where Franceville was founded in 1880, and on the Loango coast. An enlarged Gabon was attached to the French Congo in 1886 under Brazza as governor.

Establishment of frontiers

In 1910 Gabon became one of the four colonies within the federation of French Equatorial Africa. The French delimited the frontier with the Germans in Cameroon in 1885 and with the Spanish in Río Muni, or Spanish Guinea (later Equatorial Guinea), in 1900. French occupation of the Gabon interior brought little opposition; but interference with trade and such exactions as a head tax, a labour tax for public projects, and forced labour provoked considerable resistance, as did the French policy from 1898 to 1914 of seeking to develop the economy through monopolistic concessionary companies, which devastated settlement, agricultural production, and trade.

The period between the two world wars saw the creation of a pro-French but anticolonialist elite, mainly from the graduates of the boys' schools of the Brothers of Saint-Gabriel at Libreville and Lambaréné. From their ranks came most of the politicians who held office during the Fourth French Republic (1946–58) when Gabon became an overseas territory with its own assembly and representation in the French Parliament. In this era France considerably expanded public investment in the economy, in health care, and in education. In 1958 Gabon became an autonomous republic within the French Community and, after concluding cooperation agreements with France, achieved independence on Aug. 17, 1960.

Gabon since independence. Gabon favoured close relations with France and continued use of the French language and culture. It opposed political ties with the other states of Equatorial Africa, however, because of dissatisfaction with the previous federation and a desire to develop its natural resources for its own benefit.

M'ba's presidency

Attempts by the republic's first president, Léon M'ba, to institute a single-party regime provoked a rebellion by young military officers in February 1964. But M'ba, who had strong backing from French economic interests, was restored to power by forces sent on orders from General de Gaulle. This action further weakened the opposition forces led by Jean-Hilaire Aubame, previously deputy in Paris during the Fourth Republic. The intervention made possible the rise of Albert-Bernard (later Omar) Bongo to the presidency after M'ba's death in 1967 and the establishment of a single-party regime. In 1982 a new opposition group, the Movement for National Renewal (Mouvement de Redressement Nationale; MORENA), called for multiparty democracy, exercise of civil liberties, and an end to governmental corruption, but it was quickly suppressed.

In 1985 declining petroleum prices caused an economic downturn. Austerities imposed as part of a structural adjustment set off popular demonstrations against the Bongo government at Libreville and Port-Gentil in 1990. This agitation spurred the creation of a national conference that included opposition groups. The death of an opposition leader in May 1990 sparked violent disorders that led to French military intervention to protect French nationals and property. Opposition groups won seats in the new legislative assembly elected in September, but irregularities nullified the results in half of the 120 districts. (D.E.G.)

For later developments in the history of Gabon, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

Rwanda

Lying east of Lake Kivu in the heart of the Western Rift Valley, the Republic of Rwanda (French: Rêpublique Rwandaise; Rwanda: Republika y'u Rwanda) is bounded on the north by Uganda, on the east by Tanzania, on the south by Burundi, and on the west by Zaire. Like its neighbour to the south, Rwanda is a country of minute dimensions (10,169 square miles [26,338 square kilometres]), grinding poverty, and high population density. It also shares with Burundi a long history of monarchical rule. Unlike what happened in Burundi, however, the demise of the kingship came about through a grass-roots, Hutu-led upheaval that reached its denouement before the country became independent. In Rwanda the state was forged from the ground up, in the crucible of a peasant revolution; in Burundi, by contrast, it is the state that seeks to forge society from the top down. Thus, if both states can be described as ethnocracies, in Rwanda the term carries a distinctly democratic connotation inasmuch as the Hutu represent the overwhelming majority of the population.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* The landscape is reminiscent of a tropical Switzerland. Its dominant feature is a chain of mountains of rugged beauty that runs on a north-south axis and forms part of the Congo-Nile divide. From the volcanoes of the Virunga Mountains in the northwest—where the Karisimbi reaches 14,787 feet (4,507 metres)—the altitude drops to 4,000 feet (1,220 metres) in the swampy Kagera (Akagera) River valley in the east. The interior highlands consist of rolling hills and valleys, yielding to a low-lying depression west of the Congo-Nile divide along the shores of Lake Kivu.

Principal rivers

Drainage. Except for the Ruzizi, through which the waters of Lake Kivu empty into Lake Tanganyika, most of the country's rivers are found on the eastern side of the Congo-Nile divide, with the Kagera, the major eastern river, forming much of the boundary between Rwanda, Burundi, and Tanzania.

Soils. The best soils, formed from volcanic lavas and alluvium, are found, respectively, in the northwest and along the lower portions of the larger river valleys. Elsewhere the largely metamorphic bedrock has produced soils of generally poor quality. The combination of heavy rainfall and deforestation has set in motion a process of extreme soil erosion that requires a burdensome investment of time and energy to curtail.

Climate. Elevation accounts for Rwanda's generally mild temperatures, which average 70° F (21° C) year-round at Kigali, for example, in the interior highlands. There are significant variations, however, between the region of the volcanoes in the northwest, where heavy rainfalls are accompanied by lower average temperatures, and the warmer and drier interior highlands. The average annual rainfall in the latter is about 45 inches (1,140 millimetres) and, except for a short summer dry season, is evenly distributed throughout the year.

Plant and animal life. Only 3 percent of the country consists of natural forest vegetation. Reforestation programs have added eucalyptus trees to previously denuded hillsides and roadsides, though not on a scale sufficient to effectively counteract erosion. A lush, Mediterranean-type vegetation covers the shores of Lake Kivu, which stands in stark contrast to the papyrus swamps of the east and the thick bamboo forests of the Virungas. There, among the volcanoes, lives Rwanda's main tourist attraction, the mountain gorilla. For sheer diversity of animal life, however, no other region can match the resources of the Akagera National Park. Buffalo and zebras, antelope and warthogs, chimpanzees and lions, as well as many rare species—such as the giant pangolin, or anteater—are part of a fauna that also includes elephants, rhinoceroses, and hippopotamuses.

Settlement patterns. Despite a high population density, the dominant pattern is one of extreme dispersal. More than 90 percent of the population is rural and lives in nuclear family compounds scattered on hillsides. Kigali, the capital, was only a hamlet at the time of independence but has grown to become the largest city.

The people. *Ethnic composition.* As in Burundi, the major ethnic groups are Hutu and Tutsi, respectively accounting for almost 90 percent and about 10 percent of the total population. To these must be added the Twa hunter-gatherers, who constitute less than 1 percent of the population. Other minorities include a small group of Europeans, mostly missionaries and aid officials, a small number of Asian merchants, and a sprinkling of Swahili-speaking Africans from Tanzania and Zaire.

The clientage system

Though the Tutsi are generally taller and of lighter complexion than the Hutu, the physical stereotypes attributed to each group are greatly mitigated by intermarriage. Social differences between them, however, traditionally were profound, as shown by the system of patron-client ties (*buhake,* or "cattle contract") through which the Tutsi gained social, economic, and political ascendancy over the Hutu agriculturalists. During the revolution some 300,000 Tutsi were forced out of the country, thus reducing the former ruling aristocracy to an even smaller minority.

Linguistic composition. French and Rwanda (more properly, Kinyarwanda), a Bantu language closely related to Rundi, are the official languages of the country, but only a small fraction of the population speaks French. Swahili is widely spoken in the towns and is still the principal means of communication with Africans from neighbouring territories.

Religion. Nowhere in Africa has Christianity had a more decisive impact than in Rwanda. The Hutu revolution derived much of its egalitarian inspiration from the teachings of the European clergy, and Catholic seminaries served as recruiting grounds for Hutu leaders. Roman Catholicism claims the allegiance of about two-thirds of the population.

Demographic trends. Rwanda's rate of population increase is one of the highest in central Africa and is far above the productive capacity of the environment. Family-planning programs are virtually nonexistent. Approximately half of the population is under age 16; infant and child mortality rates are among the highest in Africa. Adding to the growing population pressure on the land, some 60,000 Hutu refugees from Burundi live in Rwanda, most of them having fled their homeland during the 1972 holocaust, when an estimated 100,000–150,000 Hutu perished in interethnic violence.

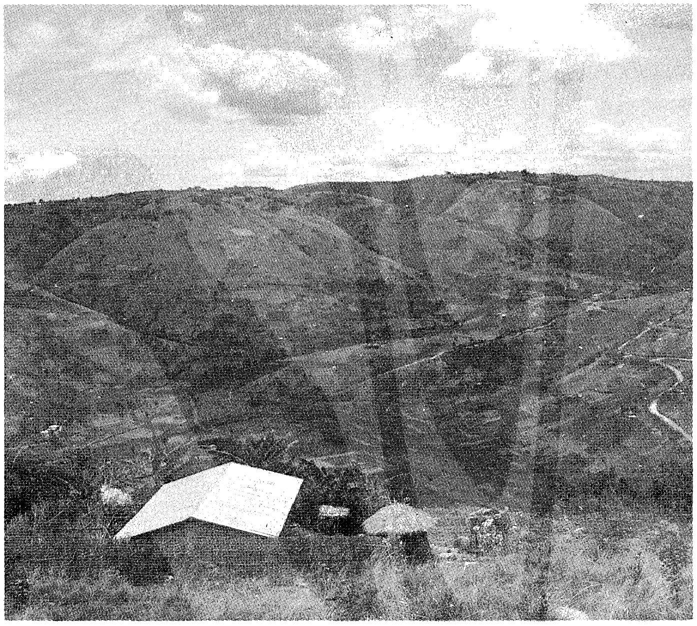
The economy. The country's economy is overwhelmingly agricultural, with coffee exports accounting for more than 70 percent of its foreign exchange and tea for more than 10 percent. An inadequate subsistence agriculture, however, is the dominant feature of the economy, with heavy infusions of foreign aid required to meet chronic food shortages. Rwanda is the largest per capita recipient of foreign aid in Africa. Mineral resources make up from 10 to 15 percent of total exports.

Resources. Mineral resources include, in addition to tin and tungsten (wolfram), tantalite, columbite, and beryl. Methane gas from Lake Kivu is used as a nitrogen fertilizer and is also converted into compressed fuel for trucks. What little gold Rwanda produces is smuggled out of the country. The Mukungwa hydroelectric power installation, the country's major source of electricity, meets only a portion of the country's energy needs, and much of the remainder must be imported from Zaire.

Major crops

Agriculture, forestry, and fishing. Intensive cultivation is practiced throughout the country, resulting in a large diversification of food crops. To the main indigenous crops—sorghum and eleusine—must be added corn (maize), potatoes, sweet potatoes, cassava (manioc), dry beans, and plantains. While eleusine is harvested in May and sorghum in July, bananas and plantains can be grown throughout the year. Arabica coffee (first introduced by European missionaries), tea, tobacco, and pyrethrum are the principal cash crops, with coffee constituting the prime export. Most of what is left of the small amount of natural forest is found on the slopes of the Virunga Mountains in the northwest. Fishing is widespread on Lake Kivu as well as in the smaller lakes of the interior, most notably Lake Muhazi and Lake Mugesera.

John Hatt/The Hutchison Library



Family settlements scattered on the deforested hillsides of Rwanda.

Industry. Aside from small-scale mining operations and limited consumer manufactures (such as textiles, soap, matches, cement, paint, some pharmaceuticals, and furniture), for the most part industrial activities involve the processing of coffee, tea, and other agricultural commodities. Most of the country's industries are located in Kigali.

Finance and trade. The sharp downward trend in the price of primary commodities since the 1970s, especially coffee and tea, has had a catastrophic effect on the country's balance of trade. It is estimated that the total civil service wage bill requires approximately half of the annual budget. Investment programs are almost entirely covered by external sources of financing. Efforts at promoting closer economic links, in the form of a customs union, between Rwanda and its neighbours through the Economic Community of Great Lakes Countries (CEPGL) have thus far met with little success.

Transportation. Rwanda claims one of the densest road networks on the continent, though only about 7 percent of it is paved. From Kigali to Ruhengeri and thence to Gisenyi, roads that were once impassable in the rainy season are now practicable throughout the year.

Administration and social conditions. *Government.* According to the 1978 constitution Rwanda is a "democratic, social and sovereign Republic whose . . . principle is 'Government of the people, by the people, for the people.' " This principle is strongly tempered, however, by the wide scope of authority vested in the presidency. The president of the republic, Major General Juvénal Habyarimana, combines the roles of head of state and head of government with that of president of the single ruling party, the National Revolutionary Movement for Development (Mouvement Revolutionnaire National pour le Development; MRND). He is elected for a five-year term by direct universal suffrage. As president of the MRND, he is the only candidate for the presidency of the republic. The legislative body is the unicameral National Development Council.

The presidency

Education. About half of the population is literate, and approximately two-thirds of the primary-school-age population is enrolled. Secondary schools have space for only 10 percent of the primary school graduates, however. The National University of Rwanda (1963) is in Butare. Ethnic quotas, reflecting the relative numerical strength of each ethnic group, have become the rule for regulating the flow of students at the secondary and university levels.

Health and welfare. Rwanda has one of the highest percentages of AIDS carriers in Africa; a quarter of a million cases were reported in 1985. Nutritional deficiencies present an even greater threat to the population, however, along with malaria and tuberculosis. Health facilities are still grossly inadequate, consisting for the most part of poorly equipped health centres and dispensaries. Welfare activities are primarily organized under the auspices of missionary societies.

Cultural life. *The arts.* Much of Rwanda's traditional cultural heritage revolves around dances, praise songs, and dynastic poems designed to enhance the legitimacy of kingship. Since the advent of the republic in 1962 another set of traditions has emerged, emphasizing a different cultural stream, identified with a Hutu heritage. Regional dances, including the celebrated hoe dance of the north, are given pride of place in the country's new cultural repertoire. Traditional crafts such as basketry, ceramics, and ironworks provide another element of continuity with the past.

Cultural institutions. Rwanda's National Ballet and the Impala Orchestra add considerable lustre to the country's cultural life, the former through a choreography leaning heavily on traditional folk dances and the latter through a distinctly modern musical repertoire. The Association des Écrivains du Rwanda (AER) keeps alive the best of Rwanda's literary traditions, while the quarterly review *Dialogue* provides a forum for a vigorous intellectual exchange on a wide range of social and cultural issues.

Press and broadcasting. The absence of stringent government censorship makes for a lively press. In addition to the weekly *Imvaho* (published in Kinyarwanda) and the monthly *La Relève,* at least two other publications deserve mention, the weekly *Kinyamateka,* published by Rwanda's Episcopal Council, and the monthly *Rafiki,* published by the Dominican Fathers.

For statistical data on the land and people of Rwanda, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL.

HISTORY

Tutsi traditions trace the birth of the Rwanda kingdom to the miraculous feats of its founding hero, Gihanga, whose coming to Rwanda is said to coincide with the advent of civilization. A more sober appraisal, however, would emphasize a long process of Tutsi migrations from the north, culminating in the 16th century with the emergence of a small nuclear kingdom in the central region.

From 1894 to 1918, Rwanda, along with Burundi, was part of German East Africa. After Belgium became the administering authority under the mandates system of the League of Nations, Rwanda and Burundi formed a single administrative entity; they continued to be jointly administered as the Territory of Ruanda-Urundi until the end of the Belgian trusteeship in 1962. By then, however, the two states had evolved radically different political systems, with Rwanda having declared itself a republic in January 1961 and forced its monarch (mwami), Kigeri, into exile. Burundi, on the other hand, retained the formal trappings of a constitutional monarchy until 1966.

Origins of the revolution

The Rwanda revolution was rooted partly in a traditional system of stratification based on an all-embracing "premise of inequality" and partly in a colonial heritage that greatly increased the oppressiveness of the few over the many. Tutsi hegemony was unquestionably more burdensome under Belgian rule than at any time prior to European colonization. By the end of World War II, a growing number of colonial civil servants and missionaries had come to recognize the legitimacy of Hutu claims against the ruling Tutsi minority. The proclamation of the republic a year and a half before the country acceded to independence testifies to the substantial support extended by the trusteeship authorities to the revolution.

What began as a peasant revolt in November 1959 eventually transformed itself into an organized political movement aimed at the overthrow of the monarchy and the vesting of full political power in Hutu hands. Under the leadership of Grégoire Kayibanda, Rwanda's first president, the Party for Hutu Emancipation (Parti du Mouvement de l'Emancipation du Peuple Hutu; PARMEHUTU) emerged as the spearhead of the revolution. Communal elections were held in 1960, resulting in a massive transfer of power to Hutu elements at the local level. And in the wake of the coup in Gitarama in central Rwanda, which was carried off with the tacit approval of the Belgian authorities, in January 1961, an all-Hutu provisional government came into being. Thus by the time independence was proclaimed in July 1962, the revolution had already run its course, and the transition from a monarchical to a republican form of government had become reality.

With the elimination of Tutsi elements from the political arena, yet another reality came into view, in the form of regional competition among Hutu politicians. By the early 1970s the political landscape had become increasingly polarized by a north-south cleavage, reflecting the comparatively privileged position of elements from the central and southern regions within the party, the government, and the administration.

Regional tensions came to a head on July 5, 1973, when a group of army officers from the north overthrew the Kayibanda regime in a bloodless coup and installed Major General Juvénal Habyarimana. The seizure of power by the army meant that northerners would have a decisive voice in state affairs. As president of Rwanda's Second Republic, Habyarimana, a northerner, has given a distinctly regional coloration to the institutions of the state.

Creation of the Second Republic

With the coming to power of a government dominated by northern elements, north-south polarities eventually gave way to the emergence of subregional factions within the northern establishment. By 1980 the principal fault line of Rwanda politics reflected the continuing tug-of-war between Bashiru and Bagoyi elements, respectively identified with the Bushiru and Bugoyi subregions. By casting his lot with the Bashiru faction, Habyarimana became the target of considerable opposition from Bagoyi elements within the army. The arrest of scores of army officers following the disclosure of an abortive, Bagoyi-inspired coup in April 1980 was evidence of the continuing significance of subregional loyalties within the broader framework of Hutu identity.

Seen from a broader perspective, the political history of Rwanda remains profoundly influenced by its revolutionary heritage. The reconstruction of society on the basis of popular participation and social equality is the paramount objective of the Second Republic. The frequency of elections, the vitality of intraparty democracy, and the widespread commitment to self-help as a major ingredient of development all bear testimony to the country's revolutionary ideology. Whether the demons of regionalism and factionalism can be effectively exorcized to allow the Second Republic to further consolidate the gains of the revolution and to translate its promise into tangible benefits for the masses remains to be seen.

(Re.L.)

For later developments in the history of Rwanda, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

São Tomé and Príncipe

The Democratic Republic of São Tomé and Príncipe (República democrática de São Tomé e Príncipe) covers an area of only 386 square miles (1,001 square kilometres) and is thus one of the world's smallest countries. It consists of two small islands and a few islets in the Gulf of Guinea. São Tomé island is oval in shape, about 30 miles (49 kilometres) long, and 332 square miles in area. The capital of the country, São Tomé city, is situated in the northeastern part of the island. Príncipe lies about 93 miles to the northeast of its sister island, but it is smaller and has a more irregular outline, being about 13 miles long and 55 square miles in area. The country's closest neighbours are Gabon and Equatorial Guinea on the Atlantic coast of central Africa.

PHYSICAL AND HUMAN GEOGRAPHY

The land. In the south and west of both islands, high volcanic mountains fall precipitously to the sea, although neither island has witnessed any volcanic activity in recent centuries. The mountains descend gradually to small plains in the northeast. São Tomé Peak, the highest point on the main island, rises to 6,640 feet (2,024 metres) above sea level, while Príncipe Peak on the smaller island reaches 3,110 feet (948 metres). These mountainous areas are deeply dissected by the effects of stream erosion, and spectacular isolated volcanic plugs stand out as landmarks. Swift and rocky streams rush down to the coast in every direction.

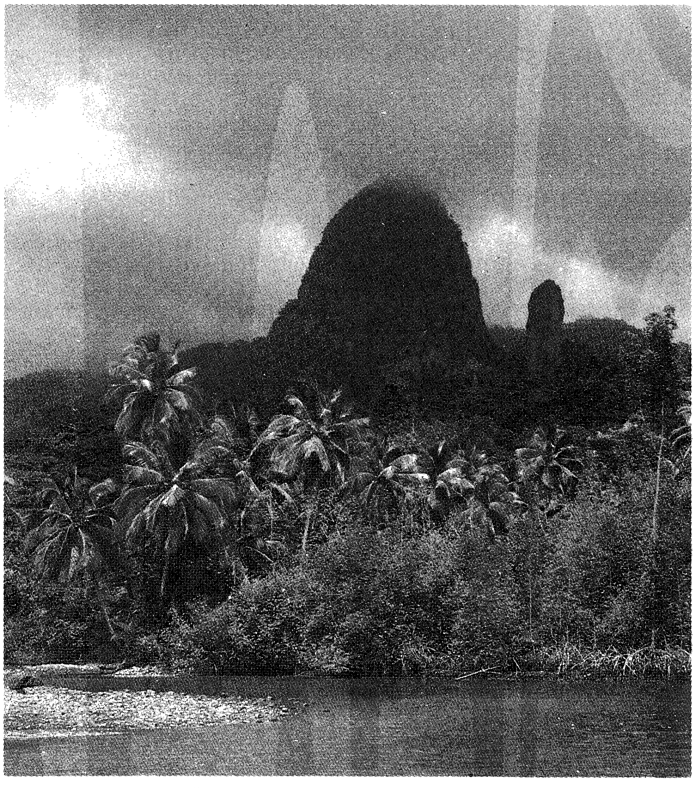
Relief and climate

The climate is basically maritime and tropical, but because of the rough topography, there is a wide range of microclimates. The prevailing moist southwesterly winds are intercepted by the mountains, so that annual rainfall exceeds 275 inches (7,000 millimetres) in the southwest of São Tomé island, while the far northeast of the island receives less than 30 inches. The dry season lasts from June to September in the northeast but is scarcely discernible in the wetter regions. In the coastal areas the mean annual temperature is high, at about 81° F (27° C), and the average relative humidity is also high, at about 80 percent. Average temperatures decline sharply with altitude, and night temperatures fall to below 50° F (10° C) at about 2,300 feet. Above 3,300 feet fine misty rain falls almost continuously, and the nights are cold, although frost and snow are unknown.

The original vegetation of the islands was luxuriant tropical rain forest, with a gradual transition from lowland forest to mist forest. A little less than half the islands' area, mainly in the south and west, is still covered with rain forest. Much of this is secondary growth on abandoned plantation land. The flora and fauna include many rare and endemic species, reflecting the isolation and environmental diversity of the islands. Many of these plants, birds, reptiles, and small mammals are threatened by pressure on the remaining rain forest.

The population is concentrated in the drier and flatter areas of both islands. While a third of the population lives in São Tomé city and its outskirts, only about 5 percent

© Dr. Peter Jones



Two volcanic plugs, João Dias Pai (father) and João Dias Filho (son), standing in the mist along the Banzu River, on the west coast of Príncipe.

of the population inhabits the island of Príncipe. Villages are clustered along the roads and are often grouped around a church. Houses made of wooden planks and raised above the ground are typical of the local building methods although there are also many concrete structures in the Portuguese colonial style. Many people still live in barracklike accommodations on the plantations.

The people. The population consists mainly of Forros, descendants of immigrant Europeans and African slaves. They speak a creolized form of Portuguese; standard Portuguese is the official language and is understood by a majority of islanders. Cape Verdeans form the largest group of foreigners, perhaps amounting to about 10 percent of the total population; many have adopted São Tomense nationality. Portuguese, Angolans, and Mozambicans make up most of the rest of the foreign community. Like the Cape Verdeans, they are relatively well integrated with the other islanders, owing to a shared Portuguese cultural background. The Angolares, descended from slaves who survived a shipwreck in the 16th century, remained apart in the isolated southern zone of São Tomé island until the late 19th century, speaking a Bantu language. They have since spread throughout the country and have become largely assimilated. Almost the entire population belongs to the Roman Catholic church, although there are a few small Protestant congregations. Traditional African religions are also practiced.

Population growth is rapid, owing to both a relatively high birth rate—though it is below average for central Africa—and a low death rate. Nearly half the population is less than 15 years of age, assuring continued rapid growth into the future. Life expectancy is relatively high for an African country, at 63 years for men and 67 years for women.

The economy. Decades of colonial stagnation were followed by economic disruption after independence in 1975. Under the tutelage of the International Monetary Fund and the World Bank, São Tomé and Príncipe has gradually restored a functioning economy by devaluing its currency, restricting the budget deficit, privatizing formerly nationalized companies, attracting foreign investment, and removing price subsidies and controls. About four-fifths of the total land area of the two islands belongs to the state and is divided into 15 large plantation enterprises, several of which have been leased out to foreign management companies. High levels of unemployment coexist with a critical labour shortage on the plantations, where wages and working conditions are poor.

Economic resources

São Tomé is endowed with excellent conditions for tropical agriculture. The growing season is long, the volcanic soils are fertile, and there is no lack of water. There are some fine timber stands remaining, but the physical problems of removal in mountainous terrain and the pressing need for effective conservation limit long-term prospects. The small size of the country prevents the significant growth of extensive livestock raising, but conditions for poultry raising are quite favourable. There are numerous sites for small hydroelectric schemes but no large rivers for major installations. The country has no known minerals aside from some lime deposits exploited for local use. Fishing resources are limited by the narrow continental shelf. Manufacturing is hampered by the small size of the internal market, the limited energy resources, and the lack of skilled labour. Tourism is perhaps the best hope for economic diversification, but the long rainy season is a considerable obstacle to overcome.

The economy remains chronically dependent on plantation agriculture and especially on cocoa. About 40 percent of the total land area is under cultivation, with cacao trees covering a little less than two-thirds of the state-owned plantation acreage; coconut palms cover most of the remainder. Large areas of plantation land have been poorly maintained since independence, being harvested from time to time but not otherwise tended. The country has never been self-sufficient in staple foodstuffs, and a combination of official price-fixing for urban consumers and foreign gifts of food have undermined the production of food crops for the local market.

The nonagricultural sectors contribute little to the economy. The country is self-sufficient in fish, and trawlers from the European Communities pay small license fees for the right to fish in the country's national waters. The deep-sea tuna resources of the Gulf of Guinea and shellfish in coastal waters represent the best hopes for fishery exports. Manufacturing accounts for about 10 percent of the gross domestic product and consists mainly of small processing factories producing foodstuffs, beverages, soap products, and sawn wood for the internal market. Tourism is largely limited to the dry season and chiefly attracts people living in neighbouring parts of Africa.

São Tomé and Príncipe is reputed to be one of the highest recipients of foreign aid per capita in the world, but this has not prevented large budgetary and balance-of-payments deficits. There is only one bank active in the country, the state-owned National Bank of São Tomé and Príncipe, which controls foreign exchange dealings and acts as the central bank. The black market in foreign exchange has shrunk as the national currency, the dobra, has progressively been devalued. Cocoa accounts for almost all foreign exchange earnings. China takes cocoa under counter-trade barter agreements, but most of it is exported to Germany and The Netherlands. Portugal is the main source of imports, and Angola supplies petroleum products at concessionary rates.

Transportation assumes particular importance in this isolated microstate. There are no natural or artificial harbours, and large ships must anchor far out at sea and be unloaded by barge. Shipping links between the islands and with the outside world are erratic, and there are long delays in unloading cargo. The international airport near São Tomé city has been expanded and modernized, and in 1986 a national airline, Equatorial Airlines of São Tomé and Príncipe, was established as a joint venture between the government and foreign interests. It links the two main islands and flies to adjacent African countries. The telephone system and the road network are both fairly good by African standards.

Administration and social conditions. The political and judicial structures adopted at independence in 1975 were those of a single-party state, but the regime never formally proclaimed its adherence to Marxism-Leninism. Free elections for the legislative assembly and the presidency were established by the constitution of 1990. Close ties with eastern European countries have been replaced by warm relations with Portugal, France, and other Western countries. Angolan troops have been stationed in the country since 1978 to guarantee internal security.

National government

Educational and health levels are high by African standards. Some two-thirds of children receive basic education, and more than half the population is literate in Portuguese. Foreign aid workers make up for the shortage of teachers. There is no university, and most students go to Portugal for higher education.

Life expectancy is more than 60 years. There are numerous clinics, although drug supplies are short, local doctors emigrate, malaria is endemic, and there are occasional epidemics of cholera. However, there are no signs of extreme destitution.

Cultural life. This small country has a homogeneous culture, profoundly marked by centuries of Portuguese colonialism, although the government has been keen to stress the country's African heritage. Language, family structure, and religion are basically Portuguese. Many African elements have been adopted in the cooking, customs, beliefs, and dress of the common people, and the poorer classes only speak creole. The single newspaper appears erratically, but the government-run radio station is active, and there have been experiments with a television station.

For statistical data on the land and people of São Tomé and Príncipe, see the *Britannica World Data* section of the BRITANNICA WORLD DATA ANNUAL.

HISTORY

Settlement by Portuguese

São Tomé and Príncipe were uninhabited when they were discovered, probably in 1470, by Portuguese navigators sailing around Africa. In the 1480s, the Portuguese sent out settlers (many of them Jewish "New Christians" expelled from Portugal by the Inquisition) and imported African slaves to grow sugar.

During the 16th century, São Tomé briefly became the world's largest producer of sugar, but the rise of Brazilian competition and the poor quality of São Tomé's badly dried product led to the decline of its sugar. This decline was accentuated by insecurity, as slaves escaped to the mountains and raided the plantations. Amador, the king of the fugitive slaves who nearly overran the whole island of São Tomé, is considered a national hero. Foreign pirates were another hazard, and the Dutch briefly captured São Tomé in 1641, only to be expelled three years later.

After the collapse of the sugar economy, the colony served as a bulking-up point for the Portuguese slave trade to Brazil; the cargoes of small slave ships were transferred to larger vessels for the Atlantic voyage, and provisions and water were obtained. The slave-worked plantations producing foodstuffs for the slave ships were mainly located on Príncipe, and the capital was moved to the port of Santo Antônio on Príncipe in 1753. In 1777–78 the Portuguese ceded the islands of Bioko and Annobón, on either side of São Tomé and Príncipe, to the Spaniards, who wished to develop their own African slave trade.

With the suppression of the Brazilian slave trade and the introduction of coffee cultivation in the 19th century, the economic centre of gravity swung back to São Tomé, and in 1852 São Tomé city once again became the capital. Cocoa replaced coffee as the main cash crop in the 1890s, and during the first two decades of the 20th century the colony was in some years the world's largest producer of cocoa. This led to the maximum expansion of plantations on the islands. Although slavery was legally abolished in 1875, Angolan slaves continued to make up the bulk of the labour force until the early 1910s. They were then replaced by forced or indentured labourers from other Portuguese colonies.

Cocoa production fell after World War I, and the islands progressively became a stagnant backwater, notorious for the brutality and corruption that reigned on the plantations belonging to absentee planters and corporations. Attempts to force the local Forros to work on the plantations led to the Batepá Massacre in 1953, seen as the beginning of the nationalist movement. The Committee for the Liberation of São Tomé and Príncipe was set up in exile in 1960, changing its name to the Movement for the Liberation of São Tomé and Príncipe (MLSTP) in 1972. However, it was never able to mount a guerrilla challenge to the Portuguese on the islands.

The nationalist movement

The Portuguese government that overthrew the Salazarist dictatorship in 1974 agreed to hand over power to the MLSTP in 1975, and many of the whites and wealthier Creoles then fled to Portugal, fearing a communist government. Independence was granted on July 12, 1975.

The MLSTP at first followed eastern European models of political and economic organization. Economic decline and popular dissatisfaction, however, led to a process of liberalization from 1985, culminating in the establishment of multiparty democracy in 1990. (W.G.C.-S.)

For later developments in the history of São Tomé and Príncipe, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

Zaire

The Republic of Zaire (République du Zaïre) is centrally located on the African continent. It has a short 25-mile (40-kilometre) coastline on the Atlantic Ocean and is otherwise landlocked, being bordered on the west by the Angolan exclave of Cabinda and the People's Republic of the Congo; on the north by the Central African Republic and The Sudan; on the east by Uganda, Rwanda, Burundi, and Tanzania; on the southeast by Zambia; and on the southwest by Angola. It has an area of 905,446 square miles (2,345,095 square kilometres) and is the third largest country on the continent; only The Sudan and Algeria have larger areas. The capital, Kinshasa, is located on the Congo River at a distance of about 320 miles from its mouth and is the largest city in central Africa. It serves as the nation's administrative, economic, and cultural centre.

Formerly known as the Democratic Republic of the Congo, the country took the name of Zaire in 1971 in an attempt to return to the source of the nation's identity and authenticity. "Zaire" is a variation of traditional African names for big rivers and specifically the Congo River, whose basin lies almost entirely within the republic. The river was named during the colonial period for the kingdom of the Kongo people, who inhabit the area along the river's mouth on the Atlantic Ocean.

Zaire is a country rich in economic resources. Its minerals include vast deposits of industrial diamonds, cobalt, and copper; its forest reserves are possibly the largest in Africa; and its hydroelectric potential comprises half that of the African continent.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* The country's major relief features include the coastal region, two major basins or depressions, high plateaus, and three mountain ranges. The narrow coastal region is composed of a fairly low plain that runs inland from the Atlantic Ocean to the Cristal Mountains, where a high escarpment rises above the plains.

Most of the country is composed of the central (or Congo) basin, topographically a vast rolling plain with an average elevation of about 1,700 feet above sea level. Its lowest point of 1,109 feet (338 metres) occurs at Lake Mai-Ndombe (formerly Lake Léopold II), and the highest point of 2,296 feet (700 metres) occurs in the hill country of Mobayi-Mbongo and Zongo in the north. This basin may once have been an inland sea whose only remaining vestiges are now Lakes Tumba and Mai-Ndombe in the west-central part of the basin.

A high longitudinal basin—the western arm of the East African Rift System—forms the country's eastern border. Along its Zaire section, the depression contains Lakes Albert (in Zaire known as Lake Mobutu Sese Seko), Edward, Kivu, Tanganyika, and Mweru.

The high plateaus

The high plateaus border almost every side of the central basin. In the north the basin is protected by the Ubangi-Uele plateaus forming the divide between the drainage basins of the Nile and Congo rivers. Rising to between 3,000 and 4,000 feet, the plateaus also separate the central basin from the vast plains of the Lake Chad system. In the south the plateaus begin at the lower terraces of the Lulua and Lunda river valleys and rise gradually toward the east. In the southeast the ridges of the plateaus of Shaba tower over the entire area; they include Kundelungu at 5,250 feet (1,600 metres), Mitumba at 4,921 feet (1,500 metres), and Hakansson at 3,609 feet (1,100 metres). The Shaba plateaus extend as far north as the Lukuga River and contain the Manika Plateau, the Kibara and the Bia mountains, and the high plains of Marungu.

The northern escarpment of the Angola Plateau rises in the southwest. In the west there is a coastal plateau zone that includes the hill country of Mayumbe and the Cristal Mountains. Mount Ula at 3,446 feet (1,050 metres) is the highest point of the Cristal Mountains.

The eastern part of the country is the highest and most rugged. It contains striking chains of mountains that are part of the East African Rift System. The Mitumba Mountains stretch along the Western Rift Valley, rising to an elevation of 9,800 feet above sea level. The snow-covered peaks of the Ruwenzori Range between Lakes Albert and Edward lie astride the Uganda border and contain Zaire's highest elevation of 16,795 feet (5,119 metres) at Margherita Peak. The Virunga Mountains, to the north of Lake Kivu, form a volcanic range that stretches across the Rift Valley.

The Congo River basin

Drainage and soils. The Congo (Zaire) River, including its 1,335,000-square-mile basin, constitutes the main system of drainage in the country. The river rises in the high Shaba plateaus and flows north and then south to cross the equator twice in a great arc. The lower river flows southwestward to empty into the Atlantic Ocean below Matadi. Along its course the Congo passes through alluvial lands and swamps and is fed by the waters of many lakes and tributaries. The most important lakes are Mai-Ndombe and Tumba; the major tributaries are the Lomami, Aruwimi, and Ubangi rivers and those of the great

Kasai River system. There is also a link to the Western Rift Valley via the Lukuga River.

There are two types of soils: those of the equatorial areas and those of the drier savanna (grassland) regions. The equatorial soils occur in the warm, humid lowlands of the central basin, which receive abundant rainfall throughout the year and are covered mainly with thick forests. This soil is almost fixed in place because of the lack of erosive forces in the forests. In the shore areas, however, swamp vegetation has built up a remarkably thick soil that is constantly nourished by humus, the organic material resulting from the decomposition of plant or animal matter.

Although in the savanna regions the soils are constantly endangered by erosion, the river valleys contain rich and fertile alluvial soils. Special note should be made of the highlands of eastern Zaire in the Great Lakes region, which are partly covered with volcanic lava that has been transformed into exceptionally rich soil. This is the most productive agricultural area of the country.

Climate. The major part of Zaire lies within the inner humid tropical, or equatorial, climatic region extending five degrees north and south of the equator. Southern Zaire and the extreme north have somewhat drier subequatorial climates.

The seasonally migratory intertropical convergence zone (ITCZ) is a major weather feature of Zaire's climate. Along this zone the trade winds originating in the Northern and Southern hemispheres meet, forcing unstable tropical air aloft. The resulting cooling and condensation of the uplifted air produces prolonged and heavy rainfall. In July and August this zone of maximum rainfall occurs in the north. It passes into central Zaire in September and October. From November to February the southern parts of the country receive their maximum precipitation. Moving northward, the ITCZ crosses central Zaire again in March and April, so that this zone has two rainfall maxima. Only the extreme eastern highlands lie outside the path of the ITCZ and are subject to the influence of the southeastern trade winds alone. Altitude and proximity to the Atlantic Ocean and its maritime influences are additional factors of climatic differentiation.

The four major climatic regions

There are four major climatic regions in the country. In the area of the equatorial climate, temperatures are hot, and the average monthly temperature rarely drops below 75° F (24° C). Humidity is high, and it rains almost throughout the year. Annual precipitation at Eala averages 71 inches (1,800 millimetres). The tropical or subequatorial climate occurs to the north and south of the equatorial region. It is marked by distinct dry and rainy seasons. The dry season may last from four to seven months (usually April to October) of the year, depending largely on distance from the equator. At Kananga about 62 inches of rain falls annually. In some areas and at indefinite periods, a short dry season of several weeks' duration may occur during the rainy season.

The Atlantic climate is limited to the west coast. It is marked by the modifying influences of low altitude and the cold Benguela Current. At Banana the average annual temperature is 77° F (25° C), and rainfall averages about 30 inches yearly. The mountain climate occurs in the eastern high plateaus and mountains. At Bukavu the average annual temperature is 66° F (19° C), and annual precipitation measures about 52 inches.

Plant and animal life. Plant life is profuse and follows climatic patterns. In the centre of the Congo basin is an intricate forest system, commonly known as the equatorial rain forest. There trees reach 130 to 160 feet in height, and many plant varieties and species can be found in a small area. In the tropical climate zone, grassland and woodland are characteristic, while in the west the coastal swamps and the mouth of the Congo are dominated by stands of mangrove. The eastern plateaus are covered by grasslands. Mountain forest, bamboo thickets, and Afro-Alpine vegetation occur on the highest mountains.

The central basin is a vast reservoir of trees and plants that are native to the area. Among these, the mahogany, ebony, limba, wenge, agba, iroko, and sapele are sources of timber. Fibrous plants include raffia and sisal. There are also plants used in traditional medicine, including cinchona (the source of quinine) and rauwolfia (an emetic and antihypertensive), as well as copal, rubber, and palm trees. Many types of edible mushrooms grow wild; other wild edible vegetables grow in the forests, grasslands, and swamps. Eucalyptus trees have been imported and form important stands in the highlands; they are used for construction timber and poles.

Animal life is also rich and diversified. Chimpanzees are found mostly in the equatorial forest, and gorillas occur in the eastern mountains around Lake Kivu. Elephants and various species of monkey and baboon are found in the forest and the savanna woodland. The short elephants are, however, exclusively forest-bound.

In the primary forests of Uele, Aruwimi, and Ituri are the okapi, the giant wild boar, and the short antelope. The lion and leopard inhabit the grasslands, and the jackal, hyena, cheetah, wildcat, wild dog, buffalo, antelope, wild hog, and black and white rhinoceroses are found in the grasslands and savanna woods. Giraffes mainly inhabit the northeastern grasslands.

Hippopotamuses and crocodiles are common in the rivers and lakes, and whales, dolphins, and lungfishes are found near the coast. Zairian rivers, lakes, and swamps are well stocked with a variety of fish, such as the capitaine from the Congo River and catfish, electric fish, eels, cichlids, and many others. There is also a good supply of jellyfish in Lake Tanganyika. Reptiles are common and include various snakes, such as pythons, vipers, and tree cobras, as well as lizards, chameleons, salamanders, frogs, and turtles.

Birdlife includes the pelicans, parrots, and many species of sunbird, pigeon, duck, goose, eagle, vulture, cuckoo, owl, crane, stork, and swallow. The insects are innumerable. There are hundreds of species of butterfly; in the savanna woodlands the butterflies have their special season at the beginning of the rains, when they can be seen flying in great numbers, filling the sky and wandering over the blooming trees. There are also bees of all types, different species of grasshopper, and caterpillars, praying mantises, beetles, dragonflies, scorpions, mosquitoes, tsetse flies, ants, termites, spiders, centipedes, and millipedes.

National parks

Much of the animal life has diminished as the result of hunting, which is now strictly regulated. Several national parks have been created, most in the eastern highlands. They include Garamba, near the Sudan border; Virunga, north of Lake Edward in the Virunga Mountains; Maiko, west of Lake Edward; Kahuzi-Biega, north of Bukavu; Upemba, north of the Manika Plateau; and Kundelungu, near the Zambian border northeast of Lubumbashi.

Settlement patterns. The traditionally inhabited regions are the forests, savanna woodlands, and grasslands. People have worked these areas and have become specialized to their environment. The individuals who live in the forests, such as the Bambuti (Pygmies) of the Ituri Forest, have specialized mostly in hunting and fishing, while agriculture has remained secondary or is nonexistent.

In the savanna woodlands the inhabitants combine cultivation with hunting and fishing. In some areas across the southern half of the country, the people are engaged in the raising of small livestock and poultry and traditionally mine copper, iron ore, and other minerals. In the grasslands inhabitants confine themselves almost solely to agriculture. In the eastern grasslands, however, agriculture is combined with the raising of large livestock.

Rural settlement

A large percentage of the Zairian population is rural, and most of the people live in scattered villages. The style of housing varies regionally, as does the general size of the villages. A village with 10 to 25 housing units is generally considered small, while one with 150 to 200 is considered large. The savanna woodlands of the south-central regions, and to some extent the coastal region, are the most populous areas, with the largest villages having 300 to 500 people. The eastern grassland areas have isolated farms and hamlets.

Such trade and administrative centres as Banana, Vivi, and Boma were established with the arrival of the Europeans in the 16th century. Most towns, however, are of more recent origin. Kinshasa, until 1966 called Léopoldville, is the seat of national political, administrative, and judiciary institutions and is also an important commercial and industrial centre. It is the creator and propagator of fashions and of many traits of Zairian cultural life. The growth of Kinshasa typifies that of many of the country's cities. In 1889 it had a population of 5,000; in 1925, when it was recognized as a *ville* (urban centre), it had grown to 28,000. The city jumped to a population of 250,000 in 1950, 1,500,000 in 1971, and about 3,500,000 in 1989—an increase by a factor of 1,000 in a century.

There are nine other major cities; all are administrative or commercial centres with the exception of Likasi, which is mainly an industrial and mining town. Kananga is the capital of Kasai-Occidental (Western Kasai) region. Lubumbashi (formerly Élisabethville), the administrative headquarters of Shaba, is the heavily industrialized capital of the nation's copper-mining activities. Mbuji-Mayi is the capital of Kasai-Oriental (Eastern Kasai) region and the country's diamond centre. Kisangani (formerly Stanleyville), the terminal point of navigation on the Congo River from Kinshasa, is the capital of Haut-Zaïre. Bukavu, the headquarters of Sud-Kivu region, is a major tourist centre; Kikwit, the former capital of Bandundu region, is the terminal port on the Kwilu River; and Matadi, the capital of Bas-Zaïre, is the country's main port. Mbandaka is a river port and the capital of Équateur region.

All of these towns were developed during the colonial period, when there were separate sectors for the Europeans and the Africans. The European neighbourhoods were characterized by big houses with large yards, wide and paved streets, and adequate electricity. The crowded African areas had smaller houses and yards and poor, if any, electric supply. These characteristics still hold true, although the traditional European sectors include Africans of the upper income group.

The people. *Ethnic composition.* It is common for the modern African to prefer an identification as simply an African or as a citizen of a particular country. It is possible, however, to distinguish ethnic, linguistic, or cultural groups among the Zairian population.

The Bantu peoples constitute a large majority of the country's population and occupy more than two-thirds of the national territory. They entered the region of modern Zaire during the 10th to the 14th century from the west and north and established kingdoms that were flourishing at the time of European penetration after the 16th century. The major kingdoms were those of the Kongo, Teke (Bateke), Luba, Pende, Yaka, Lunda, Songe, Tetela, and Kuba peoples. Major cultural clusters today include the Mongo (in the centre), Kongo (west), Luba (south-central), Lunda (south), Bemba (southeast), and Kasai (southwest). Bantu tribes in the north and northeast include Ngala, Buja, Bira, Kuumu, and Lega (Rega).

The Pygmies are considered the earliest inhabitants of the Congo basin, having arrived possibly during the Upper Paleolithic Period. The remaining Pygmies—the Bambuti, Twa, and Babinga—inhabit the forests of Kibali and Ituri and the regions of Lakes Kivu and Tanganyika and the Lualaba, Tshuapa, Sankuru, and Ubangi rivers.

There are other small non-Bantu African populations. The Sudanese groups who settled in the north include the Zande (Azande), Mangbetu, Banda, and Barambu (Abarambo). The Nilotic peoples live in the northeast; they include the Alur, Kakwa, Bari, Lugbara, and Logo. Hamitic peoples from North Africa and Rwanda are few; they include the Tutsi, who live in the lake region.

The permanent European and Asian population comprises about half of the country's aliens. Most of them came to Zaire for temporary employment. Much of the remaining alien population is composed of Africans of non-Zairian nationality.

Linguistic composition. More than 200 languages and dialects are spoken in Zaire. Communication between groups has been facilitated by four national languages: Swahili, Tshiluba (Kiluba), Lingala, and Kikongo. French is the only official language and the language of instruction, business, adminstration, and international communications. The four national languages are used in local trading and radio broadcasting. Lingala is growing rapidly; it is the official language of the military and is widely spoken in Kinshasa, where it is used in popular music.

Religion. The traditional religious beliefs in a supreme being, the power of the ancestors, spirits of nature, and the efficacy of magic were torn apart or greatly disturbed with the introduction of Christianity. There is a sizable Christian population, including the local sect of the Church of Jesus Christ on Earth by the Prophet Simon Kimbangu (Kimbanguism). The rest of the African population continues to follow traditional beliefs or professes no religion. The foreign community includes a small Jewish population and some Hindus and Muslims.

The economy. Located in the centre of the African continent, the Republic of Zaire—with its great size, population, and rich potential—is called upon to play an important regional and international economic role.

Mineral resources

Resources. The country's main economic resource is its mineral deposits. The abundance of minerals in the Shaba region (Swahili *shaba,* "copper") was a source of the desire of European powers to control the area. Minerals of Shaba include copper, cobalt, zinc, cassiterite (the chief source of metallic tin), manganese, coal, silver, cadmium, germanium (a brittle element used as a semiconductor), gold, palladium (a metallic element used as a catalyst and in alloys), and platinum.

The region west of Lake Kivu contains cassiterite, columbotantalite, wolframite (a source of tungsten), beryl, gold, and monazite (a phosphate of the cerium metals and thorium). Lake Kivu has a vast reserve of methane, carbonic, and nitrogen natural gases. There are deposits of iron ore in south-central Zaire. Industrial diamonds are found in the central regions, and gem-quality diamonds occur in the south-central part of the country.

There are gold, coal, and iron-ore deposits in northeastern Zaire, and there are prospective deposits of gold, monazite, and diamonds in the northwestern regions. The diamond deposits in the western region are insignificant for industrial exploitation. Coastal Zaire contains bauxite, gold, and offshore deposits of petroleum. The limestone deposits that occur throughout the country are considered to be among the richest in Africa.

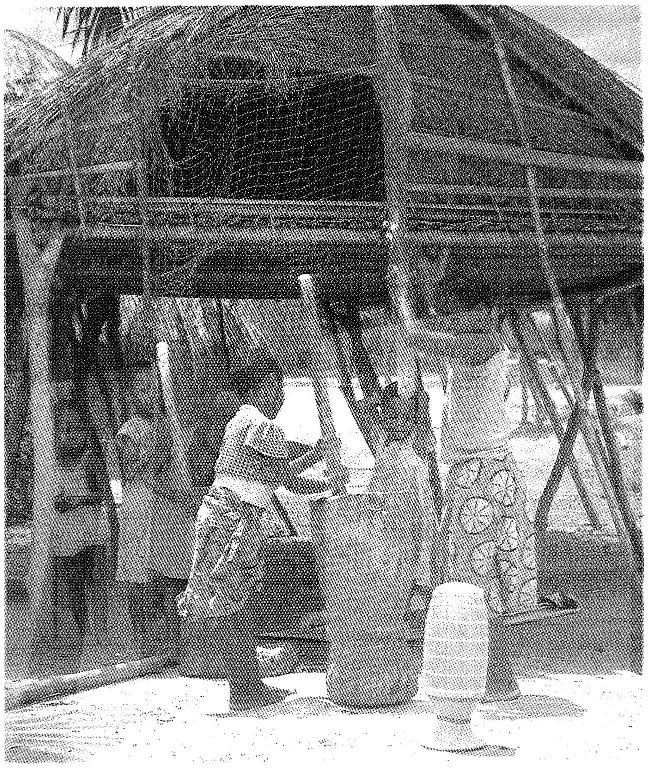
Zaire's forest reserves cover more than half of the country and are considered to be the largest in Africa. The wide variety of wild game supplements the local diet and contributes to a certain extent to local commerce. Ivory is exploited in the north, and the rivers, lakes, swamps, and ocean contain a vast reserve of fish.

The country's hydroelectric resources have an estimated potential of 13 percent of the world's capacity and 50 percent of Africa's potential capacity. This tremendous potential is derived from the many rapids along the rivers of the Congo system. Thermal energy can be derived from the forests and coal and petroleum deposits, as well as the uranium deposits in Shaba region.

Agriculture, forestry, and fishing. Domestic agriculture is the main source of food supply and cash income for the majority of the population. Although the country is rich in agricultural potential, the deterioration of the transportation network and agricultural services since independence have led to a regrowth of subsistence agriculture and a collapse of market production. Foodstuffs such as cereals and fish must be imported in increasing amounts. Coffee is the chief agricultural export; palm oil, rubber, and cotton, once mainstays of the export economy, have become almost negligible.

In the humid equatorial region, cassava (manioc) and rice are the basic food crops. Peanuts (groundnuts), oil palms, and fruit trees are also important, while robusta coffee is the main cash crop. In the eastern highlands, yams, beans, and sweet potatoes are used as food crops, while arabica coffee and tea are export commodities. On the southern plateaus, corn (maize) is of major importance for the urban populations of Shaba. Vegetable growing is widespread throughout Zaire.

Livestock and poultry are kept in every province. Cattle are raised mainly in the eastern and southern regions. Pigs are kept in the west and sheep in the eastern highlands. Other farm animals include chickens, geese, pigeons, and rabbits. Commercial meat production is limited, however, and the country depends upon imports to fulfill most of its requirements.



Lunda children pounding cassava into flour, southwestern Zaire.
John Anthony/Bruce Coleman Ltd.

A small part of the yearly production of timber is exported for veneering or plywood; most, however, is used locally for fuel. There is some commercial freshwater and ocean fishing. Local hunting and fishing for private consumption are not ordinarily reported in official statistics and are difficult to measure.

Industry. Mining produces more than half of the national budget and more than 80 percent of total exports. Zaire is a leading producer of industrial diamonds, accounting for about one-third of the world's total production. It also produces about one-half of the world's cobalt. It is a major producer of copper and tin. Coal production is low, however, because of mining difficulties and the increasing production of hydroelectricity. Other minerals mined include cadmium, silver, manganese, gold, wolframite, columbotantalite, beryl, and monazite. The most important mining company is the state-owned Générale des Carrières et des Mines (Gécamines).

Mining and quarrying

Manufacturing industries can be classified into two main categories. Consumption industries produce processed foods, beverages, cigarettes, cloth, printed material, hosiery, shoes and leather, metallic fabrics, and such chemical products as soap, paints, rubber, and plastics. The supply and equipment industries include spinning and weaving plants, chemical factories, and facilities to produce machinery, transport materials, nonmetallic minerals, and wood products. A petroleum refinery near Moanda was established in 1968; the production capacity is 750,000 tons annually.

The heaviest concentration of hydroelectric consumption is in the mining areas and in Kinshasa. The hydroelectric dam completed in 1972 on the lower Congo River at Inga Falls began initially to supply 300,000 kilowatts of electricity. After the completion of the second stage in 1982, Inga's capacity rose to 2,300,000 kilowatts. The dam has a theoretical potential estimated at 30,000,000 kilowatts. Zaire exports electricity to Zambia, Burundi, Congo, and Angola. There are thermal power plants in almost every major city that cannot be served by hydroelectric stations.

Finance and trade. The national central bank, the Bank of Zaire, is located in Kinshasa, as are numerous commercial, savings, and development banks. Most of these banks maintain branch offices in the regional capitals and major cities. There are also mortgage and credit banking institutions. Totally foreign-owned banks include U.S., British, and French institutions as well as the International Bank for Africa in Zaire.

Zaire has a favourable balance of trade. Mineral products account for most of total exports. The second most valuable exports are agricultural products; exported manufactures are of limited value and volume. Imports consist of consumer goods, machinery (largely mining and transport equipment), construction materials, leather and textiles, fuel, chemical products, metal products, and increasing amounts of foodstuffs.

Transportation. The organization of the transportation network is of the most crucial importance to Zaire, a country of continental dimensions and rich economic resources. The country's generally poor transportation infrastructure is a major factor in the underdevelopment and stagnation of the economy. The Congo River, the spinal cord of the country, and its tributaries serve as the main transport arteries. The rivers are supplemented by rail, road, and air services.

Navigation is possible throughout the year on sections of the Congo River. It is navigable from Banana to Matadi, Kinshasa to Kisangani, from Obundu to Kindu, and from Kongolo to Bukama for a total of 1,428 miles. Its tributaries add at least another 8,750 miles of navigable rivers. The main port for maritime shipping is Matadi near the mouth of the Congo River.

Railways

The agricultural region of Mayumbe is served by the Boma-Tshela railway. Other lines connect the Uele with the Itimbiri River and Lake Tanganyika with the Lualaba River, and two railways serve the rich southern regions.

There are four major routes that combine water and rail transport. The only such route to lie wholly within Zaire runs by rail from Shaba to Ilebo, by boat along the Kasai and Congo rivers to Kinshasa, and by rail to Matadi. The international routes run across Lake Tanganyika and Tanzania to the Indian Ocean port of Dar es Salaam; through Zambia, Zimbabwe, and Mozambique to Beira, also on the Indian Ocean; and through Angola to the Atlantic Ocean port of Lobito. The Angolan route and the system to Beira have been unusable for years, however, because of ongoing civil wars in Angola and Mozambique. The heavy traffic that would normally follow these routes is sent via Zimbabwe to ports in South Africa. In an effort to lessen its dependence upon its neighbours, the government plans a railway to connect Shaba directly with its Atlantic Ocean ports by linking Ilebo with Kinshasa.

Administration and social conditions. *Government.* The constitution of 1978 was Zaire's fifth since independence in 1960; trends apparent in these successive documents include the institution of an increasingly centralized presidential form of government, the exclusion of political activity not sanctioned by the Popular Movement of the Revolution (Mouvement Populaire de la Révolution; MPR), and the progressive circumscription of the prerogatives of the national legislative body by the Political Bureau of the MPR.

The MPR

The MPR is the sole legal political party. It is presided over by the president, who is assisted by the Political Bureau, composed only of individuals appointed by the president. The routine of party life on the national level is carried on by the Central Committee, whose members are appointed by the Political Bureau. The MPR has branches at every administrative level throughout the country. Party ideology is that of an anti-tribalist nationalism; the ultimate goal of building a strong nation-state is prescribed in the basic party document, the Nsele Manifesto (Le Manifeste de la N'sele).

Citizens of Zaire become members of the MPR at birth and participate in political activities by following the party teachings, voting, attending political rallies, and mobilizing on all levels for political and economic development.

According to the provisions of the 1978 constitution, the president of the republic is elected to a seven-year term (not to exceed two terms) consequent upon his election to the leadership of the MPR; the general electorate approves this choice. The president is the head of state, of the National Executive Council, and of the National Legislative

Council (the parliament) and is commander in chief of the armed forces.

The country is divided into eight *régions* and the *ville neutre* (equivalent to a federal district) of Kinshasa. Each region is divided into *sous-régions,* each *sous-région* into *zones,* each *zone* into *collectivités locales,* and each *collectivité locale* into *localités.* The *régions, sous-régions,* and *zones* are presided over by commissioners and the *collectivités locales* and the *localités* by chiefs. All are appointed to five-year terms, with the exception of the village chief, who has a completely traditional role and is elected by the villagers or may inherit the position.

Cities are divided into *zones* and *zones* into *quartiers,* headed, respectively, by *commissaires sous-régionaux,* or mayors, *commissaires des zones,* and *chefs de quartiers.* The mayor of Kinshasa is called *commissaire urbain.*

Justice. The judicial system is headed by the Supreme Court, which is located in Kinshasa. There are nine Courts of Appeal, and a tribunal of first instance is located in most subregional capitals.

The customary judicial system in the villages is not completely abolished, and villagers may settle some cases according to traditional procedures. Zaire does not apply the jury system; the judges, after deliberation, have the right to settle cases. All courts are presided over by a lawyer or person of legal training. The defendant may defend himself or choose his own lawyer or defender.

Education. Since independence public authorities have recognized the value of education and have given it greater attention. The budget for the Ministry of Education has always been ahead of that of the other sectors of national life. Primary education is compulsory, although it is difficult for a developing nation to meet this pledge because of the lack of facilities and an inadequate number of teachers.

The National University of Zaire

In 1971 the universities of Kinshasa, Kisangani, and Lubumbashi were merged into the National University of Zaire, which used the three campuses to house different departments and fields of study. This scheme was terminated in 1981, when the three former universities were reconstituted as separate, autonomous institutions by the Central Committee of the MPR. There are university institutes in the three university towns and at Buvaku and two arts academies in Kinshasa.

Health and welfare. In general, individuals build their own houses according to their needs and means. The government has established a department that builds and rents houses and also sells condominiums, especially in urban areas. In the cities, real-estate agencies and individuals build houses and apartments and make them available for rent. The government has been trying to improve housing conditions by the allocation of funds for the construction and improvement of houses.

In 1960 Zaire inherited a difficult medical situation, for there were no national doctors. The colonial administration had trained some highly qualified medical technicians and nurses while confining medical practice to European doctors and missionaries. By the late 1970s, however, most of the doctors were Zairian. For the country's first decade, experienced medical assistants, technicians, and nurses filled the vacuum left by the shortage of doctors. By the end of its third decade there was one doctor for every 14,000 persons.

With the means at its disposal and the help of such international organizations as the World Health Organization and the United Nations Children's Fund, the government has been waging a battle against the most critical and widespread diseases—tuberculosis, sleeping sickness, leprosy, and polio. Smallpox was eradicated in 1972. Special centres and programs have been established in the cities and rural areas to deal with maternity and child care, sanitary education, sanitary improvement of the environment, and preventive and curative medicine. A hospital boat equipped with doctors and modern facilities serves the people along the Congo River and its tributaries.

Zaire has an extensive medical care program for all workers. Each company is required to provide medical assistance for its employees, and public servants receive free medical treatment from state hospitals and dispensaries. Medical expenses in public hospitals are nominally low and accessible to people with minimum incomes, but shortages of equipment, supplies, and personnel make services difficult to obtain. There are a number of hospitals and dispensaries, including specialized hospitals for leprosy, neuropsychiatry, and tuberculosis.

Cultural life. Zaire's many ethnic groups and regions have developed a mosaic of traditional arts, such as painting, sculpture, music, and dance. There has been a tendency to classify sculpture and carving according to the styles of the areas from which they originate. The South-West Group is represented by the Kongo people and is known for stone and nail-studded statues; the Yaka, also of this group but from the region of the Kwango and Kwilu rivers, produce masks and figurines. The Kuba art form, the Southern Central Group, deals with human themes; there is a tendency to create statues representative of the Kuba royal court. The South-East Group is composed mainly of Luba art, which reflects the strong influence of women in the society through a multitude of statuettes relating to motherhood. North of the Luba region is the area where the Lega masks and ivories are produced. The North Group includes Zande and Mangbetu art; Zande art is characterized by cult statuettes, spear or bow shafts, and anthropomorphic pottery, while Mangbetu art is characterized by stylized elongated heads.

Traditional art styles

Painting, sculpture, and carving are still practiced. The cities, especially Kinshasa, have become the greatest creators, propagators, and promoters of national cultural life and arts. The Academy of Fine Arts in Kinshasa offers training programs in painting, sculpture, carving, architecture, and ceramics. The National Institute of the Arts offers training in classical and some traditional music and drama. The writing of poetry, plays, and novels has been developing rapidly; they are usually written in Lingala and French, but other local languages are also used. The development of scientific literature is supported by the universities, various scientific organizations, and the government. Several publishing houses have been established throughout the country.

Surviving national folk traditions are evident in pottery and the weaving of raffia, in ceremonial dress or costumes, in dancing styles, and in songs.

Sports include soccer, swimming, boxing, basketball, and riverboat racing. Zaire's unique popular music results from a mixture of traditional rhythms and instruments borrowed from other cultures, civilizations, and continents. This music, popular all over Africa, has given birth to the great variety of specific dance steps and styles known as the Zairian dance.

There are museums and public libraries in most large cities, with national museums in Kananga, Mbandaka, and Lubumbashi. The capital city houses the national archives and the National Theatrical Troupe. There are libraries at all three universities. (N.Pa./B.M.W.)

For statistical data on the land and people of Zaire, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL.

HISTORY

What began as a king's private domain (the Congo Free State), evolved into a colony (the Belgian Congo), and came to be known at the time of independence in 1960 as the Republic of the Congo (later the Democratic Republic of the Congo) and in 1971 as Zaire, is the product of a complex concatenation of historical forces. Some are traceable to the precolonial past, others to the legacy of colonial rule, others still to the political convulsions that followed in the wake of independence. All, in one way or another, have left their imprint on Zairian societies.

Precolonial perspectives. Before experiencing the radical social transformations of the colonial era, Zairian societies had already suffered major disruptions. From the 15th to the 17th century several important state systems came into existence in the savanna region in the southern half of the area. The most important were the Kongo kingdom in the west and the Luba and Lunda empires in the east. All three developed fairly elaborate political structures, buttressed by the symbolic force of kingship as well as by military force. Typically, power emanated

Kongo, Luba, and Lunda kingdoms

from the capital city to the outlying areas through the intermediation of appointed chiefs or local clan heads. Competition for the kingship often led to civil strife, however, and with the development of slave-trading activities a new source of instability was injected into regional politics. The history of the Kongo peoples in the 16th century is largely the story of how the Atlantic slave trade created powerful vested interests among provincial chiefs, in time greatly lessening the capacity of the kingdom to resist the encroachments of its neighbours. Thus, in the late 16th century, the kingdom had all but succumbed to the attacks of the Jaga, a group of warriors from the east. Two centuries later the Lunda and Luba peoples underwent a similar process of internal fragmentation followed by attacks from various interlopers, including Arabs and mestizos, eager to control the trade in slaves and ivory. On the eve of the European conquest their political institutions were both fractious and oppressive.

The radically different ecological conditions prevailing in the tropical rain forest raised formidable obstacles in the way of state-building. Small-scale segmentary societies, organized into village communities, were the rule. Corporate groups that combined social and economic functions among small numbers of related and unrelated people formed the dominant mode of organization. Among such corporate groups, exchange took place through trading activities and reciprocal gift-giving. Social interactions in time produced a measure of cultural homogeneity among otherwise distinctive communities, as among Bantu and Pygmy. Bantu communities absorbed and intermarried with their Pygmy clients, who brought their skills and crafts into the culture. The element of continuity discernible in the persistence of house and village organization stands in sharp contrast with the more centralized state structures characteristic of the savanna kingdoms. Nonetheless, on the eve of the Belgian conquest most Zairian societies had reached a degree of internal decomposition that greatly lessened their capacity to resist a full-scale invasion.

Resistance to outside forces in the savanna region was hampered by the devastating raids and civil wars that followed in the wake of the slave trade, by the improved capacity of Africans to destroy each other through the use of firearms, and ultimately by the all-too-familiar divisions between collaborators and resisters. The relative ease with which Zairian societies yielded to the European conquest bears testimony to the profound internal dislocations most of them had experienced in the course of previous centuries.

The Congo Free State. The catalyst for organizing the conquest of the huge domain that was to become his personal fief was King Leopold II of the Belgians. His thinly veiled colonial ambitions paved the way for the Berlin West Africa Conference (1884–85); thus armed with a mandate of international legitimacy, and under the cover of the African International Association, Leopold created one of the most coercive instruments of colonial hegemony. What became known as the Congo Free State (1885–1908) is most readily associated with the extraordinary hardships visited upon the Congolese masses in the name of the Leopoldian "civilizing mission." "Without the railroad," said Leopold's agent, the British explorer and journalist Henry Morton Stanley, "the Congo is not worth a penny." Without recourse to forced labour, however, the railroad could not be built, and the huge concessions made to private companies would not become profitable; nor could African resistance in the east be overcome without a massive recruitment of indigenous troops. The cruel logic of the revenue imperative left Leopold with no other option than to transform his nascent administrative system into an infernal machine designed to extract a maximum output of labour and natural resources from the land.

Necessity of the railroad

Not until 1908 did the Belgian Parliament vote in favour of annexation as the most sensible response to the flood of international criticism generated by the Leopoldian system. The impact of the Free State on the African populations outlived its relatively brief life span, however. The widespread social disruption resulting from the application of physical violence did more than complicate the establishment of a viable system of administration; it also left a legacy of anti-Western sentiment on which subsequent generations of nationalists were able to capitalize.

Belgian paternalism and the politics of decolonization. Belgian colonial rule bore traces of its Leopoldian pedigree: the irreducible tendency to treat Africans as childlike creatures and a firm commitment to political control and compulsion—on which Belgian paternalism was based—were both characteristic features of Leopoldian rule. The elimination of the more brutal aspects of the Congo Free State notwithstanding, Belgian rule remained conspicuously unreceptive to political reform. By placing the inculcation of Western moral principles above political education and welfare benefits above the apprenticeship of social responsibility, Belgian policies virtually ruled out all initiatives designed to foster political experience and responsibility.

Not until 1957, with the introduction of a major local government reform (the so-called *statut des villes*), were Africans given their first taste of democracy. By then the impact of social change had become apparent in the rise of a class of Westernized Africans (*évolués*) anxious to exercise their political rights beyond the urban arenas; the heavy demands made upon the rural masses during the years of the two world wars, coupled with the profound psychological impact of the postwar constitutional reforms introduced in neighbouring French-speaking territories, created a climate of social unrest suited for the development of nationalist sentiment and activity. The precipitating factor behind the political awakening of the Congolese masses was the publication in 1956 of a political manifesto calling for immediate independence. Penned by a group of Bakongo *évolués* affiliated to the Alliance des Bakongo (ABAKO), an association based in Léopoldville (now Kinshasa), the manifesto was the response of ABAKO to the ideas set forth by a young Belgian professor of colonial legislation, A.A.J. van Bilsen, in his "Thirty-Year Plan for the Political Emancipation of Belgian Africa." Far more impatient in tone, the ABAKO manifesto stated: "Rather than postponing emancipation for another thirty years, we should be granted self-government to-day."

The ABAKO manifesto

Under the leadership of Joseph Kasavubu, ABAKO transformed itself into a major vehicle of anticolonial protest; the ferment of nationalist sentiment quickly spread through the lower Congo region, and, in time, the nationalist contagion reached the rest of the colony. Scores of self-styled nationalist movements mushroomed almost overnight in each province. In the welter of political parties brought into existence by the *statut des villes,* the Congolese National Movement (Mouvement National Congolais; MNC) stood out as the most powerful vector of territorial nationalism. Although the MNC never disavowed its commitment to national unity (unlike ABAKO, whose appeal was limited to Bakongo elements), not until the arrival of Patrice Lumumba in Léopoldville, in 1958, did the party enter its militant phase.

The turning point in the process of decolonization came on Jan. 4, 1959, when anti-European rioting erupted in Léopoldville, resulting in the death of scores of Africans at the hands of the security forces. On January 13, the Belgian government formally recognized independence as the ultimate goal of its policies—a goal to be reached "without fatal procrastination, yet without fatal haste." By then, however, nationalist agitation had reached a threshold of intensity that made it virtually impossible for the Belgian administration to effectively control the course of events. To this growing turbulence the Belgian government responded by convening a Round Table Conference in Brussels, in January 1960, involving the participation of a broad spectrum of nationalist organizations. The aim was to work out the conditions of a viable transfer of power; the result, however, was an experiment in instant decolonization. Six months later, on June 30, the Congo formally acceded to independence, hurtling toward a self-induced apocalypse.

The Congo crisis. The triggering element behind the "Congo crisis" was the mutiny of the army (the so-called Force Publique) near Léopoldville on July 5, immediately followed by the intervention of Belgian paratroopers, ostensibly to protect the lives of Belgian citizens. Adding

Belgian intervention

to the confusion created by the collapse of the Force Publique, the constitutional impasse arising from the opposition between the president and the prime minister brought the machinery of government to a halt. President Kasavubu revoked Prime Minister Lumumba from his functions; Lumumba responded by dismissing Kasavubu. Meanwhile, on July 11, the country's richest province, Katanga, declared itself independent under the leadership of Moise Tshombe. The support given by Belgium to the Katanga secession gave a measure of credibility to Lumumba's claims that Brussels was trying to reimpose its authority on its former colony, and on July 12 he and Kasavubu appealed to UN Secretary-General Dag Hammarskjold for UN security assistance.

While intended to pave the way for the restoration of peace and order, the arrival of the UN peacekeeping force added yet another source of tension between President Kasavubu and Prime Minister Lumumba. The latter's insistence that the United Nations should use force if necessary to bring Katanga back into the fold of the central government met with categorical opposition from Kasavubu. Lumumba then turned to the Soviet Union for logistic assistance to send troops to the Katanga, at which point the Congo crisis became inextricably bound up with East-West issues.

As the process of fragmentation set in motion by the Katanga secession reached its peak, resulting in the breakup of the country into four separate fragments (Katanga, Kasai, Orientale Province, and Léopoldville), Chief of Staff Joseph Mobutu (later Mobutu Sese Seko) announced on Sept. 14, 1960, that the army would henceforth rule with the help of a caretaker government. The threat posed to the new regime by the Lumumbist forces was substantially lessened by the capture of Lumumba in December 1960, after his dramatic escape from Léopoldville, and his subsequent execution at the hands of the Tshombe government. Although Kasavubu's surrender of Lumumba to the Katanga secessionists was intended to pave the way for a reintegration of the province into the fold of the central government, not until January 1963, and only after a violent showdown between the European-trained Katanga gendarmerie and the UN forces, was the secession decisively crushed. It would take another year for the last bastion of secessionism, the pro-Lumumba Stanleyville government, to be brought to heel. Meanwhile, following the convening of parliament in Léopoldville, a new civilian government headed by Cyrille Adoula came to power on Aug. 2, 1961.

Even more than his inability to deal effectively with the Katanga secession, Adoula's decision to dissolve parliament in September 1963 brought his popularity to its lowest ebb. His move contributed directly to the outbreak of rural insurgencies, which, from January to August 1964, engulfed 5 provinces out of 21 and suddenly raised the ominous prospect of a total collapse of the central government. Because of its poor leadership and fragmented bases of support, the rebellion failed to translate its early military successes into an effective power apparatus; even more important in turning the tide against the insurgents was the decisive contribution made by European mercenaries in helping the central government regain control over rebel-held areas. For this, much of the credit goes to Moise Tshombe who, by July 10, had replaced Adoula as prime minister. Ironically, a year and a half after his defeat at the hands of the UN forces, the most vocal advocate of secessionism had suddenly emerged as the providential leader of a besieged central government.

1966 Katanga mutiny

Mobutu's regime. Mobutu's second coup, on Nov. 24, 1965, occurred in circumstances strikingly similar to those that led to the first—a struggle for power between the incumbent president, Joseph Kasavubu, and his prime minister, Moise Tshombe. Unlike Lumumba, however, Tshombe managed to leave the country unharmed—and determined to regain power. Rumours that the ousted prime minister was plotting a comeback from his Spanish retreat hardened into certainty when in July 1966 some 2,000 of Tshombe's former Katanga gendarmes, led by mercenaries, mutinied in Kisangani (formerly Stanleyville). Exactly a year after the crushing of the first mutiny another broke out, again in Kisangani, apparently triggered by the news that Tshombe's airplane had been hijacked over the Mediterranean and forced to land in Algiers, where he was held prisoner. Led by a Belgian settler named Jean Schramme, and involving approximately 100 former Katanga gendarmes and about 1,000 Katangese, the mutineers held their ground against the 32,000-man Congolese National Army (Armee Nationale Congolaise; ANC) until November 1967, when Schramme and his mercenaries crossed the border into Rwanda and surrendered to the local authorities.

The fragility of Mobutu's power base was again demonstrated in 1977 and 1978, when the country's main opposition movement, the Congolese National Liberation Front (Front de la Libération Nationale Congolaise; FLNC), operating from Angola, instigated two major invasions into Shaba (formerly Katanga). On both occasions external intervention from friendly governments—mostly from Morocco in 1977 and from France in 1978—saved the day, but at the price of untold casualties among Africans and Europeans. After the capture of Kolwezi in May 1978 an estimated 100 Europeans lost their lives, partly at the hands of the rebels and partly at the hands of the ANC. At any rate, and quite aside from the part played by the FLNC in spearheading the invasions, the sharp deterioration of the Zairian economy after 1975, coupled with the rapid growth of anti-Mobutu sentiment among the poor and the unemployed, were crucial elements in the background of the Shaba invasions.

The timing of the first Shaba invasion, 11 years after the creation of the Popular Movement of the Revolution (Mouvement Populaire de la Révolution; MPR), made plain the shortcomings of the single-party state as an agent of national integration and of Mobutism as a legitimizing formula. Officially described as "the nation politically organized," the MPR may be better seen as a weakly articulated patronage system. Mobutu's effort to extol the virtues of Zairian "authenticity" did little to lend respectability either to the concept or to the brand of leadership for which it stood. As befit his chiefly image, Mobutu's rule was based on bonds of personal loyalty between himself and his entourage. His hegemony was absolute, however, and extended to every level of the government. Whether Mobutu's decision, in April 1990, to lift the ban on opposition parties will decisively alter Zairian politics remains an open question. Although provision has been made for the introduction of a three-party system to replace the single-party rule of the MPR, the sheer brutality of the repression that followed in the wake of student protests at the University of Lubumbashi—resulting in the deaths of anywhere from 50 to 150 students, according to Amnesty International—leaves one to wonder whether Mobutu's professed commitment to democracy can be taken seriously. Thirty years after Zaire's independence and 82 years after the demise of the Congo Free State, the Leopoldian quality of the Mobutist state remained evident in its thoroughly centralized power apparatus, highly personalized style of governance, and readiness to use force whenever circumstances required. To the extent that history repeats itself, nowhere has it been more tragically repetitive than in the complex encounter of Zairian societies with the forces of modernity. (Re.L.)

For later developments in the history of Zaire, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

BIBLIOGRAPHY

Physical and human geography. *Africa South of the Sahara* (annual); and *Africa Contemporary Record* (annual), contain updated essays on all aspects of the central African countries. Further information can be found in the relevant sections of PIERRE GOUROU, *L'Afrique* (1970); JACQUES DENIS, PIERRE VENNETIER, and JULES WILMET, *L'Afrique centrale et orientale* (1971); PIERRE VENNETIER, *L'Afrique équatoriale* (1972); WILLIAM A. HANCE, *The Geography of Modern Africa*, 2nd ed. (1975); C. GREGORY KNIGHT and JAMES L. NEWMAN (eds.), *Contemporary Africa: Geography and Change* (1976); R.J. HARRISON CHURCH, *Africa and the Islands*, 4th ed. (1977); A.T. GROVE, *The Changing Geography of Africa* (1989); and ALAN B. MOUNTJOY and DAVID HILLING, *Africa: Geography and Development* (1988). The geology of the area is covered by LUCIEN CAHEN

and N.J. Snelling, *The Geochronology of Equatorial Africa* (1966); and Michael F. Thomas, *Tropical Geomorphology: A Study of Weathering and Landform Development in Warm Climates* (1974).

Geographic studies of particular countries or features include Gilles Sautter, *De l'Atlantique au fleuve Congo: une géographie du sous-peuplement,* 2 vol. (1966), covering both the Congo basin generally and aspects of the river itself; and Peter Forbath, *The River Congo: The Discovery, Exploration, and Exploitation of the World's Most Dramatic River* (1977). An annotated review of literature on the region may be found in the periodic essays by Henri Nicolai, "Progrès de la connaissance géographique au Congo, au Rwanda, et au Burundi," *Bulletin de la Société Belge d'Études Géographiques,* 36:273–315 (1967), 40:263–317 (1971), 45:135–186 (1976), 50:63–96 (1981), 55:175–223 (1986), and 58:159–207 (1989); the name Zaire instead of Congo is used in the title after 1976.

Discussions of the climate of the region may be found in B.W. Thompson, *The Climate of Africa* (1965), and *Africa: The Climatic Background* (1975); and in Marcel Leroux, *The Climate of Tropical Africa,* 2 vol. (1983). Plant and animal life is described by P.W. Richards, *The Tropical Rain Forest: An Ecological Study* (1952, reissued 1979); D.F. Owen, *Animal Ecology in Tropical Africa,* 2nd ed. (1976); and J.L. Cloudsley-Thompson, *The Zoology of Tropical Africa* (1969).

Studies of central African peoples are contained in George Murdock, *Africa: Its Peoples and Their Culture History* (1959); Jocelyn Murray (ed.), *Cultural Atlas of Africa* (1981); Colin M. Turnbull, *The Forest People* (1961, reissued 1976), on the Pygmy peoples; Reuben K. Udo, *The Human Geography of Tropical Africa* (1982); Georges Balandier, *Sociologie actuelle de l'Afrique noire: dynamique sociale en Afrique centrale,* 4th ed. (1982); Pierre Sirven, *La Sous-Urbanisation et la villes du Rwanda et du Burundi* (1984); and three essays in David Birmingham and Phyllis M. Martin (eds.), *History of Central Africa,* vol. 1 (1983): Dennis D. Cordell, "The Savanna Belt of North-Central Africa," ch. 2, pp. 30–74; Jan Vansina, "The Peoples of the Forest," ch. 3, pp. 75–117; and Thomas Q. Reefe, "The Societies of the Eastern Savanna," ch. 5, pp. 160–204.

Central African agriculture, policies, and development are analyzed in Marvin P. Miracle, *Agriculture in the Congo Basin: Tradition and Change in African Rural Economies* (1967); D.F. Owen, *Man in Tropical Africa: The Environmental Predicament* (1973); Robin Palmer and Neil Parsons (eds.), *The Roots of Rural Poverty in Central and Southern Africa* (1977); B.W. Hodder, *Africa Today: A Short Introduction to African Affairs* (1978); Robert H. Bates, *Markets and States in Tropical Africa: The Political Basis of Agricultural Policies* (1981); Jonathan Barker (ed.), *The Politics of Agriculture in Tropical Africa* (1984); O. Aboyade, *Issues in the Development of Tropical Africa* (1976); and David Siddel and Kenneth Swindell, *Rural Change in Tropical Africa: From Colonies to Nation-States* (1990). (He.Ni.)

History. *General:* Overviews can be found in J.D. Fage and Roland Oliver, *The Cambridge History of Africa,* 8 vol. (1975–86); Unesco International Scientific Committee for the Drafting of a General History of Africa, *General History of Africa* (1981–); and Roland Oliver and J.D. Fage, *A Short History of Africa,* 6th ed. (1988). David Birmingham and Phyllis M. Martin (eds.), *History of Central Africa,* 2 vol. (1983), is a comprehensive survey of both northern and southern central Africa; each chapter has a bibliographic essay.

Developments to the 19th century: J. Desmond Clark, *The Prehistory of Africa* (1970, reprinted 1984), by the pioneer prehistorian of central Africa, surveys the Stone Age. David W. Phillipson, *African Archaeology* (1985), is a more recent overview by a specialist on the later prehistoric period. Phyllis M. Martin, *The External Trade of the Loango Coast, 1576–1870* (1972), is a path-breaking study of international relations on the Congo coast. David Birmingham, *Central Africa to 1870: Zambezi, Zaïre, and the South Atlantic* (1981), contains chapters from *The Cambridge History of Africa.* Richard Gray and David Birmingham (eds.), *Pre-colonial African Trade* (1970), contains several essays on the economic history of central Africa before 1900. Joseph C. Miller, *Kings and Kinsmen* (1976), is an innovative study of the use of oral evidence for the construction of central African history; his *Way of Death: Merchant Capitalism and the Angolan Slave Trade, 1730–1830* (1988) is mainly concerned with south-central Africa but illustrates the history of the slave trade in ways not hitherto attempted. Jan Vansina, *Kingdoms of the Savanna* (1966), was the pioneering survey of state formation in precolonial central Africa; his *Paths in the Rainforest: Toward a History of Political Tradition in Equatorial Africa* (1990) is a companion volume on the forest peoples and their forms of social organization. Vansina's *The Children of Woot: A History of the Kuba Peoples* (1978), radically reinterprets Kuba history as first understood by scholars of the 1950s. Anne Hilton, *The Kingdom of Kongo* (1985), is a sophisticated analysis of the state, utilizing the extensive surviving early Italian, Dutch, and Portuguese records. John K. Thornton, *The Kingdom of Kongo: Civil War and Transition, 1641–1718* (1983), carries the history of the kingdom through a phase of disintegration. Dennis D. Cordell, *Dar al-Kuti and the Last Years of the Trans-Saharan Slave Trade* (1985), looks at state formation on the Muslim fringe of north-central Africa. Robert W. Harms, *River of Wealth, River of Sorrow: The Central Zaire Basin in the Era of the Slave and Ivory Trade, 1500–1891* (1981), is one of the great classics of central African history. Thomas Q. Reefe, *The Rainbow and the Kings: A History of the Luba Empire to 1891* (1981), significantly revises previous interpretations of the leading inland empire of central Africa.

Charles Perrings, *Black Mineworkers in Central Africa* (1979), offers a radical history of the Katanga copper mines. Françoise Latour da Veiga-Pinto, *Le Portugal et le Congo au XIXe siècle* (1972), is an important case study of the diplomacy of the scramble for central Africa. Eric de Dampierre, *Un Ancien Royaume bandia du Haut-Oubangui* (1967), discusses state-building and society in the northern savanna. L.H. Gann and Peter Duignan, *The Rulers of Belgian Africa: 1884–1914* (1979), is scholarship of the dispassionate school. Eugenia W. Herbert, *Red Gold of Africa: Copper in Precolonial History and Culture* (1984), is a brilliantly innovative and deeply researched cultural history. Sidney Langford Hinde, *The Fall of the Congo Arabs* (1897, reprinted 1969), offers an eyewitness account of the colonial conquest of eastern Zaire in the 1890s. Wm. Roger Louis, *Ruanda-Urundi, 1884–1919* (1963, reprinted 1979), provides a diplomatic history of the German enclave in central Africa.

From the 19th century to the present: Surveys include Patrick Manning, *Francophone Sub-Saharan Africa, 1880–1985* (1988); Virginia Thompson and Richard Adloff, *The Emerging States of French Equatorial Africa* (1960), an encyclopaedic survey of terminal colonialism; and Jean Suret-Canale, *French Colonialism in Tropical Africa: 1900–1945* (1971; originally published in French, 1964). Catherine Coquery-Vidrovitch, *Le Congo au temps des grandes compagnies concessionnaires, 1898–1930* (1972), recounts the private enterprise dimension of colonialism. Marie-Louise Martin, *Kimbangu: An African Prophet and His Church* (1975; originally published in German, 1971), studies the independent church of Zaire. Further studies of the central African countries under colonial rule and after independence may be found in the bibliographies of the individual countries below. (D.Bi.)

Burundi: An introduction to the country's geography can be found in Françoise Cazenave-Piarrot, Alain Cazenave-Piarrot, and Albert Lopez, *Géographie du Burundi: le pays et les hommes* (1979); and *Atlas du Burundi* (1979). The classic source for precolonial ethnography and history is Hans Mayer, *Die Barundi* (1916), also available in a French edition excellently annotated by Jean-Pierre Chrétien, *Les Barundi* (1984). Emile Mworoha (ed.), *Histoire du Burundi: des origines à la fin du XIXe siècle* (1987), is also useful. The significance of oral traditions for an understanding of past and present history is well brought out in L. Ndoricimpa and Cl. Guillet (eds.), *L'Arbre-mémoire* (1984). The colonial period is ably analyzed in Joseph Gahama, *Le Burundi sous administration Belge* (1983), which includes an English-language summary. Postindependence developments are dealt with at some length, up to 1970, in René Lemarchand, *Rwanda and Burundi* (1970). For more recent developments, see René Lemarchand and David Martin, *Selective Genocide in Burundi* (1974), which is supplemented by Reginald Kay, *Burundi Since the Genocide* (1985), both short reports from the Minority Rights Group. The 1988 crisis is systematically, but not always objectively, analyzed in Jean-Pierre Chrétien, A. Guichaoua, and G. Le Jeune, *La Crise d'août 1988 au Burundi* (1989). Warren Weinstein, *Historical Dictionary of Burundi* (1976), includes a chronology and bibliography. (Re.L.)

Central African Republic: Thomas O'Toole, *The Central African Republic: The Continent's Hidden Heart* (1986), is the best single source on all aspects of the country. Gérard Grellet, Monique Mainguet, and Pierre Soumille, *La République Centrafricaine* (1982), is the best single source on the geography of the Central African Republic. Pierre Vennetier and Yves Boulvert (eds.), *Atlas de la République Centrafricaine* (1984), is also useful. Three other standard references are by Pierre Kalck, *Central African Republic: A Failure in Decolonisation,* trans. from French (1971), now somewhat dated, *Historical Dictionary of the Central African Republic,* trans. from French (1980), and the extremely sound *Histoire de la République Centrafricaine: des origines préhistoriques à nos jours* (1974). Of some interest to the specialist is the uneven and ideologically slanted work of Yarisse Zoctizoum, *Histoire de la Centrafrique: violence du développement, domination, et inégalités,* 2 vol. (1983–84), covering the period 1879–1979.

For those interested in the earliest centralized polities in the area, PIERRE VIDAL, *La Civilisation mégalithique de Bouar: prospection et fouilles, 1962–1966* (1969), is of critical importance. MARC MICHEL, *La Mission Marchand, 1895–1899* (1972), is a sound work on early colonial intrusions. RAPHAËL NZABAKOMADA-YAKOMA, *L'Afrique centrale insurgée: la guerre du Kongo-Wara (1928–1931)* (1986), should be read in conjunction with THOMAS O'TOOLE, "The 1928–1931 Gbaya Insurrection in Ubangui-Shari: Messianic Movement or Village Self-Defense?" *Canadian Journal of African Studies,* 18(2):329–344 (1984). (T.E.O'T.)

Congo: PIERRE VENNETIER (ed.), *Atlas de la République Populaire du Congo* (1977), graphically presents many aspects of the country. PIERRE VENNETIER, *Les Hommes et leurs activités dans le nord du Congo-Brazzaville* (1965), is an ethnographic study. RENÉ GAUZE, *The Politics of Congo-Brazzaville* (1973), examines politics and government. MARCEL SORET, *Histoire du Congo: capitale Brazzaville* (1978), although a bit dated, remains the only book-length history of the Congo. GEORGES DUPRÉ, *Un Ordre et sa destruction* (1982), is an encyclopaedic effort to show the effect of colonialism and capitalist penetration on a Congolese society, the Nzabi. JAN VANSINA, *The Tio Kingdom of the Middle Congo, 1880–1892* (1973), provides a micro-level study of Tio villages and traditions paired with a macro-level analysis of the place of the Tio kingdom in the early years of colonial conquest and administration. WILLIAM J. SAMARIN, *The Black Man's Burden* (1989), discusses colonial labour on the Congo and Ubangi rivers during 1880–1900. DENNIS D. CORDELL, "Extracting People from Precapitalist Production: French Equatorial Africa from the 1890s to the 1930s," in DENNIS D. CORDELL and JOEL W. GREGORY (eds.), *African Population and Capitalism: Historical Perspectives* (1987), pp. 137–152, includes a separate section on the demographic impact of the Congo-Ocean Railway. (D.D.C.)

Gabon: ROLAND POURTIER, *Le Gabon,* 2 vol. (1989), provides an introduction. INSTITUT PÉDAGOGIQUE NATIONAL (GABON), *Géographie et cartographie du Gabon* (1983), is an illustrated atlas. Two studies of the Mpongwe are HENRY BUCHER, "The Atlantic Slave Trade and the Gabon Estuary: The Mpongwe to 1860," in PAUL E. LOVEJOY (ed.), *Africans in Bondage* (1986), pp. 137–154, and "The Village of Glass and Western Intrusion: An Mpongwe Response to the American and French Presence in the Gabon Estuary: 1842–1845," *The International Journal of African Historical Studies,* 6(3):363–400 (1973). JAMES W. FERNANDEZ, *Bwiti: An Ethnography of the Religious Imagination in Africa* (1982), examines the most important syncretic cult. PIERRE-CLAVER MAGANGA-MOUSSAVOU, *Economic Development—Does Aid Help?* (1983; originally published in French, 1982), critiques French economic involvement in independent Gabon. MARC AICARDI DE SAINT-PAUL, *Gabon: The Development of a Nation* (1989; originally published in French, 1987), discusses economic policies and conditions. Early history is presented in DAVID E. GARDINIER, "The Beginnings of French Catholic Evangelization in Gabon and African Responses, 1844–1883," *French Colonial Studies,* no. 2 (1978), pp. 49–74, on the planting of Catholicism in Gabon, and "Les Frères de Saint-Gabriel au Gabon, 1900–1918, et la naissance d'une nouvelle élite africaine," *Mondes et Cultures,* 46(3):593–606 (1986), on the education of the anticolonialist elite prominent in Gabon's political life since 1944. K. DAVID PATTERSON, *The Northern Gabon Coast to 1875* (1975), examines the economic and political evolution of northern Gabon. BRIAN WEINSTEIN, *Gabon: Nation-building on the Ogooue* (1966), describes political development, especially from the 1940s to the early '60s. CHARLES F. DARLINGTON and ALICE B. DARLINGTON, *African Betrayal* (1968), is an account by the American ambassador to Libreville who witnessed the coup of 1964 and the French intervention. FRANÇOIS GAULME, *Le Gabon et son ombre* (1988), traces the political, economic, and social evolution since 1960. MICHAEL C. REED, "Gabon: A Neo-Classical Enclave of Enduring French Interest," *The Journal of Modern African Studies,* 25(2):283–320 (June 1987), focuses on the recent modern period. DAVID E. GARDINIER, *Historical Dictionary of Gabon* (1981), concentrates on the political evolution in the 20th century, with a large bibliography. (D.E.G.)

Rwanda: J.F. GOTANEGRE, CHRISTIAN PRIOUL, and PIERRE SIRVEN, *Géographie du Rwanda* (1974); and CHRISTIAN PRIOUL and PIERRE SIRVEN (eds.), *Atlas du Rwanda* (1981), provide introductions to the country. The standard work on the history of Rwanda is JAN VANSINA, *L'Évolution du royaume du Rwanda des origines à 1900* (1962). For valuable insights into the rituals and traditions of the monarchy, see MARCEL D'HERTEFELT and ANDRÉ COUPEZ (eds.), *La Royauté sacrée de l'ancien Rwanda* (1964). For a detailed analysis of the dynamics of ethnicity in prerevolutionary Rwanda, CATHARINE NEWBURY, *The Cohesion of Oppression* (1988), remains unsurpassed. The role of the church prior to and during the revolution is ably analyzed in IAN LINDEN and JANE LINDEN, *Church and Revolution in Rwanda* (1977). JEAN-PAUL HARROY, *Rwanda* (1984), is a general survey of the transition to independence, by a former high-ranking colonial civil servant. The country's recent political history is discussed at length in RENÉ LEMARCHAND, *Rwanda and Burundi* (1970); and FILIP REYNTJENS, *Pouvoir et droit au Rwanda* (1985). (Re.L.)

São Tomé and Príncipe: TONY HODGES and MALYN NEWITT, *São Tomé and Príncipe: From Plantation Colony to Microstate* (1988), is the only general study of the country and is the basic book for practically all topics. FRANCISCO TENREIRO, *A Ilha de São Tomé* (1961), is the standard geographic text. ARTHUR WALLIS EXELL, *Catalogue of the Vascular Plants of S. Tomé (with Príncipe and Annobon)* (1944), is useful for the flora. LUIZ IVENS FERRAZ, *The Creole of São Tomé* (1979), analyzes the local language. HELDER LAINS E SILVA, *São Tomé e Príncipe e a cultura do café* (1958); and PABLO B. EYZAGUIRRE, "The Ecology of Swidden Agriculture and Agrarian History in São Tomé," *Cahiers d'Études Africaines,* 26(1–2):113–129 (1986), discuss agricultural matters. TONY HODGES, "São Tomé and Príncipe: Combating Cocoa Colonialism," *Africa Report,* 13:61–66 (1986), is a brief overview. MARTIN SCHÜMER, *São Tomé und Príncipe: Ausbruch aus der Isolation* (1987), provides a short general survey of foreign relations and economic policy since independence. GERVASE CLARENCE-SMITH, *The Third Portuguese Empire, 1825–1975: A Study in Economic Imperialism* (1985), provides the Portuguese colonial context for the 19th and 20th centuries. JAMES DUFFY, *A Question of Slavery* (1967), includes a detailed study of the labour system in the late 19th and early 20th centuries. CARLOS ESPÍRITO SANTO, *Contribuição para a história de S. Tomé e Príncipe* (1979), is a short work by a local historian. (W.G.C.-S.)

Zaire: IRVING KAPLAN (ed.), *Zaïre: A Country Study,* 3rd ed. (1979); GEORGES LACLAVÈRE (ed.), *Atlas de la République du Zaïre* (1978); and BERND WIESE, *Zaire: Landesnatur, Bevölkerung, Wirtschaft* (1980), are useful introductions. J. VANDERLINDEN (ed.), *Du Congo au Zaïre, 1960–1980: essai de bilan* (1980), reports on all aspects of Zaire. LUCIEN CAHEN, *Géologie du Congo Belge* (1954), is a thorough study of geology, rock formation, and mineralogy in what is now Zaire. FRANZ BULTOT, *Atlas climatique du bassin Congolais,* 4 vol. (1971–77), offers a detailed study of meteorologic conditions in Zaire. Ethnographic and sociological studies include JAN VANSINA, *Introduction à l'ethnographie du Congo* (1966); JEAN-LUC VELLUT, *Femmes coloniales au Congo Belge* (1987); and VALDO PONS, *Stanleyville: An African Urban Community Under Belgian Administration* (1969), a minor classic of social anthropology. MICHAEL G. SCHATZBERG, *Politics and Class in Zaire* (1980), analyzes the linkages between class formation and development. Studies of Zairian politics include DANIEL BIEBUYCK and MARY DOUGLAS, *Congo: Tribes and Parties* (1961); and HERBERT F. WEISS, *Political Protest in the Congo* (1967). JOSEPH CORNET, *Art of Africa: Treasures from the Congo,* trans. from French (1971), is a remarkable attempt to uncover the cultural explanation and meaning of Zairian art. MICHEL LONOH (LONOH MALANGI BOKOLENGE), *Essai de commentaire de la musique congolaise moderne* (1969), provides a comprehensive essay on the development of Zairian popular music. (B.M.W.)

RUTH SLADE, *English-speaking Missions in the Congo Independent State (1878–1908)* (1959), analyses Baptist missionary activity in the lower Congo. Slade's book *King Leopold's Congo* (1962, reprinted 1974); ROGER ANSTEY, *King Leopold's Legacy: The Congo Under Belgian Rule, 1908–1960* (1966); and NEAL ASCHERSON, *The King Incorporated* (1963), provide excellent coverage of the Congo Free State. WM. ROGER LOUIS and JEAN STENGERS (eds.), *E.D. Morel's History of the Congo Reform Movement* (1968), is an important study of the merchant criticism of Leopold's Congo and the role of Robert Casement. The most useful account of colonial rule is the classic by CRAWFORD YOUNG, *Politics in the Congo* (1965), to which must be added RENÉ LEMARCHAND, *Political Awakening in the Belgian Congo* (1964, reprinted 1982). Selected aspects of the Congo crisis are discussed in ALAN P. MERRIAM, *Congo: Background of Conflict* (1961); ERNEST W. LEFEVER, *Crisis in the Congo* (1965); JULES GÉRARD-LIBOIS, *Katanga Secession,* trans. from French (1966); RAJESHWAR DAYAL, *Mission for Hammarskjöld* (1976); and MADELEINE KALB, *The Congo Cables* (1982). BENOÎT VERHAEGEN, *Rébellions au Congo,* 2 vol. (1966–69), is a documentary study of the postindependence rebellions. THOMAS KANZA, *The Rise and Fall of Patrice Lumumba: Conflict in the Congo,* expanded ed. (1977), is a personal account by a participant driven to exile. Postindependence politics in Zaire are meticulously dissected by MICHAEL G. SCHATZBERG, *The Dialectics of Oppression in Zaire* (1988); JEAN-CLAUDE WILLAME, *Patrimonialism and Political Change in the Congo* (1972); and CRAWFORD YOUNG and THOMAS TURNER, *The Rise and Decline of the Zairian State* (1985). NZONGOLA-NTALAJA (ed.), *The Crisis in Zaire: Myths and Realities* (1986), collects essays by international experts on postcolonial Zaire. (Re.L.)

Central America

Central America, in the strictest sense, is a region of North America that lies between Mexico and Panama, the latter a part of Colombia until 1903 and thus sometimes technically still included in South America. (Geologists and physical geographers often extend the boundary of Central America as far north as the Isthmus of Tehuantepec in Mexico.) Within the region are the countries of Guatemala, Belize (until 1973 British Honduras), Honduras, El Salvador, Nicaragua, and Costa Rica. Through custom Panama has come to be included as a part of Central America, however, and that convention is followed in this treatment.

Central America makes up most of the tapering isthmus that separates the Pacific Ocean from the Caribbean Sea. At its narrowest point, in Darién (Panama), the isthmus is only about 30 miles (50 kilometres) wide, and there is no location in Central America that is more distant than 125 miles (200 kilometres) from the sea. An arc joining Central America's most distant points would be about 1,140 miles long. The seven countries of the region have a land area of 202,265 square miles (523,865 square kilometres), and together they are only about half the size of neighbouring Colombia and about one-fourth that of adjoining Mexico.

Anthropologists often use the word Mesoamerica to define those areas that were the seats of high civilizations in pre-Columbian time; a line drawn from the Gulf of Honduras in the Caribbean Sea south to the Gulf of Fonseca in the Pacific Ocean and as far as the Gulf of Nicoya (Costa Rica) would separate Mesoamerica to the north and west from the rest of Central America. Cultural geographers include Central America as part of a larger region, Middle America, which includes Mexico and the Caribbean islands. Middle America is commonly divided into the Mainland, which accommodates most of Central America, and a circum-Caribbean region, called the Rimland, which includes the coastal lowlands of eastern Central America. In the Rimland the indigenous peoples have been largely swamped by immigrant populations, notably from northwestern Europe, Africa, and more recently the United States. Mainland Central America, on the other hand, has a stronger American Indian and part American Indian presence, as well as ways of life that still owe much to pre-Columbian and Spanish colonial times.

Major physical divisions

Central America is a fragmented region, a fine-grained mosaic of different landscapes; many parts are still physically isolated from each other. Highlands predominate over lowlands, steep slopes over flatlands. Altitude mitigates the climatic effects of a tropical latitude. Although the sea is close, few have chosen to live by it; the bulk of the population lives between the 3,000-foot (900-metre) and 8,000-foot (2,400 metre) lines of altitude and enjoys the lower temperatures and the freedom this provides from the diseases of the coastal lowlands. History and geography have dictated that most Central Americans occupy the highlands close to the Pacific and have eschewed the Caribbean lowlands. The majority of the eastern half of the isthmus remains under forest and empty of people. In contrast, in western Central America there are areas of intense population pressure on the land, and little of the natural vegetation has survived.

The brief political unity of Central America after independence from Spain lasted no longer than two decades before the provincialism of today's states asserted itself. Subsequently, the countries of Central America developed stronger links with the foreign nations providing markets for their export commodities, particularly the United States, than with their neighbours. Attempts to build a new political and economic community in the 1960s and '70s stalled in the financial crisis that followed. The aftermath of the crisis, the widespread civil unrest, and the political divisions of the 1980s increased the disunity and the internal contrasts within the isthmus. Central America remains a region of dichotomies, but perhaps the most glaring is the disparity between the poverty of the many and the wealth of a few.

This article is divided into the following sections:

THE REGION

Physical and human geography

THE LAND

Regional tectonics

Relief, drainage, and soils. Widespread volcanic activity and the frequency of severe earthquakes testify to the tectonic instability of many parts of Central America. This instability is produced by the interactions between the four relatively small crustal plates that provide the tectonic setting of the region. The northeastern edge of the Cocos Plate runs parallel to the Pacific coast some 60 to 125 miles offshore. It abuts on the southwestern edge of the Caribbean Plate, whose northern edge is marked by three fault zones that extend across southern Guatemala to include the active Cayman trough in the Caribbean Sea. North of the Cocos Plate to the west and north of the Caribbean Plate to the east is the North American

Plate, which is relatively stable and has allowed the steady accumulation of the limestones of the Yucatán Peninsula. The eastern edge of the Cocos Plate is in contact with the Panama block of the larger Nazca Plate.

It is the interaction between the Caribbean and the Cocos plates that is the most important, since the Cocos Plate is moving northeastward relative to the Caribbean Plate at, by geologic standards, the lightning speed of 33 feet per century. The movement is accommodated by subduction of the Cocos Plate where it meets the Caribbean Plate along the line of the submarine Middle America Trench and by the breaking up of the Caribbean Plate into blocks ahead of the trench. Subduction of the Cocos Plate brings with it uplift of land beyond the front; more dramatically, this results in subterranean pressure being released, which reverberates as earthquakes and volcanic eruptions at the surface. Earthquakes in Central America have proved much more destructive of life and property than have volcanic outbursts, although the region is notorious in both respects.

© D. Donne Bryant—D. Donne Bryant Stock

A small farm nestled in the rugged highlands of central Honduras.

Four-fifths of Central America is hilly or mountainous, and areas of flatland away from the coasts are restricted. One familiar image of Central America is provided by the line of more than 40 volcanoes that tower above the Pacific coast for 900 miles from Tacaná (13,428 feet) on the Guatemalan-Mexican border to Turrialba (10,955 feet) in Costa Rica. The summit of Tacaná's neighbour Tajumulco (13,845 feet) is the highest point in Central America. In general the volcanic chain forms the watershed between the Caribbean and the Pacific. Those rivers draining eastward are longer than the westward-flowing streams and are well served with rainwater, but few are navigable far upstream. Although a quarter of the volcanoes are extinct and half are dormant, the remainder together provide the most active volcanic belt in the Americas. Fuego (12,346 feet), some 20 miles from Guatemala City, is one of the largest and has erupted four times since 1880. Other active volcanoes include Santa María in Guatemala, Izalco in El Salvador, Las Pilas-Cerro Negro and Concepción in Nicaragua, and Poás and Irazú in Costa Rica. Lava flows have caused great damage by impounding rivers until they burst their banks, but volcanic dust has rejuvenated local soils downwind. As spectacular as the great cones are the cliff-rimmed lakes or calderas—such as Lake Atitlán in Guatemala and Lake Ilopango in El Salvador—formed by volcanic collapse.

The calderas

The narrow Pacific plain (some 30 miles wide) southwest of the volcanoes is made of overlapping fans of river alluvium interspersed in El Salvador and Nicaragua by volcanic hills; the coastal sandbars and lagoons are broken only by the downfaulted Gulf of Fonseca. To the northeast of the volcanic axis at the point where Honduras, El Salvador, and Guatemala meet is the geologic heartland of Central America, the Chortis block, an area of Paleozoic metamorphic and igneous rocks overlain by moderately deformed Mesozoic and Cenozoic marine and continental sediments and by volcanic rocks.

In the far north at the foot of the Yucatán Peninsula is the low, rolling karstic country of the Petén, broken by lake- and swamp-filled depressions (*bajos*) such as Lake Petén Itzá in Guatemala. South of the Petén the landscape has been fashioned into a series of parallel, arcuate ranges and depressions trending east-west in western Guatemala and northeast-southwest in southern Belize, eastern Honduras, and Nicaragua, mirroring geologic structures of Cretaceous origin. The Cockscomb Range (3,675 feet high) of the Maya Mountains in Belize and the hills of the southern Petén are minor northern outposts of these ranges.

There are three major mountain ranges in Guatemala: the high, flat plateau (llanos) of the Sierra los Cuchumatanes (9,800 feet) in the northwestern part of the country and in the east the broken lower Sierra de las Minas (10,200 feet) of Verapaz and the knife-edge ridges of the lower Sierra de Merendón. Guatemala's major river, the Motagua, occupies a structural depression between the last two ranges. Steep-sided river valleys and deep canyons make overland access difficult.

The parallel ranges of Honduras and northern Nicaragua are broken by a number of small, alluvium-filled, fault-guided basins that run obliquely to the Caribbean coast, as do the rivers. In northern Honduras the crystalline bedrock impregnated with mineralized veins has weathered, producing a rugged landscape (with pockets of alluvial gold). In northeastern Honduras and Nicaragua east of Lakes Managua and Nicaragua the older rocks are buried under a thick covering of Tertiary volcanic material cut into by the numerous rivers that flow eastward across almost the full width of the isthmus. They have created a series of hilly basins separated by high ridges (3,300 to 6,600 feet) whose amplitude of relief declines eastward toward the Mosquito coastal plain. Here the rivers flow in shallow trenches, and their basins include a series of modest escarpments. This section of the Caribbean Plain is the most extensive of Central America's lowlands and is underlain by Pliocene marine gravels and sandy clays that unfortunately produce infertile lateritic soils. The Mosquito Coast is one of deltas, sandbars, and lagoons.

The Mosquito Coast

Southward the highlands end abruptly where a major rift valley in Nicaragua separates them from the volcanoes farther to the southwest. This rift valley runs diagonally across the Central American isthmus from its submarine expression as the Gulf of Fonseca, widening inland, where it is partly flooded by the fresh water of Lakes Managua and Nicaragua, before continuing as the valley of the San Juan River.

The San Juan is an exceptional river for Central America, having proved itself useful as a navigable routeway. It is about 125 miles from the point where the river drains Lake Nicaragua to the Caribbean Sea. The continental divide to the west of the lake is only 165 feet above the Pacific and only about 15 miles from the shore. These short distances and the low divide make the river-lake link an attractive route between the two oceans, and it was much used in the 19th century. It was indeed the route favoured by the first (1876) of the U.S. commissions investigating alternative transisthmian canal sites, a choice that ultimately fell to Panama.

South of the rift, in Costa Rica, is a portion of Cretaceous oceanic crust overlain by later marine and volcanic rocks that suffered severe deformation during late Tertiary and early Quaternary times and subsequent volcanic activity. Overlooking the rift are the high, volcanic Cordillera Central and northern Cordillera de Talamanca, intercalated by highland basins. The major part of the Cordillera de Talamanca is a granitic intrusion that blocks off the southern end of the volcanic axis. This is the most massive of the Central American mountain ranges, with 10 peaks rising above 9,800 feet, which were sculpted by glaciers in Pleistocene times. Slopes are steep, road building expensive, and landslides easily provoked; it is a refuge for small Indian groups even to this day. The Pacific face of the

Cordillera de Talamanca is a fault scarp that overlooks the structural basin of the General River and the low coast ranges beyond.

Volcanism resumes in western Panama, where Barú (Chiriquí) Volcano (now inactive) reaches 11,401 feet, and highly dissected volcanic ranges declining in height form the spine of the country to beyond the Panama Canal. The mountainous Azuero Peninsula extends southward into the Pacific and separates the Gulf of Panama from that of Urabá; rolling lowlands made fertile by ejecta from the nearby volcanoes lie between the Azuero Peninsula and the central cordillera of Panama to the north.

Climate. The climates of Central America are essentially tropical, tempered by proximity to the sea, by altitude, by latitude, and by local topography; in consequence, they may vary substantially over short distances. There is a net east-to-west flow of air across Central America, with pressure higher on the Caribbean side and lower on the Pacific side. The adjoining sea surfaces are warm, averaging about 81° F (27° C) throughout the year, and the Caribbean current in the east and the equatorial countercurrent in the Pacific carry their warmth northward beyond the isthmus. The atmosphere tends to be moisture-laden, but there is more rainfall to the south and the Caribbean side of the isthmus is wetter than the Pacific side.

Altitudinal climatic regions

The effect of altitude on temperature has long been popularly recognized in Central America. The *tierra caliente* ("hot land") is commonly defined as land below 3,300 feet in altitude, with mean annual temperatures exceeding 72° F (22° C); the *tierra templada* ("temperate land") between 3,300 and 6,500 feet, with mean annual temperatures ranging between 60° and 72° F (16° and 22° C); the *tierra fría* ("cold land") between 6,500 and 9,800 feet, with mean annual temperatures below 46° F (8° C); and the *tierra helada* ("frozen land") above that. The relationship between altitude and temperature is not a linear one: the higher the altitude the more rapid the falloff in temperature as the absolute humidity declines. Probably the more important climatic contribution of altitude in Central America is made when topographic barriers athwart the airflow force humid air to rise, perhaps cooling it below its dew point, shrouding the land in cloud, and dousing the higher slopes with rain; as the air descends the leeward side, it brings warmer and drier weather.

The seasonal movement of the sun means that the intertropical convergence zone (the ITCZ, marked by the axis of the equatorial low-pressure belt of the doldrums) is at its most northerly extent in late summer, when it lies to the north of Panama along approximately latitude 10° N in the east, veering northwestward in the vicinity of San José to bisect Lake Nicaragua and run along the crestline of the Pacific coastal ranges. It brings with it unstable weather marked by convectional rainfall, thunderstorms, and even hail in the Guatemalan highlands. To the south of the zone the surface winds are southwesterlies; to the north the trade winds blow from the east. The southern part of Central America is under the influence of the ITCZ for much of the year. Weak, ill-defined easterly waves in the flow of air on the north side of the ITCZ form over the Caribbean several times during a normal summer and move westward into Central America, bringing *temporales,* days with clouds and heavy rain.

The distinction between a drier winter and a wetter summer is more marked in the north. Furthermore, the seasonal reversal of winds on the Pacific side means that they are frequently onshore in summer, causing wetter weather, and offshore in winter, bringing drier conditions. Central America, north of latitude 12° N, is occasionally visited in winter by the outer edges of cold polar air masses that bring frontal storms, high winds (*nortes*), cool temperatures, and generally unsettled weather. Between May and November, and particularly from August to October, the Caribbean coast of northern Central America is exposed to the possibility of hurricane damage. Hurricanes generally increase in frequency northwestward. The tropical storms that form along the ITCZ off the Pacific coast are less numerous but are at their most frequent in September.

Precipitation

The combination of maritime, orographic, seasonal, and latitudinal influences and diurnal fluctuations gives great local variety to the climates of Central America. Tropical wet climates characterize the Caribbean coastal plains and piedmont, the Petén, Darién, and the Pacific coast between and including the Osa and Azuero peninsulas. In these areas monthly temperatures exceed 64° F (18° C) throughout the year, rainfall exceeds about 80 inches (2,000 millimetres), and there is no seasonal drought. The wettest area is around San Juan del Norte (Greytown), Nicaragua, where the annual rainfall averages more than 236 inches (6,000 millimetres), with about 6 inches (150 millimetres) falling in the driest month (March) and 31 inches (800 millimetres) in the wettest (November). The sunnier months are the drier months; in April, for instance, Cristóbal at the Caribbean end of the Panama Canal records three-fourths of the total sunshine possible, while in July and November clouds reduce the proportion to 38 percent.

The lowlands fronting the Gulf of Panama, the Pacific half of Nicaragua including the lake basins, the Gulf of Fonseca, El Salvador, and the Pacific slopes of Guatemala are all within the *tierra caliente* but experience a distinct dry season of four to six months. Only about 15 percent of the rain on the Pacific coast falls between November and April, less than in each of the three wettest months (September, October, and June) individually. Annual rainfall on the Pacific coast ranges between 39 and 79 inches (1,000 and 2,000 millimetres). In highland Central America mean temperatures are lower; rainfall tends to be more intense than in the corresponding lowlands, and the rain shadow effect can be strong.

Plant life. The vegetation of Central America reflects its intercontinental situation, the major influence of climate, the more localized impact of soil quality, topography, and the selective and accelerating modifications made by humans. Together these factors produce a great variety of landscapes. The tropical landmass of South America and, to a lesser extent, adjoining North America have added a rich immigrant flora to that indigenous to the isthmus.

A generous supply of solar energy, and the relative absence of environmental stress in lowland areas over recent geologic time has encouraged plant speciation. The lowland rain forests have strong similarities with the selva of South America, and the evergreen forests that clothe the lower Pacific slopes from Costa Rica northward remain essentially South American in floral composition; above 3,300–5,200 feet, affinities with North America are closer and the number of species fewer. For example, the important trees of the forested highlands of northern Central America are the pine (*Pinus*) and the oak (*Quercus*), as in Mexico. The pines extend no farther south than north-central Nicaragua; in the Cordillera de Talamanca in Costa Rica the oaks are partnered by conifers of South American provenance. Above the altitudinal tree line the bunchgrass landscape of Guatemala has Mexican, even U.S., associates; that of Costa Rica resembles the Andean *páramo* (barren plain).

The rain forest

Tropical rain forests are the natural vegetation of the eastern half of lowland Central America, possibly excluding northeastern Honduras, and of Pacific Panama. They are characterized by a broad variety of distinct tree species that form a closed crown forest of four or five stories; undergrowth is restricted to, for example, shade-tolerant palms, figs (*Ficus*), and large-leafed aroids (*Xanthosoma*). Vines (lianas) and epiphytes (for example, Spanish moss [*Tillandsia*]) are common. The trees are broad-leaved and evergreen; their trunks are often smooth, straight, and buttressed, and they rarely grow in pure stands. The forest canopy commonly reaches 130 feet above the ground and varies in composition from place to place. Along riverbanks and wherever the crown is broken and sunshine reaches the ground, a dense jungle may grow; otherwise the forest floor is relatively open. Among the rain forest trees that remain commercially attractive are the breadnut, mahogany, sapodilla, or chicozapote (whose latex, chicle, is the basis of chewing gum), tropical cedar in the Petén and in Belize, various dyewoods from the Mosquito Coast, cashew in the Dulce Gulf area of Costa Rica, and rubber tree in Panama.

The original vegetation of northeastern Honduras and northeastern Nicaragua and the Caribbean coastal plain of central and southern Belize is probably pine (*Pinus caribaea*) savanna. The rainfall would seemingly support rain forest, but porous quartzitic soils permit only a dry drought-tolerant evergreen formation. The pines may grow to 115 feet, sometimes in stands attractive to timber companies, but more usually widely spaced in a parklike landscape; elsewhere the trees may be small and interspersed with shrubs in a savanna emulsion cut by ribbons of riparian hardwoods, as is the case in the limited savanna that separates the Nicoya Peninsula from the rest of Guanacaste in Costa Rica. Human activity has extended these savannas. In many places along both coasts almost impenetrable mangrove swamps of salt-tolerant trees thrive, some limited to either the Caribbean or the Pacific sides of the isthmus.

The natural cover of the Pacific slopes from the Nicoya Peninsula northward is a forest that loses its leaves during the dry season (*monte alto*). The forest declines in height from about 100 feet, and the number of xerophytic species present and the proportion of shrubs to trees rise as the altitude and the intensity of the dry season increase.

Montane forest

The high interior of Guatemala and Honduras and of Nicaragua east of the lakes, as well as the central cordillera of Costa Rica and western Panama, are under montane forest, that is, forests where high altitude, notably through decreased temperature, imposes various structural limitations not existing at lower elevations. On the Caribbean side the tropical lowland rain forest blends upward into an evergreen montane forest, and the number of stories drops to two once the *tierra templada* is reached. With increased altitude the upper story becomes lower (about 65 feet), and in the *tierra fría* mosses and tree ferns become more important.

At about 6,500 feet (in southwestern Costa Rica 4,900 feet) cloud forest, dripping wet throughout most of the year, creates an unusual landscape in which evergreen oaks and laurels, epiphytes (especially bromeliads), and orchids are significant. Above the cloud forest oaks and euphorbias grow among an undergrowth of barberry, myrtle, and brightly coloured herbs, which in turn give way to a tangled evergreen woodland of shrubs and low trees. Above 9,800 feet in Costa Rica is the *páramo,* open areas of evergreen herbs, shrubs, and berries of the saxifrage, heath, and vaccinium families, myrtle, and sphagnum moss.

Animal life. Central American wildlife is similar to but not as rich as that of South America. A number of species also have North American ties, and some endemic species have evolved from western Panama, eastern Costa Rica, and the highlands of Guatemala, Honduras, and northern Nicaragua. Uncontrolled hunting, the demand of external markets, the destruction of natural habitats, and the pressures of a growing human population, however, have taken a severe toll on Central America's wildlife; many of the region's better-known inhabitants are endangered or seriously depleted species, and some are in imminent danger of extinction.

The jaguar, ocelot, jaguarundi, and margay, all South American cats, may be found in the isthmus but are becoming rarer. The puma, gray fox, and coyote have colonized from North America, the latter only as far as northern Central America. The raccoon has used the isthmus as a corridor into South America; and, in reverse, the armadillo and the opossum have made their way into the United States, and the quiet kinkajou and giant anteater have used the isthmus as a route into Mexico. There are many overlaps of northern (Nearctic) and southern (Neotropical) fauna in Central America. There are also some unaccountable breaks in the chain. For example, there are bears (the spectacled bear) in Mexico and Panama but none in between.

Forest fauna

The Central American forests are relatively sparsely populated with mammals, generously populated with reptiles, and extremely rich in birds and insects. The shaded forest floor supports few grazing ungulates, the peccary, the tapir, and the deer being among these; all are sought for food. Other forest mammals are arboreal. For example, monkeys are represented throughout Central America by the howler and the spider; the capuchin is found as far north as Honduras. The red-backed squirrel monkey of Panama and Costa Rica (where it is protected) has been heavily sought for the biomedical industry.

Water animals and reptiles are numerous. The amphibious river otter is on the endangered list. One of the more unusual mammals is the manatee, which inhabits lagoons and estuaries; it has been decimated through hunting, however. The landlocked shark found in Lake Nicaragua is one of the more interesting freshwater fish. Among the more familiar endangered reptiles are sea turtles. The tortoiseshell of the hawksbill and the meat of the green turtle are particularly prized, and the eggs of others are eaten. Lizards are well represented and include the gecko; the large common iguana and the related black iguana are sold live for meat in local markets. The caiman is found only as far north as latitude 14° N. Snakes are in abundance. The boas are represented by boa constrictors, but none of the giant anacondas of South America penetrate the isthmus. Three-fourths of the snakes belong to the Colubridae family. There is a rich fauna of amphibia, including tree frogs.

Central America's resident bird population is enriched by migratory flocks, their paths converging as the isthmus tapers southward. Parrot species are numerous. Some of the many genera of hummingbirds reach into the highest parts of the isthmus. The massive monkey-eating eagle is one of the largest birds of the tropical rain forests. The quetzal, whose feathers were so highly sought after by Maya, Aztec, and British Victorians alike, is now confined to the more remote parts of the cloud forests. The toucans penetrate as far north as Mexico.

Insects abound and are particularly obvious along rivers; colourful butterflies, armies of ants, and swarms of mosquitoes are witness to many other less visible insects.

Settlement patterns. Central America can be roughly divided into a very lightly peopled Caribbean half and a slightly more populous Pacific coastal slope, separated by a sequence of relatively densely settled highland regions. Rural population densities of under 13 persons per square mile (5 persons per square kilometre) are the rule on the Caribbean side of the isthmus, and many of the small towns there are closer in form and organization to those of the old British West Indies than to those farther west. On the Pacific slope settlement has often been fairly recent. Brash towns built to a gridiron plan and offering a range of commercial services are fringed by self-built, one-story family houses in a rural setting of scattered plantations, ranches, or farms that include associated accommodations for labourers.

Rural densities

In contrast, rural population densities in excess of 260 per square mile are widespread on the fertile volcanic soils of the older-settled highlands, notably on the southwestern highlands of Guatemala, in much of El Salvador, around the lakes in western Nicaragua, and in the highland basins of central Costa Rica. These highlands supported large populations before the Spanish conquest, and the availability of their labour, a comfortable climate, and healthier living conditions helped confirm this pattern in colonial and postcolonial times.

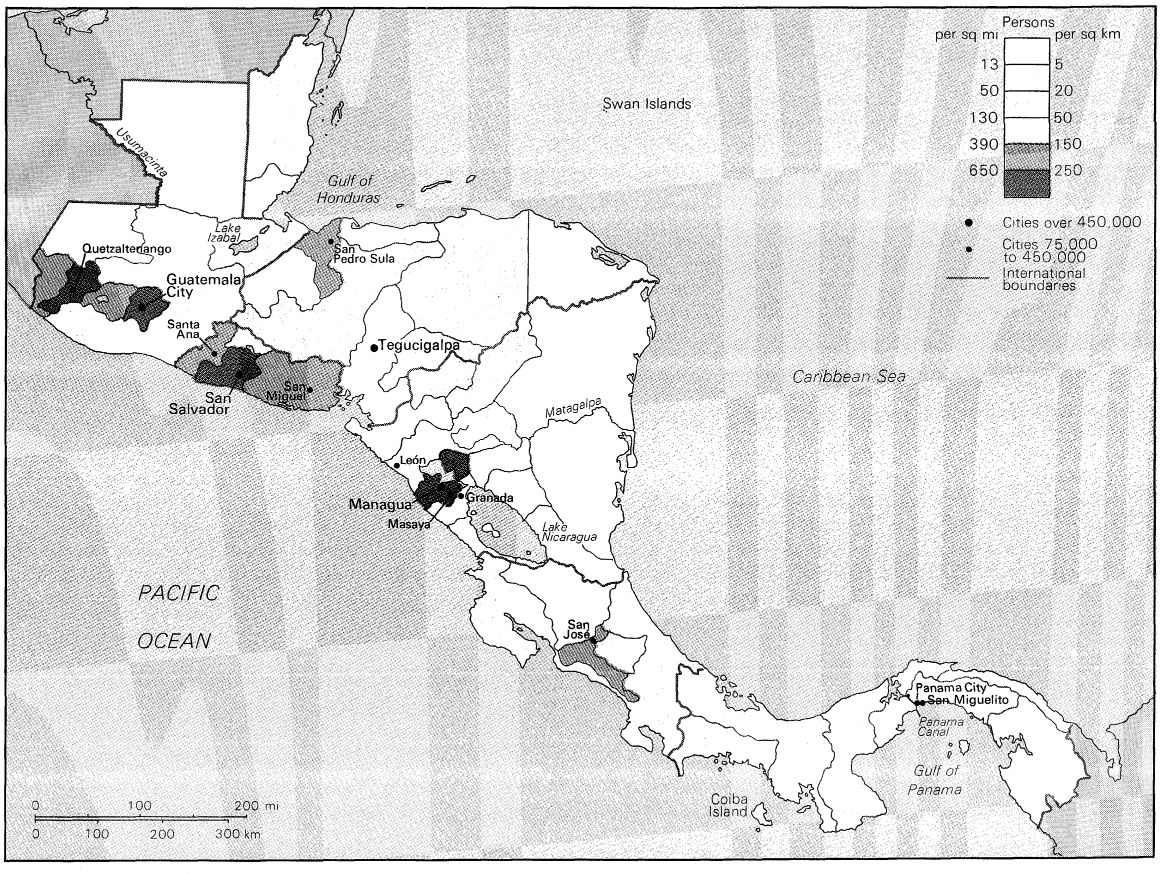
In the more heavily Indianized areas of Guatemala people live in individual homesteads scattered irregularly among their crops but with an association, and perhaps a second residence, in a meeting place or concourse, normally unoccupied but housing one or two civic or ceremonial buildings and whose main function is to serve as a periodic marketplace. Such concourses may be likened to the ceremonial centres of pre-Columbian times. Other highland peoples, of more varied ethnic origin, are more likely to live in small, compact towns whose structures are clearly planned and exhibit characteristics identifying their Hispanic origins. The town centre is likely to be an arcaded plaza bordered by an imposing church, administrative offices, public buildings, and the homes of some of the more important citizenry. A rectilinear grid of streets is aligned on the sides of the plaza. The farther from the centre, the lower the social class of the neighbourhood. This is the colonial mold that has been followed throughout highland Central America. More recently glass and steel office blocks and hotels have begun to change the skylines of the larger towns, and in some the original plaza has ceded its premier place to a more fashionable city centre in a newer part of town.

THE PEOPLE

Ethnic composition. At least two-thirds of Central Americans are of mixed race. Census figures estimate that 60 percent are of mixed European and American Indian blood (called ladinos in Guatemala and mestizos elsewhere), 5 percent are of mixed European and black origin (mulattoes), and 1 percent are of mixed American Indian and black descent (zambos). A further 20 percent is pure American Indian, or Amerindian, as they are often called in Middle and South America. Some 12 percent claims white European ancestry, while the descendants of Chinese and East Indian indentured labourers and others make up about 2 percent. Seven out of every eight persons classed as American Indians live in Guatemala, making up about 55 percent of that country's total population. One-third of the remaining American Indians live in adjoining Honduras, and another one-fourth in El Salvador; elsewhere, only in relatively empty Belize are American Indians a significant element (10 percent) in the population. Almost all the American Indians in Guatemala belong to branches of the Mayan family.

American Indians

Linguistic evidence suggests that the Maya core area was near Huehuetenango in northwestern Guatemala and that the first of a number of migrations began some four and a half millennia ago, resulting in the many distinct Maya tribal groupings present in the isthmus today. The Ameri-



Population density of Central America.

can Indians of northeastern Petén and northern Belize are members of the Yucatecan Maya (for example, the Itzá and Mopan), most of whom live on the Yucatán Peninsula in neighbouring Mexico. The northwest highlands of Guatemala are home to the Mamean people, including the Mam proper, the Ixil, and, straddling the Mexican border, the Kanjobalan, Chuj, and Jacaltec. The largest concentration of American Indian language speakers is that of the Quichéan peoples, who live in the midwestern highlands of Guatemala; they include the Quiché proper, the Cakchiquel, and the Tzutujil. The eastern highlands of Guatemala house the Pokomam, with a Quichéan language root, and include the Kekchí of Verapaz and southern Belize; the Chortí, who inhabit the area where Honduras, El Salvador, and Guatemala meet, share their linguistic roots with the American Indians of Tabasco in Mexico.

Costa Rica is the only country with a majority of residents descended from white Europeans. That country had only a small American Indian population in the 16th century and was unattractive to Spanish conquistadores, but it has been more attractive to later European migrants than have the other countries. Blacks are proportionally higher in numbers in Belize (40 percent) and Panama (14 percent), where West Indians were imported in large numbers to help build the Panama Canal.

Spanish linguistic dominance

Linguistic composition. Spanish is the dominant language of Central America and the official language in six of the republics; English is the lingua franca of much of the Caribbean coast and the official language of Belize.

Many of the American Indians are monolingual, some speak Spanish as a second language, and a considerable number speak more than one American Indian language. There has been an exchange of vocabularies among the languages. There are also various Cariban languages, with trans-Caribbean roots, spoken by the Black Caribs (*morenos*) and the small groups of Jicaque, Paya, Miskito, and Sumo of the Mosquito Coast and parts of Belize.

Religion. Roman Catholicism is the professed religion of six out of every seven Central Americans; almost all the remaining share various Protestant faiths. The conversion of the native peoples during colonial times was often accompanied by the absorption of Roman Catholicism into the rituals of pre-Hispanic beliefs and practices, and these remain today. More recently, evangelical Protestant sects have made substantial inroads into traditionally Roman Catholic communities, particularly in Guatemala and El Salvador, undermining the political importance of the Catholic hierarchy. There are small numbers of Muslims and Hindus among the East Indian population.

Demographic trends. The rapidly growing population of Central America reached 10 million in the early 1950s, 20 million in the late 1970s, and more than 28 million in mid-1988. About one-third of the people live in Guatemala, a sixth in El Salvador, another sixth in Honduras, an eighth in Nicaragua, a tenth in Costa Rica, and a twelfth in Panama; less than 1 percent of the people live in Belize.

Comparative vital statistics

The region retains one of the highest rates of population growth in the world, but it has been declining. The variables that determine demographics have been changing significantly; for example, crude death rates at 15 per thousand in 1965 were halved by 1987, while birth rates fell by 25 percent and net emigration increased. There are substantial national differences; for example, the relatively low death rates in Costa Rica, Belize, and Panama are half those in the other countries. Children born in Costa Rica and Panama can expect to live into their 70s, 10 years longer than those born in the northerly republics. Crude birth rates are also lower in Costa Rica and Panama than in El Salvador and the rest of the isthmus. More revealing are the contrasts in fertility rates; although falling, they are very high in Guatemala, Honduras, Nicaragua, Belize, and El Salvador but considerably lower in Costa Rica and Panama. The increased use of modern contraceptives is the most important factor influencing these variations.

Central Americans have become more mobile. In the past there was a net gain from migration—notably of West Indian labourers brought in to help build the Panama Canal and to work on the banana plantations of the largely empty Caribbean lowlands—but in more recent years there has been a net outflow of people from the isthmus. During the 1970s and '80s and into the '90s there was a substantial emigration of Central Americans—particularly to Mexico, the United States, and Canada—seeking escape from poverty, persecution, and the civil wars in their native lands.

Within Central America the greatest pressure to emigrate has been felt in El Salvador: 300,000 Salvadorans had migrated to neighbouring Honduras before the Soccer War of 1969, which resulted in the repatriation of some 130,000. More recently, the civil unrest of the 1980s displaced up to 1,000,000 people, including an estimated 500,000 Salvadorans who entered the United States, about 40 percent illegally. Tens of thousands of others migrated to Mexico, Guatemala, Honduras, and other countries in the region. There has long been a seasonal migration from Guatemala to pick the coffee beans of Mexico's Soconusco coast, and many have made the migration permanent.

Internal migration has made the population of Central America more urbanized. In 1960 only about one-third of the total lived in towns; by the late 1980s the proportion was more than 45 percent. Capital cities have attracted the greatest urban migration. About one-half of urban Costa Ricans live in metropolitan San José, for example; one-third of urban Panamanians live in Panama City; one-third of the townspeople of Nicaragua live in Managua; and a similar proportion of Guatemala's urban population lives in Guatemala City, the most populous city of the isthmus. But most of the towns are small, and urban life is strongly rooted in the local countryside.

Where there is a large American Indian population, as in northern and western Guatemala, rural traditions are particularly strong: two out of every three Guatemalans are officially classed as rural. Although the rural population of the isthmus has increased less rapidly than the urban and much of Central America's countryside remains uncrowded, there are a number of areas where the local pressure on land resources has become difficult if not impossible to contain. These areas include the uplands basins of western Guatemala, the core area of El Salvador, the Meseta Central of Costa Rica, and, to a lesser extent, the lakes region of Nicaragua. These are the originating areas of many of the internal migrants.

THE ECONOMY

Gross national product

The gross national product of Central America is small compared to more developed regions of the world. In the late 1980s it was, for example, on a par with that of Peru but only a fifth of that of Mexico. This suggests the small size of domestic markets in Central America and explains why the main economic focus over the years has been on producing commodities for export (or, in the case of Panama, providing international services). The performance of the Central American economies has closely mirrored that of the world, thanks to their export orientation. Thus, the overall trend of a 10-fold growth in real gross domestic product (GDP) between 1920 and 1990 has had imposed upon it the local impacts of the downturns of the Great Depression, World War II, and the 1980s, as well as the booms that followed both world wars and that of the 1970s.

The first export staple was coffee, firmly established on a commercial basis in Costa Rica by 1830 and in El Salvador, Nicaragua, and Guatemala by 1860; bananas joined coffee in 1900, and for the next half-century the two dominated trade and investment. Governments acquiesced with the interests of both the highland coffee growers, mainly nationals well integrated into local politics, and the U.S.-owned banana companies in the coastal lowlands. Accordingly, the governments wielded relatively little power; in contrast, by 1929 two fruit companies (the United Fruit Company and the Standard Fruit and Steamship Company) controlled all banana exports and most banana production in the isthmus. The addition of cotton, sugar, and beef to the mixture of export staples after World War II helped reduce the exposure of national economies to adverse changes in the prices of coffee or bananas but did not lessen the overall dependence upon external commodity markets.

The formation of the Central American Common Market (CACM) in 1960 gave a further impetus to economic diversification. By introducing import substitution policies and the manipulation of tariffs, national industries were encouraged to manufacture for the wider isthmian market. The enlarged market generated new employment, mainly in the towns, and helped encourage urban migration, and it created a new, if not very significant, regional trading pattern. In the 1970s government policies encouraged further diversification by promoting new exports. In addition, Panama's location at an international crossroads proved most useful in attracting offshore manufacturing and banking facilities. The effective demise of the CACM in 1980 (Panama and Belize, for different reasons, had never been members) reversed the limited progress made toward regional economic cooperation and helped highlight some of the national differences within the isthmus.

Causes of economic disruption

National circumstances have provided further departures from regional compatibility. The differing degrees of dependency upon particular commodities, for example, have been an important discriminant; another has been the greater encouragement given to import substitution policies in foodstuffs during the 1930s and in manufactured goods in the 1960s by Costa Rica, El Salvador, and Guatemala. Also important in several countries has been the variety of oppressive military governments and of open wars, guerrilla activity, and counterinsurgency measures.

These differences were compounded in the 1980s by changes in the terms of trade and the burden of huge external debts. The disbursed external debt of the isthmus rose fivefold in the 1970s and fivefold again in the '80s. The differing degrees of indebtedness and of ability to attract overseas assistance and investment helped widen the distinctions between the individual countries. By the end of the decade Nicaragua owed most, suffered the highest ratio of interest payments to export earnings, and was the least creditworthy. Panama and Costa Rica were more indebted, but payments due to service public debt were more onerous for Honduras and Guatemala. Overseas aid, which included military assistance, was made more readily available to Costa Rica, El Salvador, and Honduras but was essential to all.

Per capita production in Central America grew between 1960 and 1980 but actually fell during the 1980s. It was the poor who suffered most from this reversal. At the beginning of the decade there were already great disparities between the incomes of the poor and the rest of society in Central American countries. Thus, the poorest 20 percent of the isthmian population had only 3 percent of the national product at their disposal, while the richest 20 percent had 56 percent of the national income. The economic crisis of the 1980s exaggerated these differences.

Revised credit policy

The important roles foreign institutions and overseas markets have played in steering Central American economies in the past has meant that the growing influence assumed by the government of the United States and the various international financial agencies (notably the International Monetary Fund and the World Bank) over the direction of these nations' policies in the aftermath of the 1980s crisis was more readily accommodated than perhaps elsewhere in Latin America. The generally open, export-led nature of Central American economies has made them better able to adjust to the policies imposed by their modern creditors. These creditors, for example, have insisted on more effective and equable fiscal policies and a more efficient use of agricultural land, matters that were of relatively little concern to governments in earlier days.

Agriculture. Agriculture looms large in the lives of Central Americans. More than one-half of the people continue to live in the countryside, and many of those who live in towns continue to earn their livelihoods directly or indirectly from the land. The contribution agriculture makes to Central America's GDP (about 25 percent) is considerably higher than that of Latin America as a whole. About half the agricultural production of the isthmus is for export, a fraction that has held fairly steady since the 1920s; exports of unprocessed foodstuffs continue to provide more than one-half of isthmian trade. Five commodities dominate the commercial agricultural production of the isthmus: coffee, bananas, sugar, cotton, and beef.

In the late 1980s about 13 percent of Central America was classified as arable, the same proportion as in Mexico or the Southern Cone countries of South America. A further 26 percent was in pasture, and about 35 percent was under forest. Almost one-fifth of the arable land was cultivated; the rest was in temporary meadows or left fallow. More than one-third of the cultivated land was irrigated.

Coffee is the oldest and most valuable export staple; production is almost on a par with Colombia and contributes about a tenth of the world's total. During the 19th century the coffee growers created not only plantations (fincas) but also the other material facilities needed to market coffee overseas. They established national banking systems and financed many of the railways, ports, and other elements of a new outward-looking infrastructure and became the political elite of the isthmus. During the 20th century their political and economic power has continued.

Most coffee is grown on the Pacific side of the isthmus. There, seasonal rains provide the moisture needed by the plant during the early part of the growing season, and the succeeding dry months allow the bean to ripen to perfection. Coffee is grown on shaded slopes between elevations of 1,000 and 5,600 feet, where the well-drained, volcanic soils are naturally fertile. Coffee picking makes large demands on temporary labour, and about a million pickers help bring in the harvest each year; government policies have helped ensure the requisite supply of cheap labour. Traditionally profits have been high, taxes on production low, and the rewards concentrated in a small number of hands: between 80 and 90 percent of production is controlled by the top 5 percent of growers. There are marked differences in coffee production costs and yields; yields on the Meseta Central in Costa Rica are the highest, and those on well-managed estates in El Salvador and Guatemala are six times what is typical of Honduras or Nicaragua.

Banana cultivation

Bananas have flourished best in Central America in the tropical warmth and persistent moisture of the coastal lowlands of the Caribbean. The first commercial banana plantations were begun to help pay the construction costs of the Northern Railway, built to carry Costa Rican coffee to the Caribbean port of Limón. Today Caribbean banana plantations are most intensively developed in the lower river valleys of northern Honduras and neighbouring Guatemala. In the 1930s, when banana infestation devastated the southern Caribbean, new plantations were established on the Pacific coast of Costa Rica and in western Panama.

Bananas, unlike coffee, are a perishable commodity, harvested throughout the year, and they need fast, frequent, and cheap shipping facilities for marketing. Thus, heavy capital investment in ports, railways, drainage, and the like was a prerequisite for success. Large numbers of permanent plantation labourers also had to be imported for the early Caribbean plantations, and housing and social services provided; most of the new workers were English-speaking West Indians. Major U.S. companies with the available capital and technology have dominated the banana economy from its beginning.

Sugarcane was introduced to Central America by the Spanish soon after the conquest and was grown in the foothills behind the Pacific Coast from Guatemala to Nicaragua. It is still mainly grown there, taking advantage of a climate that is warm and moist during the growing season but dry just before harvest time. Sugarcane is raised on both conventional plantations and peasant plots. Central American sugar is sold chiefly in domestic markets.

Large-scale cotton growing has been a feature of Central American agriculture only since the construction of roads along the Pacific littoral in the early 1950s opened up virgin land with rich alluvial and volcanic soils and a climate well suited to cotton. The international attack on malaria helped make these lands habitable, modern insecticides allowed man to harvest a crop, and the overseas demand for cotton attracted entrepreneurs and capital. The lakes region of Nicaragua, in particular, became a focus for large-scale mechanized cotton farms. Land was revalued and subsistence farmers dispossessed of land over which they had only traditional rights. The increased use of fertilizer, as soils needed replenishment, and insecticides, as immunities built up, emphasized the growing capital-intensive (and ecologically damaging) nature of the new machine-based agriculture. In contrast to coffee and banana growing, the demand for wage labour in cotton production was modest and seasonal. The cotton boom generally benefited those with access to capital, and it spawned cotton gins, vegetable oil factories, textile mills, and agricultural suppliers. The example of cotton led to a spread of modern agricultural practices with other crops, including rice and sugar, on the Pacific lowlands.

The modernization of Central America's cattle ranching economy began in the late 1950s with the opening in Managua of the first beef-packing station approved by the U.S. Department of Agriculture; 20 years later there were more than two dozen such plants in Central America. It was a development promoted by U.S.-backed aid agencies and directed toward exploiting the huge demand for lower-grade beef in the United States. As with bananas, much of the private capital and expertise needed to introduce improved strains of cattle and grasses, to build efficient slaughterhouses, to provide refrigerated transport facilities, and to research the market was provided by U.S. corporations. The new cattle economy prospered on land not fertile enough for cotton, bringing large areas of Pacific Central America into the export economy for the first time, at the expense of exacerbating economic and social differences. Forests had to be cleared and subsistence farmers evicted to make way for beef cattle.

U.S. input in cattle raising

The growth of towns has led to an increased production for local markets. Dairy farms and market gardens cater to the sophisticated demands of middle-class townspeople, and an increasing share of the everyday food staples grown in Central America on peasant smallholdings finds its way to urban markets. Although the majority of subsistence farmers now produce cash crops, the agricultural systems used are those that have provided a livelihood throughout the centuries. Thus, in the densely populated altiplano of western Guatemala, for example, virtually every cultivatable acre remains under corn (maize), the staff of life of the American Indians. The great variety of corn grown, sometimes planted with traditional beans and squash, and the tiny size of hand-tilled individual holdings, sometimes on quite steep slopes, creates a landscape very different from that of the plowed lands of commercial monoculture elsewhere in the isthmus. In drier, but equally densely populated, El Salvador sorghum is often grown with corn, partly to provide an insurance for the largely mestizo farmers against a poor corn harvest. Both sets of farmers, American Indian and mestizo, increasingly have come to supplement their incomes by looking for temporary work in the towns or in the coffee plantations, in the cane fields, or on the cotton farms.

On the emptier Caribbean side of the isthmus different subsistence agricultural traditions survive; cassava is the main staple, supplemented by sorghum, plantains, and rice, and slash-and-burn agriculture persists in Pacific Panama, eastern Nicaragua, and central and southern Honduras. However, this extensive form of cultivation has become less sustainable as fallow periods are shortened in response to rising demographic pressures and the forest soils lose their ability to recuperate.

Forest products

Although rain forest covers much of the Caribbean lowland, forests have economic significance only in Belize and Honduras. Until about 1960 half the value of Belizean exports was supplied by the forests. Logwood and mahogany had drawn British timber companies to Belize (and the Mosquito Coast) in the 19th century, and during the 20th Caribbean pine became worth cutting. But changing taste, alternative cheaper sources, and poor management have restricted production. Central America's commercial timber now comes mainly from coniferous forests in interior Honduras and broad-leaved forests in Costa Rica.

Fishing makes only a modest contribution to the Central American economy, although shellfish middens testify to its importance in pre-Columbian diets, and inshore fishing remains important for some coastal American Indians today. It is an underexploited resource except, perhaps, in Panama, where the completion of a new port and fishing terminal at Vacamonte in 1979 has turned fish, mainly shrimps, into an important export. Exports of fresh and frozen lobster and conch from Belize to the United States have been of local importance since 1960.

Industry. The search for placer gold in the rivers of Caribbean Central America spurred early Spanish exploration but produced little permanent settlement. In contrast, the discovery of veins of silver in interior Honduras led to sustained production and a strong mining industry. Bullion was the mainstay of the Honduran economy during colonial times and the first century of independence. In the late 1800s silver and gold accounted for three-fourths of its exports, and the mining town of Tegucigalpa was chosen as the national capital.

In the 20th century lead and zinc have become significant minerals in Honduras, but the overall importance of mining there is now modest; it is even less important in the other Central American countries. The most important mineral prospect is probably the copper deposit at Mount Colorado, Panama, one of the largest of its type in the world; its development, however, is dependent upon relatively high copper prices. Most current interest has reverted to gold, both the discovery of new deposits and the reworking of old ones.

Central America is largely reliant upon imported oil. Both Belize and Guatemala have hopes that the rich southern Mexican oil fields will prove to extend into their territories. Half the undeveloped reserves of hydroelectricity are in Costa Rica.

Manufacturing is hampered by limited raw materials, few sources of energy, and the restricted size of local markets. Between one-fifth and one-fourth of the growth in manufacturing between 1964 and 1974—visible as large factories making such products as paints, detergents, tires, paper, fertilizers, and insecticides serving the member states—was due to CACM legislation. By 1980 domestic production was meeting about two-thirds of the internal demand for manufactured goods. Since 1980 protectionist measures and cooperation have been much reduced, and economic recession has both increased the costs of imported raw materials and decreased local demand. The real value added by manufacturing in Central America peaked between 1978 and 1981 and remained below that level for the next decade. Manufacturing plays a lesser part in the life of the isthmus than it does elsewhere in most of Latin America, accounting for only one-sixth of the isthmus's GDP.

The role of manufacturing

Much of the industrial employment is in cottage industries, and only a minority works in establishments employing more than 10 people; artisans outnumber factory workers. The dominant activities are those that require relatively little capital to reach an efficient level of production. The food, beverage, and tobacco industries account for about half the value added in manufacturing and more than one-third of the employment; textile, clothing, and shoe manufacturing account for a further fifth of the value and a fourth of the labour force. The woodworking industries, including furniture and leather making and printing, are important traditional activities. In contrast, the newer industries support relatively little employment. The chemical industry is the most important of these, responding to the rising agricultural demand for fertilizers and insecticides until it was hit by the 1980s recession; oil refineries, seemingly promoted as necessary symbols of nationhood, have proliferated.

Two-thirds of Central America's industrial employment is in the 10 most populous towns, and Guatemala City is home to one-fifth of all the industrial establishments in the isthmus and has one-fifth of the total employment in manufacturing. Much of the large urban employment in providing services is unrecorded. Probably between 40 and 50 percent of the working population of the larger cities of Central America is in occupations for which there is no official record. Many in this sector are self-employed artisans, outworkers (taking in work from the formal sector), vendors, and market traders intent on making an honest living. Some are small-scale criminals, petty thieves, or prostitutes who live outside the law but according to widely understood and accepted rules; a few may be part of the larger criminal economy of the international drug trade. Panama has achieved some notoriety as a funnel for channeling South American cocaine to North America; Belize has been a conduit as well as a grower of marijuana for the U.S. market.

Tourism generates an income equivalent to about 10 percent of Central America's export trade. This is well below the potential of the industry because of widespread civil and military unrest. For example, in Guatemala the dramatic scenic attractions of the volcanic highlands and lakes, the rich archaeological remains at Tikal and elsewhere, and the ethnic appeals of the American Indian communities are negated by the activities of guerrillas; tourists have also come to be deterred from visiting Nicaragua and El Salvador, and even the relatively stable Costa Rica has suffered some tourist loss. In contrast, Panama has long had the largest income from nonresidents in Central America—a third of the receipts coming from U.S. military personnel stationed in the canal area.

Import-export balance

Trade. An important economic role has been played by trade in all Central American countries since independence, allowing a limited number of primary commodities to be exchanged for manufactured and other goods produced more cheaply abroad. In general, the value of imports has exceeded that of exports except in years of exceptional commodity prices. Coffee supplies between one-fourth and one-third of Central America's exports and bananas up to one-sixth, followed by sugar, beef, and cotton. The degree of importance of trade to individual countries varies significantly: Honduras and Costa Rica are highly dependent, El Salvador moderately dependent, and Nicaragua and Guatemala less so. Panama is in a separate category because of its own huge imports of crude oil. Half of the export earnings of Costa Rica and El Salvador during the 1970s and '80s came from coffee, as did more than one-third of Guatemala's. Bananas provide between one-fourth of Panama's and one-third of Honduras' income and about one-fourth of Panama's and of Costa Rica's. Sugar makes up one-third of the value of Belizean exports and cotton one-fourth of Nicaragua's.

The United States and Canada are the destinations of one-half of Central America's exports, and the countries of western Europe, notably Germany, the other half. Regional trade within the countries of CACM reached record levels in 1980, but political instability and civil strife combined with disinvestment, capital flight, reduced domestic demand, and the erection of national protectionist barriers to imports sharply reversed this trend. Ninety percent of regional transactions are between Guatemala, El Salvador, and Costa Rica. The United States supplies about 40 percent of the isthmus's imported goods, two-thirds of which are manufactured items. Nicaragua has been exceptional in relying heavily upon the Soviet Union and other countries of the Eastern bloc as trading partners following the trade embargo imposed by the United States in 1985. Nicaragua ran the largest trade deficit in the isthmus in the late 1980s, with imports running three to four times ahead of exports in value.

Transportation. The major transport artery of Central America is the Pan-American Highway. It runs almost the entire length of the isthmus, from Cuauhtémoc on the Mexican-Guatemalan border to Chepo in the foothills of Darién. The highway became drivable in the mid-1960s and is now paved, although it is prone to landslides in the wet mountainous sections. Engineering obstacles and the lack of capital to surmount them, as well as political differences, have stood in the way of completion of the final link (across the Darién Gap) to the South American road network. New roads have made the Pacific coastal lowlands accessible since 1950, and a limited number of others have helped incorporate the Caribbean lowlands into the national life of the isthmus. By the late 1980s, however, only about 16 percent of all roads were paved. The Costa Rica and El Salvador road networks are four times as dense as those of the other countries.

Disuse of railroads

There are less than 2,400 miles of railway track in Central America, much of it not used. The systems are fragmented, and many give preference to particular customers (for example, the banana railways of northern Honduras) rather than the general public. Most railways are state-owned, and they largely suffer from neglect and a lack of investment. Many have been supplanted by roads, and none is of major importance.

Most ports are small and, like the railways, were built for particular users. The Panama Canal is the major seaway of the region, but, with the completion of the transisthmian pipeline in 1982 and the diversion of crude-oil shipments from the canal, the number of ships daily transitting it has fallen and revenue has shrunk. In 1986 a commission was set up to consider the possibility of building a new canal (perhaps a sea-level cut) to supplement the existing one.

There are some 30 airports in Central America offering scheduled services and many other public, military, and private landing strips, some reputedly used for smuggling contraband, particularly narcotics. (D.J.Fo.)

History

PRE-COLUMBIAN CENTRAL AMERICA

Central America, an archaeological bridge connecting North and South America, was, before the arrival of the Europeans, home to various nomadic and sedentary cultures. Maya civilization occupied much of the northwestern part of the isthmus, from Chiapas and Yucatán, now part of southern Mexico, through Guatemala, Honduras, Belize, El Salvador, and into Nicaragua. Although the Maya were the most advanced pre-Columbian civilization in the hemisphere, they were never unified. Unlike the Aztec or Inca empires, their autonomous city-states remained independent, presaging the political fragmentation that would characterize Central America to the present day. What unity existed was cultural, rather than political. In addition to the Maya, other American Indian nations occupied Central America, bringing influences from both North and South America.

There is scant evidence of human life in Central America before 8000 BC. Primitive human habitation in the region before that date is likely, perhaps as early as 40,000 BC, but civilized society did not emerge until the 2nd millennium BC. Between 4000 and 1000 BC, people of the region made the transition from hunting and foraging to plant cultivation. Pottery in the Parita Bay region of Panama, dating from about 2130 BC, reflected South American cultural influence, which eventually reached as far north as Guatemala and Chiapas. Mexican influence in Chiapas dates from at least 1500 BC, and thereafter it extended as far south as Nicaragua and Costa Rica. Central America thus became a meeting ground for Mesoamerican, South American, and Caribbean peoples. After 1000 BC, organized, sedentary farming communities became numerous, and active commerce and communications developed among them. Although manioc and other tubers were important to Indians of the Caribbean coast, corn (maize) was the most important staple food of most Central Americans, accompanied by a wide variety of beans, squash, and other vegetables and fruits.

Mexican influence

The Olmec culture and other Mexican influences substantially affected the development of Maya civilization, while central Mexican Nahuatl influence challenged the Maya and stretched along the Pacific coast, notable especially among the Pipil of El Salvador and the Chorotega and Nicarao of Nicaragua. In Panama and Costa Rica, South American Chibcha influence was prevalent, while Caribbean cultural patterns penetrated the coastal plain from Panama to Honduras. Fugitives from the European conquistadores in the Caribbean increased this influence considerably at the close of the 15th century. The Miskito, Sumo, Rama, and other tribes on the Nicaraguan and Honduran Caribbean shores have survived to the present.

Emergence of the Maya. After 500 BC an advanced Mayan civilization emerged in the highlands of Guatemala and El Salvador. A large population developed at the city of Kaminaljuyú, on the outskirts of present-day Guatemala City, and other Mayan cities arose from Chiapas southeastward to Nicaragua. Early in the 1st millennium AD, Classic Maya civilization arose in the Petén region of northern Guatemala, as well as in Belize and Honduras; this probably was the result of migration from the highlands, although Pre-Classic Mayan cultures had also developed in this lowland region contemporaneously with such highland centres as Kaminaljuyú. Large new cities arose at Uaxactún, Tikal, Quiriguá, Copán, and elsewhere, characterized by great stone temples, pyramids, and markets. Although the highlands remained heavily populated, these lowland cities became the centres for a higher civilization. Overcrowding, famine, climatic change, or major geologic catastrophes may have contributed to migration, but contact between the highland and lowland peoples continued as merchants carried cultural, economic, and social traits from one place to another. Tazumal, for example, in western El Salvador, was influenced by Copán, the Maya scientific centre in northwestern Honduras. Influence from as far away as Teotihuacán in the present-day Valley of Mexico and El Tajín in Veracruz also continued.

Mayan cultural advancements

The lowland Mayan cities were located in an area that the Europeans thought of as uninhabitable because of the hot, humid climate and the accompanying insects and diseases. But the Maya developed the highest culture of pre-Columbian America, which reached its height between AD 600 and 900. Maya priests made discoveries in astronomy and mathematics comparable to similar advancements in ancient Egypt. They developed an advanced system of writing, and their hieroglyphs on stone monuments (stelae), erected throughout the Maya lands, recorded their history. Brilliant Mayan artistic and scientific achievements in ceramics, sculpture, weaving, and painting, some of which were more advanced than European accomplishments of the same era, all showed remarkable artistic sensitivity. They developed an accurate calendar and complex systems of agricultural and water management. The Maya could not match their European counterparts in technology, however. Their architectural works were also less impressive than those of ancient and medieval European civilizations. The Maya were unable to develop energy-saving machines, the wheel being employed on children's toys but not adapted to any practical application. Animals were not domesticated, and all work was done by human hand labour directed by an elite group.

Decline of the Maya. Maya civilization began to decay after AD 900, perhaps owing to stresses in the social structure, overpopulation, and deforestation. A number of important cities emerged in the late Classic period, mostly on the periphery of the classic Mayan region, in present-day Chiapas or Yucatán. The peoples of these cities, much influenced by invaders from central Mexico, built striking stone architectural monuments, but their scientific and artistic achievements were less remarkable than the earlier advances of the Classic period. Their economies remained underdeveloped, however. In the meantime, internal civil war and intervention from central Mexico sapped Maya strength and vitality. By the time of the Spanish conquest, Maya civilization was thoroughly in decline, yet they resisted subjugation longer than either the Aztec of Mexico or the Inca of Peru. Returning to northern Guatemala, where they established the city of Tayasal as a place of refuge, some Maya maintained their autonomy until 1697. Not far away, the Lacandón Maya defied pacification throughout the Hispanic period, resisting from remote jungle and mountain refuges along the Usumacinta River. Disease and the social disruption brought with the Spanish conquest annihilated a large part of the native population during the 16th century. Although estimates of the pre-Columbian population of Central America vary widely, it is generally agreed that the region's population did not again reach its pre-Columbian level until the 20th century.

THE SPANISH CONQUEST

Early Spanish claims

Rodrigo de Bastidas was first to establish Spain's claim to the isthmus, sailing along the Darién coast in March 1501, but he made no settlement. A year later Christopher Columbus, on his fourth voyage, sailed along the Caribbean coast from the Bay of Honduras to Panama, accumulating much information and a little gold, but again making no settlement. Other navigators from Spain followed, some seizing natives as slaves, and in 1509 Fernando V, the king of Spain, granted concessions for colonization of the region to Alonso de Ojeda and Diego de Nicuesa. Both suffered staggering losses from disease, shipwrecks, and hostile natives. Remnants of these expeditions, under the leadership of a stowaway, Vasco Núñez de Balboa, who had earlier been with Bastidas, survived at Santa María la Antigua del Darién, on the Gulf of Urubá near the present-day Colombia-Panama border. Balboa turned the survivors into a disciplined and productive colony in 1510. Crossing the isthmus, Balboa discovered the "South Sea" (Pacific Ocean) in 1513 and claimed for Spain all the lands it touched. Balboa cultivated good Indian relations, made extensive explorations, and found enough gold and pearls to make Castilla del Oro, as it was called, the first profitable colony in the New World. The explorations took their toll on the Indians of the region, however, many of whom were wiped out by European diseases.

Appointment of Pedrarias. The king relieved Balboa with a trusted general, Pedro Arias de Ávila (known as Pedrarias Dávila), although he allowed Balboa to continue his explorations on the Pacific coast. Pedrarias, however, distrusted the ambitious Balboa and, accusing him of treason, had him beheaded in 1517. Pedrarias expanded the colony but was responsible for enslaving and murdering the Indian population, despite royal orders for more humane treatment. In 1519 he established Panama City on the Pacific coast and moved the capital there in 1524, abandoning the hot, humid Darién.

Pedrarias sent a kinsman, Gil González Dávila, to explore northward, and he found civilization on the shores of Lake Nicaragua. The jealous Pedrarias forced him to flee to Santo Domingo before a Spanish colony could be planted, however, and instead sent Francisco Hernández de Córdoba in 1524, who established Granada on Lake Nicaragua and León on Lake Managua. But when Córdoba attempted to set up a kingdom independent of Panama, Pedrarias came to Nicaragua himself and put Córdoba to death after a year of civil war.

While Pedrarias and Córdoba conquered lower Central America, the conqueror of Mexico, Hernán Cortés, looked southward. In 1524 he sent Cristóbal de Olid by sea to Honduras and Pedro de Alvarado overland to conquer Guatemala. Olid founded the port of Triunfo de la Cruz but immediately declared himself independent of Cortés, a common practice among the conquistadores. Accompanied by a large force of Indian warriors from central Mexico and preceded by a smallpox epidemic, Alvarado faced little opposition until he reached Guatemala. There he allied with the Cakchiquel Maya against the rival Quiché. He allegedly defeated the Quiché chief, Tecúm-Umán, in hand-to-hand combat at Xelajú, near present-day Quezaltenango. Alvarado went on to conquer the Pipil of El Salvador in the same year, but a bloody rebellion by the Cakchiquel took four more years to quell.

Internal struggle of the conquistador leaders

In Honduras a three-way struggle developed between the forces of Pedrarias, Cortés, and González, who had returned to Central America to press his claim to Nicaragua. The discovery of gold in Honduras made the struggle more intense. Cortés first sent Francisco de Las Casas to relieve the rebellious Olid, but then marched to Honduras himself to reprimand Olid. Before he arrived, however, Las Casas and González had united against Olid and put him to death. Cortés' difficult trip to Honduras thus turned out to be unnecessary, but before leaving he consolidated his control of the Honduran coast with the establishment of Puerto Natividad (renamed Puerto Cortés in 1869). The loyal Alvarado consolidated Cortés' control over Honduras as well as Guatemala and El Salvador, confronting the forces of Pedrarias, with whom rivalry continued for years.

Alvarado went on to participate in the conquests of Peru and of northern Mexico, while retaining his governorship of Guatemala. Uniquely, upon his death in 1541 in Jalisco, his widow, Beatriz de la Cueva, succeeded him as governor of Guatemala, chosen by leading officials in the Guatemalan capital upon news of Alvarado's death. The rule of Doña Beatriz, however, lasted but two days, for she died when a massive flood and mud slide destroyed the city on Sept. 10, 1541. Construction of a new capital, Santiago de los Caballeros de Guatemala (present-day Antigua, Guat.), began a few miles away in 1543.

Further conquests of the Indians. Indian resistance delayed the conquest of Costa Rica until 1561, when Juan de Cavallón led a successful colonization expedition there. Although none of his settlements in the Nicoya Bay region survived, he and his men began the permanent Spanish occupation of Costa Rica. A year later Juan Vásquez de Coronado took over as governor of Nicaragua and Costa Rica, and in 1564 he established Cartago as the seat of government in the central valley of Costa Rica, where a small but industrious population developed.

Spanish domination of Central America was achieved by relatively few Spanish military forces, but at a cost of millions of Indian lives. Remote areas, however, especially in northern Guatemala and along the Caribbean coast, remained outside Spanish control throughout the colonial period, eventually allowing Great Britain to colonize Belize and the Mosquito Coast of Nicaragua.

Reforms of Bartolomé de Las Casas

Yet the conquest was not entirely military. A Dominican friar, Bartolomé de Las Casas, made a notable effort to ameliorate treatment of the Indians in Central America. The brutality of the Spanish conquest had repelled Las Casas in the Caribbean. After his Dominican monasteries in Nicaragua and Guatemala failed to bring better treatment to the Indians, he went to a province of northern Guatemala to pacify it without military force. His experiment in this province, which he called the Verapaz, was only partially successful, but it served as the basis for his arguments to the Spanish crown against abuse of the Indians. The resulting New Laws of 1542 began the suppression of the encomienda system of exploitation of Indian labour.

THE HABSBURG PERIOD (1524–1700)

Unification of the isthmus. Political jurisdiction over Central America under Spanish rule evolved slowly because of the rivalries among conquistadores. These rivalries led to violence and civil war among the Spaniards in the early years of colonial rule and retarded the unification of Central America. Decentralization of authority characterized the Habsburg period, despite royal efforts to maintain close control through its agents. Municipal councils (ayuntamientos) were the most important governing units in the early days. By 1530 Guatemala, Nicaragua, Honduras, Chiapas, and Panama all functioned under separate royal orders, but the death of Pedrarias in 1531 and the prestige of Alvarado contributed to the unification of the isthmus thereafter. In 1535 the establishment of the Viceroyalty of New Spain at Mexico City included the northern portion of Central America, but the establishment of an audiencia at Panama in the same year continued the confusion over jurisdiction in Nicaragua. In 1543 Spain unified the entire isthmus from Tabasco and Yucatán to Panama as the Audiencia de los Confines, with its capital centrally located in Honduras in 1544 at the gold-mining boomtown of Gracias. The gold soon gave out, however, and the town was otherwise isolated and remote. Responding to protests from Panama City and Santiago de Guatemala, in 1548 the crown moved the capital back to Santiago. Philip II moved the capital to Panama from 1563 to 1567, but finally, after removing Panama, Tabasco, and Yucatán from its jurisdiction, he restored Santiago as the capital of the Kingdom of Guatemala, stretching from Chiapas to Costa Rica.

Development of Guatemalan dominance

Rise of the Creole elite. Santiago grew to become the third largest city in the hemisphere (after Mexico City and Lima), and established itself as a bureaucratic, ecclesiastical, and commercial metropolis. The Creole elite that emerged there favoured the development of Guatemala over the other provinces of the kingdom, causing provincial resentment and contributing to the eventual political fragmentation of the isthmus. Royal authority over the region was exercised by an audiencia, presided over by the royally appointed president, who also carried the titles of governor and captain general. Creole power was centred in the municipal council of Santiago and in their control of the land and labour of the Indians through the institutions of encomienda and repartimiento, which involved the collection of tribute and forced labour. While Creole elites developed in each province as well, and their bloodlines often were connected to the Guatemalan elite, the provincial elites were less wealthy and powerful than their Guatemalan counterparts. The Roman Catholic church participated closely with the state in developing colonial Central America, but it was strongest near the seats of authority and weakest in remote areas such as Costa Rica.

Colonial economy and society. Spain encouraged the mining of precious metals, but Central American deposits were thin, and agriculture came to dominate the economy of the colony. Cacao, mostly grown on the Pacific coast, was the principal export of the 16th century, but in the 17th century it declined because of competition from areas with better access to markets. Indigo eventually replaced it as the principal Central American export. Yet most people were involved only in subsistence agriculture, with large haciendas, in feudal style, raising cattle and grains for the local population. In the 17th century especially, as European rivals and Caribbean-based buccaneers raided Spanish commerce and shore settlements, the Kingdom of Guatemala withdrew into a self-sufficient, feudallike existence.

The colonial social structure that became entrenched during the Habsburg period thus comprised two small upper classes, one representing official Spanish administrative and ecclesiastical authority and the other the Creole landholding elite, with a large mass of Indian or mestizo rural workers tied to the land. There were also small numbers of African slaves brought during the colonial period. In the cities there were small middle sectors of artisans, provisioners, and wage labourers, but they did not constitute a true middle class. Nor were the professionals of the cities a middle class, for they were more clearly associated with one or the other of the two upper classes.

Importance of Panama

In Panama the river and mule trail across the isthmus was the principal economic resource for the commercial and bureaucratic elite that developed there. As the link between Europe and the rich mines of Peru, Panama was of strategic importance and received considerable military protection against attacks from marauding buccaneers such as the Welshman Henry Morgan, whose destruction of Panama City caused the Spanish to move the city several miles and rebuild it in 1671. Politically, Panama was tied to the Viceroyalty of Peru until the 18th century, when it was included in the new Viceroyalty of New Granada, with its capital at Bogotá. Panama's importance as a commercial and slave-trading centre justified its having its own audiencia from 1753.

THE BOURBON CENTURY (1701–1808)

Accession to the Spanish throne by the Bourbon Philip V at the beginning of the 18th century plunged the empire into a costly war, opening a century in which war and international rivalry seriously altered Central American history. The close relations of the Bourbons to France and the penetration of Central America by English traders, especially via their settlements at Belize and the Mosquito Coast, brought significant foreign commercial, administrative, military, and ideological influences. While the Spanish may have diffused the Enlightenment, it nonetheless contributed to vital changes in Creole thinking. Bourbon policy, especially after 1750, was directly responsible for much of the change, as it centralized authority and reasserted the royal control that had diminished during the previous century, while beginning to limit the political and economic power of the clergy. It also built up the military and promoted agricultural exports, especially of Salvadoran indigo, but also of Costa Rican cacao and tobacco. The Bourbon emphasis on exports began a trend in Central American economic history that would continue to the present. Indeed, the Bourbon reforms not only laid the foundation for much of Central America's political and economic development in the 19th century but they also heightened the strong regionalism on the isthmus, as provincial elites resisted the growing power of the Guatemalan mercantile and bureaucratic establishment.

An earthquake destroyed Santiago de Guatemala in 1773, causing the capital to be moved to the present site of

Guatemala City in 1776. As the century closed, the growing preference of the crown for appointment of Spaniards contributed to Creole resentment against royal policy. At the same time, there emerged in the Guatemalan capital a group of progressive Central Americans who promoted liberal economic and political ideas, especially through the publication of the *Gazeta de Guatemala* beginning in 1793 and the establishment of an economic society in 1795.

INDEPENDENCE (1808–23)

Disruption of European wars

Despite revitalization of the colonial economy and of Spanish military strength under the Bourbons, the French Revolution and subsequent Napoleonic Wars brought disintegration to Spain's empire. The Kingdom of Guatemala suffered hard times resulting from the disruption of Spanish shipping in the war. Combined with locust plagues and competition from other producing areas, this caused a decline in indigo exports during the first two decades of the 19th century. The French invasion of Spain in 1808 increased the difficulties by adding burdensome taxes and demands for "patriotic donations" to support the resistance against the French; nevertheless, the kingdom remained loyal to the Spanish government at Cádiz during these difficult years. That government, ruling in the name of the captive Prince Ferdinand, made major reforms in an effort to maintain colonial loyalty and support. The Cádiz Constitution of 1812 provided for colonial representation in the Spanish parliament and elections for municipal and provincial offices. These innovations triggered intense political activity, greatly increasing the importance of municipal and provincial councils and laying the foundations for Creole democracy.

A strong captain general, José de Bustamante y Guerra (1811–18), and Creole fear of Indian uprisings were factors that prevented Central Americans from seizing power as had been done in South America. The government easily put down such attempts in San Salvador, Nicaragua, and Guatemala. In 1814, after the defeat of Napoleon, Ferdinand VII promptly annulled the 1812 constitution. This ungrateful act caused Creole opposition to Spanish rule in Central America to mount, especially against the repressive rule of Bustamante. The restoration of the constitution in 1820 once more permitted popular political activity in Central American towns and led to the emergence of factions that would form the basis of the Liberal and Conservative parties destined to dominate Central America for the following century.

A council of notables in Guatemala City accepted the independence plan of the Mexican Creole Agustín Iturbide on Sept. 15, 1821, but there were wide differences among the municipalities on the next step. Some favoured independence from Mexico as well as from Spain, and some of the provinces wanted independence from Guatemala as well. This divisive action by the municipalities was a product of their newly acquired vitality under the constitution, but it also reflected their resentment against centralized authority in Guatemala. Conservatives in Guatemala succeeded in annexing the kingdom to Iturbide's Mexican empire, but this led immediately to civil war, as San Salvador and Granada refused to accept the decision. Mexican and Guatemalan troops subdued San Salvador after a long siege, but in the meantime Iturbide's empire collapsed and was succeeded by a liberal republic that allowed Central America to go its own way.

THE UNITED PROVINCES (1823–40)

The assembly of July 1, 1823

A Liberal-dominated assembly elected from all the provinces convened in Guatemala, and on July 1, 1823, it declared the independence of the former kingdom under the name the United Provinces of Central America. In 1824 it adopted the Constitution of the Federal Republic of Central America, a document similar to the Spanish Constitution of 1812, providing for a federation of Guatemala, El Salvador, Honduras, Nicaragua, and Costa Rica. Chiapas had elected to stay with Mexico, and Panama had become part of the Republic of Colombia in 1821.

The first election. The 1824 constitution provided for a single-house legislature and reserved considerable autonomy to the states, yet it offered an adequate framework for a strong union. Political difficulties from the outset and the failure of federal leaders to enforce the constitutional provisions led to its disintegration. The provincial jealousies and ideological differences that had emerged in the late colonial period had already sown the seeds of Central American disunion. The first presidential election, in 1825, was disputed and began a pattern of civil war and bad faith. Manuel José Arce, a liberal Salvadoran army officer, won that election over a moderate Honduran attorney and prominent intellectual, José Cecilio del Valle, despite the appearance that del Valle had more popular votes. The intrigue connected with the electoral process alienated not only Conservatives supporting del Valle but also extreme Liberals who accused Arce of selling out to Conservatives in the congress in order to gain their votes. Arce did, in fact, ally himself with Conservative interests in Guatemala City. When he deposed the Liberal Guatemalan state governor, Juan Barrundia, and replaced him with a staunch Conservative, the Salvadoran state government rebelled, touching off a civil war from 1826 to 1829. The bloody struggle established animosities between Conservatives and Liberals throughout the federation that would last well beyond the brief life of the United Provinces. The Honduran general Francisco Morazán led the Liberals to victory in 1829. Under his presidency during the decade following, the Liberals exiled leading Conservatives, including the archbishop and other clergy, and instituted sweeping anticlerical, economic, social, educational, and judicial reforms. Morazán also moved the federal capital to San Salvador in 1834.

Rebellion of Anastasio Aquino

Morazán's presidency. Resistance to Liberal policies against Indian interests surfaced in El Salvador in the rebellion of the Indian leader Anastasio Aquino beginning in 1833, but Morazán succeeded in repressing this insurrection. In the presidential election of 1834, the opposition candidate José Cecilio del Valle defeated Morazán, but he died before taking office, leaving Morazán as president. In Guatemala, opposition to the Liberal policies of Governor Mariano Gálvez, including anticlericalism, encouragement of foreign immigration, land grants, judicial reform, and a general head tax, combined with panic caused by a cholera epidemic, led to peasant revolts beginning in 1837. Behind the charismatic leadership of Rafael Carrera, the peasants not only toppled Gálvez but also sharply divided the Liberals in Guatemala and allowed the Conservatives to gain control. Taking advantage of these problems, the western departments of Guatemala, under Liberal leadership, seceded and formed a sixth state, called Los Altos. Carrera quickly reconquered these departments in January 1840, however, and when Morazán brought federal troops into the conflict, Carrera defeated him soundly at Guatemala City in March 1840. The federation was already in disarray, as Nicaragua, Honduras, and Costa Rica had seceded in 1838. Morazán fled to Panama.

FORMATION OF THE REPUBLICS (C. 1840–C. 1870)

Rafael Carrera quickly dismantled the Liberal program in Guatemala and supported Conservative caudillos in other Central American states. Although many gave lip service to reunification, all attempts failed, and Conservative rulers in all the states opposed reunification.

Morazán returned in 1842 and seized power in Costa Rica, seeking to make it a base for restoration of the federation. He found little support for this and was himself ousted by Costa Rican Conservatives and executed in San José on Sept. 15, 1842.

In 1847 Guatemala declared itself a sovereign republic, quickly followed by Costa Rica in 1848, and eventually by the other regional states. The alliance of Nicaraguan Liberals with the American filibuster William Walker in 1855 caused Central Americans from all five states to unite against Walker, who made himself president of Nicaragua in 1856. In what became known as the "National War," this united army defeated Walker in 1857. Yet attempts to turn this united effort into a new federal union gained little support from the Conservative elites in each state; thus, the most lasting legacy of the Conservative period was the fragmentation of the United Provinces into the five city-state republics. The middle of the century also witnessed strong British-U.S. rivalry in Central America for commercial rights and control of transisthmian transportation routes. Early 19th-century British commercial dominance later gave way to U.S. economic, diplomatic, cultural, and military dominance in the region.

THE LIBERAL PERIOD (C. 1870–C. 1945)

The death of Rafael Carrera in 1865 signaled a Liberal resurgence throughout Central America. By 1872 the Liberals had returned to power in all the states except Nicaragua, where the legacy of alliance with William Walker had so discredited the Liberals that it delayed their return to power until 1893. Liberal domination of Central America from about 1870 through the mid-20th century resulted in a completion of anticlerical reform and strong emphasis on agricultural exports as the key to national modernization. Coffee became the most important commodity promoted by Liberals, and it supported the rise of planter elites in most of the states. Banana exports, developed in the coastal regions by U.S. fruit companies (notably United, Standard Fruit and Steamship, and Cuyamel) in collaboration with the Liberals, also were important in developing the transportation and communications infrastructure and in bringing Central America more fully into the North Atlantic trading economy. Despite their Liberal political rhetoric, military dictatorships were the characteristic political institution of the period, as the planter elites depended on greater military strength to defend their interests.

Liberal agricultural export emphasis

MODERN CENTRAL AMERICA (C. 1945 TO THE PRESENT)

By the middle of the 20th century the powerful political and economic elites associated with the export-led economies promoted by the Liberal parties faced strong challenges from middle- and working-class representatives. This challenge to the elite parties took many forms, from formation of broader-based political parties to violent revolution, accounting for most of the political crises of the mid- and late 20th century. The demands for significant socioeconomic reforms brought revolts to every state, and Central American politics in the late 20th century became characterized by strong conflict between free market and Marxist development models. Also influencing political trends was the growth of Evangelical Protestantism.

Although the Liberals had traditionally favoured unification, the strength of the local elites in each of the republics prevented numerous attempts at reunification from succeeding even under Liberal rule. Modern manifestations of the continued concept of Central American nationalism and desire for unification were seen, however, in the formation of the Organization of Central American States in 1951, followed by the formation of the Central American Common Market in 1960 and the 1987 Central American peace plan, also called Esquipulas II, instigated by President Oscar Arias Sânchez of Costa Rica. The latter included plans for a Central American national parliament along lines similar to the European unification plan. While state sovereignty and the strength of the individual city-state elites remain strongly rooted in the Central American political tradition, there continues to be a strong residue of sympathy for Central American reunification. (R.L.W.)

THE COUNTRIES OF CENTRAL AMERICA

Belize

Belize (called Belice in neighbouring Spanish-speaking countries), a constitutional monarchy and a member of the Commonwealth, is located on the east coast of Central America. After El Salvador, it is the smallest political unit on the mainland of the Americas. It has an area of 8,867 square miles (22,965 square kilometres). To the north and northwest, it is bounded by Mexico, to the south and west by Guatemala, and to the east by the Caribbean Sea, on which it has a 174-mile (280-kilometre) coastline. Belize City was ravaged by a hurricane in 1961, and in 1970 a new capital, called Belmopan, was built about 50 miles (80 kilometres) inland. Belize was the last British colony on the American mainland and achieved independence Sept. 21, 1981.

The name Belize is traditionally believed to have been derived from the Spanish pronunciation of the last name of Peter Wallace, a Scottish buccaneer who may have begun a settlement at the mouth of the Belize River about 1638. It is also possible, however, to trace the name to any of several Mayan words.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief and drainage.* Situated south of the Yucatán Peninsula, Belize is a land of mountains, swamps, and tropical jungle. The southern half of the country is dominated by the rugged Maya Mountains, an igneous plateau cut by erosion into hills and valleys that stretch in a southwesterly to northeasterly direction. The Cockscomb Range, a spur of the Maya Mountains, runs toward the sea, culminating in Victoria Peak (3,681 feet [1,122 metres] high), the highest point in Belize. The northern half of the country consists of limestone lowlands less than 200 feet (60 metres) above sea level, much of which are swamp. The lowlands are drained by the navigable Belize River (on which stands Belize City), the New River, and the Hondo River; the latter forms the northern frontier with Mexico. Both the New and the Hondo rivers drain into Chetumal Bay to the north. South of Belize City the coastal plain is crossed by short river valleys. About 15 miles off the coast the second largest barrier reef in the world runs parallel to the coast and is fringed by dozens of small islands called cays.

The Maya and Cockscomb mountains

Climate. Belize has a subtropical climate, with a well-marked dry season from late February to May and a wet season from June to November that is interrupted from August to September by another dry season. The mean temperature at Belize City is 74° F (23° C) in December and 84° F (27° C) in July. The mean annual rainfall increases sharply from 51 inches (1,295 millimetres) at Corozal on the northern frontier to 175 inches (4,445 millimetres) at Punta Gorda in the south. At Belize City

rainfall amounts to 74 inches (1,880 millimetres), but there are, here as elsewhere, considerable yearly variations. Trade winds blow onshore most of the year, and from September to December northerly winds bring cooler, drier air. Hurricanes are a threat from July through November.

Plant and animal life. Almost half of Belize consists of forests. There are at least 50 different forest tree species, which include mahogany, Santa Maria, cedar, and ironwood. In the north limestone soils support deciduous forest, and sapodilla and mahogany predominate. In the south the forest is taller and is evergreen. Santa Maria, rather than mahogany, flourishes on the plateau, and oak and pine grow on some of the plateau ridges. The rivers are largely bordered by swamp forests. On the southern coastal plain and inland from Belize City, open savanna (grassland) is marked by scattered oaks, pines, and palmetto palms. The coast is fringed with mangrove trees.

The abundant wildlife of Belize includes such animals as deer, jaguar, puma, tapir, American crocodile, and manatee, as well as many species of turtles, tortoises, birds, reptiles, insects, and fish.

Farm types

Settlement patterns. Only a small proportion of the land is actively utilized, and a substantial part of this is agricultural land. Nearly all the farms are less than 100 acres (40 hectares) in area, many of them *milpas* (temporary forest clearings). On most of these farms, traditional shifting agriculture is practiced, largely because of the nutrient-poor soils of the lowlands. The remaining farms or plantations are large, devoted to the raising of export crops, mainly sugarcane, citrus fruits, and bananas. In the 20th century, the government has tried to increase the production of export and domestic crops. The highlands are mostly forested and largely uninhabited.

Belize City, the former capital and most populous town, is located just above sea level and is surrounded by a mangrove swamp. Its growth has been unplanned, and it contains a mixture of old colonial structures, wooden frame buildings, and new concrete houses.

The people. Many Belizeans are of racially mixed ancestry. English-speaking people of largely African and European ancestry, who are called Creoles, predominate in the central coastal regions, while Maya Indians and mestizos (of mixed Maya and European ancestry) predominate in the more sparsely inhabited interior. Several thousand Garifuna, formerly called Black Caribs, who are descendants of the Carib Indians and Africans exiled from British colonies in the eastern Caribbean (Lesser Antilles) in the 18th century, live in communities on the south coast.

English is the official language, but most of the population also speak a Creole patois. The mestizos speak Spanish, and the Maya speak Spanish or Yucatec, Mopan, or Kekchi Maya. The Garifuna speak their own Arawakan-based language and also English or Spanish. Many Belizeans are multilingual.

Anglicans, who established the first church in the early 19th century, were soon followed by Baptist and Methodist missionaries. The Roman Catholic church was established in 1851, and more than three-fifths of the population are adherents of that religion. The next largest denominations are Anglican and Methodist, but evangelical and fundamentalist churches, many of them based in the United States, are growing rapidly.

Immigration

Migration patterns are changing the ethnic composition of the population. Groups of Mennonites migrated from Mexico and Canada after 1958 and established agricultural settlements to the north and west of Belize City. In the 1980s, an estimated 25,000 Spanish-speaking refugees, mostly from Guatemala and El Salvador, settled in Belize, while an even larger number of Belizeans, mostly Creole, migrated to the United States.

The economy. *Agriculture, forestry, and fishing.* The export of timber was for years the basis of the Belizean economy, but by 1960 the combined value of sugar and citrus exports exceeded that of timber. Chicle, used in the manufacture of chewing gum, is obtained from the sapodilla tree, and mahogany, pine, cedar, and rosewood have increased in economic importance. Furniture and power and telephone poles are the major products of the forestry industry, which includes many sawmills.

More than one-fourth of the population is engaged in agriculture. Sugarcane is grown in Corozal and Orange Walk districts, and sugar is exported to the United States and the European Economic Community. Citrus fruits (oranges and grapefruit) and bananas are grown mainly in the Stann Creek and Cayo areas, south and west of Belize City. Rice is raised on large mechanized farms in the Belize River valley, while corn (maize), roots and tubers, red kidney beans, and vegetables are raised throughout the country, mostly by small farmers. Marijuana is widely, though illegally, grown in Belize for illegal export to the United States.

The Mennonite community at Spanish Lookout has developed fresh milk and cheese production and has introduced large-scale chicken farming. Beef cattle and pigs are raised in many parts of Belize.

Fishing for lobster, shrimp, scale fish, conch, and sea turtles is conducted mainly by several cooperatives, some of which have freezing plants. Exports of seafood to the United States are substantial.

Industry. Manufacturing, accounting for about one-eighth of the gross national product (GNP), is oriented toward both the domestic and export markets. The Belize government has stressed the substitution of imports to promote industrial development. Fertilizer and animal feed plants have been opened, while the numerous sawmills, a wire and nail plant, and a roofing-material plant serve the construction and furniture-manufacturing industries. Footwear, beer, soft drinks, and cigarettes are also produced. Food-processing industries include a sugar refinery at Tower Hill, citrus-processing plants in the Stann Creek district area, beef-packing and rice-processing plants, and fish-freezing and canning factories. Garment factories utilizing imported fabric produce clothing for the export market.

Transportation. Agricultural and forest produce is usually transported by road, although rivers are still used. The road network extends west to the Guatemalan border and north to the Mexican border. All-weather roads link Belize City and Belmopan with other towns in the central and northern areas of Belize and with Punta Gorda on the southern coast.

The ports

Belize City is the main port but does not have modern facilities; vessels with more than the allowable draft must still anchor more than a mile offshore. Another port, at Commerce Bight, handles the citrus exports of the Stann Creek district; smaller ports are at Riversdale and Big Creek, and Punta Gorda handles seaborne trade with Guatemala and Honduras.

The Philip S.W. Goldson International Airport is about nine miles from Belize City; scheduled flights link it to the United States, Mexico, and other countries of Central America, and to the Caribbean through Jamaica. There are also scheduled domestic flights to Belmopan and other major towns, including Independence (near Big Creek) and San Pedro on Ambergris Cay.

Government and social conditions. The structure of government is based on the British parliamentary system, and the legal system is based upon the common law of England. The 1981 constitution provides for universal suffrage for citizens over the age of 18 and for a bicameral National Assembly composed of an elected House of Representatives with 28 members and an appointed Senate with 8 members. General elections to the House must be held within five years of the preceeding election. The governor-general, a Belizean national who represents the British crown, normally appoints as prime minister the leader of the majority party in the House and an opposition leader from the minority party. The prime minister appoints the Cabinet. Local government consists of the Belize City Council and six town boards with authority over most municipal affairs. Most villages have councils, and some Maya villages have an *alcalde* (mayor) with limited powers. A chief justice heads the Supreme Court, the nation's highest court, which is independent of the national government.

The vast majority of the population over 15 years of age is literate. Primary schooling is compulsory between the ages of 6 and 14. Most schools are government-subsidized denominational schools, chiefly Roman Catholic, and the Mennonites operate their own schools. About one-third of the secondary schools are run by the government, and the remainder are managed by the churches. About half of the primary-school graduates go on to secondary school, but only a tiny elite receive any higher education. The University College of Belize and an extramural department of the University of the West Indies in Belize City provide postsecondary education.

Health and welfare

The majority of Belizeans have access to government hospitals, clinics, and maternal, child-care, and dental facilities. As a result the people's health has improved. Infant mortality rates, in particular, have been reduced by improved water supplies, waste disposal systems, and disease control and vaccination programs. Malaria, however, remains a problem. Nurses are trained locally, but there remains a shortage of doctors and dentists, especially in the rural areas. A new social security program was created in the 1980s to provide pensions for senior citizens and to extend assistance to pregnant, sick, disabled, and unemployed workers and to the survivors of deceased insured workers.

Cultural life. The small population of Belize is culturally diverse. Most of the people are the descendants of immigrants from Europe, Africa, and India, as well as of the indigenous Maya, and of the various mixtures of these peoples. The multiplicity of languages, religions, modes of dress, cuisines, styles of music, and folklore reflects the cultural mix. While there are many ethnically distinct communities, people of different groups also mix in many social contexts: at work, in schools, and in the political parties that are not ethnically based. Though prejudices exist, there is no history of interracial or interethnic violence in Belize.

Since World War II, Belizeans have created a variety of institutions to meet their social and cultural needs, including trade unions, credit unions, cooperatives, and many other nongovernmental organizations that address the needs of health care, social services, women's rights, education, and community development.

The Baron Bliss Institute in Belize City promotes the arts and houses a small archaeological museum and the National Library Service, which has branches in the districts and operates mobile libraries throughout the country. The national archives are in Belmopan.

The government-operated Belize Radio broadcasts in Spanish and English. There is no national television station, but Belize receives U.S. channels via satellite. Most of the nation's several weekly newspapers are politically affiliated. Press censorship is minimal, but most of the journalism is of poor quality, and Belize relies heavily on external, chiefly U.S., news sources. *Belizean Studies,* a journal published three times a year by St. John's College (a secondary school), is an outlet for local research and writing, as is Cubola Productions, which publishes both fiction and nonfiction. The Society for the Promotion of Education and Research (SPEAR) publishes books and reports and a monthly newspaper on Belizean issues.

(A.E.A./O.N.B.)

For statistical data on the land and people of Belize, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL.

HISTORY

Maya Indians lived in the area now known as Belize for centuries before the arrival of Europeans. The Spanish penetrated the area in the 16th and 17th centuries and tried to convert the Maya to Christianity, but with little success. It was British buccaneers and logwood cutters who finally settled on the inhospitable coast in the mid-17th century.

British treaty rights for logwood

Spain regarded the British as interlopers in their territory. By treaties signed in 1763 and 1783, Spain granted to British subjects the privilege of exploiting logwood and, after 1786, the more valuable mahogany, within specified but poorly surveyed limits. Spain retained sovereignty over the area, which Britain called a settlement, as distinct from a formal colony. While formal government was not allowed by Spain, the British settlers conducted their affairs with a public meeting and elected magistrates. Superintendents, appointed by the British government after 1786, slowly established their executive authority at the expense of the settlers' oligarchy. In 1798 the British defeated the last attempt of Spain to remove them by force, and Belize became a colony in all but name. The superintendent was instructed by the British government to assume authority over the granting of land in 1817, and he assumed the power to appoint magistrates in 1832. In 1854 a constitution formally created a Legislative Assembly of 18 members elected by a limited franchise, and the next year the Laws in Force Act validated the settlers' land titles.

Guatemala challenged the British occupation on the grounds that it had inherited Spanish interests in the area, and from time to time Mexico also asserted a claim to part of Belize. Great Britain and Guatemala appeared to have settled their differences in 1859 by a treaty that defined boundaries for Belize. The final article of the treaty, however, bound both parties to establish "the easiest communication" between Guatemala and Belize. When the communication route was not developed, Guatemala insisted that the entire treaty was thus invalidated and asserted a claim to possession of the whole territory.

Britain proclaimed Belize to be the colony of British Honduras in 1862 and a crown colony in 1871, when the Legislative Assembly was abolished. British Honduras remained subordinate to Jamaica until 1884, when it acquired a separate colonial administration under an appointed governor.

The British settlers, who called themselves Baymen, began importing African slaves in the early 18th century to cut logwood and then mahogany. Although the conditions and organization of labour in timber extraction were different from those on plantations, the system of slavery was cruel and oppressive. There were four slave revolts in Belize, and hundreds of slaves took advantage of the terrain and the freedom offered over the frontiers to escape. A flourishing transit trade with neighbouring Spanish Central America, established early in the 19th century, continued after the Spanish colonies attained independence in the 1820s, but plantations, which were forbidden by the treaties with Spain, were not developed. After emancipation in 1838, the former slaves remained tied to the logging operations by a system of wage advances and company stores that induced indebtedness and dependency. When the old economy, based on forest products and the transit trade, declined in the mid-19th century, these Creole freedmen remained very poor.

Plight of freed slaves

Beginning in the early 19th century, Garifuna immigrants settled on the southern coast of Belize. The Caste War in Yucatán between 1847 and 1853 resulted in several thousand Spanish-speaking refugees settling in northern Belize, while Maya communities were reestablished in the north and west. These immigrants introduced a variety of agricultural developments, including traditional subsistence farming and the beginning of sugar, banana, and citrus production. In the 1860s and '70s the owners of sugar estates sponsored the immigration of several hundred Chinese and East Indian labourers. In the late 19th century Mopan and Kekchi Maya, fleeing from oppression in Guatemala, established largely self-sufficient communities in southern and western Belize.

By the early 20th century, the ethnic mixture of Belize was established, but the economy was stagnant and crown colony government precluded any democratic participation. In the 1930s, the economy was hit by the depression, and Belize City was largely destroyed by a hurricane in 1931. A series of strikes and demonstrations by labourers and the unemployed gave rise to a trade union and to demands for democratization. The elective principle was reintroduced in 1936, but property, literacy, and gender qualifications severely limited the franchise. When the governor used his reserve powers to devalue the currency at the end of 1949, leaders of the trade union and the Creole middle class joined in a People's Committee to demand constitutional changes. The People's United Party (PUP) and its leader, George Price, emerged from the committee in 1950 and led the independence movement.

Belize evolved through several stages of decolonization, from universal adult suffrage in 1954 to a new constitution and internal self-government in 1964, when Price, who had been called first minister, became premier. Unrelenting Guatemalan hostility, however, impeded independence. In the 1970s, Belize internationalized its case for self-determination at the United Nations and in the Nonaligned Movement. Although the dispute between Guatemala and Great Britain remained unresolved, Belize became independent on Sept. 21, 1981. Belize was admitted to the United Nations but has been denied membership in the Organization of American States because of a rule that bars admission to states involved in territorial disputes with another member. Because the Belize Defence Force is small, a British military presence remains to deter Guatemalan aggression.

20th-century Belizean politics

The United Democratic Party (UDP), formed in 1973 and led by Manuel Esquivel, won the general election in 1984, but in 1989 the PUP won the election and Price again became prime minister, as the office was now called. Although democratic politics is well established in Belize, the struggling, dependent economy, the impact of regional civil wars, and the increasingly pervasive influence of the United States continue to make the developing nation of Belize highly vulnerable to the fluctuations and pressures of political and economic forces. (W.J.Gr./O.N.B.)

For later developments in the history of Belize, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

Costa Rica

A nation of the isthmus of Central America, the Republic of Costa Rica (Spanish: República de Costa Rica) is located between Nicaragua, situated on its northern border, and Panama, on its eastern border. Costa Rica's greatest length, between the two neighbouring countries, is 288 miles (463 kilometres), and, at its narrowest, the distance between the Pacific Ocean and the Caribbean Sea is 74 miles (119 kilometres). The country's total area is approximately 19,730 square miles (51,100 square kilometres).

Costa Rica played a role in the federation of Central American states from 1823 to 1838 and is a member of the Organization of Central American States founded in 1951. Of the states that have been partners in these two enterprises, Costa Rica is the most Spanish in character and is generally regarded as having the most stable government and economy. Its well-populated heartland is devoted to harvests of coffee, its most important product, while in its outlying reaches banana cultivation is most significant. The capital is San José.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* Two mountain chains together run almost the entire length of Costa Rica. These are, in the north, the Cordillera Volcánica, noted, as the name implies, for its volcanic activity, and, in the south, the Cordillera de Talamanca. The Cordillera Volcánica may be divided into three ranges: from northwest to southeast, the Cordillera de Guanacaste, the Cordillera de Tilarán, and the Cordillera Central. The Cordillera de Talamanca is a massive granite batholith, quite different geologically from the volcanically active northern ranges. Costa Rica's highest point is Mount Chirripó, in the Talamanca system, at 12,533 feet (3,820 metres). Two of the highest peaks in the Cordillera Volcánica, Irazú (11,260 feet) and Poás (8,871 feet), have paved roads reaching to the rims of their active craters. These volcanoes overlook the densely populated upland basin called the Meseta Central (Valle Central), and they pose a serious natural hazard, as do earthquakes for most parts of the country.

Meseta Central

The Meseta Central is separated into two parts by the continental divide. The eastern part is drained by the Reventazón River to the Caribbean, and the western sector forms part of the basin of the Río Grande de Tárcoles, which flows into the Pacific. Another large structural valley, the Valle del General, lies at the base of the Cordillera de Talamanca in the southern part of the country. To the north and east of the mountainous central spine lie the Caribbean lowlands, about one-fifth of the country and less than 400 feet in altitude. The Pacific lowlands, which contain several small valleys and plains, include only about one-tenth of Costa Rica's territory.

© Elizabeth Harris from TSW—CLICK/Chicago

Climate. Thermal convection and onshore breezes bring abundant rains to the Pacific coast in the wet season, generally May to October in the north and April to December in the south. Northeasterly trade winds on the Caribbean provide ample year-round precipitation. The higher mountain ranges have warm temperate climates, the Pacific slopes having alternatingly wet and dry seasons, while the Caribbean side has year-round rainfall.

San José's weather records report monthly averages of rainfall from well under 1 inch (25 millimetres) in February to more than 12 inches (300 millimetres) in September, with more than 70 inches (1,800 millimetres) the yearly average. Temperatures vary with altitude, San José at 3,760 feet reporting a mean of 69° F (21° C), a nearby station at 7,665 feet reporting a mean of 59° F (15° C), and another at 682 feet reporting a mean of 80° F (27° C).

Plant and animal life. Dense broad-leaved evergreen forest, which includes mahogany and tropical cedar trees, covers about one-third of the landscape. On the Talamanca range grow numerous evergreen oaks and, above the timberline, mountain scrub and grasses. The northwest, with the longest dry season, contains open deciduous forest. Palm trees are common on the Caribbean coastline, and mangroves grow on the shallow, protected shores of the Nicoya and Dulce gulfs along the Pacific.

Mammalian life is both abundant and varied and has major ties to South and North American populations. The South American species include monkeys, anteaters, and sloths; the North American, deer, wildcats, weasels, otters, coyotes, and foxes. There is a wide variety of tropical birds in the lowlands, and reptiles, such as snakes and iguanas, and frogs are common.

19th-century coffee-based expansion

Settlement patterns. Since the beginnings of European colonization, the Meseta Central has been the heartland of Costa Rica. In the 19th century, settlement slowly expanded from the core areas around Cartago and San José, the capital, into the western parts of the valley. This expansion was based on coffee production from small family farms. Such farms still prevail; more than half of Costa Rica's coffee farms are 10 acres (4 hectares) or less in size, a factor that contributes to the democratic heritage for which the country is famed.

During the 20th century, Costa Rica's settlement frontiers expanded outward rapidly from the Meseta Central to incorporate peripheral areas, until virtually all the suitable lands in the country were settled and the spread of population effectively ended.

In the Caribbean lowlands the banana industry thrived from the 1880s until the 1920s, when disease forced closure of the plantations. New, disease-resistant varieties of bananas allowed reestablishment of the Caribbean plantations in the late 1950s, thus reviving the economy. The southern Pacific coastal region was opened for settlement about 1938 by the development of banana plantations around Parrita and Golfito. After World War II, banana production declined, and the last Pacific region company-owned plantations were closed or planted in oil palm by 1985. Elsewhere in the south, habitation of the Valle del General increased rapidly following construction of the Inter-American Highway during the 1950s.

The San Carlos Plain, part of the northern lowlands, was settled mainly after 1945, when roads connected it with the Meseta Central. In the 1970s and '80s more new roads brought additional expansion of agriculture and cattle grazing to this fertile area.

The northwestern *provincia* of Guanacaste, where many people work on large cattle ranches, or haciendas, and also maintain small agricultural plots of their own, was once a part of Nicaragua and still retains a variety of Nicaraguan cultural influences. In many ways, this is the least traditionally Costa Rican part of the country.

San José is the only true metropolitan area in Costa Rica. The congested downtown contains the major stores, government buildings, and offices of many businesses. The few high-rise buildings are located in this city-centre area. Outside the downtown, San José has expanded outward to incorporate surrounding towns. The San José metropolitan area, which contains overall about half of Costa Rica's population, is a functionally integrated urban region that reaches from Alajuela on the west to Cartago on the east.

The people. *Ethnic and religious groups.* Costa Rica is noted for having the largest percentage of Spanish population in Central America. The Meseta Central, with more than half the nation's population, is the most predominantly Spanish region in both its manner of living and its ancestry. Spanish is spoken with distinctive national accents and usages. In Central America, a Costa Rican is called a Tico, for Costa Ricans replace the diminutive ending *-tito* with *-tico,* a practice known elsewhere but uncommon in Central America.

Spanish culture in the Meseta Central

The population of Guanacaste *provincia,* which makes up about 8 percent of the country's total, is a blend of colonial Spanish, Indian, and African peoples; their spoken Spanish is more like that of Nicaragua than that of the Meseta Central.

People of African ancestry live mostly in the Caribbean lowland *provincia* of Limón, which contains overall about 7 percent of Costa Rica's population. They are the descendants of workers brought from the West Indies to build railroads and raise bananas, and most of them speak both Spanish and a Jamaican style of English, the majority being descended from people who came from that island. There are also a substantial number of Chinese, many of whom are also the descendants of imported labourers.

Less than 1 percent of Costa Rica's population is Amerindian. The Bribrí and Cabécar peoples are the most numerous and inhabit valleys in the Cordillera de Talamanca. The Boruca and Térraba groups live in the hills around the Valle del General. There are also a few hundred Guatuso peoples living on the northern plains in Alajuela *provincia.* Most of Costa Rica's Indians are rapidly becoming assimilated, but those on the Caribbean side in the southern Talamanca region maintain their separate ways, including their animistic religions. Although Costa Rica's Amerindian groups are legally assigned to protected reserves, the land is infertile, and the Amerindians, most of whom survive through subsistence agriculture, are among the country's poorest people.

About 90 percent of Costa Ricans are Roman Catholics. Roman Catholicism is the official religion, and it is supported with a small part of the national budget. Most of the remaining population is Protestant, the majority of whom live in Limón province. A small Jewish congregation resides in San José.

Demographic trends. At the mid-20th century, Costa Rica's population growth rate was among the highest in the world. As general prosperity and urbanization increased, however, the population growth rate decreased, despite a drop in both the general and the infant mortality rates. Life expectancy is substantially longer than for most other Central American nations.

European immigration and customs have molded Costa Rican history and influenced its character. However, in the 1980s, immigration of largely mestizo refugees from Nicaragua and other Central American countries and from Cuba became important, representing a growing influence on the character of the country. Costa Rica has also become a mecca for retirees from the United States, tens of thousands of whom now live there.

The economy. Costa Rica is neither rich, as its name ("Rich Coast") implies, nor as poor as many of its neighbours. The country's wealth is better distributed among all social classes than elsewhere in Central America. Through the 1980s, the standard of living declined somewhat as a result of economic stagnation and inflation, and Costa Rica lost to Panama its place as the Central American country with the highest per capita gross national product.

Government controls

The government controls key utilities, including electricity, water, telephone, and port and rail facilities, and the entire population is eligible for free medical care, but private enterprise is still strong and influential in policy-making. Repeated efforts to diversify the economy have failed to reduce the traditional dependence on agriculture, but there has been some success at diminishing Costa Rica's reliance on the two traditional export crops, coffee and bananas. Despite stringent efforts to reduce spending, the Costa Rican government operates at a deficit, a condition that increases the country's already large international debt and high rate of inflation.

Resources. Costa Rica's agricultural land and climate are its most important natural resources. The country has few mineral resources. The most important are yet unexploited bauxite deposits in the General and Coto Brus valleys and copper in the Cordillera de Talamanca. There is manganese on and near the Nicoya Peninsula, gold on the Osa Peninsula and parts of the Pacific slopes, and magnetite on scattered beaches, particularly on the southern Caribbean coastline. Geologic conditions are promising for petroleum in the southern Caribbean coast, but exploration has proved disappointing. Much of Costa Rica's timber reserves were wastefully cleared to make way for pasture or cropland. The best remaining stands of tropical hardwoods are in protected parks and forest reserves. Hydroelectric power has the potential to supply domestic needs with enough surplus for export. The largest facility is the Arenal hydroelectric and irrigation project in Guanacaste, which opened in 1979.

Agriculture. More than one-fourth of Costa Rica's economically active people work in agriculture, which contributes about one-fifth of the national product. Coffee, from the highlands, and bananas, produced mainly in the Caribbean lowlands, are the most important crops, accounting for nearly half the total value of all exports. Beef, chiefly from the Pacific northwest, is the third largest export, but is declining in importance. Nontraditional exports of growing importance include ornamental plants and cut flowers and pineapple. Palm oil for domestic consumption is an important product from the southern Pacific lowlands. Costa Rica has the capacity to feed itself but dedicates a large share of its land to production of export crops. As a result, the country imports staples such as corn (maize) and beans, which it could produce, along with products such as wheat, for which the Costa Rican climate is not suitable.

Major manufactured items

Industry. Manufacturing contributes more than one-fifth of the gross national product and employs approximately one-sixth of the economically active population. Most industry is concentrated in the Meseta Central, but a few plants operate in Puntarenas and Limón. Food and beverage processing and textile, shoe, and furniture making are domestically important. The main items manufactured for export are clothing and cloth, medicines, thread, and electrical appliances. The textile industry grew in the late 20th century, largely owing to the development of plants making clothing from imported cloth for export to the United States.

A substantially larger number of Costa Ricans are employed in the service industries than in manufacturing. Commerce, finance and real estate, public administration, transport, construction, and utilities are other important branches of economic activity. Tourism has considerable potential and is developing.

Finance and trade. Costa Rica has both state-owned and private banks, and a national federation of savings and loan cooperatives supervises an extensive network of local agencies. There is a small national stock exchange. Insurance is a state monopoly controlled by the National Insurance Institute. Costa Rica is generally favourable toward foreign investment, and foreign-owned companies control a large segment of both agricultural and industrial production. Per capita national debt is among the largest in Central America.

Costa Rica imports wheat from the United States and corn and beans from its neighbours. Nonfood imports include insecticides and other chemicals, machinery, crude oil and petroleum products, and paper products. More than one-third of imports by value come from the United States, with most of the rest originating in Japan, Germany, Guatemala, and Venezuela.

Coffee is shipped in greatest quantity to the United States, western and central Europe, the Soviet Union, and Saudi Arabia. Bananas go chiefly to the United States, Italy, Germany, and Belgium. Other exports of importance are beef, textiles, fish and shrimp, sugar, pineapple, and cut flowers. About 40 percent of exports, by value, go to the United States; other countries receiving Costa Rican exports include Germany, Panama, the United Kingdom, and Guatemala.

Highway system

Transportation. The hub of Costa Rican transportation is the Meseta Central. A four-lane highway extends west from San José to beyond San Ramón. Another highway, completed in 1987, has greatly reduced distance and travel time between San José and the Caribbean lowlands. Elsewhere in the Meseta Central are narrow, often tortuous, paved routes, with few interconnections, that reach the many valley and mountain communities in the immediate area. National railroad lines link San José with Puntarenas and Limón. The Inter-American Highway (the Central American part of the Pan-American Highway) connects Costa Rica with the rest of Central America and beyond.

Limón and Puntarenas have new port facilities constructed at nearby Moín and Caldera, respectively. These modern facilities have rail access and are equipped to handle containerized cargo and, in the case of Moín, petroleum shipments. The southern Pacific port of Golfito, once an important banana shipping centre, handles little trade since the decline of banana production there. Limón is the busiest of the three ports.

Juan Santamaría, near San José, is the only international airport used by commercial jet planes. Tobías Bolaños Airport at Pavas, a suburb of San José, has a paved runway used by small aircraft. Paved runways at Limón, Golfito, and Liberia and gravel strips at a few other airports offer local service.

Administration and social conditions. *Government.* Costa Rica is governed by its constitution of November 1949, the 10th in its history. A president, two vice presidents, and a unicameral Legislative Assembly are elected at one time for a term of four years, the assembly by proportional representation. The president is not eligible for reelection. Magistrates of the Supreme Court are chosen by the assembly for eight-year terms, being then automatically continued in office unless removed by a two-thirds vote. An independent Supreme Electoral Tribunal oversees the election process.

The nation's seven *provincias* are administered by governors appointed by the president. Their importance is mainly as judicial and electoral jurisdictions, most government agencies having their own administrative organization that ignores provincial boundaries. Each *provincia* is divided into *cantones,* and each *cantón* into *distritos.* Councilmen for the *cantones* are elected locally, but budgets for all political units are approved by the national government, which controls nearly all the funds available to local governments.

Costa Rica has a stable democratic government. The fairness of national elections has been indicated by the fact that almost every four-year period since the mid-20th century has seen a change in the party winning the presidency. Two parties dominate: the National Liberation Party (Partido de Liberación Nacional; PLN) and the Social Christian Unity Party (Partido Unidad Social Cristiana; PUSC). The former, founded by the moderate socialist José Figueres Ferrer in 1948, was largely responsible for establishing the health, education, and welfare reforms for which Costa Rica is noted. The PUSC, a four-party coalition formed in 1977, is more conservative and business-oriented than the PLN.

System of justice

In the Costa Rican system of justice, cases may be decided by a single judge or by a panel of judges; the jury system is not used, but the courts are generally noted for their fairness. Capital punishment is banned, and sentences to the penitentiary must be for a stated number of years. The highest court is the Supreme Court of Justice. Costa Rica has no army, only a nonconscripted civil guard that has police duties. There also are district police.

Education. The constitution provides for free and compulsory education. The government oversees school attendance, curricula, and other educational matters. About one-fourth of the nation's budget is allocated to education, and literacy rates exceed 90 percent. School attendance is relatively high, with almost 90 percent of children aged 6 to 11 enrolled in primary schools and nearly 40 percent of students aged 12 to 16 enrolled in secondary schools. The University of Costa Rica has a well-planned, functional campus in San Pedro, a suburb of San José; the National University has a smaller campus in Heredia; and the "open" university (Universidad Estatal a Distancia) offers courses by television from offices in San José. The Autonomous University of Central America (founded in 1976) is also located in San José, as are several private institutions of higher education. The Technological Institute of Costa Rica, located near Cartago, provides engineering and other technical training.

Health and welfare. Costa Rica has greatly reduced the incidence of diseases associated with tropical climates. Malaria has been virtually eliminated except in the border areas with Nicaragua; water-borne diseases are rare, and mortality rates are low. The incidence of cancer and heart disease has risen, however.

Though the break between the wealthy and the manual worker is less distinct in Costa Rica than in other Central American nations, there remains a large number of agricultural and industrial workers who earn very small wages. The poorest areas are the province of Limón, the Cordillera de Talamanca, the northern lowlands, and isolated parts of the Pacific coast. The San José metropolitan area stands out as the area of greatest affluence.

Cultural life. Most Costa Rican diversions are cosmopolitan rather than nationalistic in nature. The people attend films with great frequency, enjoying international cinema. They listen to an extraordinary variety of music, especially from the many radio stations in the country. Residents of the Meseta Central attend the National Theatre, where the music played and the drama performed may come from any part of the world.

Pre-Columbian art

Costa Ricans take a strong interest in their pre-Columbian art, which includes large statues from the Pacific northwest, smaller examples of carved relief in stone from other districts, and some fine work done in the form of small objects of gold. Samples of all these may be seen in the national museum. Guayabo National Park, near Turrialba, features the country's only preserved pre-Columbian archaeological site. Genuine colonial architecture is rather scarce, the most famed example being a 17th-century mission in Orosí. Cartago's older buildings, destroyed by earthquakes, have in some cases been restored; new ones like them have also been built. Among the folk arts, Costa Rica is most famous for its highly decorative oxcarts.

The fine arts have seldom flourished in Costa Rican history, but they have received some impetus from government support, particularly with the creation in 1970 of the Ministry of Culture, Youth, and Sports. Painting, sculpting, and music all showed considerable development in the latter part of the 20th century. Particular pride was taken in the growth of the National Symphony Orchestra since 1971, with the ensemble playing large halls and also taking music to the countryside. Costa Ricans have been marginally active in the field of literature. Roberto Brenes Mesén and Ricardo Fernández Guardia were widely known as independent thinkers in the fields of education and history, respectively. Fabián Dobles has attracted international attention as a writer of novels on social-protest themes.

Costa Rica has developed the largest national park system of any Latin American country, relative to its territorial extent. These parks include a bewildering range of tropical ecosystems, such as tropical rain forest, cloud forest, dry forest, and elfin forest. Other parks include active volcanoes, turtle nesting sites, and coral reefs. The national parks are a major attraction for Costa Ricans, who flock to them on weekends and major holidays such as Easter Week, Independence Day (September 15), and the week between Christmas and New Year's Day. International tourists are also attracted by these parks, some of which are noted worldwide for their vegetation and wildlife.

Publishing

Numerous publishing houses operate in the country, issuing both fiction and nonfiction on a wide range of topics. The government-operated Editorial Costa Rica and the Editorial Universitaria Centroamericana are among the most prolific of the publishing houses. Both the number and variety of publications available in Costa Rican bookstores surpasses those of any other Central American country and some South American countries as well. *La Nación,* an independent but conservative daily, is the most widely read of Costa Rica's newspapers. It is balanced by *La Républica* and *La Prensa Libre,* independents that lean more toward reform ideas. There are several television stations, one of which is government-owned.

(F.D.P./G.S.E.)

For statistical data on the land and people of Costa Rica, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL.

HISTORY

In 1502 Christopher Columbus' fourth Atlantic voyage brought him to the shores of Costa Rica, where he remained for 18 days refitting his ships. Relations with the natives became friendly enough that they brought him a number of items of gold, possibly prompting Columbus to name the land "Rich Coast," although there is some dispute over the origin of the name. Other more promising regions forced Spain to neglect the area, however, and the few Spanish colonists clung to the coast for 60 years. In 1564 the Spanish crown established the Meseta Central village of Cartago as the first permanent settlement. Theoretically under the political jurisdiction of the captain general of Guatemala and the spiritual guidance of the bishop of León in Nicaragua, Costa Rica was ignored by both administrations. The absence of great mines meant the collection of few taxes from the Ticos, as Costa Ricans called themselves; consequently Spain provided little help in developing the infrastructure of the province. Compared with other colonies Costa Rica lacked a large labour force, so essential in the Spanish scheme of conquest. Costa Rican Indians were not numerous, and they resisted capture and disappeared into the forests rather than succumb to the encomienda, Spain's usual system of forced labour. Lacking products for a great overseas market, the Costa Ricans eked out a subsistence economy based on cacao and tobacco. Hence most people were small landowners with a close personal interest in local affairs. Historians often give credit to these developments for the growth of the democratic ideals that have become associated with Costa Rica. It should be noted, however, that some persons who became rich established a small finca- (estate-) based oligarchy which led the nation in the independence era.

Independence. When Mexico declared its independence from Spain in 1821, Costa Rica, with other parts of Central America, joined the short-lived Mexican Empire. In 1823 Costa Rica helped create the United Provinces of Central America but, disenchanted with the strife in the other four states of the federation, severed its ties in 1838. Already a pattern of isolationism had been formed, and in the many attempts to revive the federation the Costa Ricans have invariably shown little interest.

Costa Rican isolationism

From the 1840s a constant stream of oxcarts carried coffee from the Meseta Central to Pacific ports and ships bound for Europe. This trade brought British investment. Farmers with even small acreage could derive an adequate if simple existence, and the ground was laid for a society that demanded schools and roads from its government and found political participation necessary to achieve these goals.

Costa Rica's policy of isolationism did not completely save it from foreign troubles. In 1825 the province of Guanacaste seceded from Nicaragua and joined Costa Rica, creating an issue that was contended until the boundary treaty of 1896. Sharing the San Juan River with Nicaragua, Costa Rica also shared some of the canal and filibustering fevers that nearly destroyed its neighbour.

Material progress came to Costa Rica during the era of General Tomás Guardia, who dominated the nation from 1870 until 1882. His government curtailed liberty and increased the debt, but it also brought increases in coffee and sugar exports as well as widespread construction of schools. A new constitution, adopted in 1871, remained in effect until 1949. The emphasis on agricultural exports strained transportation, and, with mainly British funds, Costa Rica sought to link the Meseta Central with the seaports by railway. The chief promoter was an American, Minor C. Keith, who made a fortune with the opening of his rail line between Cartago and Limón. With vast land grants, Keith then entered the banana business. By the late 19th century, bananas were beginning to rival coffee as the chief source of Costa Rican foreign exchange, especially after Keith's investments were merged with others to form the United Fruit Company in 1899.

The last decades of the century were also marked by a gradual decline in Roman Catholic church activity in secular affairs. The Jesuits were expelled for a few years, cemeteries were secularized, and public education was expanded. In 1886 free public education became compulsory; normal schools, a museum, and a national library were founded. Though the government continued to support the church, the constitution of 1871 provided for religious toleration. Strengthening the tradition of democracy for which Costa Rica was to become famed throughout Latin America was the victory in 1890 of President José Joaquín Rodríguez in what is considered the first entirely free and honest election in all Central America.

20th century. When Nicaragua, in the Bryan-Chamorro Treaty of 1916, gave the United States permission to use the San Juan River (the border between Nicaragua and Costa Rica) as part of an interoceanic canal route, Costa Rica protested that its rights were being ignored. The claim was brought before the Central American Court of Justice, which ruled that Nicaragua had violated Costa Rican claims to the river; Nicaragua refused to accept the decision and withdrew from the court, a major factor in the court's death a year later.

Boundary dispute with Panama

Costa Rica's boundary with Panama (originally with Colombia) was also in dispute. Arbitration awards by France and the United States in 1900 and 1914, respectively, had been generally favourable to Costa Rica and were rejected by Panama. In 1921 Costa Rica attempted forcible occupation of this area (on the Pacific coast) but was diverted by the intervention of the United States. Panama then evacuated the region, but relations between the two small states were not reestablished until 1928. In 1941 the governments finally reached an accord over the boundary.

When Costa Rica held an election under direct suffrage for the first time in 1913, no candidate won a majority, and the Legislative Assembly chose Alfredo González Flores as president. General Federico Tinoco Granados, disgruntled over reforms proposed by González, in 1917 led one of the nation's few revolutions. Tinoco's despotic behaviour soon cost him his popularity. His administration was also impeded by the refusal of the U.S. government to recognize his regime, and revolts and the threat of U.S. intervention caused him to resign in 1919.

This experiment in dictatorship was not repeated, and

Costa Rica continued its tradition of democratic elections and orderly government. A literacy test for voters was adopted in 1920 and the secret ballot in 1925. On Dec. 8, 1941, the day after Japan attacked Pearl Harbor, Costa Rica declared war on Japan and on December 11 extended the declaration to Germany and Italy.

Costa Rica's most serious political crisis since 1917 came in 1948. A faction containing some alleged communists tried to prevent the seating of the president-elect, Otilio Ulate. José Figueres, a socialist landowner, put down the rebellion and turned the government over to Ulate. A new constitution, promulgated in 1949, prohibited the establishment or maintenance of an army, and the army was replaced by a Civil Guard. Elected in his own right in 1953, Figueres nationalized the banks and threatened the holdings of the United Fruit Company and several utility corporations. In 1955 he repelled an invasion by exiles residing in Nicaragua. Figueres was elected again in 1970, having meanwhile established his PLN as the dominant group in the Legislative Assembly.

In 1974 Daniel Oduber succeeded Figueres as president. Although both belonged to the PLN, they soon fell out over Figueres' ties to the U.S. financier Robert Vesco, who had found refuge in Costa Rica from an indictment on conspiracy charges in New York City. Vesco left Costa Rica in 1978, but the splintering of the PLN made possible the presidential victory of Rodrigo Carazo Odio in that year. Carazo faced serious diplomatic and economic problems. When rebellion broke out against the Somoza regime in Nicaragua, thousands fled to Costa Rica. After the overthrow of that regime in 1979, Costa Rica was further strained by the arrival of refugees escaping from civil war or civil-rights abuses in the other states of Central America. Many refugees were deported for using Costa Rica as a military base.

Economic problems

Even more enduring were economic troubles. Inflation rates fluctuated sharply, and unemployment rose. Hospital, dock, banana, and railroad workers received small raises after disruptive strikes. Economic growth slowed to near zero when the price of oil became so high that almost the entire coffee crop was needed to pay for that single import. Many years of easy credit, excessive government spending, and unfavourable trade balances brought the nation to the brink of economic ruin. Carazo and the bankers failed to reach agreement and left the problem for the new president, Luis Alberto Monge Álvarez of the PLN, who took office in 1982. In return for extending Costa Rica's debts, the International Monetary Fund and the World Bank insisted that Monge impose severe austerity measures, including devaluation of the colón, budget and tax cuts, and suspension of some subsidies.

In 1986 Monge was succeeded by another member of the PLN, Oscar Arias Sánchez, who faced many of the same economic problems. The nation continued to be beset by nearly $5 billion in foreign debt, too-rapid urbanization, inadequate housing, unemployment, and adjustments necessitated by privatization of state monopolies. More than one-third of the nation's income was derived from international loans. Civil wars elsewhere in Central America continued bringing thousands of fugitives into Costa Rican exile, and illicit drug traffic imposed new forms of corruption on the land.

Aside from some easing of the debt structure, Arias could accomplish little with these matters, but he created for himself a powerful role in international affairs. A wealthy coffee grower and political scientist, Arias spent most of his term leading a regional peace movement designed to end the bitter strife in El Salvador, Nicaragua, and Guatemala. Although often receiving little support from the United States, he achieved considerable success and did more than any other person to reduce tensions and create machinery to end the bloody Central American struggles. In 1987 President Arias received the Nobel Prize for Peace for his efforts. Arias, constitutionally ineligible to run in 1990, was succeeded by Rafael Angel Calderón Fournier of the opposition PUSC. (T.L.K.)

For later developments in the history of Costa Rica, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

El Salvador

The Republic of El Salvador (Spanish: República de El Salvador), with a total area of 8,124 square miles (21,041 square kilometres), is the smallest and most densely populated of the Central American countries. Its territory is situated entirely on the western side of the Central American isthmus, and it is therefore the only Central American nation that lacks a Caribbean coast. El Salvador is bounded to the south by the Pacific Ocean, to the northwest by Guatemala, and to the north and east by Honduras. The capital is San Salvador. Despite having little level land, El Salvador is largely an agricultural country, heavily dependent upon coffee exports. Since the late 1970s the nation has been a focus of international attention owing to its continuing civil war and external involvement in the country's intense internal conflicts.

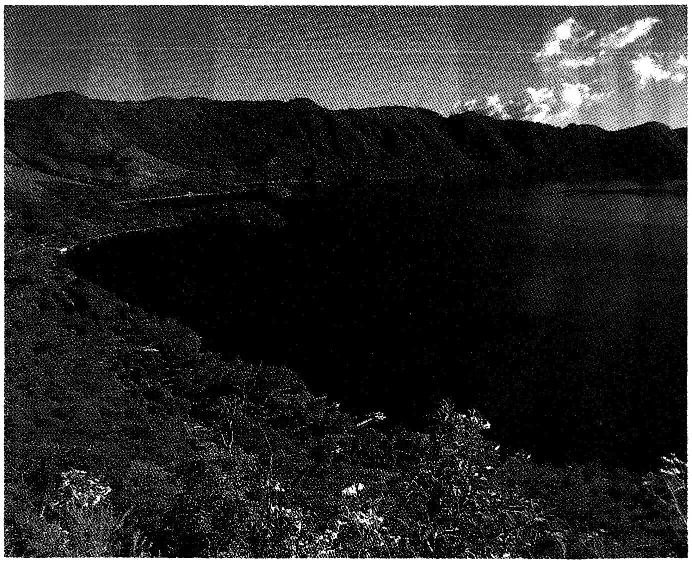
PHYSICAL AND HUMAN GEOGRAPHY

The volcanic axis

The land. *Relief and soils.* The entire territory of El Salvador is situated on the Central American volcanic axis, which determines the major geographic regions of the country. Relief is dominated by the central highlands, consisting largely of a west-east line of volcanoes, many still active, that crosses the centre of the country. This volcanic range includes 20 cones, from the westernmost Izalco Volcano (6,266 feet; 1,910 metres), through those of San Salvador (6,430 feet) and San Miguel (6,988 feet), to that of Conchagua (4,078 feet) in the extreme east. Along this line flooded volcanic craters provide the country's largest lakes at Coatepeque (15 square miles; 39 square kilometres), Ilopango (25 square miles), and Olomega (20 square miles). These volcanoes are separated by a series of basins (commonly referred to as El Salvador's central plain), situated at elevations of between 3,500 and 5,000 feet (1,000 and 1,500 metres), whose fertile soils, derived from volcanic ash, lava, and alluvium, have for centuries supported large concentrations of population.

To the south, where these central highlands fall away to the Pacific coast, is a narrow coastal plain with average elevations of between 100 and 500 feet (30 and 50 metres). Its level, fertile soils, deposited by the numerous small rivers draining from the central highlands, combined with high year-round temperatures and abundant rainfall, provide favourable conditions for plant growth and agriculture. North of the central highlands, and parallel to them, a broad interior plain drained by the Lempa River is situated at elevations between 1,300 and 2,000 feet (400 and 600 metres). Intermittently broken by ancient dormant volcanic structures, and adversely affected by poor drainage and high soil acidities, this interior plain has provided a less attractive environment for human habitation.

© Lawrence Berlin—Photo Researchers



Lake Coatepeque, one of the largest of a line of flooded volcanic craters in western El Salvador.

Extending along the entire northern border region are a range of highlands, with average elevations of 5,000 to 6,000 feet, formed by ancient and heavily eroded volcanic structures. The steepness of slope, excessive forest clearance, and overuse of soils have led to serious deterioration of the environment of this northern region. In the extreme northwestern part of the country there are limited outcrops of limestone rock associated with the older nonvolcanic structures of Honduras.

The Lempa river system

Drainage. Two principal river systems and their associated tributaries drain the major part of the country. Most important is the Lempa, which enters El Salvador from Guatemala in the northwestern corner of the country and flows eastward for 80 miles (130 kilometres) across the interior plain to form part of the border with Honduras before turning sharply south to run 65 miles (105 kilometres) through the central highlands and across the coastal plain to its mouth on the Pacific. The Lempa was navigable for several miles inland prior to the construction of two major hydroelectric installations on its middle reaches: the Cerron Grande and First of November dams. The eastern part of the country is drained by the Rio Grande de San Miguel system. A series of short north-south streams drain directly from the central highlands to the Pacific.

Climate. The climate of El Salvador is tropical but is moderated by altitude in the interior; in general it is warm rather than hot, varying between 59° and 73° F (15° and 23° C). Heavy rains, known as the *temporales,* fall in the winter season from May to October. The dry summer season lasts from November to April. There is considerable climatic variation in the different regions. The Pacific lowlands and low areas in the middle Lempa River valley have mean monthly temperatures between 78° and 85° F (25° and 29° C). At San Salvador, the capital, which is 2,156 feet above sea level, the maximum monthly mean temperature is 94° F (34° C) in March, and the lowest monthly mean is 60° F (16° C) in January. In the mountains, above 4,800 feet, mean monthly temperatures vary between 63° and 72° F (17° and 22° C). Annual precipitation on the Pacific lowlands averages about 68 inches (1,700 millimetres); on the southern and northern mountain ranges, at heights between 2,000 and 3,500 feet, the average is between 70 and 97 inches (1,800 and 2,500 millimetres); the higher mountains receive a little more. Annual precipitation recorded in the deeper valleys and surrounding plateaulike areas is between 45 and 60 inches (1,100 and 1,500 millimetres).

Plant and animal life. The higher mountain regions have temperate grasslands and the remnants of deciduous oak and pine forests. On the central plains and in the valleys small deciduous trees, bushes, and subtropical grasslands are found. The coastal plains and the lower slopes of the southern mountains are covered with either savanna (parklike grassland) or deciduous forests. Among the many species of trees is the balsa, known for its beauty and soft perfume; its trunk yields excellent lumber as well as resin that is used in antiseptics and medicinal gums.

Trees and tree products

Valuable wood also is obtained from the cedar, mahogany, laurel, nispero, and madrecacao trees and is used for the manufacture of furniture. Particularly beautiful is the maquilishuat, the pink-tufted national tree of El Salvador. Several species of palm and coconut trees grow in the coastal zone, and there are many varieties of tropical fruit, such as coconut, tamarind, melon, watermelon, and mango. The izote is the national flower.

Because of the amount of land under cultivation, El Salvador is considerably less rich in animal life than most Central American countries. Rodents, reptiles, and insects of many kinds, however, are common. There is a wide variety of birdlife, which includes wild duck, the white and the royal heron, the urraca (which has a blue breast and a grey head and is known for its call resembling a scoffing laugh), the blue jay, and many more, some of which have fine plumage. A wide variety of fish, as well as turtles and crocodiles, inhabit the streams, lakes, and rivers.

Settlement patterns. More than three-fourths of the present population live in the intermontane basins of the central highlands. For millennia before the Spanish conquest these areas supported large agricultural communities of Amerindians dependent on the cultivation of indigenous crops, such as corn (maize), beans, and squashes. The ruins of their cities are evident at sites such as Chalchuapa, Sihuatán, and Cara Sucia. The major Spanish colonial settlements, which became the nation's principal cities, were also situated in these central basins: Santa Ana, Ahuachapán, San Salvador, San Vicente, and San Miguel. This concentration of population was perpetuated during the colonial period by the commercial production of indigo and sugar on private estates, owned by a few wealthy families, alongside the continuing indigenous subsistence farming of Amerindian peasants living in poverty. From the 19th century these basins and their surrounding slopes provided an ideal environment for the cultivation of coffee, which became the basis of the national economy. In the 20th century urban growth and industrialization increased the concentration in the highland centre of the country. More than one-half of the national population now live in the central cities. This distribution of population exacerbates the effects of natural disaster in a zone prone to seismic activity, and most of these cities have been subject to one or more destructive earthquakes.

San Salvador, the capital, was founded in 1525 and in the 20th century has grown rapidly to absorb many surrounding settlements. This major conurbation now stretches continuously from Nueva San Salvador in the west to Lake Ilopango in the east. It contains an estimated one-fifth of the total population. In the east San Miguel, located on the slope of the volcano San Miguel, is a thriving city where the old Spanish colonial and modern life-styles merge. The city of Santa Ana is the commercial centre of western El Salvador.

Central highlands emigration

The overpopulation in the central highlands has resulted in out-migration to the coastal plain, which, since 1945, has been transformed by extensive cotton and cattle farming. Past settlement in the northern highlands has caused severe deforestation and soil degradation in a region of steep slopes and poor soils. The region remains overpopulated by dispersed peoples, the majority of whom are restricted to subsistence farming.

The people. Before the Spanish arrived in Salvadoran territory in the 16th century, it was occupied by a complex of Indian tribes. Of these the Pocomam, Chortí, and Lenca, all related to the Maya, were the more ancient, but the Pipil, whose civilization resembled that of the Aztecs in Mexico, were predominant. The Pipil name for their territory as well as for their capital was Cuscatlán, meaning "Land of the Jewel"; the name is still sometimes applied to El Salvador today. Archaeological ruins dating from Indian times are to be seen at Tazumal, Pampe, El Trapito, and San Andrés. Of several large towns founded by the Indians, Sonsonate and Ahuachapán still exist.

The intermarriage of Spanish settlers with the local population has resulted in a racially homogenous people. Almost nine-tenths of the contemporary population is mestizo; the remainder is Indian (notably the Izalco Indians and the Pancho from the village of Panchimalco near the capital) and white.

During the pre-Spanish epoch various Indian dialects were spoken, the most important of these being Nahuatl, spoken in the central region of the country, and Poton, spoken in the east. After the initial conquest, Spanish became the official language, and the Indian dialects slowly fell into disuse. A government effort is being made to preserve Nahuatl. Most Salvadorans profess the Roman Catholic religion.

Severe economic conditions complicated by the civil war beginning in 1979 caused dramatic changes in El Salvador's demographics. It is estimated that about 20 percent of the population left the country, departing in about equal numbers for neighbouring countries and the United States. Within the remaining population there has been massive displacement characterized by a general movement of people from the conflict zones in the north and east to the central cities. The disruption of lifeways and the emigration of many young Salvadorans has brought an accompanying decline in the rate of natural increase. Nevertheless, overcrowding is a severe problem.

The economy. The economy is predominantly agricul-

Primacy of agriculture

tural, although there was rapid industrial expansion in the 1960s and '70s. Despite its concentration on agriculture the country has trouble feeding itself and must import food. The main cause is the disproportionate distribution of land in favour of commercial crops, leaving many of the peasants landless and unable to grow subsistence crops.

The most important agricultural products are coffee, cotton, corn, and sugarcane. Coffee alone accounts for a substantial part of the value of the total agricultural production and more than half of the value of exports; the biggest buyers are the United States, Germany, The Netherlands, and Japan. Cattle raising is also an important activity. While some woods are used for furniture making, as mentioned above, much of it is also used for fuel; other forest products are dyewoods and balsam, a medicinal gum of which El Salvador is the world's main source.

Commercial fishing, regulated by the government, has added to the country's export earnings. Most of the fish caught commercially or for sport come from offshore waters and coastal lagoons; they consist chiefly of crustaceans (including lobster and shrimp), mullet, snappers, jacks, groupers, sharks, and anchovies. There is no mineral exploitation of significance. The main power sources, meeting most of the country's needs, are the hydroelectric projects on the Lempa River 35 miles northeast of San Salvador, which are administered by a government agency.

In the middle and late 20th century there was a steadily increasing investment in industry, stimulated by the Central American Common Market. Industrial plants rose throughout the country, and existing facilities were expanded, helped by government incentives, an advanced banking system, and development credits from abroad. In 1979, however, manufacturing began a serious decline, which continued into the 1980s. Civil unrest and political instability were the primary causes. Manufactures include beverages, canned foods, organic fertilizers, cement, plastics, cigarettes, shoes, cotton textiles, leather goods, petroleum products, and machinery.

Tourism

Tourism was an increasing source of income but also suffered a decline after 1979. In 1980 the nation's commercial banks and the export marketing agencies were nationalized. Government revenue is mostly raised by sales taxes and by customs and export duties on coffee. Since 1980 the government has relied heavily on large aid disbursements from the United States.

El Salvador has adequate transportation facilities except in some of the remoter areas. Two main routes of the Pan-American Highway system cross El Salvador from Guatemala to Honduras, forming the framework of a road system that reaches almost all parts of the country; one of these routes runs across the central highlands, the other across the coastal plains. Several paved all-weather roads connect with these main highways. The country's narrow-gauge railroad is operated by a national agency; the main tracks link the capital with ports on the coast and with the Guatemalan border. For sea commerce, El Salvador relies on three ports—Acajutla, La Libertad, and Cutuco (near La Unión). El Salvador's outlet to the Atlantic is through the Guatemalan port of Puerto Barrios, with which San Salvador is linked by road and rail, via Guatemala City. A new international airport was constructed in the 1970s on the coastal plain 25 miles south of the capital. It replaced Ilopango airport, which now serves as a military base. Severe damage to the nation's transportation network resulted from the civil war.

Administration and social conditions. *Government.* The constitution of 1983 provided for a representative form of government with three branches—legislative, executive, and judicial. All Salvadoran men and women who have attained the age of 18 have the right and duty to vote. Executive power is exercised by the president, who serves a nonrenewable five-year term, the cabinet ministers, and the undersecretaries of state. Legislative power is vested in a unicameral, popularly elected Legislative Assembly, which also has the power to appoint the president and vice presidents, if no candidate has an absolute majority in an election, and to veto presidential appointments; its members serve three-year terms. The judicial branch is composed of a Supreme Court of Justice, whose magistrates are selected by the Legislative Assembly, and of other tribunals as established by statute.

Local administration

El Salvador's territory is divided into 14 *departamentos,* each of which is divided into *distritos* (districts), which are further divided into *municipios* (municipalities). Each department has a governor and a substitute governor, appointed by executive power; and each municipality has a popularly elected municipal council composed of a mayor, a secretary, and aldermen, the number of whom are in proportion to the population.

Education. All public and private institutions of learning are under the jurisdiction of the Ministry of Education. Since 1968 the school system has been composed of preschool, primary, and secondary educational categories, followed by university-level education. Primary education is free and compulsory, but the illiteracy rate is relatively high. Among the institutions of higher education are the University of El Salvador, the University Dr. José Matías Delgado, and the Central American University José Simeón Cañas. There are also schools for technology, fine arts, agriculture, social services, and nursing.

Social welfare and health. The traditionally low standard of living of artisans and agricultural labourers has worsened as a result of the civil war. More than 60 percent of the economically active population are unemployed or underemployed. Attempts are being made by the government to achieve a more equitable distribution of income through a major program of agrarian reform and through education, vocational training, and community projects. Progress, however, has been exceedingly slow, particularly in the area of land reform, which has been resisted by the powerful landowning elite. Low-cost housing, medical assistance, and employment programs have been introduced in an attempt to meet the needs and problems of the displaced and the unemployed. Such programs, however, have difficulty keeping up with deteriorating conditions. The doctor-to-patient ratio is low and falling, and most doctors serve urban areas. The war and population displacement have caused the reappearance and spread of diseases, particularly malaria, in many areas; malnutrition is increasingly prevalent.

Cultural homogeneity

Cultural life. The cultural life of El Salvador, like its population, is an amalgam of Indian and Spanish influences. There is greater cultural homogeneity than in any other Central American country, with Spanish spoken universally and Indian customs (though little spoken language) surviving in small clusters of villages, such as those around Izalco and Nahuizalco, and traditional crafts being maintained in Ilobasco (pottery) and Izalco (textiles). The present indication of this cultural mix is represented in the country's rich tradition of folklore, poetry, and painting.

The Roman Catholic church has been a major influence on almost every aspect of cultural life. In higher education, for example, the earliest institution, the Colegio de la Asunción, was founded in 1841 to teach Latin and theology, while the nation's leading contemporary university, Central American University, is a Jesuit foundation.

Private benefactors have played as important a role as that of the government in patronizing the arts. San Salvador's principal theatre was built by public subscription; the majority of newspapers and publishers are privately owned; the major national parks were established by private funds; and the principal museum originally was a private foundation. More recently the government has increased its contribution to national cultural life, particularly in its expansion of secondary and advanced education. (R.S.V./D.G.B.)

For statistical data on the land and people of El Salvador, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL.

HISTORY

The colonial period. The Spanish conquest and colonization of El Salvador began in 1524 with the arrival of an expedition from Guatemala led by Pedro de Alvarado. Alvarado's troops met determined opposition from a Nahua tribe, the Pipil, who occupied much of the region west of the Lempa River. However, superior tactics and armaments enabled the Spaniards to push on to the Pipil capital

The Spanish conquest

of Cuscatlán. Alvarado soon returned to Guatemala, but a second expedition in 1525 founded a Spanish town called San Salvador near the site of Cuscatlán. Pipil warriors forced the Spanish settlers to withdraw, however, and the community would be resettled several times before it was permanently established in 1528.

Thereafter, the town of San Salvador would serve as the capital of a province of the same name that included most of the eastern three-fourths of the territory of modern El Salvador. The area to the west (comprising the present-day departments of Sonsonate, Santa Ana, and Ahuachapán), which the Pipil called Izalcos, was organized in 1558 as the autonomous province of Sonsonate and would not be incorporated as a part of El Salvador until 1823.

The lands that would form El Salvador became the agricultural heartland of the captaincy general of Guatemala. Although most of the inhabitants were obliged to depend on subsistence farming, the more fortunate Spaniards found wealth in the export of a variety of local products, all of which experienced periods of "boom and bust." Cocoa was the most important source of wealth during the 16th century. Increased competition from other colonies led to a marked drop in revenue from cocoa by 1590, and the following century was clearly a period of stagnation for the region. Recovery in the 1700s came as a result of increased exports of indigo.

The indigo trade led to the development of a fairly sophisticated form of commercial agriculture and the creation of large estates operated by families whose members played a leading role in provincial affairs. For the native people, however, the indigo boom chiefly meant that an additional burden was placed on an already exhausted work force.

Indigo planters' independence role

Independence. A variety of considerations caused the Salvadoran indigo planters to take a leading role in agitating for Central American independence. These included the hard times caused by a sharp decline in indigo production during the first decade of the 19th century, a long-held hostility toward Guatemalan merchants who controlled much of the economy of San Salvador, and the conviction that the province should be organized as a bishopric so that it need no longer depend upon the archbishop of Guatemala for pastoral services.

In November 1811 the arrest of a member of one of the planter families ignited an uprising led by José Matías Delgado, the provincial vicar of San Salvador, and his nephew Manuel José Arce. The rebels held the government for nearly a month before Spain's authority was restored by the captain general of Guatemala, whose measures seemed more conciliatory than repressive. A second, shorter uprising in 1814 had wider popular support, and it provoked a more severe response from the captain general, costing Arce more than four years in prison.

Conflict with Mexico

In 1821 the province endorsed Guatemala's declaration of independence from Spain. The Salvadorans, however, opposed the Guatemalan decision to accept incorporation into Agustín de Iturbide's Mexican Empire, a stance that led to confrontations with Guatemalan and Mexican armies. Faced with defeat late in 1822, a Salvadoran congress sought adoption of a resolution providing for the province's annexation to the United States; but this scheme was abandoned when Iturbide's government collapsed in 1823. Meeting in June of that year in Guatemala City, a Central American constitutional convention chose Delgado as its president, appointed Arce as a member of the provisional executive triumvirate, and went on to draft a constitution, which was completed in 1824. The state thus created was now called the Federal Republic of Central America, having earlier been termed the United Provinces of Central America; in 1825 Arce became its first president.

Nationhood. The state of San Salvador (the modern name, El Salvador, was not used until 1841) played an important part in the affairs of the Central American federation. Not only was it the birthplace of the federation's first president, it was also there that a revolt was sparked against Arce in 1827, beginning the civil war in which Central American Liberals and Conservatives contested for control of the new nation. This conflict, which caused the collapse of Arce's presidency, ended in 1829 with the seizure of the federal government by Francisco Morazán, commander of the Liberal army. Having cast their lot with Morazán, the Salvadorans became his most loyal allies and were rewarded in 1834 with the transfer of the federal capital to the city of San Salvador. The Salvadorans were so attached to the ideals of federation that the state did not assume sovereign powers until 1841, after the other four states had already left the union.

Sovereignty did not signal the arrival of peace and prosperity for El Salvador; if anything, the nation experienced increased civil strife and international conflict for several decades after 1841. From that year until 1863, just one chief of state could claim continuous service that ran two full years. During this time, El Salvador was involved in wars with neighbouring countries that usually arose from attempts to meddle in their politics. Often El Salvador found that the final arbiter of its political affairs was Rafael Carrera, Conservative dictator of Guatemala from 1839 until his death in 1865. In the midst of this turmoil, the nation secured the establishment of the long-sought bishopric and saw the beginnings of the coffee industry, which was advanced in part by the policies of President Gerardo Barrios Espinosa (1861–63).

Liberal reforms

A coffee republic. The presidency of Francisco Dueñas (1863–71) pointed toward greater political stability in the nation; real change came, however, when his overthrow in 1871 marked the beginning of 60-year period of rule by Liberals who focused on the pursuit of economic growth and domestic tranquility. Late in the 19th century, a substantial shift in the nation's economy became essential when the development of synthetic dyes severely reduced the income normally generated by the export of indigo. Salvadorans solved this problem by means of a "coffee revolution." New lands had to be opened to cultivation, a step facilitated during the administration of Rafael Zaldívar (1876–85), who authorized the sale of Indian lands. These proceedings provoked Indian uprisings, which were put down by a newly created rural mounted police force.

The coffee planters developed a highly efficient system of plantation enterprises and formed a closely knit elite that used its growing economic strength to ensure that the government served its interests. Among the small number of controlling families, just two—the Meléndez and Quiñónez families—monopolized the office of president between 1913 and 1927.

Military dictatorships. The coffee barons' direct control of the presidency ultimately came to an end as a consequence of the worldwide depression that began in 1929. A coup installed General Maximiliano Hernández Martínez as president in December 1931 and initiated a succession of military governments that controlled the nation through 1979.

La matanza

The persistence of military rule can be partly explained as a result of a two-day revolt by farm workers in January 1932 that was organized by Augustín Farabundo Martí, head of the recently formed Salvadoran Communist Party. Hernández Martínez easily suppressed the rebellion and authorized the summary execution of at least 10,000 suspected participants. The uprising and its brutal repression, which is referred to as *la matanza* ("the slaughter"), were momentous events in the history of the nation. The revolt demonstrated the value of the military dictatorship to the landed elite, which became convinced of the need for eternal vigilance against the menace of a communist revolution. It also eliminated the immediate threat from the left as well as most of the last vestiges of Indian culture.

Personally honest and austere, Hernández Martínez sought to emulate the fascist dictators of Europe, but he may be best known for his interest in occult arts. His regime survived a coup in April 1944, but the following month a general strike launched by university students brought the nation to a standstill and caused the dictator to resign from office. There was no real change, however, until 1948, when a revolt by young army officers installed a junta headed by Major Oscar Osorio. This "Majors' Revolution" gave rise to policies and patterns of behaviour that would have a central role in the practice of Salvadoran politics during the next 30 years.

Elected to a six-year term as president in 1950, Osorio organized the Revolutionary Party of Democratic Unification (Partido Revolucionario de Unificación Democrática; PRUD) and launched a variety of reform projects, such as the development of hydroelectric facilities and urban housing projects. He also extended collective bargaining rights to urban workers; but, for the most part, the reforms served to encourage economic growth and to benefit the middle class. Osorio's successor, Lieutenant Colonel José María Lemus (1956–60), continued these programs, but there was no improvement in the living standards of workers. When faced with open discontent, Lemus resorted to repressive measures, and a military coup deposed him in October 1960.

A second coup in January 1961 brought Lieutenant Colonel Julio Adalberto Rivera (1962–67) to power. PRUD was dismantled and replaced by the National Conciliation Party (Partido de Conciliación Nacional; PCN), which would control the national government for the next 18 years. Under the banner of the Alliance for Progress, Rivera advanced programs aimed at economic growth and diversification which enabled El Salvador to take advantage of the increased trade opportunities offered by the recently formed Central American Common Market (CACM). A greater degree of political liberty seemed evident from the rise of the Christian Democratic Party (Partido Demócrata Cristiano; PDC) and the victory of its candidate, José Napoleón Duarte, in the 1964 mayoral election in the city of San Salvador. At the same time, the Rivera government oversaw the formation of the Democratic Nationalist Organization (Organización Democrática Nacionalista; ORDEN), a large, secretive paramilitary organization.

The Soccer War

Colonel Fidel Sánchez Hernández (1967–72) encountered difficulties as a result of the decline in world prices for coffee and cotton, but in 1969 the nation's attention was diverted from economic problems by the outbreak of the Soccer War (Guerra de Fútbol) with Honduras. This conflict broke out shortly after the two nations had played three bitterly contested matches in the World Cup competition, but the real causes for the war lay elsewhere.

In the first place, there was a long-standing dispute concerning the location of portions of the border between the two countries. Also, Hondurans resented the substantial trade advantage El Salvador held over them on the basis of the rules of the CACM. Most important was the problem raised by some 300,000 Salvadorans who had migrated to Honduras in search of land or jobs and who now found themselves threatened by an involuntary repatriation program begun by the Honduran government. Spurred by reports of the mistreatment of these refugees, the Salvadoran government opened hostilities on July 14, 1969. A ceasefire took effect on July 18, but El Salvador continued to force the action until the OAS threatened economic sanctions against the country on July 29. The brief war had cost several thousand lives, and a peace treaty between the two nations was not concluded until 1980.

Continuing economic troubles and the growing popularity of José Napoleón Duarte, the PDC candidate who headed a coalition slate, suggested that the military might lose control of the government in the 1972 elections. Members of ORDEN supervised voting in the outlying provinces, however, and managed to assure the victory of the PCN's Colonel Arturo Armando Molina. An attempted coup afterward achieved little more than Duarte's arrest and exile to Venezuela, where he resided until 1979.

During the period that encompassed the tenure of President Molina (1972–77) and that of his successor, General Carlos Humberto Romero (1977–79), the nation experienced more frequent expressions of public discontent and growing abuses of human rights. The growing opposition among Roman Catholic clergymen to the church's traditional defense of the status quo provided one clear sign of widening concern about the problem of social injustice in El Salvador. This period also witnessed the formation of mass popular front organizations that expressed the grievances of peasant groups and labour unions by such means as strikes, demonstrations, and parades. By 1979 several separate guerrilla organizations were operating in El Salvador.

Increasing government repression

Apart from an agrarian reform proposal that was offered (and quickly retracted) in 1976, the government had no response to this opposition other than tightening the screws of repression. Peasants surely suffered the brunt of efforts to stifle dissent, but the most egregious example of government violence came in 1975, when at least a dozen university students were shot to death while protesting the use of public funds to hold the Miss Universe contest in El Salvador. The political situation steadily worsened until Romero was removed from office by a military coup in October 1979.

Civil war. By the time of Romero's ouster, the nation was plunged into a civil war that would drag on into the 1990s. There were other significant consequences to be noted. Most obvious was the military's loss of the monopoly it had held on the direct exercise of governmental authority for nearly 50 years. At the same time, there was a change in the relationship between the military and the nation's propertied elite. The latter group felt it could no longer rely entirely on the armed forces for protection and sought to broaden its base of support by the formation in 1981 of a new political organization, the Nationalist Republican Alliance (Alianza Republicana Nacionalista; ARENA) led by Roberto D'Aubuisson Arrieta.

In addition, the role of the United States, which previously had shown very little interest in the affairs of El Salvador, changed markedly with Ronald Reagan's inauguration as president in January 1981. During the balance of the decade, the United States supplied El Salvador with financial aid amounting to $4 billion, assumed responsibility for the organization and training of elite military units, supported the war effort through the provision of sophisticated weaponry, and used its influence in a variety of ways to guide the political fortunes of the nation.

The years following Romero's downfall provided a kaleidoscopic array of events. The governing junta formed in October 1979 collapsed three months later when its civilian members resigned because of their failure to reach agreement on reforms and their inability to bring the military under control. José Napoleón Duarte returned from exile and became head of the second junta, which enacted a package of laws that included an agrarian reform program. Reforms did not mean that there would be any reduction in the level of political violence. That was made clear in March 1980 when Archbishop Oscar Arnulfo Romero, who had become a vehement critic of the military establishment, was assassinated while offering mass. The message was reiterated at the end of the year, when the military murdered three American nuns and a Roman Catholic lay worker.

By that time, the guerrilla units had joined in a single organization, the Farabundo Martí National Liberation Front (Frente Farabundo Martí de Liberación Nacional; FMLN), and announced the opening of a "final offensive" in January 1981. The offensive was by no means final, however, and the fortunes of the guerrilla army would ebb and flow throughout the balance of the decade. During that time, the guerrillas initiated and survived hard-fought battles with government troops who were trained and supplied by the United States.

Election of 1982

Elections held in 1982 enabled the formation of a constituent assembly that organized a provisional government and drafted a new constitution (the third since 1948) which was promulgated in December 1983. Duarte was elected president the following March. Although a meeting held with guerrilla leaders in the fall of 1984 raised hopes that Duarte could negotiate an end to the civil war, the talks led nowhere; furthermore, his presidency was plagued by misfortune. He made no progress in his efforts to achieve peace or advance social and economic reforms. At the end of his term, charges of widespread corruption in the government contributed to the victory of the ARENA candidate, Alfredo Cristiani, in the 1989 presidential election. Duarte died of stomach cancer shortly after Cristiani's inauguration.

Cristiani continued to enforce harsh strictures on dissent, but he also showed willingness to examine FMLN proposals for peace. The war endured into the 1990s, however, by which time at least 70,000 people (mostly noncombatants) had lost their lives, the economy was in shambles, and massive damage to the infrastructure was evident everywhere. Clearly, the nation was far from the goals of peace, prosperity, and social justice that it had long sought. (P.F.F.)

For later developments in the history of El Salvador, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

Guatemala

The Republic of Guatemala (Spanish: República de Guatemala) lies within the western portion of the isthmus connecting North and South America. Its land borders are with Mexico to the west and north, with Belize to the northeast, and with Honduras to the east and El Salvador to the southeast. The Pacific Ocean marks its southern shores, and a short coastline in the northeast opens upon the Caribbean Sea. With an area of 42,042 square miles (108,889 square kilometres), it is one of the larger nations in Central America and the most heavily populated. Its capital, Guatemala City, is the region's major metropolitan centre. The dominance of an Amerindian culture within its interior uplands distinguishes Guatemala from its neighbours. Politically, Guatemala has a long history of unstable governments prone to frequent and often violent military overthrows.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* The surface of Guatemala is dominated by four major features. In the south is a landscape of volcanic origin that extends for a distance of 180 miles (290 kilometres) between neighbouring Mexico and El Salvador. It is bordered on its seaward margin by the Pacific Ocean. The Petén *departamento,* a large, somewhat rectangular area, juts northward to occupy a portion of the Yucatán Peninsula, a limestone platform shared with Mexico and Belize. Sandwiched between the volcanic landscape and the Petén are the high ranges and valleys of the sierras of northern Central America. These arc gently eastward from Mexico for a distance of 210 miles, extending into northern Honduras and continuing on beneath the surface of the Caribbean.

The southern volcanic region

The southern volcanic region of Guatemala consists of three elements: a row of volcanoes of geologically recent origin, flanked by a deeply eroded volcanic tableland of older origin to the north and a narrow coastal plain constructed of volcanic debris on the south. The alignment of volcanic cones begins with the Tacaná Volcano (13,428 feet [4,093 metres]), located on the frontier with Mexico, and continues eastward across Guatemala into El Salvador. The highest peak is Tajumulco (13,845 feet [4,220 metres]). Among these are three continuously active volcanoes—the growing summit of Santiaguito located on the southern flanks of Santa María (12,375 feet [3,772 metres]), Fuego (12,582 feet [3,835 metres]), and Pacaya (8,371 feet [2,552 metres]).

Brilliantly costumed Indian women shopping at the Almolonga market in the western highlands of Guatemala, near Quezaltenango.

The rugged and deeply dissected volcanic tableland, which lies to the north of the volcanic row, averages 9,000 feet in elevation near the Mexican border and declines gradually to 3,000 feet at the opposite border with El Salvador. Ash-filled basins and a number of scenic lakes are scattered throughout this region. From the base of the volcanic row, the Pacific coastal plain slopes south to the shoreline of the Pacific Ocean. Rising imperceptibly from sea level to an elevation of 1,500 feet, the plain extends east-west for a distance of about 150 miles. Ranging between 25 and 50 miles in width, it is one of the nation's richest agricultural areas. Three-fourths of the population and most of the major cities are concentrated there, and the volcanic eruptions and earthquakes characteristic of this region have repeatedly taken a heavy toll of property and life.

The range and valley landscape of the sierras provides a major barrier between the heavily occupied volcanic landscape to the south and the sparsely populated Petén to the north. Sierra los Cuchumatanes to the west rises to elevations in excess of 10,000 feet. Eastward, the lower sierras of Chamá, Santa Cruz, Chuacús, Las Minas, and the Montañas del Mico are separated by deep valleys that open eastward upon a narrow Caribbean shoreline.

The Petén, lying largely below 1,000 feet in elevation, exhibits a knobby, or hilly, surface dominated by subsurface drainage of water. The region is replete with scattered lakes, Lake Petén Itzá being the largest. Extensive flooding takes place during the rainy season.

Drainage. The east-flowing Motagua River and west-flowing Cuilco pass in opposite directions through a structural trough that serves as the boundary between the volcanic terrain of southern Guatemala and the sierras that extend across the midsection of the nation. South of this trough, the land is drained by a series of small rivers that drain into the Pacific Ocean.

The sierra region is drained by larger rivers that flow primarily north into the Gulf of Mexico by way of the Usumacinta River. The 250-mile-long Motagua River is the longest of a series of rivers draining eastward toward the Caribbean. Because of the nature of the bedrock in the Petén, much of the region is drained by the subsurface flow of water.

Erosion problems

Soils. The volcanic belt of southern Guatemala contains some of the nation's most productive soils; nevertheless, the northernmost sector of this region is particularly subject to erosion induced by the prevalence of steep slopes, and deforestation. Within the sierra region, heavier rainfall combined with thinner soils on the steep slopes and the wanton destruction of forests have led to widespread erosion. The limestone surface of the Petén provides for shallow and stony soils that have greatly restricted the development of agriculture.

Climate. Located within the tropics and with elevations ranging between sea level and more than 13,000 feet, Guatemala experiences a diversity of climates. Below 3,000 feet in elevation average monthly temperatures range between 70° and 80° F (21° and 27° C) throughout the year; between 3,000 and 5,000 feet (900 and 1,500 metres) temperatures range between 60° and 70° F (16° and 21° C); and from 6,000 to 9,000 feet (1,500 to 2,700 metres) between 50° and 60° F (10° and 16° C). Above 9,000 feet temperatures are marginal for crops, but the grazing of animals is possible.

Near-desert conditions prevail in the middle section of the Motagua River valley, whereas precipitation in excess of 150 inches (3,800 millimetres) occurs at higher elevations of the Pacific-facing volcanic row and on the north- and east-facing slopes of the sierras. In general, a dry season prevails between November and April; however, moisture-laden trade winds from the Caribbean yield rainfall throughout the year on north- and east-facing slopes. In general, an average of 40 to 80 inches (1,000 to 2,000 millimetres) of precipitation is received in southern and eastern Guatemala, but this is doubled in areas located nearer the Caribbean shoreline.

Severe tropical storms, especially during the months of September and October, often deluge the country with damaging floods. Strong winds accompanying these storms as well as winter invasions of cold air occasionally place crops at risk.

Plant and animal life. In the Petén, a dense rain forest is interspersed with patches of savanna grasslands. The sierras are forested with oak and pine. Except for the highest slopes in the volcanic highlands, stands of pine, fir, and oak have been largely destroyed. On the Pacific coastal plain, the landscape largely has been cleared of its tropical forest and savanna.

Lowland fauna

The richest variety of animal life inhabits the lowland forest areas, although some species, such as deer, monkeys, peccaries, tapirs, ocelots, and jaguars, are increasingly rare. The birdlife of the rain forests is particularly exuberant and includes the radiantly plumaged quetzal, the national bird, for which a reserve has been set aside in the sierras near Cobán. Among the reptiles of note are numerous snake species, crocodiles, and iguanas.

Settlement patterns. Approximately 60 percent of the population of Guatemala is concentrated within the volcanic uplands and adjacent Pacific coastal plain to the south and west of Guatemala City. A little more than 10 percent live to the east and south, while only about 2 percent reside within the Petén. The remaining populace resides in the region of the sierras. Of the urban dwellers who make up some 40 percent of the population, nearly one-half inhabit the metropolitan area of Guatemala City.

Quezaltenango is the most important city of the western highlands. A line of cities follows along at the juncture between the upper Pacific coastal plain and the line of volcanoes. The largest of these are Retalhuleu, Mazatenango, and Escuintla. Puerto Barrios, Zacapa, and Cobán in the east and Huehuetenango to the west are the major urban centres in the sierras.

Rural settlements tend to radiate around the county seats (*cabeceras*) of the hundreds of *municipios* into which the country is divided. The living conditions in the vast majority of these contrast sharply with the modern amenities of Guatemala City. Running water and up-to-date sanitary facilities are lacking in most homes. Dwellings tend to be made of adobe, cane, or planks and roofed with thatch, tiles, shakes, or corrugated metal. Homes commonly have earthen floors.

The people. *Ethnic composition.* On the basis of cultural traits, the population is divided into two main ethnic groups—Ladinos and Amerindians. The Ladinos comprise those of mixed Hispanic-Amerindian origin in addition to those Amerindians who have adopted Western ways of life. While Amerindians account for some 45 percent of the nation's total population, they make up 75 percent of the population in the western highland provinces. The Ladinos are the more commercially and politically influential group, and they make up most of the urban population. Most of the small number of blacks, called Black Caribs, inhabit the Caribbean lowlands.

Amerindian languages

Linguistic composition. All official transactions in Guatemala are conducted in Spanish. There are, however, about 20 Amerindian languages spoken, most of them of Mayan origin. The largest Amerindian groups are the Mam, who reside in the western departments of Guatemala; the Quiché, who occupy areas to the north and west of Lake Atitlán; the Cakchiquel, who extend from the eastern shores of Lake Atitlán to Guatemala City; and the Kekchi, who are concentrated in the sierras to the north and west of Lake Izabal. Many of the Amerindians also speak Spanish.

Religion. While Roman Catholicism is the dominant religion of Guatemalans, among Amerindians it is often heavily infused with beliefs of pre-Columbian origin. From the mid-20th century, however, there has been a surge of conversions to Protestantism, particularly among the poor—that religion offering strong encouragement toward self-improvement. The most important shrine in Central America is the Roman Catholic Black Christ of Esquipulas (named for the dark wood from which it is carved), located in eastern Guatemala.

Demographic trends. Guatemala has a relatively high rate of population growth. Within Central America, Guatemala has one of the highest birth, death, and fertility rates, in addition to a low life expectancy. Due to impoverishment, thousands of the rural poor in search of a livelihood migrate seasonally to the Pacific coastal plain to harvest crops, to the major urban centres, or to sparsely populated areas in the Petén to the north. Civil conflict in the rural areas occupied by Indians has also led to the mass flight of refugees into neighbouring Mexico, Belize, and the United States.

The economy. Guatemala is a developing country largely dependent upon traditional commercial crops as the basis of its market economy. Vigorous economic growth during the 1960s and '70s was followed by a severe economic downturn during the '80s. The government has attempted to revitalize the economy by fostering the diversification and expansion of nontraditional exports, and free trade zones have been established to encourage the expansion and decentralization of manufacturing. The collection of personal income taxes has improved significantly; the government, however, continues to rely upon revenue from other tax sources, such as customs duties, sales taxes, and excises on liquor and tobacco.

Although labour unions and student and peasant organizations have greater freedoms, leaders continue to suffer harassments and threats of death. In an effort to sustain the government, the United States has greatly increased economic and military aid since 1980. Negative trade balances and foreign indebtedness, however, continue to hamper the economy.

Resources. Surveys have long reported Guatemala to have a wealth of mineral resources; this potential has had only minimal fulfillment, however. Since 1981 several million barrels of petroleum have been extracted annually from oil wells located in the Petén. The export of concentrates of lead, zinc, and antimony is minimal. The export of nickel from the region of Lake Izabal was terminated in 1981.

Arable land

The agricultural resources of Guatemala are rich. Although rugged landscapes prevail in much of the volcanic region, numerous highland basins and the Pacific piedmont and coastal plain provide productive soils for agriculture. Within the sierras, the lower Motagua valley offers excellent soils. The wide range of climates allows for a diversity of crops. The efficient exploitation of soils is primarily limited by the inequitable distribution of land (large landowners not being required to maximize land use) and the inability to provide the agricultural sector with adequate financial support—*i.e.,* funding of small farms.

Forest and fishing resources have considerable potential. Forest products are derived primarily from the tropical forests of the Petén and the coniferous forests of the highlands. Limited accessibility, however, hinders the exploitation of forest resources. The coastal waters of the Pacific in particular provide fishing resources of some importance.

Agriculture, forestry, and fishing. Although agriculture provides employment for more than one-half of the work force, it contributes only one-fourth of the gross national product (GNP). Traditional peasant agriculture, focused upon the production of corn (maize), beans, and squashes for domestic consumption, is concentrated on small farms in the highlands. In contrast, commercial plantation agriculture, emphasizing the production of coffee, cotton, sugarcane, bananas, and cattle for foreign markets, is restricted to large estates on the Pacific piedmont and coastal plain and in the lower Motagua valley.

Guatemala has developed into a major world supplier of cardamom. Increasingly, peasants who have long produced grains and beans and tended sheep are turning to the production of nontraditional commodities—fruits, vegetables, flowers, and ornamental plants—destined for export and for rapidly growing urban markets within the country.

Lumber, primarily pine, is exported in small volume and used domestically in construction and the crafting of furniture. But the most important use of cut wood is for fuel, more than half going to that purpose. Commercial fishing in the Pacific has developed and includes a catch of crustaceans, especially shrimp, and such fish as tuna, snapper, and mackerel; most of the catch is exported.

Industry. Manufacturing grew rapidly between 1960 and 1980 but expanded more slowly during the 1980s. During the late 1980s it contributed 15 percent to the GNP. Mining and the production of energy contributed an additional 3 percent. Food processing and beverages, the processing of tobacco and sugar, publishing, the manufacture of textiles, clothing, cement, tires, and pharmaceuticals, and the refining of petroleum are primary industrial activities. Most of the industrial activity is concentrated in the environs of Guatemala City.

Energy

The primary sources of energy are petroleum, hydroelectricity, and fuelwood. Fossil fuels and hydroelectricity both contribute substantially to the nation's electricity requirements. Throughout the more densely populated regions, wooded areas provide firewood and charcoal for cooking, heating, the firing of ceramic ware, and the production of lime.

The growing service sector is the largest contributor to the GNP. Increasing emphasis is being placed upon tourism as a source of income and employment. Noteworthy archaeological ruins are located at Tikal in the Petén, Zacaleu on the outskirts of Huehuetenango, and Quirigua in the lower Motagua valley. Antigua Guatemala offers a wealth of colonial architecture. Volcanic landscapes and mountain valleys provide incomparable settings for villages occupied by colourfully attired Indians. Of renown is the Indian marketplace of Chichicastenango.

Finance. The government-controlled Bank of Guatemala is the note-issuing authority and oversees the country's banking system. It also handles all international accounts. A number of other public and private banks are in operation, and a stock exchange was established in Guatemala City in 1987. Guatemala's monetary unit is the quetzal.

Trade. The United States is Guatemala's primary trading partner in terms of both imports and exports. Other major trading partners are Germany, El Salvador, and Japan. The Central American Common Market, founded in 1960, and of which Guatemala is a member, fosters trade between Central American nations. Mexico and Venezuela are major suppliers of petroleum. Other leading imports include electrical machinery, transport equipment, paper, metal products, pharmaceutical and other chemical products, textiles, and food. The major export is coffee, followed by sugar, bananas, chemical products, cardamom, and cotton. The exports of vegetables, fresh fruits, flowers, and seafoods are of increasing importance.

Transportation. A network of highways, concentrated in the southern portion of the nation, is the major means of transport. Railroads have markedly diminished as a means of conveying freight and passengers. Commercial domestic flights within the country are basically limited to those between Guatemala City and the Petén.

Highways

Two primary highways extend east-west across Guatemala. The Inter-American Highway lies to the north of the southern chain of volcanoes. A Pacific coast highway lies to the south. These routes are linked by a number of roads that pass through the chain. The Pacific coastal plain is served by a number of paved highways that extend south from the primary coast highway. The primary north-south highway extends from San José on the Pacific to Puerto Barrios on the Atlantic, by way of Guatemala City. By far the greater number of passengers are carried by bus rather than by private car.

The primary Pacific coast highway and the north-south interoceanic highway are paralleled by the nationally owned railroad. At Zacapa, a rail line branches southeast to El Salvador.

Most of the foreign trade is handled through the Caribbean port of Santo Tomás de Castilla. New Pacific port facilities (Puerto Quetzal) are in operation at San José.

La Aurora International airport, located on the southern outskirts of Guatemala City, is served by international airlines providing service to points throughout the Western Hemisphere and in Europe. The privately operated national airline is Aviateca.

Administration and social conditions. *Government.* The constitution adopted in 1986 defines the country as a sovereign democratic republic and divides power among three governmental branches: legislative, executive, and judicial. Legislative power is delegated to a unicameral Congress elected every five years by direct, popular suffrage. Executive power is vested in the president and vice president, also elected every five years by popular vote. All citizens over the age of 18 are obliged to register and to participate in elections.

The Supreme Court, with at least nine justices, has jurisdiction over all the tribunals of the country. The justices are elected by Congress for terms of four years. The national territory is divided into *departamentos,* each headed by a governor appointed by the president. The departments in turn are divided into *municipios* (municipalities), which are governed by councils presided over by mayors, elected directly by popular ballot.

Broad guarantees are provided for the organization and functioning of political parties, except for the Communist Party and any other that is deemed to be dedicated to the overthrow of the democratic process. Only authorized political parties may nominate candidates for president, vice president, and Congress. Candidates for mayor and other municipal offices need not be nominated by political parties.

Political parties

There is a constant flux in the formation and demise of political parties. Those displaying the most continuity are the Revolutionary Party (Partido Revolucionario; PR), which has shifted from left to right in political orientation, the centrist Guatemalan Christian Democratic Party (Partido Democrácia Cristiana Guatemalteca; PDCG), the right-leaning Institutional Democratic Party (Partido Institucional Democrático; PID), and the right-wing National Liberation Movement (Movimiento de Liberación Nacional; MLN).

Although constitutionally outside of politics, the army nevertheless represents a powerful element in political struggles and has often controlled the government.

Education. Education is in theory free, secular, and compulsory through the primary school. Secondary schools train teachers, agricultural experts, industrial technicians, and candidates for universities. An enrollment of 65 percent of those eligible to attend primary schools declines to less than 20 percent for secondary schools. In rural areas, even many of those who have attended primary schools (usually only to the third grade) are functionally illiterate as adults. Impoverishment and a low premium paid upon education contributes to the lowest level of literacy to be found in Central America.

Universities are concentrated in the capital. The largest is the national University of San Carlos, founded in 1676. The private universities of Rafael Landívar, Del Valle, Francisco Marroquín, and Mariano Galvez have been founded since 1960.

Health and welfare. The inadequacy of medical and health services, particularly in rural areas, is reflected in the high rates of infant mortality. Inadequate sanitation and malnutrition are contributory factors. In larger communities the Ministry of Public Health and Social Assistance maintains hospitals that provide free care, and there are also numerous private hospitals. During the 1980s rural health centres staffed by personnel trained in preventive medicine were established in hundreds of localities in an effort to improve the health of rural inhabitants.

Since 1946 the Guatemalan Social Security Institute has provided medical insurance for public and private employees. The benefits cover accidents and common illness, as well as maternity care. The institute also maintains several hospitals.

Cultural life. *Daily life.* The nation's society is marked by pronounced extremes in the conduct of daily life. In the capital city families live much as they do in the cosmopolitan centres of Europe, whereas within an hour's drive of the capital are Indians whose patterns of daily life remain those of past centuries. The pattern of culture is characterized by sharp contrasts, whether it be in the language spoken or in matters pertaining to the household, cuisine, attire, or family affairs.

The nation's populace is increasingly exposed to the in-

Foreign cultural influences

trusion of foreign influences upon their way of life. All aspects of communication—periodical news, the comics, soap operas, film—are primarily of foreign origin. A multitude of products, from soaps and boxed cereals to automobiles and bottled drinks, bear foreign brand names.

The arts. The evidence of Mayan culture pervades the country. Today, although native crafts involve a variety of forms of expression, they are best represented in colourful handwoven textiles. Traditional dances, music, and religious rites that have survived in the Amerindian regions are important tourist attractions. The art of the colonial period is chiefly represented in the architecture and decor of Roman Catholic churches.

For the most part, the recognition of modern painters, composers, and authors tends to be limited to within the nation. A major exception is the author Miguel Angel Asturias, a poet and novelist who received the Nobel Prize for Literature in 1967. As with Asturias' writings, expressions of the various art forms tend to focus upon the Amerindian heritage of the nation.

Cultural institutions. Virtually all of the more highly recognized centres of cultural activity are concentrated within Guatemala City. These include the National Theatre, the Conservatory of Music, the Museum of Modern and Contemporary Arts, the Ixchel Museum of Indian Attire, a museum of natural history, and the National Museums of Archaeology and Ethnology and of Arts and Popular Crafts. The National Archives have a rich collection of materials on Mexico and all Central America except for Panama. The Society of Geography and History ranks as one of the oldest and most highly respected learned societies in Guatemala.

Recreation. Heavily attended fairs and religious festivals are scheduled in every part of Guatemala throughout the year. Easter celebrations at Antigua Guatemala draw enormous throngs. Among the most important of the national holidays is the day of independence, September 15. The media devotes much attention to soccer, a sport that is widely enjoyed in all parts of the nation. In larger communities, recreational parks draw large crowds on weekends.

Press and broadcasting. Major newspapers and publishing houses, as well as radio and television stations, are located within the capital. Among the most widely circulated newspapers are *La Prensa Libre, El Gráfico, La Hora,* and *Siglo Veintiuno. Diario de Centroamérica* is published by the government. Radio and television have assumed a major role in reaching large numbers who are illiterate or who reside in remote areas of the nation. All means of communication are ostensibly free of government censorship. Censorship has been imposed in times of crisis, however, and intimidation and threats of physical harm have often hindered the free expression of thought. (O.H.H.)

For statistical data on the land and people of Guatemala, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL.

HISTORY

Origin of the republic's name

The origin of the name Guatemala is Indian, but its derivation and meaning are undetermined. Some hold that the original form was "Quauhtemallan" (indicating an Aztec rather than a Mayan origin), meaning "land of trees," and others hold that its origin was "Guhatezmalha," meaning "mountain of vomiting water," referring no doubt to such volcanic eruptions as the one that destroyed Santiago de los Caballeros de Guatemala, the first permanent Spanish capital of the captaincy general.

The colonial period. Under the Spanish, the capital was reestablished at the nearby location of present-day Antigua Guatemala. The capital achieved a certain magnificence, and the other major towns acquired some aspects of Spanish culture, but the outlying areas were only lightly affected. When the capital was razed by an earthquake in 1773, it was moved by royal order to the site of modern Guatemala City.

The colony developed no great degree of economic prosperity. The cultivation for export of agricultural staples, principally cacao and indigo, by Indian or black labour was the major economic activity, exclusive of production for subsistence. Commerce, however, was never extensive; a satisfactory port was never developed, internal transportation was difficult, and pirates harassed the coasts and preyed on shipping. The importance of Guatemala City lay in the fact that it was the administrative centre of the region, being the headquarters of the captain general and the high court (Audiencia).

The postcolonial period. Following independence from Spain (1821) and Mexico (1823), Guatemala was the political centre of the United Provinces of Central America. The principal factor in the collapse of the federation was the backcountry uprising in Guatemala led by Rafael Carrera, who established himself as the military arbiter of the state (1838) and, from the executive's chair or from behind it, controlled policy until his death in 1865. Elections were dispensed with in 1854, when the presidency was conferred upon him for life.

Carrera, with Conservative support, returned Guatemala to a regime similar to that of the colonial period. He restored the church to its position of privilege and power and catered to the aristocracy. Carrera followed a nationalistic policy, and in March 1847 he formally declared Guatemala an independent and sovereign nation. In 1859 he failed to get Britain to follow through on a treaty defining the status and boundaries of British Honduras, an issue that remained unsettled even after Belize became independent.

Revolution of 1871

In 1871 a revolution headed by Miguel García Granados and Justo Rufino Barrios overthrew General Vicente Cerna, Carrera's Conservative successor in office, and inaugurated a period of Liberal ascendancy that extended almost unbroken to 1944. After a brief period in the presidency, García Granados ceded to Barrios (1873), who became known as the Reformer because of the sweeping changes he introduced.

With the approval of the assembly, Barrios broke the power of the local aristocracy; brought the church under civil control and confiscated its properties; instituted lay education; promulgated a new constitution (1876); fostered the construction of roads, railways, and telegraph lines; encouraged development by private initiative of Guatemala's resources; and opened the country to foreign capital. He stimulated the cultivation of coffee and enacted legislation that assured producers of a ready supply of labour. He was an ardent exponent of a Central American union, and, when political means failed to produce results, he invaded El Salvador and lost his life at the Battle of Chalchuapa (1885) in an attempt to accomplish his goal.

After the death of Barrios, Manuel Lisandro Barillas occupied the presidency. He was succeeded by José María Reina Barrios, a nephew of the Reformer, who was elected in 1892 and assassinated in 1898. Manuel Estrada Cabrera then became provisional president, regularized his status by an election, and by repeated reelections maintained himself in power until leaders of the opposition Unionist Party forced him from office by having the assembly declare him insane (1920). During his long tenure, Estrada Cabrera fostered economic development and progress along the lines established by Barrios. He encouraged improvements in agriculture, made concessions to the United Fruit Company (owned by U.S. businessmen), continued to build roads, and supported railroad construction, seeing completion of the railroad to the Atlantic. Health conditions were improved, and education was stimulated. Estrada Cabrera persecuted political opponents, disregarded individual rights, muzzled the press, and summarily disposed of his enemies.

After the fall of Estrada Cabrera the presidency was held by a series of short-term rulers. In 1931 General Jorge Ubico was elected president without opposition and began the fourth of Guatemala's extended dictatorships.

Jorge Ubico

Contemporary period. Ubico stressed economic development and, in particular, the improvement and diversification of agriculture and the construction of roads. He balanced the national budget and transformed a deficit into a surplus. His paternalistic policies toward the Indians established him as their patron, although his vagrancy law (1934) made workers, especially Indians, liable to periods of forced labour at critical seasons. During his motorcycle tours of the country or in his office, he listened to their complaints and dispensed immediate "justice." This relationship deluded Ubico (called Tata, "Father") into stating that Guatemala no longer had an Indian problem. Education was of but slight interest to him.

Ubico's administration dramatized the degree to which Liberal thought had lost its idealism and was concerned principally with material progress. The new socioeconomic groups found no stimulation and no hope in the dreary materialism and military repression that had come to characterize Liberal regimes, and these potential sources of opposition were brought together by the increasing disregard shown for individual rights and liberties. The discontent was increased by economic dislocation during World War II. In December 1941 Ubico's government declared war on Japan, Germany, and Italy.

Juan José Arévalo

In June 1944 a general strike forced Ubico to resign. Labour was allowed to organize, political parties were formed, and a presidential electoral campaign was begun, in which Juan José Arévalo soon emerged as the most popular candidate. General Federico Ponce Vaides, head of the interim government, was deposed on Oct. 20, 1944, by a popular uprising; and a revolutionary junta presided over the drafting of a new constitution and the electoral campaign, which was won by Arévalo. The Arévalo administration attempted to consolidate the social revolution implicit in the October uprising. A favourable labour code was enacted, and a social security system that promised progressive extension of benefits was inaugurated. Arévalo also pressed the Belize issue with Great Britain, subjected foreign enterprises to regulation, and attempted to guarantee Guatemalan labourers larger benefits. Thus, the Arévalo regime transferred political power from the military to a popular group, of which organized labour was the most important element.

Lack of leadership from the rank and file allowed Guatemalan communists to organize the labour movement and use it for their own ends. Arévalo was not friendly to their activities, but his nationalistic bent gave them opportunity to establish themselves as his most enthusiastic and reliable supporters.

Successors to Arévalo

The most likely candidates to succeed Arévalo were two military men, Francisco Arana and Jacobo Arbenz. Arana was assassinated in 1949. Arbenz became the official candidate, was elected—with communist support—over General Miguel Ydígoras Fuentes, and assumed office in March 1951. Arbenz made agrarian reform the central project of his administration. With communist support, the National Congress passed a measure providing for the expropriation of unused portions of landholdings in excess of a specified acreage and for the distribution of the land among landless peasants.

The land reform, which had a heavy impact upon the U.S.-owned United Fruit Company, and the growth of communist influence became the most troublesome issues of the Arbenz regime. The U.S. Central Intelligence Agency (CIA) began efforts to destabilize the regime and recruited a force of Guatemalan exiles in Honduras, which was led by the exiled Colonel Carlos Castillo Armas. When the invasion began, the army would not fight for Arbenz, however, and in June 1954 he was forced to resign.

Castillo Armas emerged from a military junta as provisional president, and a plebiscite made his status official. He extirpated communist influence, quashed agrarian reform, and broke labour and peasant unions with considerable violence. He sought to restore the confidence of foreign investment capital, but he was assassinated in July 1957. After two temporary governments and an election nullified by the congress, Ydígoras Fuentes was declared elected to the presidency and took office on March 2, 1958. In March 1963 a coup led by the defense minister, General Enrique Peralta Azurdia, removed Ydígoras. As provisional president, Peralta canceled the election, promising to hold one later. The frustration, during these regimes, of the social reforms promised by the revolution of 1944 made restive elements of the population increasingly receptive to counsels of resistance and even of violence.

An orderly election on March 6, 1966, gave Julio César Méndez Montenegro, a law professor and the candidate of the moderately left-wing Revolutionary Party (Partido Revolucionario; PR), an unexpectedly large plurality of votes over the candidate of the military regime but not the absolute majority required for election. Congress elected him, but the understanding with the military officers that had to be reached before a civilian government could take office undermined his authority. Hopes for reform, therefore, were largely frustrated, and the energies of the administration were consumed in attempts to control the increasing violence and terrorism. Rural guerrillas were substantially eliminated by military and paramilitary operations such as those conducted by Colonel Carlos Arana Osorio, but urban guerrilla and terrorist activity worsened.

Carlos Arana Osorio

Arana Osorio, the "law-and-order" candidate, won the election of 1970. His major activity was "pacification" of the country by the extermination of "habitual criminals" and leftist guerrillas. Assassination of opposition leaders of the democratic left by so-called death squads, often linked to the military and the police, gave rise to the conviction that Arana was attempting to eliminate all opponents, whether left, right, or centre. With dissent eliminated or hushed, the country experienced a period of relative quiet. As the election of 1974 approached, optimists could find some reason to hope that a new basis had been laid for reform. The coalition of opposition parties chose General Efraín Ríos Montt, a leading officer of the progressive wing of the military forces, to contend with General Kjell Laugerud García, a nonpolitical military officer representing the coalition of rightist parties.

When returns showed Ríos Montt winning an absolute majority, which constituted election, the government abruptly suspended election reports, brazenly manipulated the results, and finally announced that Laugerud García had won a plurality of votes. The government-controlled National Congress promptly elected him. Deprived of moral force, Laugerud took office as the protégé of Arana. He faced problems of inflation, a series of volcanic eruptions, and division and consequent weakening of his principal political support, the MLN. He met a renewal of leftist violence and terror with the same repressive measures that Arana had applied.

The pattern of electoral manipulation set in 1974 persisted in subsequent elections. General Fernando Romeo Lucas García, declared the winner in 1978 after another suspect count, presided over a regime that essentially continued that of Laugerud. Both administrations confronted the nation's problems with resources greatly reduced in consequence of natural calamity. The devastating earthquake of February 1976 was labeled the greatest natural disaster ever recorded in Central America.

A major factor in both administrations was the discovery of oil in northern Guatemala. Because the deposit was thought to extend across British Honduras (now Belize) to the continental shelf, resolution of persistent, conflicting boundary and territorial claims was sought. On March 11, 1981, Guatemala, Great Britain, and British Honduras reached preliminary agreement, but a final settlement was not reached, and in September 1981 Great Britain granted independence to Belize over Guatemala's protest. The discovery of oil was also thought by some to be behind government violence in the largely Indian departments of the north. The devastation that occurred there drove thousands of Indians into Mexico, suggesting that the administration might be clearing lands for others to appropriate. Certainly, Indians moved in unprecedented numbers into the guerrilla movements.

In the elections of March 1982, the government coalition candidate, General Angel Aníbal Guevara, was declared elected. On March 23, however, young army officers seized the government and installed a junta headed by General Ríos Montt, who had been denied the presidency in 1974.

Ríos Montt

Ríos Montt dissolved the junta and pledged to rout corruption, disband the notorious death squads, and end the guerrilla war. The new leader failed to follow through on his promises, however, and conditions in Guatemala worsened. Ríos Montt's economic policies were not effective, and the political violence that he had promised to end was soon renewed with even greater intensity, again forcing many peasants to flee into Mexico and driving others into guerrilla camps, thus fueling the insurgency. A Protestant in a largely Roman Catholic country, Ríos Montt had trouble holding support.

In August 1983 Ríos Montt, unable to hold support, was overthrown by General Oscar Humberto Mejía Víctores, who promised a quick return to the democratic process. Violence continued in the countryside, however, and the United States, seeking human rights improvements, restricted aid to the new regime; military aid had been curtailed since 1977 for human rights violations. Elections for a constituent assembly were held in July 1984, and the parties of the centre pulled about a third of the vote, indicating a movement away from the support of the right-wing groups said to influence the kidnappings, murders, and other violence often attributed to death squads.

A new constitution, bringing greater emphasis to human rights guarantees, was approved in May 1985, and presidential elections held the following December produced a landslide victory for the centrist PDCG leader, Marco Vinicio Cerezo Arévalo, who received some 68 percent of the vote. It was the first election of a civilian president in Guatemala in 15 years. Despite Cerezo's sweeping victory, the new government faced onerous and complex problems that could only be resolved with consummate skill and effort. On taking office Cerezo told the nation to prepare itself for severe austerity measures that were necessary to combat Guatemala's worst economic depression in 50 years.

Continued reliance on U.S. aid

Hopes that Cerezo's election could support human rights reforms and end the violence were quickly dashed. There was a resurgence of death squad activity, particularly in the capital. The various bands of Marxist guerrillas, largely checked in the time of Ríos Montt and Mejía Víctores, found a new unity in the formation of the Guatemalan National Revolutionary Unity (Unidad Revolucionario Nacional Guatemalteco; URNG). A series of attempted military coups were put down by Defense Minister General Héctor Alejandro Gramajo. Labour and peasant unrest also increased during the Cerezo presidency. Some painful economic progress was made, but Cerezo had to rely on U.S. aid as the insurgency and violence continued to grow in intensity into the 1990s. (W.J.Gr./T.P.A.)

For later developments in the history of Guatemala, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

Honduras

The Republic of Honduras (Spanish: República de Honduras) is a small nation of Central America situated between Guatemala and El Salvador to the west and Nicaragua to the south and east. The Caribbean Sea washes its northern coast, the Pacific Ocean its narrow coast to the south. With an area of 43,277 square miles (112,088 square kilometres)—including the offshore Caribbean department of the Bay Islands—Honduras is one of the largest countries of Central America. The bulk of the population lives a generally isolated existence in the mountainous interior, a fact that may help explain the rather insular policy of the country in relation to Latin and Central American affairs. Its economy is primarily agricultural, bananas and coffee for export being particularly important, although corn (maize) is the chief domestic staple. The capital is Tegucigalpa, but—unlike most other Central American countries—there are other cities, such as San Pedro Sula, that are equally important industrially and commercially.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* More than 75 percent of the land area is mountainous, lowland being found only along the coasts and in the several river valleys that penetrate toward the centre of the interior. The interior takes the form of a dissected upland with numerous small peaks. The main surface features have a general east-west orientation. Except for a narrow plain of alluvium bordering the Gulf of Fonseca in the south, the southwestern mountains, the Volcanic Highlands, consist of alternating layers of rock composed of dark, volcanic detritus and lava flows, both of Tertiary age (from 1.6 million to 66.4 million years old). The northern mountains in other regions are more ancient, granite and crystalline rocks predominating.

The four regions

Four distinct geographic regions may be discerned: (1) The eastern Caribbean lowlands (including the northern part of the area called the Mosquito [Miskito] Coast) and mountain slopes embrace about one-fifth of the total land area. Hot and humid, this area is densely forested in the interior highlands, lumbering being an important economic activity. Subsistence agriculture and fishing are the main support of the scattered population. (2) The northern coastal and alluvial plains and coastal sierras make up about one-eighth of the land area and contain about one-fourth of the population. This is an economically important area, the clayey and sandy loam soils producing rich crops of bananas, rice, cassava (manioc), oil palm, corn, citrus fruits, and beans. Cattle, poultry, and pigs are raised. The nation's railroads are confined to this northern area, which has four of the five important ports of entry. (3) The central highlands take up two-thirds of the national territory and contain the vast majority of the population. The mountains are rugged, rising to more than 9,200 feet (2,800 metres) in the west, and the numerous flat-floored valleys are situated at altitudes of from 1,000 to 3,000 feet. The generally fertile soils, derived from lava and volcanic ash, produce coffee, tobacco, wheat, corn, sorghum, beans, fruits, and vegetables. Cattle, poultry, and pigs are raised. (4) The Pacific lowlands, centred on the Gulf of Fonseca, and the adjacent lower mountain slopes constitute only a small part of the land area and contain an equally small part of the population. The soils are fertile—composed of alluvium or volcanic detritus—and produce sesame seed, cotton, and small amounts of corn and sorghum. Cattle are raised on the lowland pastures, and coffee is grown on the nearby uplands.

Climate. The climate is generally hot, with high humidity in the tropical coastal lowlands becoming modified by altitude toward the interior. Lowlands below 1,500 feet have mean annual temperatures between 79° and 82° F (26° and 28° C). The north coast is occasionally affected from October to April by cool northern winds of continental origin. Mountain basins and valleys, from 2,000 to 4,000 feet, have mean annual temperatures of 66° and 73° F (19° and 23° C). At Tegucigalpa, located on hilly terrain at an altitude of 3,200 feet, the rainy season starts in May and continues until the middle of November, with temperatures sometimes reaching 90° F (32° C) in May and dropping to 50° F (10° C) in December, the coolest month. Around 7,000 feet, mean annual temperatures are about 58° F (14° C). In the northern and eastern coastal and alluvial plains and on adjacent mountains, mean annual precipitation ranges from 70 to 110 inches (1,800 to 2,500 millimetres) or more, with a less rainy season from March to June; these areas occasionally have summer hurricanes with heavy rains. Pacific plains and mountain slopes get 60 to 80 inches (1,500 to 2,000 millimetres) of rain annually but from December to April receive little or no rain. Interior sheltered mountain basins and valleys receive 40 to 70 inches annually.

Coastal and lagoon swamps

Plant and animal life. In eastern Honduras the coastal and lagoon swamps have mangrove and palm forests, and west of these are low, rainy, sandy plains with pine-savanna (*Pinus caribaea*) forests, extending inland for 40 miles or more. West of the pine-savanna forests, in low valleys and on lower mountains, which are rainy all year, and on the low, rainy northern mountains are broad belts of dense evergreen broad-leaved forests with many species of large trees, including mahogany, lignum vitae, Spanish cedar, balsa, rosewood, ceiba, sapodilla (yielding chicle used for the base of chewing gum), and castilloa rubber. The high, rainy mountain slopes of highland Honduras support excellent oak-pine forests. Open, dry, deciduous woodlands and temperate grasslands are spread throughout the interior highland basins and valleys. The Pacific plains and adjacent mountain slopes have deciduous tropical forest and savanna. Mangrove occupies the low coastal swamps.

Insects, birds, and reptiles are the most conspicuous animal forms. There are many species of butterflies, moths, beetles, bees, wasps, spiders, ants, flies, and mosquitoes, many of them beautifully coloured. Waterfowl in large numbers inhabit the coastal areas. Crocodiles, snakes, lizards (giant iguana and others), and turtles are found in the tropical forest areas. The fauna also includes deer, peccaries, tapir, pumas, jaguars, and ocelots. Fish and mollusks are abundant in lagoons and coastal waters.

The people. Honduras has been inhabited since well before the Common Era: the ruins at Copán in western Honduras indicate that the area was the centre of Mayan civilization before the Maya migrated to the Yucatán Peninsula. Most of the American Indians are Lenca and are now found in the southwest, near the Guatemala border, close to the most important Indian centres of the pre-Columbian period. Small, isolated groups of non-Spanish-speaking Indians—such as the Jicaque, Miskito (Mosquito), and Paya—continue to live in the northeast, although their numbers are declining. The largest sector of the population, however, is mestizo (a mixture of Spanish and Indian). The mestizos of Honduras are generally darker and more Indian in appearance than those of other Latin-American countries such as Chile, Uruguay, and Argentina. Blacks of West Indian origin and Black Caribs make up a small part of the population, living mainly along the Caribbean coast, an area in which considerable English is spoken.

Official language

The official language of Honduras is Spanish, and the predominant religion is Roman Catholicism, more than 90 percent of the population being adherents. The largest of the remaining groups are Protestant, with notable congregations in the east and on the Bay Islands.

A pronounced shift in population took place during the early part of the 20th century from the interior to the hot, humid north coast, where employment opportunities were provided by the United Fruit Company. These northwestern lowlands and the western and southern highlands constitute the most densely populated parts of the country. The population is growing extremely fast, posing a considerable problem in employment and housing. The majority of the population is rural, living in small villages or isolated settlements. The mountainous, forested terrain and rather poor road transportation are conducive to local isolation.

The economy. Honduras is a poor country, and the majority of Hondurans work under extremely difficult conditions. The government has, however, adopted more active economic policies since the mid-1900s. In 1954 the trade union movement obtained one of its most resounding triumphs, resulting in the promulgation of a labour code that is considered one of the most complete instruments of its kind in Latin America. The code has generally resulted in a higher standard of living for the worker and better operating conditions for business.

Honduras possesses a limited natural resource base that includes agricultural lands along the northern coast and interior river valleys, extensive pine forests not yet exploited, and small deposits of silver, lead, zinc, and low-grade iron ore. The economy is geographically divided between the highlands, where subsistence farming, stock raising, and mining have long dominated, and the lowlands, where plantation agriculture based largely on bananas is the chief occupation.

Agriculture, forestry, and fishing. In terms of the gross domestic product, agriculture contributes the largest portion. Agriculture also employs the majority of the labour force. Two large U.S. corporations—United Brands (formerly United Fruit Company) and Standard Fruit and Steamship Company—hold a disproportionate amount of the country's agricultural land and produce a substantial part of the national income by growing the majority of the country's banana crop. Important export crops other than bananas include coffee beans, cotton, tobacco, and sugarcane. Cattle raising is the main livestock activity, and beef has become an important export.

About two-thirds of the country's land is covered by forests, making forest products a potentially large source of national income. The extensive pine forests were attacked by blight in the 1960s, and mahogany—the major timber export—began declining in importance. The practice of shifting agriculture, employing widespread burning of forests and the cutting of wood for fuel, has caused a depletion of the forest resources. Present commercial practices of forest exploitation are inefficient. A substantial portion of timber harvested for commercial purposes does not reach the sawmill, and less than half of the timber that arrives at the mill is processed into lumber. To help alleviate the wasteful forestry practices the government put all forest trees under state ownership in 1974, but forests continue to be depleted at a rapid rate.

Depletion of forest resources

Fishing is a small but developing industry, carried on mainly off the Caribbean coast. Shrimp is the most important part of the catch, the largest portion of which is shipped to the United States.

Industry. Manufacturing is dominated by small-scale firms that are at intermediate levels of technology and possess limited processing capabilities. The major products manufactured and processed are food products, beverages, textiles, clothing, chemicals, lumber, and paper products. The production of capital and heavy intermediate goods is minimal. Industrial plants are located largely in the urban areas of San Pedro Sula and Tegucigalpa.

Mineral resources are considerable, though largely unexploited, and include antimony, iron, mercury, and copper. Production of silver and gold has remained of some importance, and lead and zinc are produced in commercial quantities.

Honduras has a few hundred miles of public-service railroads. The Honduras National Railway, which is owned by the government, extends from Puerto Cortés to San Pedro Sula. It hauls timber and agricultural products. The Tela Railway, once owned by the United Brands Company and acquired by the Honduras government in 1975, provides service for plantations in the eastern Sula Valley and the coastal plain. Another government-owned railroad runs east along the coastal plain to Balfate, with a branch extending into the Aguan Valley.

Roads in Honduras carry the vast majority of the freight tonnage and almost all the passenger traffic. The rugged terrain of the Honduras countryside favours the development of roads instead of railroads. The exception to this is along the northern coastal plain where railways serve the banana plantations. The heart of the primary road network is the north-south highway that links the Pacific port of San Lorenzo and the Caribbean port of Puerto Cortés, stopping at Tegucigalpa and San Pedro Sula. The highway provides access to important agriculture areas in the Sula and Choluteca valleys and along the Caribbean coast. The Inter-American Highway cuts across southern Honduras for about 100 miles. Highways also run southwest from San Pedro Sula to the El Salvador border and along the north coast from San Pedro Sula to La Ceiba.

All Honduran ports are operated by the National Port Authority. The major ports in the country are Puerto Cortés, Tela, La Ceiba, and Puerto Castilla. The Pacific coast provides deepwater anchorage at Amapala on El Tigre Island and at the mainland port of San Lorenzo, completed in 1978.

Domestic air travel, although declining, supplements rail and highway travel, which includes intercity bus and truck service. Villeda Morales Airport at San Pedro Sula is the largest airfield. The airport at Tegucigalpa has a substantially shorter runway and is minimally suitable for modern jet travel.

Administration and social conditions. *Government.* Since acquiring independence in 1821, Honduras has been described constitutionally as a democratic, representative, unitary state with power divided among the legislative, executive, and judicial branches. The country's constitution was rewritten 17 times between the years 1821 and 1982. Power, however, has frequently been mobilized and changed by violent, undemocratic means. Although the legislature is given the power to pass laws, practically all important legislation is drafted by the executive and his assistants. The National Assembly in theory has great authority to check the administrative activities of the president, but only during the period 1925–31, when several Cabinet ministers appointed by the president were forced to resign through censure, was such authority effective.

Power of the executive

The president is elected directly by popular vote for an unrenewable term of four years. The single-house National Assembly is composed of 134 legislators elected to four-year terms. The major political parties are the Liberal Party of Honduras (Partido Liberal de Honduras) and the National Party (Partido Nacional). All citizens over 18 years of age are permitted to vote.

For purposes of local administration, Honduras is divided into 18 *departamentos*. Governors are appointed by the president, one for each department, to carry out central government decisions. The departments are divided into *municipios* (municipalities), which are further partitioned into *aldeas* (villages, or hamlets). Rural areas are grouped into *caseríos* (settlements), which are subdivisions of *aldeas*. Localities may elect a mayor, a legal representative, and a council.

The justices of the Supreme Court are appointed by the president. The Supreme Court exercises centralized control over the lower courts, including the appointment of justices, and has original and exclusive jurisdiction to declare acts of the legislature unconstitutional.

Education. The Honduran educational system follows the European model of centralized control through the Ministry of Public Education. According to law, education is free and, at the primary level, compulsory for all children. Efforts have been made to combat illiteracy, which is very high for older people. Higher education is centred at the National Autonomous University of Honduras in Tegucigalpa (founded 1847).

Welfare and health. By the late 20th century Honduras, like most other Latin-American countries, had moved more and more in the direction of the interventionist, or welfare, state. In 1955 the Honduran basic labour code came into effect, granting the right to work, minimum wages, an eight-hour day, freedom to form labour unions, collective bargaining, conciliation, and the right to strike. Social security and social welfare benefits were not improved appreciably, however, and many Honduran workers outside the public sector and not employed by business or industry are not covered. Health care is also generally inadequate for the poor urban and rural labourers. Death rates are high among the lower economic groups, who suffer from two severe health problems in particular, malnutrition and malaria.

The Honduran basic labour code

Cultural life. The art and architecture of pre-Columbian and Spanish colonial periods are strongly evident in Honduran culture. Of special interest is the great Mayan city of Copán, which was restored in 1839 after its discovery in a thick jungle more than 250 years earlier; it represents the height of the Mayan Classic period. Spanish architecture reflects Moorish, Gothic, and, especially, Baroque styles. Modern Honduran culture has not produced many strong representatives of its art, the country's widespread poverty being a major impediment. Most contemporary artists reflect their colonial heritage, while the pre-Columbian heritage is seen mainly in Indian crafts. Social themes may also be reflected in paintings and literary works, the latter being generally represented by poetry and short fiction.

Cultural institutions in Honduras include the National School of Music and the National Museum, both in Tegucigalpa, and the Archaeological and Historical Museum in Comayagua. Noteworthy among other institutions are those dedicated to the production of theatrical works in both Spanish and English.

Family recreation often revolves around religious festivals honouring local saints. Soccer (football) is the favourite team and spectator sport, and international matches often arouse great emotion.

There is general freedom of the press in Honduras, and daily newspapers are published in the principal cities of the country. Those of Tegucigalpa and San Pedro Sula are most noteworthy. The progressive and rapid development of radio and television has provided the country with excellent facilities for speedy and effective communication. There are private radio and television networks that cover the entire country. (J.R.M.R./Ed.)

For statistical data on the land and people of Honduras, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL.

HISTORY

Early history. When the Spanish arrived to colonize Honduras, the land was occupied by a variety of indigenous peoples, the most advanced of whom were the Maya. During the early colonial period, in the 1570s, a silver strike in the highlands brought a rush of prospectors to Honduras, resulting in the rise of an important population centre at Tegucigalpa, which competed thereafter with the traditional capital, Comayagua. Agriculture, however, the enduring economic base of Central America, was slow to develop in Honduras. Development of Spanish society in the Honduras area was hindered by coastal attacks from the pirates and buccaneers endemic to the Caribbean Sea and eventually by a concerted British effort to control the coastal areas of Central America. For long periods the Spanish utilized a soft defense against the Caribbean threat, falling back to the highlands and to the Pacific coastal areas, which were generally closer to their network of communication and transportation. Thus, the British came to control the Caribbean's Mosquito coastal region. The Sambo-Miskito peoples along the coast were the indispensable allies of the British in this endeavour. In the 18th century, however, the Spanish Bourbon kings made a sustained effort to recover the Caribbean coastal areas, and their success in the Gulf of Honduras was manifested by the completion of a fort at Omoa on the gulf by 1779.

Indigenous peoples

Independence from Spain came after 1821. Francisco Morazán, elected to head the United Provinces of Central America in 1830, was a Honduran Liberal whose influence derived from a principal goal of liberalism, to curtail the traditional power and privileges of the church and clergy. Honduras declared its absolute independence on Nov. 5, 1838. The pro-church Conservatives in Honduras took control under Francisco Ferrera, who was inaugurated as the first constitutional president on Jan. 1, 1841.

Domination by the Conservatives lasted until the 1870s, and the church was restored to its former position. In 1861 the Honduran government signed a concordat with the Holy See. After 1871 the ascendancy of Justo Rufino Barrios in Guatemala influenced a return to liberalism in Honduras, where Marco Aurelio Soto, a Liberal, assumed the presidency (1876). A new constitution (1880) sought to undo the work of the Conservatives. Five years later, Liberals in Honduras and elsewhere proved to be nationalists first and blocked an attempt by Guatemala to unify the isthmus by force.

The 20th century. In the first decade of the 20th century, the strongman in Nicaragua, José Santos Zelaya, put Miguel Dávila into the Honduran presidency. This led in 1911 and 1912 to something more serious than periodic revolutions. The U.S. president, William Howard Taft, sent marines to protect U.S. banana investments, which by this time had grown considerably, with three companies exploiting this Honduran product. All three made large capital outlays in the form of improved port facilities, railroads, workers' settlements, and similar developments.

In 1918 Honduras declared war on Germany but took no active part in World War I. Political upheavals continued after the war. In 1932, after years of unrest, another strongman, General Tiburcio Carías Andino, was elected president and remained in office until 1949, dealing with several abortive revolutions during his virtual dictatorship. Honduras declared war on Japan, Germany, and Italy in December 1941. Lack of shipping brought much economic distress during the war; export surpluses of bananas, coconuts, and copra piled up, leading to widespread unemployment and consequent unrest. But the government was able to maintain itself, and it promulgated some beneficial reforms. Carías survived a revolution in 1947, but a year later he resigned under pressure.

Carías Andino

Policies under Juan Manuel Gálvez (1949–54), Julio Lozano Díaz (1954–56), and Ramón Villeda Morales (1957–63) brought some modernization to the transportation system and to labour legislation. The International Court of Justice awarded the large disputed area north of the Coco River to Honduras in 1960. In 1963 Villeda Morales was deposed by a military coup led by Colonel Osvaldo López Arellano, who declared himself head of state. In the summer of 1969 the Soccer War with El

Salvador broke out, triggered indeed by a soccer game but caused by severe economic and demographic problems. Though brief, the war dampened hopes for economic and political integration in Central America.

After 1963 Honduras was ruled by military governments until the election of Ramón Ernesto Cruz (1971–72). Cruz's election resulted from the Soccer War, which Honduras had lost militarily. But López Arellano, as chief of the armed forces, retained real power, and in December 1972 he removed Cruz from office. Pressured toward modernizing reforms by younger military officers, López Arellano astonished many by announcing, in January 1974, a reform program that included land redistribution. His program had little success, however.

López Arellano was discredited and forced to resign in 1975 because of an international bribery scandal; he was replaced by Colonel Juan Alberto Melgar Castro (1975–78). Honduras prospered under Melgar. High earnings from the elevated world coffee market during those years were particularly helpful. His administration was weakened, however, by a series of scandals.

General Policarpo Paz García, who attained power through a bloodless military coup in late 1978, pledged to continue Melgar's policies, but he soon faced harder times. Central America entered a cycle of violence with the revolution in Nicaragua that overthrew Anastasio Somoza Debayle in the summer of 1979 and the revolution in El Salvador that was under way in that same year. Honduras appeared to be an island of stability as its neighbours experienced guerrilla warfare. In November 1981 the country elected a civilian government after 17 years of almost continuous military rule. The new Honduran president, Roberto Suazo Córdova of the Liberal Party, was a noted anticommunist who favoured strong relations with the United States. Hopes ran high for internal improvements, but these were dashed as Honduras became embroiled in the growing regional conflicts. Protests grew over the presence of Nicaraguan Contras, who were using U.S.-sanctioned Honduran border areas as bases for attacks against Nicaragua's Sandinista government. There was also dissension over U.S.-run camps for training Salvadorans in counterinsurgency to combat the growing civil war in their country; a ban against this practice was passed in 1984. These events seemed a reprise of Honduras' role in Central America during most of the 19th and 20th centuries, when, because of geography and a lack of national organization, Honduras had suffered repeated invasions and served numerous third parties as a base for attacks upon its neighbours.

Controversy over the Contras

The United States had hoped that its relations with Honduras would help establish the country as a model Central American democracy, but that image was tarnished when a controversy arose over Suazo's alleged manipulations in choosing the Liberal Party's presidential candidate for the November 1985 elections. It was finally agreed that each party could run multiple candidates, with the presidency going to the leading candidate of the party drawing the most votes. On that basis José Azcona Hoyo of the Liberal Party was declared the winner with only 27.5 percent of the vote, against Rafael Leonardo Callejas of the National Party, who drew about 41 percent. In the late 1980s the government joined the other isthmian governments in a cooperative movement for peace in Central America; this brought increased pressure at home and from abroad to restrict Contra activity and to reduce the U.S. presence. In 1990 a new president, Rafael Leonardo Callejas, took office; it was the first time in 57 years that an opposition government had taken office peacefully. (W.M.Cl.)

For later developments in the history of Honduras, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

Nicaragua

The Republic of Nicaragua (Spanish: República de Nicaragua) is located in the middle of Central America and is bounded by Honduras on the north, the Caribbean Sea on the east, Costa Rica on the south, and the Pacific Ocean on the west. Despite territorial losses to its neighbours, it is the largest of the Central American republics, with an area of 50,464 square miles (130,700 square kilometres). Its population, mostly mestizo, represents a racial mixture that reflects the country's history. The capital is Managua, the nation's largest city.

Nicaragua can be characterized by its agricultural economy, its history of autocratic government, and its imbalance of regional development; almost all settlement and economic activities are concentrated in the western half of the country. Most of the population is engaged in subsistence farming, and the national economy is heavily dependent upon exports of coffee and cotton. The government was in the hands of the family of the former president Anastasio Somoza García from 1936 to 1979, when the Sandinista National Liberation Front seized power. The Sandinista government held power until 1990, when it was defeated in a national election.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* The western half of the country is made up generally of valleys separated by low but rugged mountains and many volcanoes. This intricately dissected region includes the Cordillera Entre Ríos, on the Honduras border, the Cordilleras Isabelia and Dariense, in the north-central area, and the Huapí, Amerrique, and Yolaina mountains, in the southeast. The mountains are highest in the north, and Mogotón Peak (6,900 feet [2,103 metres]), in the Cordillera Entre Ríos, is the highest point in the country.

Western mountains

To the west and south of the central mountain core is a string of about 40 volcanoes that stretches northwest-southeast along the Pacific coast. They are surrounded by low plains extending from the Gulf of Fonseca in the north to the Bay of Salinas in the south and are separated from the mountains by the great basin that contains Lakes Nicaragua, Managua, and Masaya. The volcanoes, some of which are active, are divided into two groups; in the north they are known as the Cordillera de los Marrabios and in the south as the Pueblos Mesas. The highest volcanoes include San Cristóbal, which rises to 5,840 feet; Concepción, which attains 5,108 feet; and Momotombo, at 4,462 feet.

The eastern half of Nicaragua has low, level plains. Among the widest Caribbean lowlands in Central America, they average 60 miles (100 kilometres) in width. The coast is broken by river mouths and deltas and large coastal lagoons and by coral reefs, islands, cays, and banks that dot Central America's largest continental shelf.

Drainage and soils. The central mountains form the country's main watershed. The rivers that flow to the west empty into the Pacific Ocean or Lakes Managua and Nicaragua. They are short and carry a small volume of water; the most important are the Negro and Estero Real rivers, which empty into the Gulf of Fonseca, and the Tamarindo River, which flows into the Pacific.

The eastern rivers are of greater length. The 425-mile-long Coco River flows for 295 miles along the Nicaragua-Honduras border and empties into the Caribbean on the extreme northern coast. The Río Grande de Matagalpa flows for 267 miles from the Cordillera Dariense eastward across the lowlands to empty into the Caribbean north of Pearl Lagoon (Laguna de Perlas) on the central coast. In the extreme south, the San Juan River flows for 124 miles from Lake Nicaragua into the Caribbean in the northern corner of Costa Rica. Other rivers of the Caribbean watershed include the 158-mile-long Prinzapolka River, the 55-mile-long Escondido River, the 60-mile-long Indio River, and the 37-mile-long Maíz River.

The west is a region of lakes. Lake Nicaragua, with an area of 3,156 square miles (8,157 square kilometres), is the largest lake in Central America. Located in the southern isthmus, the lake and its distributary, the San Juan River, have long been discussed as a possible canal route between the Caribbean and the Pacific.

Nicaragua's lakes

There are six freshwater lakes near the city of Managua. They include Lake Managua, which covers an area of 400 square miles; Lake Asososca, which acts as the city's reservoir of drinking water; and Lake Jiloá, which is slightly alkaline and is a favourite bathing resort. Lake Masaya is prized for its swimming and fishing facilities; the sulfurous waters of Lake Nejapa have medicinal properties ascribed to them; and Lake Tiscapa, which lies within the capital city, is the site of the Presidential Palace.

Other lakes in the Pacific watershed include Lake Apoyo, near Lake Masaya; Lake Apoyeque, picturesquely located between two peaks on Chiltepe Point, which juts into Lake Managua; and the artificial Apanás Reservoir on the Tuma River, which generates much of the electricity consumed in the Pacific zone.

Soils on the Caribbean coast are varied and include fertile alluvial types along waterways and relatively infertile types in the pine-savanna and rain forest regions. On the Pacific coast the soil is volcanic, and about 85 percent of its area is fertile.

Climate. The climate is slightly cooler and much wetter in the east than in the west. The Pacific side is characterized by a rainy season from May to November and a dry season from December to April. The annual average temperature is 81° F (27° C), and precipitation averages 75 inches (1,910 millimetres) yearly. On the Caribbean side of the country, the rainy season lasts for about nine months of the year, and a dry season extends from March through May. The annual average temperature is 79° F (26° C), and annual precipitation averages almost 150 inches (3,810 millimetres). In the northern mountains temperatures are cooler and average about 64° F (18° C). Prevailing winds are from the northeast and are cool on the high plateau, warm and humid in the lowland.

Tropical forest

Plant and animal life. More than one-third of the country is covered with a broad expanse of tropical forest. The numerous types of trees include the valuable cedar and mahogany. The quebracho, or axbreaker, yields hardwood; the guaiacum, or lignum vitae, yields one of the ironwoods; the guapinol yields resin; and the medlar produces fruit similar to the crab apple. The eastern lowlands comprise pine savannas, the streams of which are lined with forests.

The country is rich in wildlife. Deer are common in the forested regions, and the fauna also includes such cats as the puma, jaguar, ocelot, and margay; several species of monkey; and peccaries. The hot and rainy regions are inhabited by various types of reptiles, including crocodiles, lizards, snakes, and turtles. There are many species of water and land birds, and the rivers, lakes, and lagoons are inhabited by freshwater and saltwater fishes and mollusks. Rodents and insects are abundant.

Settlement patterns. The western volcanic mountains and surrounding lowlands and lakes contain the majority of the country's population, most of its cities, and most of its industry. The area also yields most of Nicaragua's agricultural produce. The valleys of the western central mountains contain a substantial population and yield about one-quarter of the national agricultural production. Although they make up about one-half of the country, the eastern lowlands are lightly populated. The region is important, however, as a vast resource of timber.

Nicaragua is predominantly urban. By far the largest city is Managua, on the southeastern shore of Lake Managua. Other important urban centres include León, Granada, Masaya, and Chinandega, all in the west. Matalgalpa, Estelí, Juigalpa, and Jinotega are among the largest cities of the central mountains. Bluefields and Puerto Cabezas are the largest towns on the Caribbean coast.

The people. Most of Nicaragua's population is a product of racial admixture. The overwhelming majority of the people are mestizos (persons descended from mixed European and American Indian ancestry), called Ladinos in Nicaragua. The country has about equal numbers of blacks and whites, together making up some 20 percent of the population, and American Indian peoples make up less than 5 percent of the total. The west coast has a small number of Monimbo and Subtiaba Indian peoples. The peoples of the east coast include Miskito, Sumo, and Rama Indians and Garifuna (descendants of African slaves and Carib Indians), and there are a number of Creoles (mostly black English-speaking peoples) and some Ladinos.

Languages

Nicaragua has many languages, but Spanish, the official language, is spoken by the vast majority of the people. American Indian languages are commonly spoken on the east coast, as is English. On the west coast Indian languages have all but disappeared from use, but their influence remains in place-names and in many nouns in Nicaraguan Spanish.

Roman Catholicism is the predominant religion of the Nicaraguan people. Small Protestant and Jewish communities are concentrated in the larger cities. There is no official religion.

Nicaragua's population was decimated by the Sandinista-Contra war that took place during the 1980s; the number of refugees and exiles leaving the country was estimated at some 20 percent of the population. As in the other countries of the region, the migrations within Nicaragua have been from rural to urban, causing a rapid growth rate in the cities.

The economy. By the 1990s Nicaragua had become one of the poorest of Latin-American countries as a result of almost two decades of civil strife, complicated by a U.S. economic embargo and failed Sandinista economic programs during the 1980s. By the time a newly elected government took over in 1990 the country suffered from massive shortages of goods, and economic assistance from countries such as Cuba and the Soviet Union had been greatly reduced. In addition, a huge foreign debt had accumulated. Aid from the United States and European countries became an important factor in dealing with the problems of rebuilding the economy.

Much of the economic sector was nationalized under the Sandinistas. The government in 1990 began to return to private control many economic activities, such as export industries. Public participation in the economy increased. Independent trade unions, having been limited under the Sandinistas, began again to add to their memberships.

Resources. Nicaragua is rich in natural resources, most of which have not been exploited on a large scale. The economy is basically agricultural, and industry is in an incipient stage of development.

Mineral resources include known deposits of gold, silver, zinc, copper, iron ore, lead, and gypsum. The forests are a vast resource of hardwoods and softwoods, and the inland and coastal waters contain abundant food fishes. Nicaragua's potential hydroelectric resources are considered immense.

Major crops

Agriculture, forestry, and fishing. Agriculture, forestry, and fishing engage as much as two-fifths of the labour force and produce about one-fourth of the total national income. The major cash crops are coffee and cotton, most of which are produced for export. Other crops include corn (maize), sugarcane, sorghum, bananas, rice, beans, plantains, cottonseed, sesame, tobacco, cassava (manioc), and wheat. A variety of fruits and vegetables are also produced for the local market.

Cattle are significant as a source of hides, meat, and dairy products in the west and of meat in the east. The cattle industry increased rapidly after World War II until the

1980s, when internal conflicts and disruption prompted many ranchers to reduce or move their herds to neighbouring countries. Other livestock includes goats, hogs, horses, and sheep.

Forestry, once a rapidly expanding activity, also was reduced by the conflict of the 1980s, which destroyed most of the sawmills. Shrimping is the most important marine activity. Almost all the shrimps, caught in both the Pacific and Caribbean, are exported; lobsters are also exported in moderate quantities. Nicaragua's fish resources, however, are relatively unexploited because of lack of investment, and marine fishing remains largely a subsistence activity.

Industry. Of all the country's minerals, only gold was mined intensively. Mineral reserves are not exploited, because of lack of financing.

The industrial sector

Nicaragua's developing industry is based on the production of consumer products, many of which require the importation of raw materials. In the late 20th century the government actively supported the diversification of production and the use of domestic raw materials. Products include refined petroleum, matches, footwear, soap and vegetable oils, cement, alcoholic beverages, and textiles.

Finance. The Central Bank of Nicaragua, established in 1961, has the sole right of issue of the national currency, the cordoba. The financial system is dominated by the government-owned Finance Corporation of Nicaragua, an amalgamation of the nation's banks that was established in 1980.

Under the Sandinistas (1979–90), Nicaragua's chief trading partners were Cuba, the Soviet Union, and eastern European countries; a U.S. embargo limited trade to many other nations. In 1990, the new government reestablished trade relationships with Western countries. Imports are largely machinery, transport equipment, medicines, nonferrous metals, and petroleum. Exports include coffee, cotton, beef, bananas, gold, sugar, shrimps, and lobsters.

Transportation. Most of the country's transportation system is confined to the western zone. There is a network of highways, parts of which are impassable during the rainy season. The system includes the 255-mile (410-kilometre) Nicaraguan section of the Pan-American Highway, which runs through the west from Honduras to Costa Rica. An important road runs from the Pan-American Highway, 24 miles from Managua eastward to Port Esperanza at Rama. Another road connects Managua with Puerto Cabezas on the Caribbean.

There are a few hundred miles of railways. The main line runs from Granada northwest to Corinto, on the Pacific Ocean. A branch line leads north from León to the coffee area of Carazo.

The chief ocean ports of Corinto, which handles most foreign trade, Puerto Sandino, and San Juan del Sur serve the Pacific coastal area. The Caribbean ports include Puerto Cabezas and Bluefields, the latter connected to the river landing of Port Esperanza by regular small craft service. The short rivers in the west are navigable for small craft. In the east, the Coco River is navigable in its lower course for medium-sized vessels.

The main international airport, seven miles from Managua, has service to North America and Latin America. Another large commercial airport is at Puerto Cabezas. Other airports have scheduled domestic flights. Air services are offered by Aeronica, a private airline, and by other Central American and international airlines.

Administration and social conditions. *Government.* Nicaragua had 10 constitutions between 1838 and 1974. In 1979 a junta assumed power, supported by the Marxist-oriented Sandinista National Liberation Front (Frente Sandinista de Liberación Nacional; FSLN). It replaced the long dictatorial reign of the Somoza family, which had lasted 43 years. The old constitution was abrogated. An elected president and National Assembly replaced the junta and its appointed council in 1985, and a new constitution was promulgated in 1987.

The FSLN

The Sandinista regime lasted for almost 11 years, during which time there was virtually constant insurgency from as many as 13 resistance groups, some of which were known as the Contras and backed by the administration of U.S. President Ronald Reagan. In the election of February 1990 the Sandinista government was defeated by a 14-party coalition, the National Opposition Union (Unión Nacional Oposicion; UNO), and a new government was installed in April of that year. Immediate steps were taken to dismantle the socialist-style institutions of the Sandinista government and to return to a more typically Western-type democracy and a free-market economy. The Sandinistas retained enough seats in the National Assembly, however, to prevent constitutional change, impeding somewhat the progress of the new administration.

Education, health, and welfare. Primary education is free and compulsory for those between the ages of 6 and 13. The nation's facilities and teaching staff are inadequate, however, and can accommodate only about three-fourths of the school-age children. Of those who attend school, most leave before completing the secondary level.

Institutions of higher learning include the Nicaraguan branch of the Central American University, in Managua, founded in 1961, and the National Autonomous University of Nicaragua, at León, founded in 1812.

After decades of neglect by the Somoza administrations, health services were at first improved under the Sandinista government. Welfare services are offered by both the labour unions and the government, and a national social security program has been available to all Nicaraguans since 1982. By the late 1980s, turmoil caused by war and economic failures had produced a reversal of many of the social gains.

Cultural life. Nicaragua's long periods of unstable government and dictatorial rule, during which censorship was often practiced, hampered the growth and development of cultural and intellectual expression in the country. Nevertheless, some notable individual artists and institutions have emerged, and, of course, the country has a long tradition and strong interest in pre-Columbian art, which is the basis of a rich present-day American Indian folk art.

Literature

The arts. Nicaragua's literary tradition was consolidated in the late 19th and early 20th centuries with the poetry and prose of Rubén Darío, known as the "prince of Spanish-American literature." Later writers of importance include Santiago Argüello, Lino Argüello, Salomón de la Selva, and Salvador Buitrago Díaz. José de la Cruz Mena is to Nicaraguan music what Darío is to its literature. Although he has not received international recognition, his waltzes are masterpieces of melody and harmony. The composers Edwin Krüger and José Ramírez excel in folkloric music.

Cultural institutions. The National Library at Managua maintains branches in most of the major cities. The National Museum, with a strong concentration on American Indian culture, is located in the capital city, and the Tenderi Museum of Indian artifacts is at Masaya.

Recreation. Fiestas based on religious holidays occur throughout the year and are of particular significance in rural areas. They often involve gambling games and sporting activities, including the nation's favourite, baseball.

Media. Nicaragua has several daily newspapers, among which are *La Prensa, El Nuevo Diario,* and *Barricada,* the official Sandinista organ. There are two major television stations and numerous radio stations. (R.A./B.Ni.)

For statistical data on the land and people of Nicaragua, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL.

HISTORY

The Spanish conquistador Gil González Dávila made the first attempt to conquer what is now Nicaragua in 1522. Though he claimed to have converted some 30,000 American Indians, carried off 90,000 pesos of gold, and discovered a possible transisthmian water link, González was eventually run out of Nicaragua by angry native inhabitants. Some of the latter were commanded by Nicarao, from whom the country's name derives. It was not until 1524, under Francisco Hernández de Córdoba, that permanent colonization began.

The Spanish conquest was a disaster for the native population of Nicaragua's Pacific region. Within three decades, an estimated Indian population of one million plummeted to a few tens of thousands, as approximately half of the indigenous people died of contagion with Old World diseases, and most of the rest were sold into slavery in other New World Spanish colonies. Few were killed in outright warfare.

British-Miskito Indian alliance

After the initial depopulation, Nicaragua became a backwater of the Spanish empire. In this setting, two colonial cities, Granada and León, emerged as competing poles of power and prestige. The former derived its income from agriculture and trade with Spain via the San Juan River; the latter came to depend on commerce with the Spanish colonies of the Pacific coast. Both tiny outposts were subjected to frequent pirate attacks. Late in the 17th century, Great Britain formed an alliance with the Miskito Indians of the Caribbean coastal region, where the community of Bluefields had been established. The British settled on the Mosquito Coast, and for a time (1740–86) the region became a British dependency.

Independence. In 1811, inspired by struggles in Mexico and El Salvador, revolutionaries deposed the governing intendant of Nicaragua. León, however, soon returned to the royalist cause, and Granada bore the brunt of the punishment for disobedience. In 1821 León rejected and Granada approved the Guatemalan declaration of independence from Spain. Both accepted union with Mexico (1822–23), but they fought one another until 1826, when Nicaragua took up its role in the United Provinces of Central America. After Nicaragua seceded from the federation in 1838, the rivalry between León, identified with the Liberal Party, and Granada, the centre of the Conservative Party, continued.

Foreign intervention. After the withdrawal of Spain, relations between the "king" of the Mosquito Coast and the British government strengthened until again there were British officials in Bluefields. In 1848 they seized the small Caribbean port of San Juan del Norte, renaming it Greytown. The discovery of gold in California drew attention to the strategic position of Nicaragua for interoceanic traffic, and Cornelius Vanderbilt's Accessory Transit Company began a steamship and carriage operation between Greytown and the Pacific. In 1856 William Walker, an American who had been invited to assist the Liberals in warfare (1855), made himself president of the country, but he was routed a year later by the efforts of the five Central American republics and the transit company.

Conservatives ruled from 1857 until 1893, bringing relative peace but little democracy to Nicaragua. As a compromise between Granada and León, Managua was made the capital in 1857. In 1860 a treaty with Great Britain provided for the nominal reincorporation of the east coast with the rest of the nation but as an autonomous reservation. Complete jurisdiction over the Miskito people was not established until the Liberal presidency (1893–1909) of José Santos Zelaya.

Zelaya, though a dictator, was a committed nationalist. He promoted schemes for Central American reunification and refused to grant the United States transisthmian canal-building rights on concessionary terms, thus encouraging the United States to choose Panama for the project. This, plus rumors that Zelaya planned to invite Japan to construct a canal that would have competed with the U.S. waterway, caused the United States to encourage Zelaya's Conservative opposition to stage a revolt. When two U.S. citizens who participated in the revolt were executed, the United States landed marines in Bluefields and thus blocked a Liberal victory. Though Zelaya resigned, the United States refused to recognize his successor, José Madriz (1909–10). Further civil war led to the presidency of a Conservative, Adolfo Díaz (1911–17), for whom the U.S. Marines intervened in 1912. A 100-man guard at the U.S. embassy symbolized that country's support also for Conservative presidents Emiliano Chamorro (1917–21) and his uncle Diego Manuel Chamorro (1921–23). The Bryan-Chamorro Treaty, signed in 1914 and ratified in 1916, gave the United States exclusive canal privileges in Nicaragua (to prevent a competing canal from being built) and the right to establish naval bases.

The U.S. Marine guard's withdrawal in 1925 led quickly to another crisis, with Emiliano Chamorro in rebellion against a new regime. Díaz returned as a compromise president (1926–28), reinforced in 1927 by 2,000 U.S. Marines. The Liberal leaders Juan Bautista Sacasa, José María Moncada, and Augusto César Sandino rose in rebellion, but after six months Sacasa and Moncada made peace, and subsequent elections under U.S. auspices brought the presidency to both of them (Moncada, 1928–33, and Sacasa, 1933–36). Sandino, however, fought on as long as the Marines remained in the country.

The Somoza years. The Marines withdrew upon the inauguration of Sacasa, and Sandino submitted to his government. A Nicaraguan National Guard (Guardia Nacional), trained by the U.S. Marines and commanded by General Anastasio Somoza García, was now responsible for maintaining order in the country. In 1934 high-ranking officers led by Somoza met and agreed to the assassination of Sandino. Somoza then deposed Sacasa with the support of factions of both Liberals and Conservatives, and in a rigged election, he became president on Jan. 1, 1937.

Somoza (known as Tacho) revised the constitution to facilitate the consolidation of power into his own hands and ruled the country for the next two decades, either as president or as the power behind puppet presidents. Export activities grew from the 1930s onward. However, the Somoza family and their associates, rather than the Nicaraguan people was a whole, were the main beneficiaries of the country's income.

Assassination of Somoza

On Sept. 21, 1956, a day after Somoza's Nationalist Liberal Party of Nicaragua (Partido Liberal Nacionalista de Nicaragua; PLN) had nominated him for another term, a liberal poet named Rigoberto López Pérez shot the president, who died eight days later. Congress at once gave Luis Somoza Debayle his father's position, and in February 1957 he was elected dubiously to his own term (1957–63). Somoza Debayle ruled more gently than his father had. He accepted a settlement in favour of Honduras of a long-standing border dispute between the two countries (1960) and cooperated with the United States in the so-called Bay of Pigs invasion of Cuba (1961). In 1961 three Marxists, including Carlos Fonseca Amador, founded the guerrilla Sandinista National Liberation Front (Frente Sandinista de Liberación Nacional; FSLN) in opposition to the regime. Named for Augusto César Sandino, its members are called Sandinistas.

A proposal that the 1963 election be supervised by neutral observers was refused by Somoza Debayle, and the two parties in consequence declined to nominate candidates. René Schick Gutiérrez, the PLN candidate and a friend of the Somozas, thus easily won the presidency in a virtually uncontested election. The economy was prospering, though the poverty of the masses remained relatively unchanged. Lorenzo Guerrero Gutiérrez became president for one year upon the death of Schick in office. Luis Somoza Debayle died in 1967, and in that year his younger brother, Anastasio Somoza Debayle (called Tachito), in another rigged election, defeated Fernando Agüero Rocha for the next term. In 1970 the Bryan-Chamorro Treaty was abrogated.

On May 1, 1972, constitutionally ineligible to succeed himself, Somoza relinquished the presidency to a triumvirate (composed of Agüero and two leaders of Somoza's own party). On December 23 an earthquake in the city of Managua left 6,000 persons dead and 300,000 homeless. Somoza (commanding the National Guard) took charge as the head of a National Emergency Committee. Agüero, who protested, found himself replaced (March 1, 1973) on the triumvirate. The population suffered from the destruction as Somoza and his friends profited privately from international aid programs. In March 1974 a new constitution (the country's 10th) made it possible for Somoza to be reelected president, and on December 1 he again assumed the office.

Before the end of the year, two genuine opposition groups attracted wide attention—the Sandinistas and the organization founded by Pedro Joaquín Chamorro, editor and publisher of *La Prensa* of Managua, called the Democratic Union of Liberation (Unión Democrática de Liberación; UDEL). In December 1974 the Sandinistas staged a successful kidnapping of Somoza elites, for which ransom and the release of political prisoners was obtained. In response, the regime embarked on a two-and-a-half-year counterinsurgency effort that, in addition to leading to the death of Carlos Fonseca in 1976, took the lives of thousands of peasant noncombatants. In 1977 a group called Los Doce (The Twelve) sought an anti-Somoza alliance to include UDEL, the Sandinistas, and other organizations. Assassins murdered Pedro Joaquín Chamorro on Jan. 10, 1978, and a general strike and violence followed. On August 22 the Sandinistas occupied the national palace, holding more than 1,000 hostages for two days and winning most of their demands. Although the National Guard regained partial control, the insurrection spread, with another general strike and the Sandinistas seizing and holding several major cities. The uprising was eventually quashed, at the cost of several thousand lives. The following June the FSLN staged its final offensive. City after city fell to the insurgents, backed by tens of thousands of local civilian combatants. On July 17 Somoza resigned and fled the country; two days later, the Sandinistas entered Managua and accepted the surrender of what was left of his army, ending the long years of Somoza rule. (F.D.P./T.W.Wa.)

End of the Somoza regime

The Sandinista regime. The new government inherited a devastated country. About 500,000 people were homeless, more than 30,000 had been killed, and the economy was in ruins. In July 1979 the Sandinistas appointed a 5-member Government Junta of National Reconstruction. The following May it named a 47-member Council of State, which was to act as an interim national assembly. In 1981 the junta was reduced to 3 members and the council increased to 51.

In 1979–80 the government expropriated the property held by Anastasio Somoza Debayle, members of his government, and their supporters. Local banks and insurance companies and mineral and forest resources were nationalized, and the import and export of foodstuffs were placed under government control. The Statutes on Rights and Guarantees, which acted as the country's new constitution, assured basic individual rights and freedoms. The government disclaimed any responsibility for the assassination of Somoza, on Sept. 17, 1980, in Asunción, Paraguay.

Although the Sandinista government expanded ties with noncommunist nations, it also established close relations with Cuba and other socialist-bloc nations. The U.S. government interpreted this posture as an indication of further communist expansion in the Western Hemisphere. In 1981 the United States suspended economic aid to Nicaragua, and later that year U.S. President Ronald Reagan authorized nearly $20 million for the creation and arming of an irregular force of Nicaraguan counterrevolutionaries to fight the Sandinistas. These insurgents, who came to be called Contras, established bases in the border areas of Honduras and Costa Rica. The Contra army was expanded to around 15,000 soldiers by the mid-1980s. Eventually, the Nicaraguan government expanded its military forces, acquired crucial equipment such as assault helicopters, and implemented counterinsurgency strategy and tactics, which enabled it in the late 1980s to contain and demoralize the Contras. In 1987, the U.S. Congress voted against supplying further military aid to the Contras. That August, the first of several Central American peace agreements was signed, which gradually moved the locus of Nicaraguan conflict from the military to the political sector.

Daniel Ortega Saavedra

Meanwhile, on Nov. 4, 1984, the FSLN and its presidential candidate, Daniel Ortega Saavedra, won 63 percent of the vote in an election that international observer teams had deemed fair and competitive. Ortega was inaugurated in January 1985, and the new Constituent Assembly produced a constitution two years later, which called for regularly held elections, the first for national office to take place in 1990.

The Reagan administration, which had denounced the 1984 election as a sham, continued to exert pressure on the Sandinista government. A U.S. trade embargo was declared in 1985. Washington used its leverage within the World Bank and the Inter-American Development Bank to block most Nicaraguan loan requests from 1982 onward. These measures and the damage and economic dislocation caused by the civil war combined with Sandinista economic errors to cause Nicaragua's economy to plummet from 1985 onward. An annual inflation rate of more than 30,000 percent in 1988 was followed by harsh and unpopular austerity measures in 1989. Government programs in health, education, housing, and nutrition were drastically curtailed.

Against this background, and under intense international observation, the 1990 general elections were held. Contra activity increased during the electoral period. On Feb. 25, 1990, the U.S.-endorsed and -financed National Opposition Union (Unión Nacional Oposición; UNO) coalition and its presidential candidate, Violeta Barrios de Chamorro, the widow of the martyred newspaper editor, won an upset victory, and a peaceful transfer of administrations took place. A cease-fire with the Contras was implemented, and Chamorro eventually was able to reach an agreement with them to lay down their arms, although some factions were considerably reluctant to do so. (T.W.Wa.)

For later developments in the history of Nicaragua, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

Panama

The Republic of Panama (Spanish: República de Panamá) is a country in Central America that is situated on the S-shaped Isthmus of Panama that joins North and South America. Its area is 29,762 square miles (77,082 square kilometres), of which 29,187 square miles is on the mainland and 575 square miles is divided among islands. The Panama Canal, which connects the Atlantic and Pacific oceans, runs through the country.

Location and boundaries

Panama extends for about 480 miles (770 kilometres) from the Costa Rican frontier in the west to the Colombian border in the east. The shortest distance across the isthmus is 30 miles, stretching from the mouth of the Nergalá (Necategua) River, which flows into the Gulf of San Blas on the northern (Caribbean) shore, to the mouth of the Chepo River on the Pacific coast. Panama is bounded on the north by the Caribbean Sea, on the south by the Pacific Ocean, on the east by Colombia, and on the west by Costa Rica. Panama City, the capital, is located on the Pacific coast to the east of the Panama Canal.

About one-third of the economically active population of Panama is engaged in agriculture and cattle raising. Panama also has a strong services sector, especially in transport, banking, and international trade, which has developed on the basis of the country's strategic location.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* A central spine of mountain ranges extends almost the entire length of Panama, dividing the country into Atlantic- and Pacific-facing slopes. The two principal mountain ranges, the Tabasará Mountains (Cordillera Central) in the west and the Cordillera de San Blas in the east, are separated near the centre of the country by a saddle of lower land. This depression (the Panama Canal site) divides the country again—roughly into western and eastern halves. Of the four quadrants thus formed, the southwestern is the most important: with the canal area itself it accounts for most of Panama's population and commerce. The country's highest peak is an inactive volcano, Barú (Chiriquí; 11,401 feet [3,475 metres]).

Paralleling the principal mountain chains, a lower mountain arc extends along Panama's southern coast. It appears only in well-separated segments—for example, on Azuero Peninsula as the Canajagua Massif and, in eastern Panama, as the Sierra de Jungurudó, Sapo Mountains, and the Majé Mountains.

The land surface may also be divided roughly into two geologic categories: the above-named highlands and mountains, which are made up mainly of igneous rocks (predominantly old volcanics), and lowlands, which commonly consist of sedimentary rocks, such as slates and shales. Such lowlands include the plains of Panamá and Chiriquí provinces, the plains and hills of Colón province, the Chepo and Chucunaque river basins in the east, and the narrow northeastern plains of the Caribbean region.

The irregular Pacific coastline (extended by the Azuero Peninsula and the Gulf of Panama and by numerous headlands and bays) is considerably longer than the Caribbean coastline; the largest embayment on the Caribbean side is Chiriquí Lagoon. Similarly, the continental shelf is much wider on the Pacific side than on the Atlantic.

Offshore islands

Most of the republic's more than 1,600 islands are off its Pacific coast; they include the Perlas Archipelago (Pearl Islands) and the islands of Toboga, Cêbaco, Parida, Jicarón, and Coiba, the largest. The principal archipelagoes off the Caribbean coast are those of Bocas del Toro and San Blas.

Drainage and soils. Of Panama's many rivers, those that flow to the Caribbean include the Sixaola, Changuinola, Indio, Cricamola, La Miel, and Chagres. Rivers flowing to the Pacific include the Chiriquí Viejo, Santa María, Chepo, and Chucunaque. A few are navigable during the rainy season; the Tuira is navigable for about 40 miles and the Chepo for about 20 miles.

Soils are commonly reddish to brown and rich in clay. They vary in fertility, and in many areas crops can be grown continuously only if fertilizers are applied. On poorer soils, a shifting subsistence agriculture is practiced. Under this system small plots are cleared, cropped for a few years, then abandoned until their natural fertility is restored—a practice called *roza* in Panama.

Areas of alluvial soils (which develop from clay, silt, sand, and gravel deposited by streams) are especially fertile. Such soils, however, are not extensive, being limited to the lower parts of river valleys. The commercial banana plantations around Puerto Armuelles and in western Bocas del Toro province are mainly on alluvial soils. Some of the soils along the inland edges of coastal mangrove swamps have also proved quite productive. Soils that develop from volcanic ash are exceptionally fertile.

Climate. The climate is markedly different on the Atlantic and Pacific sides of western Panama, especially in the amount and seasonal distribution of rainfall. On the Caribbean slopes of the Tabasará Mountains, which face the rain-bearing trade winds, average rainfall is approximately twice as heavy as on the leeward Pacific slopes. The Caribbean coast receives between 60 and 140 inches (1,500 and 3,500 millimetres) per year, while the more populated Pacific region receives between 45 and 90 inches (1,140 and 2,290 millimetres). Furthermore, on the Caribbean side, rain falls almost throughout the year, while on the Pacific side—in Chiriquí province, for example—there is a pronounced dry season lasting from January to April; March is usually the driest month. In accordance with this rainfall pattern, tropical rain forest is the typical vegetation on Caribbean slopes, while southward in the seasonally dry areas found between the Tabasará Mountains and the Pacific shoreline, savannas are typical. Toward the Colombian border both sides of the isthmus have year-round rainfall and extensive rain forests.

Temperatures

Rarely on either coast does the mean temperature of the coldest month drop below 78° F (26° C). On mountain slopes three altitudinal climatic zones are recognized in Panama: a low, hot zone, lying at altitudes below 2,300 feet (700 metres), which makes up more than 85 percent of the country's territory; a temperate zone, at altitudes of between 2,300 feet and 4,900 feet, which makes up about 10 percent of the land; and a cold zone, lying above 4,900 feet and covering less than 5 percent of the total area. Each zone has its characteristic plant growth and crops; thus, cacao and bananas are produced mainly in the hot lowlands, while coffee is grown in the temperate zone.

Plant and animal life. Despite its relatively small area Panama has a great variety of landscapes and habitats, including tropical rain forest, savanna (tropical grassland), cool montane forest, tidal lands covered by stilted mangrove trees, coral reefs, and beaches.

Because of its ancient role as a land bridge over which species have migrated between the continents, the isthmus is home to a rich intermixture of plant and animal life. As a result of this interchange, Panama's wildlife includes such mammals as sloths, anteaters, and armadillos—which derive from South America—as well as the jaguar, tapir, and deer—which came originally from North America. Also among Panama's rich fauna are several species of giant sea turtle, which lay their eggs on the beaches. Few comparable areas have a larger number of bird species.

Settlement patterns. Almost half of the Panamanian population is rural, with people living in hamlets or isolated dwellings and engaged in subsistence agriculture. The densest rural population is found in the broad savanna area of plains and low hills lying between the Azuero Peninsula and the Tabasará Mountains. The least densely settled areas are in the eastern third of the country, especially in the large province of Darién, and on the Atlantic slopes of the Tabasará Mountains.

The percentage of the population living in cities has grown rapidly in recent decades, and in the early 1980s the country became predominantly urban. The most densely settled part of Panama is a broad coast-to-coast strip of land that crosses the country where it is at its lowest and narrowest: in the vicinity of the canal. This general area, partly drained by the Chagres River, is known as the Chagres, or Route, region. It includes the cities of Panama City and Colón, the district of San Miguelito, and the towns of Balboa, La Chorrera, Gamboa, and Cristóbal. Panama City, situated on the Pacific coast overlooking Panama Bay, is the dominant population centre and the centre of industrial, commercial, political, and cultural activities. San Miguelito is the second largest urban centre and Colón the third largest.

The Canal Zone

Panama Canal. The Panama Canal, built by the United States and operated continuously since its opening in 1914, has made Panama an international shipping and trade centre. From 1903 until 1979 a 10-mile-wide strip of land lying on either side of the canal, the Canal Zone, was controlled by the United States. By treaties signed between the two countries in 1977, the Canal Zone was abolished in 1979, and Panama reasserted its sovereignty over the Canal Zone, with Panama and the United States to share in the operation and defense of the canal itself through 1999.

Since 1979 the canal has been operated by the Panama Canal Commission, a joint U.S.-Panamanian agency. There are several thousand U.S. civilians and military personnel living in the area who help operate and protect the canal, and the United States, by agreement with Panama, has continued to maintain military bases there.

The people. *Ethnic and linguistic groups.* In the 16th century, when the Spaniards first went to the isthmus, it was occupied by Cuna, Guaymí, Chocó, and other Indian groups. Mestizos resulted from the miscegenation that occurred between the Spanish and the Indians. During colonial times people from Africa were brought as slaves, and still other mixed racial types developed as the Africans entered the society. During the 19th century, with the construction of the Panama City-Colón railroad, new groups arrived—North Americans (primarily from the United States), French, and Chinese. During the construction of the canal, more U.S. nationals went to Panama, as did blacks (from British Barbados and Jamaica), Spaniards, Italians, and Greeks.

Though they are but a small fraction of the total population, Indians are found scattered over a considerable area, often in rain forests on rough terrain. The most numerous of the Indian groups are the Guaymí, who live in the western provinces of Chiriquí, Bocas del Toro, and Veraguas. Next in numbers are the Cuna, who live mainly in the San Blas Archipelago and on the coast nearby. The Chocó live mainly in the province of Darién. All these groups preserve their native languages, but many persons in each can also speak Spanish. Although most are engaged largely in subsistence agriculture, fishing, and hunting, a number of Cuna are traders, sailors, and mechanics and work in other occupations. Also, many Guaymí work on the banana plantations of western Panama.

Mestizos are the largest population group in Panama. They predominate in the savannas to the west of the canal and in the central provinces of Panamá and Colón, where they have intermarried with people of African ancestry.

People of African descent who were brought to the isthmus during the period of Spanish colonization are settled throughout much of Panama—for example, in the hot lowlands of the Chagres River basin, in the eastern province of Darién, and in the Caribbean lowlands. Black peoples from the British West Indies are more recent arrivals and make up only a small minority. They live primarily in Panama City and in Bocas del Toro province.

U.S. influence

The United States has influenced both the economy and the culture of Panama. Americans live primarily in the canal area and in Panama City. Other significant minorities in Panama are Chinese, East Indians, Jews, and Middle Easterners, all of whom play an important role in commerce and industry and who participate in the country's political and professional life.

Spanish is the official language of Panama and is spoken by almost 90 percent of the people. English is spoken mainly by West Indians, who make up about 8 percent of the population; about 5 percent speak Indian languages.

Religion. Roman Catholicism is the religion of most Panamanians, but Protestant enclaves have appeared, for example, within the black population of Bocas del Toro province and among Indian groups. Panama's constitution guarantees freedom of worship.

Demographic trends. A striking attribute of Panamanian demography is the high rate of population increase. The population grew from 336,000 persons in 1911 to almost 2,500,000 by the end of the century. An important factor in population growth has been immigration, which was substantial during World War II but has since decreased. Two other demographic changes are noteworthy: the movement of rural people within the country in search of land and the movement of young people to urban areas—especially to Panama City and Colón—in search of better living and economic conditions.

The economy. Most of the work force is engaged in agriculture (including cattle raising, fishing, and forestry) and in services, manufacturing, and trade.

Resources. Clay, limestone, and salt are the leading mineral products, and gold, ferrous sand, and manganese have been produced on a small scale. There are commercially significant, but largely unexploited, deposits of copper, including the Cerro Colorado find in Chiriquí province. Deposits of bauxite, phosphates, and coal have been minimally exploited, as have various construction materials such as stone and gravel. Oil has been located offshore, in both the Pacific and the Caribbean.

Energy. Electricity is distributed by the Institute of Hydraulic Resources and Electrification. Much of Panama's electricity is generated by hydroelectric plants. The first plants were opened in 1975 at La Yeguada in Veraguas province and in 1976 on the Chepo River; the largest, at La Fortuna, opened in 1984.

Agriculture, forestry, and fishing. A seminomadic and subsistence agriculture exists alongside large commercial enterprises that use modern agricultural methods. Land tenure, allowing small farmers to acquire land, was instituted in 1962, but by late in the 20th century less than one-third of all farms were owned by the people working them. The most common agricultural products include rice, corn (maize), sugarcane, beans, bananas, and plantains. The growing conditions of the isthmus favour the cultivation of tropical fruit, although commercial production for most of them is limited. The commercial cultivation of bananas, coffee, cacao, sugarcane, and other crops has increased considerably.

Principal crops

Livestock raising (cattle, pigs, and poultry) is an important and long-established economic activity. The centres of the cattle industry, and the country's largest cattle-raising farms, are in the southwestern savannas—in Chiriquí, Los Santos, and Veraguas provinces. The quality of meat produced has been greatly improved by the introduction of better breeding stock (including Brahman cattle from Asia) and nutritious forage grasses from Africa. Beef exports began in the 1970s. Hides, however, are a much more economically significant by-product of cattle raising.

The raising of pigs has increased because of a growing urban market and relatively high prices. The provinces of Panamá, Los Santos, Chiriquí, and Veraguas raise the most pigs; Panamá, Coclé, and Colón are the largest centres for the raising of chickens and the production of eggs.

Considering Panama's abundant and valuable forest resources, there has been little use of the nation's native trees for industrial purposes. Mahogany, tropical cedar, cativo (a large tree belonging to the legume family), and other woods supply domestic sawmills, and some logs are exported. The government has found it difficult to supervise uses of the nation's forests; for instance, large tracts of Panama's fine rain forests are being felled and burned and are being replaced by pastures for an expanding cattle industry.

Fishing has developed rapidly as a commercial venture. Shrimps, prawns, and lobsters are among Panama's most important exports, with several thousand tons caught yearly. The shrimp and fish (mainly anchovies and herring) catch is taken mostly from the shallow waters of the continental shelf in the Gulf of Panama. Lobsters are caught mainly off Bocas del Toro and San Blas on the Atlantic side. Aquaculture has been successfully developed in Panama.

Leading manufactured products

Industry. Although there has long been a considerable international trade based on the country's key location as a crossroads, modern industrial development began mainly after World War II. The leading industries are cement manufacture (in the limestone areas near the Trans-Isthmian Highway), fish processing, sugar refining, processing of general food products, banana and cocoa production, oil refining (near Colón), and the production of gas and electricity. Other important industries include clothing, shoe and leather goods manufacturing, brewing, distilling, and the production of furniture, paper, hides, chemicals, and cigarettes.

The main manufacturing centre is Panama City, and there is some industry at Colón and David. Tourism plays a major role in the country's economy, providing funds for industrial development.

Finance. Government laws have promoted the development of offshore banking. Financial services are provided by representative branches of several major Latin American, North American, and European banks. Some of these banks have branches in the provinces and provide loans for industrial, agricultural, and cattle-raising ventures.

Trade. The main products purchased from abroad are crude oil, fuels and lubricants, machinery, transportation equipment, manufactured goods, food products, and chemicals. Most of the imports are from the United States, the Colón Free Zone (see below), Mexico, and Japan. Exports include food products, such as bananas, shrimps, and coffee, as well as cattle hides, clothing, and pharmaceuticals. The United States takes a large part of these exports; other notable buyers of Panamanian products are Germany and Costa Rica.

The Colón Free Zone, established in the mid-20th century at the northern end of the canal, has become increasingly important as a manufacturing, warehousing, and reexport centre. Its several hundred plants produce chemical products, manufactured articles, machinery, and transportation equipment. Raw materials or semifinished products come from the United States, Japan, the United Kingdom, and Germany. Finished products are sent largely to the countries of Central and South America, but some are used domestically.

Transportation. Historically, Panama has been indeed one of the world's great passageways. In ancient times the isthmus was an intercontinental thoroughfare for migrating plants, animals, and peoples. Today, Panama links not only the continents but the oceans as well. In addition to the canal, Panama is the site of an interoceanic highway, railroad, and oil pipeline.

The country has several thousand miles of roads, one-third of which are paved. The main routes extend from the capital to the central provinces (Coclé, Herrera, Los Santos, and Veraguas) and to the western section of the country (Veraguas and Chiriquí provinces). The principal highways include the Trans-Isthmian Highway, running across the isthmus from Panama City to Colón, and the Inter-American Highway, the Panamanian section of the Pan-American Highway; the latter has been completed from the Costa Rican border eastward, through Panama City, to a point near Yavisa in Darién province.

Inter-oceanic pipeline

In 1982 an interoceanic oil pipeline was built in western Panama, connecting the Pacific and the Atlantic coasts. The line extends some 80 miles from Puerto Armuelles over the Tabasará Mountains to Chiriquí Lagoon. A road was built through the mountains paralleling the pipeline.

A 49-mile transcontinental railroad, the Panama-Colón line, was completed in 1855 by a U.S. company. It is now administered by the government of Panama. The Chiriquí National Railroad operates both passenger and freight service between La Concepción and Puerto Armuelles and freight service between David and Pedregal on the Pacific. In Bocas del Toro province there is a railroad serving the banana-growing area.

The Panamanian coastline has many natural harbours that have excellent conditions for sheltering vessels, but the best ports are those at either end of the Panama Canal—Cristóbal, near Colón, and Balboa, near Panama City. Other important ports, primarily serving the banana trade, include Almirante and Puerto Armuelles. Coastal shipping is important for Panamanian agriculture.

There are more than 100 airports in Panama and both domestic and international Panamanian airlines. Tocumen International Airport (officially General Omar Torrijos Herrera International Airport), is Panama's major airfield; it is located 16 miles from the capital and is served by several international airlines. There are regular domestic flights from Panama City to various parts of the country.

Administration and social conditions. *Government.* After a coup d'état by the National Guard in 1968, the legislative branch of government was suspended, and Panama was administered by a provisional government led by General Omar Torrijos. A new constitution in 1972, the fourth in Panama's history, gave Torrijos virtually complete control over the government but also established an elected National Assembly of Municipal Representatives. The constitution was amended in 1978 to provide for a gradual return to democratic government within six years. Further constitutional amendments were approved in 1983, but constitutional government did not return to Panama until after the downfall of Torrijos' successor, General Manuel Antonio Noriega Moreno, in 1990.

Under the constitutional revision of 1983, executive power is exercised by the president and two vice presidents, elected by popular vote for a five-year term. The president appoints the Cabinet. The constitution established a unicameral Legislative Assembly consisting of 67 members elected for five-year terms. The assembly has powers to initiate legislation, rule on international treaties, approve the budget, and establish political divisions.

Local government

The country is divided into nine *provincias* and the *comarca* (sector) of San Blas. The *provincias* are divided into *distritos municipales* (municipal districts), which are subdivided into *corregimientos* (magistracies). The head of each *provincia* is the governor, appointed by the president. San Blas is governed by tribal leaders (caciques) of the Cuna Indians.

Justice. Judicial power rests with the Supreme Court of nine members. They are appointed for 10-year terms by the president with the approval of the Legislative Assembly. The Supreme Court is composed of separate divisions for civil, penal, and administrative cases. The justice system also includes several types of lower courts. Police services are operated by the National Guard.

The armed forces. The Panamanian Defense Force was created in 1983, incorporating the National Guard, the Air Force, the Navy, the Panama Canal Defense Force, the police, the National Department of Investigations, and the Immigration Department. Historically, the military has frequently used its power to take over and run the country.

Education. All children have the right to receive an education from the state without discrimination by race, sex, or economic standing. Elementary education is compulsory and free from ages 6 to 15. Illiteracy has been decreasing. Private schools cannot teach in a foreign language without the consent of the Ministry of Education.

The institutions of higher education include the state-run University of Panamá (founded 1935) and the privately operated University of Santa María la Antigua (1965), both in Panama City. The University of Panamá, the official university, also has branches in several provinces. A polytechnic school was founded in Panama City in 1981.

Health and welfare. The government has built a system of hospitals and health centres and has granted funds for their improvement. Hospitals and hospital-clinics are supplemented by regional health centres and by mobile medical units. A social security system provides a wide range of benefits; most permanent employees are covered. The social security administration maintains hospitals and clinics in Panama City and Colón for its beneficiaries and also supports medical centres and clinics in several places in the interior. The St. Thomas Hospital, in Panama City, provides treatment for those unable to pay hospital expenses. There are some private hospitals.

About 90 percent of the working population is protected by a minimum wage law; the government also regulates prices. Both salaries and wages are subject to great fluctuations, however. Most workers and professionals are union members, and collective labour contracts are usual. The government also has established the payment of an extra month's salary, called *décimo tercer mes* ("13th month"), each year for all workers.

Cultural life. Distinctive Panamanian cultures can be divided regionally. The cosmopolitan urban culture near the canal contrasts with the rural culture of the southwestern savannas. The latter area, with its cattle ranches and horsemanship, is something of a centre of Hispanic tradition. Old folk songs and handicrafts (like the straw-hat industry) are preserved there—for example, around the towns of Chitré and Las Tablas. Also culturally distinctive are the territories of the various Indian groups, each with its language and handicrafts, such as the needlework clothing designs (*molas*) sewn by Cuna women and the netted carrying bags made by the Guaymí. Other areas of cultural interest include the Caribbean islands of Almirante Bay with their Antillean customs.

Rural culture

The arts. To a large extent national artistic achievements did not begin to develop in Panama until after independence in 1903. Before that time artistic themes were mostly European or church-related. Some progress has been made in national expression since that time, and there has been some international recognition of Panamanian artists. The local culture is, however, supplemented by visits to the population centres from musical and theatrical groups and by poets, sculptors, and other artists.

Cultural institutions. Among the notable cultural institutions are the Panamanian Art Institute (Panarte), the National Institute of Music, the National School of Music, the National School of Plastic Art, the National School of Dance, and the National School of Theatre. Also of note are the National Commission on Archaeology and Historic Monuments, the National Museum of Panama, and the Panamanian Academy of History.

Recreation. The Panamanian Institute for Tourism encourages the preservation of traditional holidays, folk music, and folk dances. Panamanian carnivals are known for their beautiful costumes and joyous music. The National Institute of Culture promotes many types of events, including concerts, theatre, and art expositions. The National Institute of Sports promotes intraprovincial sporting events as well as Olympic competition. The most popular spectator sports in Panama, in contrast to those of other Central American countries, are baseball, boxing, horse racing, and basketball, rather than soccer. There are numerous attractive beaches and sportfishing waters, as well as cool vacationlands on the slopes of Barú Volcano. During the 1970s and '80s about one-sixth of the area of the country was designated as national parks or preserves.

Press and broadcasting. The principal newspapers are published in Panama City. Panama has many radio stations, half of them located in Panama City. There are three television networks, with several stations. The United States also operates a television station from Fort Clayton. (N.M.C./B.L.G.)

For statistical data on the land and people of Panama, see the *Britannica World Data* section in the BRITANNICA WORLD DATA ANNUAL.

HISTORY

Exploration, conquest, and settlement. The Atlantic coast of the Isthmus of Panama was first explored by Rodrigo de Bastidas in 1501, in the company of Juan de la Cosa and Vasco Núñez de Balboa. In 1510 Diego de Nicuesa, another Spanish explorer, established the settlement of Nombre de Dios at the mouth of the Chagres River, and to the southwest Alonso de Ojeda that of San Sebastian de Urabá. Because of the presence of bellicose Indians, the colony was moved, at the instigation of Balboa, northeast across the Atrato River and was given the name Santa María la Antigua del Darién. It became the first permanent settlement on the isthmus and the focus of jealous intrigues centring around Balboa.

Early explorers

As head of the colony, Balboa, by the use of persuasion and force, brought most of the Indians under submission. Some of them revealed to him the existence of a large sea and of a gold-rich empire to the south, perhaps that of the Inca. On Sept. 26, 1513, Balboa reached the sea and claimed the Pacific Ocean for his king. Returning to Santa María, he encountered much resistance from the Indians. Soon afterward Balboa was executed for insurrection on orders of the new governor, Pedrarias Dávila, known as "the Cruel," who distrusted Balboa and feared his rivalry.

In 1519 the population of Santa María moved to the new town of Panama (the first European settlement on the west coast of the hemisphere), which became the centre of commercial activity and the springboard for the conquest of Peru. The colony, also called Panama, became an important part of Spain's mercantile system, attaining the rank of audiencia in 1538, while Nombre de Dios, now resettled and linked to Panama by road, was renowned for its ferias (exchange markets). With the final destruction of Nombre de Dios in the late 16th century by Francis Drake, the English buccaneer, commercial activity was moved to the hamlet of Portobelo, overlooking the calm bay discovered by Christopher Columbus in 1502. Portobelo then became the centre of Spain's commerce in the New World and the site of great ferias.

Panama and Portobelo continued to attract the attention of English raiders, however, and both were visited with disastrous consequences, including destruction of the former by Henry Morgan (1671) and the latter by Admiral Edward Vernon (1739). In the year of Vernon's raid the colony was reduced in status when Spain made it a part of the Viceroyalty of New Granada. Portobelo was rebuilt in 1751, but by then the Spanish galleons had begun to use the route around Cape Horn, accelerating the city's decline through loss of trade. In 1673 the town of Panama was rebuilt a few miles west of the old town.

Secession from Spain and union with Gran Colombia. As the agitation for independence grew elsewhere in Spanish America, Panama, thanks to the foreign trade permitted by the crown, was prosperous and did not heed the call for insurrection. The viceroy moved his headquarters from Quito to Panama, and the isthmus sent deputies to the Cádiz Cortes (parliament) in Spain. When the Spanish merchants secured the revocation of the royal decree authorizing foreign trade, Panama changed sides. In the autumn of 1821 the colony seceded from Spain and joined the Gran Colombia union. For a time Panama enjoyed the right to elect its own governor, but in 1843 a new constitution returned that power to Bogotá. Soon afterward Panama became a state within Colombia.

Transcontinental railroad and canal projects. The building of a transcontinental railroad was negotiated in 1845. It led to the Bidlack-Mallarino Treaty of 1846, which granted the United States the right of isthmian intervention to protect the line and free transit across the continent. After many vicissitudes, stemming from both political and health problems, the railroad was completed in 1855. While construction was under way, political turmoil raged in the land. Panama inaugurated and discarded 20 presidents (formerly called governors), while New Granada (Colombia) elected, substituted, or deposed 7 in Bogotá.

The railroad helped the gold rushers destined for California after 1848, but it also encouraged canal planners. Ultimately the rights to build the canal were awarded to the French diplomat Ferdinand de Lesseps (who had been instrumental in building the Suez Canal) and his Universal Interocean Canal Company; construction began in 1880. By 1889 disease, chicanery, and financial scandals in France and Bogotá involving the management of the works ruined the corporation.

By 1892, Philippe Bunau-Varilla, a former chief engineer of the canal works, had formed a new canal company, which acquired the assets of the defunct one. After the United States became interested in the canal project, it passed the Spooner Act of 1902, which authorized the U.S. president to buy the assets of the French company. Following up on this, Bunau-Varilla pressured Colombia to negotiate the Hay-Herrán Treaty of 1903, which allowed for the transfer of the canal strip to the United States. The Colombian senate, however, rejected the treaty.

Oppressed by Colombian requisitions of property and the impressment of men as a result of their civil war and influenced by Bunau-Varilla and U.S. interests, a revolutionary junta proclaimed Panamanian independence on Nov. 3, 1903. The Colombian forces sent to crush the rebellion were left at Colón when railroad cars were unavailable. U.S. naval forces also deterred reinforcements sent from Bogotá by land. Bunau-Varilla was appointed by the secessionist junta minister to Washington, D.C., with full powers to negotiate treaties. On Nov. 18, 1903, he and Secretary of State John Hay signed the Hay–Bunau-Varilla Treaty. By this treaty the United States obtained, in perpetuity, the exclusive use, occupation, and control of the Canal Zone, a strip 10 miles wide (5 miles on each side of the waterway). Formal acquisition of the lands took place on May 4, 1904, and the canal was opened on Aug. 15, 1914.

Hay–Bunau-Varilla Treaty

The Republic of Panama. The new constitution authorized the United States to intervene militarily in Panama in order to quell disturbances. It also provided for a centralized government headed by a president who had the authority to appoint and dismiss provincial governors. Manuel Amador Guerrero became the first president. Universal suffrage was adopted in June 1907. Political and economic unrest brought bloodless military interventions by the United States in 1908, 1912, 1918, and 1925.

In January 1931 the government of Florencio Harmodio Arosemena was overthrown in a bloody coup led by Arnulfo Arias Madrid, an event that ushered in an age of political and economic turmoil. The United States acquiesced in this deed and promptly recognized as president the minister to Washington, Ricardo Alfaro, who presided over the orderly elections of 1932, when Harmodio Arias Madrid (brother of Arnulfo) was the winner.

Arias persuaded the United States to relinquish the right of intervention and its priority in seizing lands for canal purposes—resulting in the modification in 1936 of the Hay–Bunau-Varilla Treaty by the Hull-Alfaro Treaty. The United States also increased the annuity paid for the use of the Canal Zone and agreed to build a transisthmian highway. But Arias planted the seeds of future military rule by building an impregnable fortress next to the city jail and by encouraging the militarization of the police.

U.S. aquisition of defense sites

In June 1940 Arnulfo Arias was elected president, and he changed the constitution to extend the length of his term. Before the outbreak of World War II the United States requested defense sites outside the Canal Zone for landing fields, roads, antiaircraft batteries, and warning stations. Arias, who openly sympathized with fascism, demanded compensation in the form of cash and the transfer to Panama of various properties. While in Havana on a private visit, he was removed from office by the military in October 1941, and Ricardo Adolfo de la Guardia became president. After the attack on Pearl Harbor on Dec. 7, 1941, Panama transferred the defense sites to the United States.

During and after the war the United States returned 98 defense sites to Panama but continued negotiations on the remaining 36. Agreement was finally reached, but the Panamanian National Assembly, influenced by the threat of mob violence, rejected the proposals. The United States abandoned the sites in 1947.

In 1945 the National Assembly put an end to the regime of de la Guardia and selected the ambassador to Washington, Enrique A. Jiménez, as president. In the presidential elections of 1948 Domingo Díaz Arosemena was declared the winner by the National Jury of Elections, depriving Arnulfo Arias of a victory. Díaz Arosemena died in office in 1949, and under a mountain of popular protests his two vice presidents first accepted, then refused, office. This action cleared the way for a bizarre maneuver by the election jury, which declared that, after a recount, Arias had won the presidency in 1948.

In 1951 former president de la Guardia returned from exile and began to challenge the government. In May a run on, and the subsequent closing of, the Federal Trust Company savings bank brought the arrest of de la Guardia, who had protested the move. Then on May 10 the head of the National Guard, José Remón, turned against Arias, who was overthrown, and Vice President Alcibíades Arosemena assumed power on May 11. The presidential elections of 1952 made Remón president, but on Jan. 2, 1955, he was assassinated.

The year 1955 was notable for the flow of capital into Panama. Work on the Inter-American Highway and on local roads was promoted by a loan from the World Bank. Student riots against the regime of Ernesto de la Guardia (elected in 1956) and the United States led to the imposition of a state of siege in 1958. More disorders occurred during the first four months of 1959, and Independence Day generated a march, by men said to have been students, into the Canal Zone to raise the Panamanian flag. The police turned them back.

Marco A. Robles' administration

In the presidential elections of 1960, Roberto F. Chiari emerged victorious. Despite a national debt of about $83 million and a budget deficit of some $10 million, he plunged into a vast program of slum clearance, housing, hospital construction, and health service. These programs found a champion in Arnulfo Arias, whose election was thwarted by the military intimidation of the voters in 1964. The former secretary to the National Guard, Marco A. Robles, was declared the winner. Under Robles the economy of Panama was uneven. Riots in January 1964 reduced the income from the Canal Zone and frightened away foreign capital; unemployment became a serious problem. There were particularly severe disorders in March and May 1968, when Arias, a presidential candidate, with his followers in control of the National Assembly, unsuccessfully attempted the impeachment of Robles.

Arias won the election, but after 11 days in office he was removed from power by the National Guard. The guard took control of the government, and a ruling junta instituted censorship of the press, suspended constitutional guarantees, and dissolved the National Assembly.

By degrees, the junta's Colonel (later General) Omar Torrijos Herrera emerged as the leader of Panama. The constitution was again changed to strengthen and enlarge his powers. In 1972 a new national assembly of 505, selected by Torrijos, gave him full executive powers and allowed him to rule as a dictator. Behind a facade of popular government and through spectacular public works programs, the appearance of Panama City was transformed. The cost of these programs, however, plunged the country into heavy debt, and by 1977 it threatened an economic crisis. The dictatorship appointed and dismissed puppet presidents at will. In mid-1978 Torrijos' apparent triumph in obtaining U.S. approval for the Panama Canal treaties seemed to promise economic respite. (A.R.W./Gu.A.)

On July 31, 1981, Torrijos was killed in a plane crash, and command of the National Guard, by then a full-fledged army trained by the United States, went to two successive colonels. In March 1982 Colonel Rubén D. Paredes became commander of the guard; when he resigned in September 1983 to pursue the presidency, control of the guard and the country went to Colonel Manuel Antonio Noriega Moreno, former head of the secret police and a one-time operative of the U.S. Central Intelligence Agency.

Noriega and drug trafficking

Noriega consolidated the dictatorship of Torrijos. He increased the size of the army, closed every newspaper and every radio and television station that opposed his wishes, and created paramilitary regiments to brutalize and assassinate his opponents and to protect himself and his family. Customhouses, post offices, the Colón Free Zone, and other state-run enterprises were taken over by the guard. More ominous was Noriega's reported involvement in the narcotics traffic in collusion with Colombian cartels. By the spring of 1987 charges of drug-related activities, murdering of opponents, and rigging of elections were made public against Noriega by the second-in-command of the National Guard, Roberto Díaz Herrera.

In 1984 Noriega permitted the first presidential elections in 16 years. Arias was the apparent winner, but after many delays in the vote count and suspected tampering, Nicolás Ardito Barletta, Noriega's candidate, became another puppet president. Eleven months later Barletta was allegedly deposed by Noriega and replaced by the first vice president, Eric Arturo Delvalle. In February 1988, Delvalle attempted to dismiss Noriega, who was being publicly condemned by factions within and outside the country for his oppressive measures. In the United States, Noriega was indicted in the same month on counts of drug trafficking and racketeering. Delvalle's action resulted in his own dismissal, by orders of the Noriega-dominated National Assembly, and he was forced to flee Panama for his life.

U.S. President Ronald Reagan refused to recognize Delvalle's successor, and on March 11, 1988, he imposed sanctions, including the elimination of preferential trade for Panama and the withholding of canal fees. On March 16 an attempted military coup failed to overthrow Noriega, and the National Guard intensified its terroristic tactics against antigovernment demonstrators.

In the presidential elections of May 7, 1989, Guillermo Endara and his two vice presidents won by a wide margin, although they suffered brutal physical assaults by Noriega's forces, an action recorded by television cameras. Noriega then canceled the election results. Nullification of the election only exacerbated public discontent with the dictatorship, but Noriega remained impervious to criticism. On Sept. 1, 1989, he installed a classmate as president, but the failure of a bloody coup attempt against Noriega on October 3 seemed to intensify his desire to remain in power. On Dec. 15, 1989, Noriega sought and was given by the legislature the title of chief executive officer of the government. The Noriega-led assembly declared that a state of war with the United States existed. The next day Panamanian soldiers killed an unarmed U.S. Marine officer dressed in civilian clothes.

Retaliation by the United States was quick and decisive. On December 19, U.S. President George Bush ordered troops to Panama with the announced aims of seizing Noriega to face drug charges in the United States, of protecting American lives, and of restoring Panamanian liberties. Guillermo Endara and his two vice presidents were sworn in to head the government of Panama. The U.S. forces quickly quelled the resistance, but some of Noriega's soldiers carried out looting in Panama City and Colón. Noriega sought and was given refuge in the Vatican embassy in Panama, where he remained for 10 days, finally surrendering to the U.S. Army on Jan. 3, 1990. He was then transported to Miami, Fla., where he was arraigned on a host of criminal charges. In Panama Noriega was also charged with various crimes, including murder. (Gu.A.)

Treaty relations with the United States. Throughout the years of Panama's independent existence, treaty relations with the United States have been subjected to several major changes. By the protocol of 1936, the United States yielded the right of land seizure for canal purposes and the obligation to defend Panama. The worldwide depression of the 1930s and the departure from the gold standard prompted an increase in the canal annuity. In 1953 the annuity was again raised and U.S. landholdings decreased, opening the door for Panamanians to build roads across the isthmus and to manage sanitation.

In 1958 the U.S. Congress appropriated $19 million for a bridge across the canal, and an instrument of transfer was signed that conveyed to Panama real estate valued at about $25 million. The disorders in 1958–59, with the demands to fly the Panamanian flag in the Canal Zone, led to recognition by President Eisenhower that titular sovereignty over the zone resided with Panama and to the display of the flags of both nations at specified places in the zone.

On Jan. 9, 1964, U.S. and Panamanian schoolboys engaged in a scuffle over flying their flags over Balboa High School. Several thousand people turned the melee into a riot that cost the lives of about 20 persons and brought injuries to scores of others. Panama blamed the Americans, severed relations, and demanded reparations. The United States, in turn, rejected the accusations and charged Panama with inciting the riot. An International Commission of Jurists (with a minor exception) later upheld the U.S. contentions.

Treaties of 1967

Negotiations between the United States and Panama during the first part of the Robles administration led to three new protocols, signed in June 1967. The first protocol abrogated the accord of 1903, reduced the size of the Canal Zone, and provided for joint operation of the canal. The second protocol continued the responsibility of the United States for the Canal Zone's defense, and the third protocol provided for a possible sea-level canal. These proposals aroused objections from many affected quarters, and they remained unratified.

On Sept. 1, 1970, Torrijos formally notified the United States of his rejection of the agreements of 1967, but seven months later he moved to resume negotiations. Panama succeeded to one of the two hemispheric seats on the Security Council of the United Nations, and its delegate in March 1973 introduced a resolution urging continued negotiation under the auspices of the United Nations. The United States vetoed the resolution. The Panamanians continued to press their cause in negotiations that resulted in a set of principles (1974) to serve as guidelines for a new treaty; one of these was that U.S. control over canal and zone would be limited in duration.

The reaction to the proposed ultimate transfer in the U.S. Congress in 1974 and 1975 was hostile. Torrijos possessed several methods of pressure with which to respond. If there was not a peaceful settlement, he declared, then there would be violence, and this produced in Congress the abhorrent spectre of "another Vietnam." To further intimidate the opposition, Torrijos, with a considerable entourage, paid a visit to the Cuban leader Fidel Castro in January 1976.

The U.S. presidential elections of 1976 held up the treaty conversations, but after the election of Jimmy Carter progress was rapid. On Aug. 10, 1977, agreement was announced, and Carter and Torrijos signed the documents on September 7 in Washington, D.C. Despite polls that showed the treaty did not have popular support, the Senate ratified it in March 1978. The new basic treaty provided for gradual transfer of the operations of the canal to Panamanians, the phasing out of U.S. military bases, and reversion of lands and waters used in the management of the canal. Similarly, Panama was to assume jurisdiction over the zone by degrees. A second pact promised an open and neutral canal in peace and war for all nations. The transfer was to be completed by Dec. 31, 1999, but, in ratifying the treaties in March and April 1978, the Senate attached reservations that extended U.S. rights to defend the canal beyond that date and to maintain limited rights of intervention. Panama had approved the treaties in a national plebiscite in October 1977, and the ceremonies of signing were observed on June 16, 1978, in Panama City. The U.S. Congress passed legislation to implement the treaties on Sept. 26, 1979, and the treaties went into effect on Oct. 1, 1979. (A.R.W./Gu.A.)

For later developments in the history of Panama, see the *Britannica Book of the Year* section in the BRITANNICA WORLD DATA ANNUAL.

BIBLIOGRAPHY

General works: South America, Central America, and the Caribbean (annual), from the Europa Publication series, contains updated, comprehensive chapters on each of the Central American countries. KENNETH J. GRIEB, *Central America in the Nineteenth and Twentieth Centuries: An Annotated Bibliography* (1988), provides commentary on more than 5,000 books published between 1810 and 1980 on Central America, excluding Panama. The *Handbook of Latin American Studies* (1935–) includes annotated bibliographies of current books and periodical articles in all Latin American fields.

Physical and human geography of the region: ROBERT C. WEST and JOHN P. AUGELLI *et al., Middle America: Its Lands and Peoples,* 3rd ed. (1989), provides a cultural geography that describes Central America in the wider context of Mexico and the Caribbean. WILLIAM L. GRAF (ed.), *Geomorphic Systems of North America* (1987), provides a general overview, including maps, followed by selected aspects of Central American geomorphology, particularly that of Costa Rica. RICHARD WEYL, *Geology of Central America,* 2nd rev. ed. (1980), focuses on this region alone. STANLEY A. ARBINGAST *et al., Atlas of Central America* (1979), graphically presents information on all aspects of the region. WERNER SCHWERDTFEGER (ed.), *Climates of Central and South America* (1976), surveys the climatology of the larger area. D.W. GOODALL (ed.), *Ecosystems of the World* (1977–), is an exhaustive study of natural and managed terrestrial and aquatic ecosystems; it includes essays on various aspects of Central American ecology. JOHN C. KRICHER, *A Neotropical Companion: An Introduction to the Animals, Plants, and Ecosystems of the New World Tropics* (1989), systematically discusses the area's biology and ecology. MARC J. DOUROJEANNI, *Renewable Natural Resources of Latin America and the Caribbean,* rev. ed. (1982); INTER-AMERICAN DEVELOPMENT BANK, *Natural Resources in Latin America* (1983 or 1984); and H. JEFFREY LEONARD, *Natural Resources and Economic Development in Central America* (1987), succinctly review agricultural, water, forestry, fishery, and mineral resources.

ROBERT WAUCHOPE (ed.), *Handbook of Middle American Indians,* 16 vol. (1964–76), forms one of the most valuable sources on the anthropology and related sciences of Central America. Two volumes may be particularly singled out: vol. 1, *Natural Environment and Early Cultures,* ed. by ROBERT C. WEST (1964); and vol. 7, *Ethnology,* ed. by EVON Z. VOGT (1969), with numerous essays on the Maya. ERIC WOLF, *Sons of the Shaking Earth* (1959, reissued 1974), remains an excellent introduction to the cultural history of Central America. R.N. ADAMS, *Cultural Surveys of Panama-Nicaragua-Guatemala-El Salvador-Honduras* (1957), is also useful. MARY W. HELMS, *Middle America: A Cultural History of Heartland and Frontiers* (1975, reprinted 1982), gives an anthropological view of Central America, with about a third of the book dealing with post-independence changes. NICOLÁS SÁNCHEZ-ALBORNOZ, *The Population of Latin America: A History* (1974; originally published in Spanish, 1968), outlines trends from pre-Columbian times to the present.

VICTOR BULMER-THOMAS, *The Political Economy of Central America Since 1920* (1987), examines economic development in Central America, stressing the difficulties created by emphasis on export-led development; and his *Studies in the Economics of Central America* (1988) reviews Central America's economies from the vantage point of the crises of the 1980s. CHARLES DAVID KEPNER, JR. and JAY HENRY SOOTHILL, *The Banana Empire: A Case Study of Economic Imperialism* (1935, reissued 1967); and THOMAS L. KARNES, *Tropical Enterprise* (1978), discuss the development of the two giants of the fruit trade, the United Fruit Company and the Standard Fruit and Steamship Company, respectively. ROBERT G. WILLIAMS, *Export Agriculture and the Crisis in Central America* (1986), focuses on the rise of the cotton and beef agribusinesses of Central America since 1950 and explains their impact on the social and political crises of the 1980s. JOHN WEEKS, *The Economies of Central*

America (1985), studies recent economic history. MARÍA EUGENIA GALLARDO and JOSÉ ROBERTO LÓPEZ, *Centroamérica: La crisis en cifras* (1986), discusses economic and social indicators.

THOMAS P. ANDERSON, *Politics in Central America: Guatemala, El Salvador, Honduras, and Nicaragua,* rev. ed. (1988), combines analyses of political, social, and economic trends. JOHN A. BOOTH and MITCHELL A. SELIGSON (eds.), *Elections and Democracy in Central America* (1989), includes a wide variety of interpretations. DANA G. MUNRO, *The Five Republics of Central America: Their Political and Economic Development and Their Relation with the United States* (1918, reprinted 1967), is a classic work, reflecting many years of service in the U.S. State Department.

History of the region: RALPH LEE WOODWARD, JR., *Central America: A Nation Divided,* 2nd ed. (1985), is the standard English-language general history of Central America. HÉCTOR PÉREZ BRIGNOLI, *A Brief History of Central America* (1989; originally published in Spanish, 1985), offers considerable political focus on the 20th century, from a Latin American perspective. FRANKLIN D. PARKER, *The Central American Republics* (1964, reprinted 1981), is still useful for its wealth of detail. LESLIE BETHELL (ed.), *The Cambridge History of Latin America* (1984–), includes several perceptive chapters on Central American history from colonial times to the present.

SYLVANUS G. MORLEY and GEORGE W. BRAINERD, *The Ancient Maya,* 4th ed. rev. by ROBERT J. SHARER (1983), is the standard history of the Maya. DORIS STONE, *Pre-Columbian Man Finds Central America: The Archaeological Bridge* (1972), offers an excellent introduction to Central American archaeology, especially lower Central America. FREDERICK W. LANGE and DORIS STONE (eds.), *The Archaeology of Lower Central America* (1984), contains an anthology of carefully researched articles. WILLIAM R. FOWLER, JR., *The Cultural Evolution of Ancient Nahua Civilizations: The Pipil-Nicarao of Central America* (1989), gives an excellent account of Nahautl influence along the Pacific coast.

MURDO J. MACLEOD, *Spanish Central America: A Socioeconomic History, 1520–1720* (1973, reissued 1984), is a thorough and well-documented history of the Spanish conquest and the Habsburg period. WILLIAM L. SHERMAN, *Forced Native Labor in Sixteenth-Century Central America* (1979), is an important scholarly work on early Spanish labour practices. MILES L. WORTMAN, *Government and Society in Central America, 1680–1840* (1982), reviews the 18th-century history of the region and explains the impact of the Bourbon reforms on the region. TROY S. FLOYD, *The Anglo-Spanish Struggle for Mosquitia* (1967), details the colonial rivalry for the eastern coast of Central America. MARIO RODRÍGUEZ, *The Cádiz Experiment in Central America, 1808 to 1826* (1978), superbly studies the independence period and the influence of the Spanish constitution of 1812 in Central America. THOMAS L. KARNES, *The Failure of Union: Central America, 1824–1975,* rev. ed. (1976), describes the failure of the Central American federation and surveys attempts to revive it throughout the 19th and 20th centuries. E. BRADFORD BURNS, *The Poverty of Progress: Latin America in the Nineteenth Century* (1980), an interpretive study, gives considerable attention to Central America and calls attention to the damage done to folk culture by the liberal economic policies of the 19th century. JAMES DUNKERLEY, *Power in the Isthmus* (1988), offers a detailed political history of modern Central America, especially since 1920. RALPH LEE WOODWARD, JR. (ed.), *Central America: Historical Perspectives on the Contemporary Crises* (1988), looks at the origins of present-day political problems.

Belize: TOM BARRY, *Belize: A Country Guide* (1989), concisely studies politics, economy, and society, as well as foreign influences on Belize. A.C.S. WRIGHT *et al., Land in British Honduras* (1959), reports on soils and agricultural land use. O. NIGEL BOLLAND and ASSAD SHOMAN, *Land in Belize, 1765–1871* (1977), studies the origins of the system of land tenure and patterns of land use and distribution. GRANT D. JONES, *The Politics of Agricultural Development in Northern British Honduras* (1971), focuses on the Corozal region between 1848 and 1968. NORMAN ASHCRAFT, *Colonialism and Underdevelopment: Processes of Political Economic Change in British Honduras* (1973), studies small farming and urban markets in central Belize in the mid-1960s. ASSAD SHOMAN, *Party Politics in Belize* (1987), is a brief examination of the political system by a participant. JULIO A. FERNANDEZ, *Belize: Case Study for Democracy in Central America* (1989), studies Belizean politics and international affairs. O. NIGEL BOLLAND, *Colonialism and Resistance in Belize* (1988), contains nine essays on aspects of social and cultural history from the early British settlement to nationhood. VIRGINIA KERNS, *Women and the Ancestors: Black Carib Kinship and Ritual* (1983), is an anthropological study.

General histories include NARDA DOBSON, *A History of Belize* (1973), from the growth of the British settlement to 1970; D.A.G. WADDELL, *British Honduras: A Historical and Contemporary Survey* (1961, reprinted 1981), including a good but dated bibliography; A.R. GREGG, *British Honduras* (1968), a popular account written for the British government; WILLIAM D. SETZEKORN, *Formerly British Honduras: A Profile of the New Nation of Belize,* rev. ed. (1981), a wide-ranging collection of information gathered on the eve of independence; and O. NIGEL BOLLAND, *Belize: A New Nation in Central America* (1986), the first general historical and contemporary survey after independence. Specific periods are addressed by O. NIGEL BOLLAND, *The Formation of a Colonial Society: Belize, from Conquest to Crown Colony* (1977), a thoroughly researched history from the Mayan period to 1871; R.A. HUMPHREYS, *The Diplomatic History of British Honduras, 1638–1901* (1961, reprinted 1981), the standard work on the colony's international relations; J. ANN ZAMMIT, *The Belize Issue* (1978), a brief summary of the dispute with Guatemala; WAYNE M. CLEGERN, *British Honduras: Colonial Dead End, 1859–1900* (1967), a well-documented study of economic and political changes in the late 19th century; and C.H. GRANT, *The Making of Modern Belize: Politics, Society, & British Colonialism in Central America* (1976), which studies Belize between 1950 and 1974. RALPH LEE WOODWARD, JR., *Belize* (1980), is an annotated bibliography on all aspects of the country.

Costa Rica: HAROLD D. NELSON (ed.), *Costa Rica: A Country Study* (1984); and TOM BARRY, *Costa Rica: A Country Guide* (1989), provide general information on Costa Rican geography, society, economy, and history. CAROLYN HALL, *Costa Rica: A Geographical Interpretation in Historical Perspective* (1985), offers comprehensive and up-to-date information on Costa Rican geography. JOHN BIESANZ and MAVIS BIESANZ, *Costa Rican Life* (1944, reprinted 1979); and RICHARD BIESANZ, KAREN ZUBRIS BIESANZ, and MAVIS BIESANZ, *The Costa Ricans* (1982), examine Costa Rican society, history, and institutions. MITCHELL A. SELIGSON, *Peasants of Costa Rica and the Development of Agrarian Capitalism* (1980), reveals much about rural life in the country. LOWELL GUDMUNDSON, *Costa Rica Before Coffee: Society and Economy on the Eve of the Export Boom* (1986), is an excellent reevaluation of the early development of Costa Rica and includes considerable discussion of the myths of Costa Rican history and its historiography. ANTHONY WINSON, *Coffee and Democracy in Modern Costa Rica* (1989), analyzes the relationship of small-farmer coffee production and the development of democracy. CHARLES D. AMERINGER, *Democracy in Costa Rica* (1982), is the best source available in English on the formation and persistence of democracy in Costa Rica. MARILYN APRIL DORN, *The Administrative Partitioning of Costa Rica: Politics and Planners* (1989), emphasizes the lack of consistency among political (province) and administrative regionalization schemes.

CHESTER LLOYD JONES, *Costa Rica and Civilization in the Caribbean* (1935, reprinted 1967), is dated but excellent for the early national history of the country. ADELA F. DE SÁENZ and CARLOS MELÉNDEZ CH., *Nueva historia de Costa Rica,* 5th ed. (1982), provides an excellent broad survey. MARIO RODRÍGUEZ, *A Palmerstonian Diplomat in Central America* (1964), thoroughly examines the life of Frederick Chatfield, who made Costa Rica into a virtual British protectorate. WATT STEWART, *Keith and Costa Rica* (1964), discusses the fascinating career of the railroad builder, financier, and fruit company executive. JOHN PATRICK BELL, *Crisis in Costa Rica* (1971), is the definitive investigation of the 1948 revolution. CHARLES D. AMERINGER, *Don Pepe* (1978), is a political study of a major Costa Rican figure in the 20th century, José Figueres. JOSÉ LUIS VEGA CARBALLO, *Orden y progreso: La formación del estado nacional en Costa Rica* (1981), objectively surveys social and political change in Costa Rica.

El Salvador: Physical geography is graphically presented in INSTITUTO GEOGRÁFICO NACIONAL INGENIERO PABLO ARNOLDO GUZMÁN, *Atlas de El Salvador,* 3rd ed. (1979). ALISTAIR WHITE, *El Salvador* (1973, reissued 1982), provides a comprehensive analysis of social and economic development. DAVID BROWNING, *El Salvador: Landscape and Society* (1971), deals with the population as well as the country, focusing on "man-land" relationships.

PHILIP L. RUSSELL, *El Salvador in Crisis* (1984), is the best choice for an overview. Of the many general studies that centre on the period since 1931, some of the most useful include ENRIQUE A. BALOYRA, *El Salvador in Transition* (1982), a penetrating analysis of the political system; RAYMOND BONNER, *Weakness and Deceit: U.S. Policy and El Salvador* (1984), a critical account by a former *New York Times* correspondent; JAMES DUNKERLEY, *The Long War: Dictatorship and Revolution in El Salvador,* new ed. (1985), a scholarly, critical examination of events leading to the civil war; TOMMIE SUE MONTGOMERY, *Revolution in El Salvador: Origins and Evolution* (1982), an informed commentary on the role of the Roman Catholic church and the rise of the left; and MICHAEL MCCLINTOCK, *The American Connection* (1985), a detailed discussion of the U.S. role in the Salvadoran counterinsurgency effort. THOMAS P.

ANDERSON, *Matanza: El Salvador's Communist Revolt of 1932* (1971), stands as the definitive study of the peasant uprising. Anderson's *The War of the Dispossessed: Honduras and El Salvador, 1969* (1981), is an account of the Soccer War, including his firsthand observations; while WILLIAM H. DURHAM, *Scarcity and Survival in Central America* (1979), provides insightful treatment of the ecological and socioeconomic factors that led to that war. PATRICIA PARKMAN, *Nonviolent Insurrection in El Salvador* (1988), explains the fall of the Hernández Martínez dictatorship in 1944. STEPHEN WEBRE, *José Napoleón Duarte and the Christian Democratic Party in Salvadoran Politics, 1960–1972* (1979), focuses on a critical period in El Salvadoran history. RALPH LEE WOODWARD, JR., *El Salvador* (1988), offers the best bibliographic guide to further study.

Guatemala: FRANCIS GALL (comp.), *Diccionario geográfico de Guatemala,* 2nd ed., 4 vol. (1976–83), is a comprehensive work. General geographic aspects are covered in RICHARD F. NYROP (ed.), *Guatemala: A Country Study,* 2nd ed. (1983). Economic and political studies include J.C. CAMBRANES, *Coffee and Peasants: The Origins of the Modern Plantation Economy in Guatemala, 1853–1897* (1985); and PETER CALVERT, *Guatemala: A Nation in Turmoil* (1985). SEVÉRO MARTÍNEZ PELÁEZ, *La patria del criollo* (1970, reissued 1985), describes in detail the colonial social structure and the formation of the Creole mentality.

A good general history is JIM HANDY, *Gift of the Devil: A History of Guatemala* (1984). CHESTER LLOYD JONES, *Guatemala, Past and Present* (1940, reissued 1966), is still useful. THOMAS MELVILLE and MARJORIE MELVILLE, *Guatemala: The Politics of Land Ownership* (1971), discusses the question of landholding and the lack of reform. The violence that has characterized the history of Guatemala since 1945 is detailed in EDUARDO GALEANO, *Guatemala: Occupied Country* (1969); SUSANNE JONAS and DAVID TOBIS (eds.), *Guatemala* (1974); ROGER PLANT, *Guatemala: Unnatural Disaster* (1978); and JONATHAN L. FRIED, *et al.* (eds.), *Guatemala in Rebellion: Unfinished History* (1983), an Americas Watch Committee report.

Honduras: JAMES D. RUDOLPH (ed.), *Honduras: A Country Study,* 2nd ed. (1984), covers the geography, social and administrative structure, and history of the country. Political aspects of resources are discussed in KENNETH V. FINNEY, "Rosario and the Election of 1887: The Political Economy of Mining in Honduras," *The Hispanic American Historical Review,* 59(1):81–107 (February 1979); and JAMES A. MORRIS and STEVE C. ROPP, "Corporatism and Dependent Development: A Honduran Case Study," *Latin American Research Review,* 12(2):27–68 (Summer 1977).

Works on various aspects of Honduran history include ROBERT S. CHAMBERLAIN, *The Conquest and Colonization of Honduras, 1502–1550* (1953, reprinted 1966); NANCY PECKENHAM and ANNIE STREET (eds.), *Honduras: Portrait of a Captive Nation* (1985); and JAMES A. MORRIS, *Honduras: Caudillo Politics and Military Rulers* (1984). WILLIAM H. DURHAM, *Scarcity and Survival in Central America* (1979), pursues the underlying causes of the 1969 Soccer War between El Salvador and Honduras and exposes many of the socioeconomic problems of Central America and their long-term historical consequences. THOMAS P. ANDERSON, *The War of the Dispossessed* (1981), is another account of that war.

Nicaragua: JAMES D. RUDOLPH (ed.), *Nicaragua: A Country Study* (1982), is a good general introduction. On the country's geography, see JAIME INCER, *Geografía ilustrada de Nicaragua* (1973). Political and social studies include BERNARD DIEDERICH, *Somoza and the Legacy of U.S Involvement in Central America* (1981); BERNARD NIETSCHMANN, *The Unknown War: The Miskito Nation, Nicaragua, and the United States* (1989); and DAVID CLOSE, *Nicaragua: Politics, Economics, and Society* (1988). The relationship between politics and the church is addressed in MICHAEL DODSON and LAURA NUZZI O'SHAUGHNESSY, *Nicaragua's Other Revolution: Religious Faith and Political Struggle* (1990).

General works on Nicaraguan history and politics include JOHN A. BOOTH, *The End and the Beginning: The Nicaraguan Revolution,* 2nd ed., rev. and updated (1985); and THOMAS W. WALKER, *Nicaragua: The Land of Sandino,* 2nd ed., rev. and updated (1986). KARL BERMANN, *Under the Big Stick: Nicaragua and the United States Since 1848* (1986), provides a solid overview of U.S. involvement in Nicaraguan affairs since the mid-19th century. Two classic studies of important aspects of the country's prerevolutionary 20th-century history are NEILL MACAULEY, *The Sandino Affair* (1967, reprinted 1985); and RICHARD MILLETT, *Guardians of the Dynasty* (1977), which traces the history of the U.S.-created National Guard and its relationship with the Somoza family. DONALD C. HODGES, *Intellectual Foundations of the Nicaraguan Revolution* (1986), provides useful insights into both Augusto César Sandino and the Sandinistas. An informed critique of Nicaragua's revolutionary elite is DENNIS GILBERT, *Sandinistas: The Party and the Revolution* (1988). Among numerous useful studies of the conflict between the administration of U.S. President Ronald W. Reagan and Sandinista Nicaragua are PETER KORNBLUH, *Nicaragua: The Price of Intervention: Reagan's Wars Against the Sandinistas* (1987); and THOMAS W. WALKER (ed.), *Reagan Versus the Sandinistas: The Undeclared War on Nicaragua* (1987). For insight into specific aspects of the Nicaraguan revolution, see ROBERT F. ARNOVE, *Education and Revolution in Nicaragua* (1986); MARY B. VANDERLAAN, *Revolution and Foreign Policy in Nicaragua* (1986); and GARY RUCHWARGER, *People in Power: Forging a Grassroots Democracy in Nicaragua* (1987). RALPH LEE WOODWARD, JR. (comp.), *Nicaragua* (1983), is an annotated bibliography.

Panama: SANDRA W. MEDITZ and DENNIS M. HANRATTY (eds.), *Panama: A Country Study,* 4th ed. (1989), provides information on all aspects of the country. Physical geography is covered by ROBERT A. TERRY, *A Geological Reconnaissance of Panama* (1956). INSTITUTO GEOGRÁFICO NACIONAL TOMMY GUARDIA, *Atlas nacional de la República de Panamá,* 3rd ed. (1988), graphically presents information on the geography, resources, economy, social conditions, and administrative and political divisions. BURTON L. GORDON, *A Panama Forest and Shore: Natural History and the Amerindian Culture in Bocas del Toro* (1982), is also useful. The role of agriculture in the country's economy is presented by WILLIAM C. MERRILL *et al., Panama's Economic Development* (1975). STEVE C. ROPP, *Panamanian Politics: From Guarded Nation to National Guard* (1982), discusses Panama's politics and foreign relations.

Works on Panama's history include JOHN EASTER MINTER, *The Chagres: River of Westward Passage* (1948); LAWRENCE O. EALY, *Yanqui Politics and the Isthmian Canal* (1971); GUSTAVE ANGUIZOLA, *Philippe Bunau-Varilla: The Man Behind the Panama Canal* (1980); STEPHEN G. RABE, *Eisenhower and Latin America: The Foreign Policy of Anti-communism* (1988); and LESTER D. LANGLEY, *The United States and the Caribbean in the Twentieth Century,* 4th ed. (1989).

Central Asian Arts

The term Central Asia has no specific boundaries in a geographical context, but cultural historians generally apply it to the territory bordered on the north by Siberia in the Soviet Union and on the south by Iran, Pakistan, Bangladesh, and India. This area includes the present Soviet republics of Kazakhstan, Turkmenistan, Uzbekistan, Kirgizstan, and Tadzhikistan and portions of the Sinkiang Uighur Autonomous Region of China—the populations of which are largely of Turkic stock—and the kingdom of Afghanistan. For the purposes of this article, the term is further extended to include Siberia and the Soviet Arctic lands and, in the south and east, the Altaic regions of Mongolia and Manchuria (Northeast Provinces) and the Himalayan regions of Nepal, Bhutan, Sikkim, and Tibet.

This immense tract of land—with its highly varied topography and climate and its diversity of ethnic and linguistic backgrounds—encouraged the development of greatly varied artistic styles and traditions among the inhabitants of widely separated regions. These differences were magnified by the emergence of dissimilar religions, which in turn encouraged the formation of distinctive schools or traditions of art. Further artistic variances can be attributed to cultural time lag, for comparable stages of artistic development were not reached simultaneously throughout the area.

The arts that developed across Central Asia often fed or were fed by those of adjoining cultural regions or by such supraregional influences as Islām. Although reference will be made to such cross-cultural interactions wherever appropriate, more detailed information on these other areas may be found in such articles as ISLĀMIC ARTS and SOUTH ASIAN ARTS. (The peoples and traditional cultures of the region are treated in the *Macropædia* articles ASIA and UNION OF SOVIET SOCIALIST REPUBLICS.) (T.T.R.)

This article is divided into the following major sections:

Literature

Of the relatively few Central Asian languages that have developed written literatures, the most important are Turkic, Tibetan, and Mongol. (For a treatment of the Central Asian languages, see LANGUAGES OF THE WORLD.) This article will deal with Tibetan and Mongolian literatures from their inception to the 20th century and with Turkic literature from its inception to the 11th century, when the Muslim invasion introduced a period of Islāmic culture. Subsequent Turkic literature is treated in the Turkish literature section of ISLĀMIC ARTS, which also treats Central Asian literatures written in Arabic and Persian. (For literature in Chinese, see the article CHINESE LITERATURE.)

TURKISH LITERATURE

The purely Turkish period in the history of Turkish literatures came before the conversion of the Turks to Islām and covers approximately the 8th to the 11th century AD. The oldest literary legacy of the period is found in the Orhon inscriptions, found in the Orhon Valley, northern Mongolia, in 1889 and deciphered in 1893 by the Danish philologist Vilhelm Thomsen. The inscriptions are on two large monuments, erected in 732 and 735 in honour of the Turkish prince Kül and his brother Bilge Kagan; they are carved in a script used also for inscriptions found in Mongolia, Siberia, and western Turkistan and called by Thomsen "Turkish runes." They relate in epic and forceful language the origins of the Turks, their golden age, their subjugation by the Chinese, and their liberation by Bilge Kagan. The polished style suggests considerable earlier development of the language. Excavations in Chinese Turkistan have brought to light specimens of writings of the Uighur Turks from the 9th to the 11th century. Maḥmūd Kāshgarī's comprehensive dictionary (1071?) contains specimens of old Turkish poetry in the typical form of quatrains (*dörtlük*), representing all the principal genres: epic, pastoral, didactic, lyric, and elegiac. (F.I.)

"Turkish runes"

TIBETAN LITERATURE

Tibetan was developed as a literary language from the 7th century onward as a result of earlier cultural contacts with neighbouring Buddhist countries, namely, the small states of the Takla Makan, especially Khotan (Ho-t'ien) and the kingdoms of ancient northwestern India (modern Gilgit, Kashmir, and Kulu) and Nepal. Scripts of Indian origin were in use in these countries, so the Tibetans also adapted an Indian script to suit their own very different language. By far the greater number of works produced between the 7th and 13th centuries are skillful translations of Buddhist works, largely from Sanskrit, on which Indian scholars and Tibetan translators worked side by side. The Tibetans had to create an entirely new (and therefore artificial) vocabulary of religious and philosophical terms, mainly by ingenious compounding of simple terms available in their own language. Apart from some religious terms in daily use, this vocabulary remains a specialized scholarly language. An indigenous literature was also produced: annals and chronicles, sets of spells and prognostications, legendary and liturgical works, all representing the remains of ancient oral traditions. Large collections of such manuscript fragments, all earlier than the 11th century, were discovered early in the 20th century in the Cave of the Thousand Buddhas near Tun-huang (at the eastern side of the Takla Makan).

Indigenous literature of Tibet

The quasi-official work of translating authorized Indian Buddhist texts, which continued for six centuries, gave incentive to the Bon-pos (the followers of the pre-Buddhist religion of Tibet) to collect and write down their own early traditions; but in so doing they adopted many Buddhist ideas and, inevitably, used the new vocabulary. The followers of the earliest Buddhist traditions to enter Tibet (the rNying-ma-pa, or "Old Order") also committed their teachings to writing; and, conversely, these are interspersed with pre-Buddhist traditions.

The official Tibetan Buddhist canon was closed in the 13th century; it consisted of two parts, the *Kanjur* ("translated word," teachings or reputed teachings of the Buddhas themselves) and the *Tanjur* ("translated treatises," mainly commentaries by Indian teachers). By this time, however, there already existed some orthodox Buddhist works of Tibetan origin (for example, *Mi-la ras-pa* and *sGam-po-pa*); and from the 13th century onward, under the impetus given by the prolixity of religious houses and orders, there were produced such lengthy and numerous collections of historical and biographical works, treatises and commentaries, liturgy and religious drama that Tibetan literature must be one of the most extensive in the world. Just as in the European Middle Ages there was little secular literature worth the name, so there is none in Tibetan except for a great epic (*Rgal-po Ge-sar dgra'dul gyi rtogs-pa brjod-pa,* "The Great Deeds of King Gesar, Destroyer of Enemies") that recounts the exploits of the king and magic hero Gesar. This work grew through the centuries, assimilating whatever material pleased the fancy of the bards.

Secular literature

After the craft of printing from incised wood blocks was introduced from China, possibly in the 14th century, certain monasteries became famous printing houses. This form of printing continued until the Chinese invasion in 1959. Manuscripts and block-printed books are always of elongated shape, thus imitating the form of ancient Indian palm-leaf manuscripts. There are considerable collections in some European libraries—London, Paris, and Rome—but few translations are available because of the small number of scholars of Tibet.

Despite the phonetic changes in the spoken dialects since the script was fixed, the Tibetans have never changed their system of writing. Thus, once the literary language and the various types of script have been mastered, the reader has immediate access to all literature of the 7th to the 20th century, though changes in style and vocabulary have left many obscurities in the earliest works. Since there is no modern style of writing, the 20th-century colloquial language can be written only in the traditional medium (as though, for example, one had to write modern Italian with Latin spellings and grammatical forms); the Tibetans themselves compose even personal letters in a conventional literary style. (D.L.S.)

MONGOLIAN LITERATURE

Mongolian literature begins with the *Secret History of the Mongols,* an Imperial chronicle dealing with the life and times of Genghis Khan and his successors, written about 1240. *Üligers,* orally transmitted epic stories in verse, form the bulk of native literary expression. Highly stylized, these tales relate adventures of legendary heroes and villains. In spite of their great length (sometimes more than 20,000 lines), they are recited from memory by bards. Like the other epics, such as the Greek *Iliad* and the Roman *Aeneid,* Mongolian epics are genuine artistic creations. The verses alliterate in couplets or quatrains, are seven or eight syllables long, and are characterized by parallelism. In addition to Genghis Khan, the epic stories tell of heroes such as Erintsen Mergen, Engke Bolod Khan, and Gesar Khan (the last of Tibetan origin). The villain of the epics is the many-headed monster, the *manggus,* whom the hero always defeats in the end.

Mongolian historical chronicles

Historical chronicles represent another important form of indigenous literature. Usually beginning with the creation of the world from primordial elements, they attempt to link the Indian and Tibetan rulers with the house of Genghis Khan. Such are the *Altan tobchi* ("The Golden Button"), composed about 1655 and giving a world history down to Ligdan Khan (1604–34); another *Altan tobchi* (written about 100 years later); and the *Erdeni-yin tobchi* ("The Jeweled Button"), written in 1662 by Saghang Sechen.

Mongolian written literature was profoundly influenced by the introduction of Buddhism around the end of the 1500s. Earlier surviving written works (on stone or paper) are mostly official documents; and no oral epics were written down until the late 1880s. The advent of Buddhism evoked translations of its sacred writings and related works. A Buddhist canonical collection, the *Bka'-'gyur* (or *Kanjur;* comprising the *sūtra*s and *vinaya* of the *Tripiṭaka*), was translated and printed in 1635 in 108 volumes; the *Bstan-'gyur* (*Tanjur*), containing canonical commentary and noncanonical works in its 225 volumes, followed in 1741. Two especially well-known sermons (*sūtras*) of Buddha are the *Altan gerel* ("Golden Beam") and the *Chagan lingqua* ("White Lotus"), or, as they are known in Sanskrit, *Suvarṇaprabhāsa* and *Saddharmapuṇḍarīka.* None of these works, however, is indigenous.

Religious but nondogmatic birth stories (called in Sanskrit *Jātaka*) deal with Buddha's meritorious deeds, and, like the parables of Christianity, illustrate religious truths. Best known is the *Üliger-Ün dalai* ("The Sea of Stories"). Translations of other Indian fables are the *Siddhi Kür* ("Tales of the Vampire") and the *Bigarmijid* ("Saga of King Vikramāditya").

In the 18th and 19th centuries Chinese traders brought from China many Mongolian translations of Chinese novels of enchantment and romance, including the *San Kuo chih yen-i (Romance of the Three Kingdoms)* and others.

20th-century literature

In the early 20th century T. Zhamtsarano, a Russian-educated Buryat writer and intellectual, founded the short-lived Mongolian newspaper *Shine toli* ("The New Mirror"). He also translated the works of some Western authors, such as Edgar Allan Poe, Jules Verne, and H.G. Wells.

After a Soviet state was established in Mongolia in the early 1920s, the power and influence of the Tibetan Buddhist church declined, and with it the literature it sponsored. There began to arise a revolutionary and Socialist literature serving the people according to the current beliefs of the Communist Party. Popular themes were social criticism of the feudal past, with its exploitation of the people, and exemplary tales that showed new Socialist values and educated readers to overcome the resistance of reactionary forces. Mongolian reliance on and gratitude for the fraternal Soviet Union and its assistance is an ever-present undercurrent. The rise of a system of schooling, extending to the university level, has enabled many young Mongolian writers, poets, artists, and actors to achieve, within limits, a self-expression never before available to them. Leading 20th-century modern writers are Dashdorjiyn Natsagorj, Ts. Damdinsürün, D. Sengee, S. Erdene, and others. (J.R.Kr.)

Music

Music in Central Asia flowered along centuries-old caravan routes linking the Near East with China and India via Turkistan, the vast region extending from the Caspian Sea to Sinkiang province in China. Musical instruments diffused from one region to another, and many of the musical styles still display foreign influence. The variety of musical styles ranges from the systematically organized classical music of Turkistan, to the notated religious chants of Tibet, to the highly varied folk music styles of the region's numerous ethnic groups. The main thrust of this examination of Central Asian music will be on the traditions and styles first of Afghanistan and the sedentary population of Turkistan, then of the Turkic nomads, the Mongols, and the Siberian peoples, and, finally, of the Himalayan peoples in Tibet, Bhutan, Nepal, and Sikkim.

AFGHANISTAN AND THE SEDENTARY POPULATION OF TURKISTAN

This region of Central Asia includes Afghanistan, present-day Uzbek Soviet Socialist Republic (Uzbekistan) and Tadzhik S.S.R. (Tadzhikistan), and the oases of eastern (Chinese) Turkistan. The region lies within the Persian cultural area, and in the arts and in language the Persian imprint has endured over many centuries. In music the links with Persia appear most clearly in terminology and instruments. Islām, another Near Eastern heritage, predominates in this region and results in a generally low social status of musicians and musical performance—a situation generally not found in other regions of Central Asia.

The area includes two main streams of musical practice: folk music in a broad range of styles, often closely linked to specific ethnic groups; and the more exclusive, cosmopolitan, classical music, derived from the medieval court music of Bukhara, Samarkand, and other urban centres of Transoxania (modern Uzbek S.S.R., Tadzhik S.S.R., and Turkmen S.S.R.). A third stream is now in the process of formation: popular music disseminated through the mass media.

Musical instruments

Folk music. Generally characterized by a scarcity of musicians and musical instruments, folk music of this region is predominantly a matter of solo playing and singing, small ensembles, and a complete lack of musical notation or codified musical theory. In their general types, the musical instruments are closely related to those of Persia and the Near East, but specific forms and playing styles are purely local. Thus, there are numerous variants of the Persian long-necked lute, with names derived from the Persian *tanbūr* or *dūtār;* small spike fiddles, in which the neck skewers the body, forming a spike at the base; various block or fipple flutes, with air ducts like that of the Western recorder; transverse (horizontally held) flutes; oboes; metal jew's harps; and two basic drum types, a single-headed vase-shaped drum of pottery or wood and a large single-headed frame drum, or tambourine—all instrumental types widely diffused in the Near East.

Stylistically, the music relates to that of both the Near East and the surrounding nomadic Turkic peoples of Central Asia. Songs are completely monophonic (*i.e.,* consisting only of a line of melody), but instrumental music often includes two-part polyphony (music in more than one voice, or part). The polyphony may take the form of a drone (sustained note) with a melody played above it. Or it may be organum style; *i.e.,* the second part playing the same melody as the first but at a higher or lower pitch. Most common are parallel fourths or fifths (a fourth encompasses four notes of a Western major or minor scale; a fifth, five). In structure, much of the music is based on small forms, frequently binary, or two-section, and ternary, or three-section. Small musical units may be repeated many times and varied slightly at each appearance. The recurrence of melodic phrases and an emphasis on marked rhythms is common and is related to the frequent role of music as dance accompaniment. Thus in the following example, a dance tune from Afghan Turkistan, sections A and B are similar in their overall melodic structure, and also in the small units of three or four notes on which they are built. The sequence ABAB, etc., is repeated throughout the dance. Vocal music may have greater rhythmic flexibility and melodic range, but in form it is almost always subordinated to the structure of the song text. Quatrains such as the *rubai* and *charbaitai* are the most prominent village verse forms, with the exception of the *lundai,* a couplet used by the nomadic Pashtuns of Afghanistan. In the urban oases, couplet forms based on the classical Persian *ghazal,* a lyric poem of 6 to 15 couplets, are more common.

Attitudes toward music

The generally negative attitude of Islām toward music has led in Afghanistan to strictures against musical performance and to extremely low social status for musicians. Music is heard mainly in male-dominated public teahouses or at private celebrations such as weddings and circumcisions. Women may have their own musical genres within their enclosures; in this context the strong tradition of women's music in the Fergana Valley of the Uzbek S.S.R. is noteworthy.

Within this general picture there is enormous diversity. The Uzbeks (a Turkic people) and Tadzhiks (an Iranian group), who live side by side across northern Afghanistan and southern Turkistan, tend to share many musical traits and instruments. In contrast, most groups, such as the Pashtuns, Ḥazāra, and Baluchs of Afghanistan and Pakistan or, in the extreme, the isolated mountain peoples of Nūrestān in Afghanistan and of the Pamirs in the Tadzhik S.S.R. and Afghanistan, have maintained distinctive musical styles and, in some cases, unique musical instruments. The Nūrestāni *vaji,* an arched harp (having a bow-shaped body with no forepillar), is a striking case of the possible survival of an instrument type on the margins of a now disintegrated culture area; there are no other harp traditions today between the Caucasus and Burma, although iconographic evidence indicates that in ancient times harps were widespread in Central Asia, the Near East, and India. The music of the Ḥazāra includes vocal effects produced by striking the throat while singing, causing a break in the sound, and Baluchi music also features a broken-voice style.

Medieval court music

Classical music. In contrast to the folk music styles just described, the court-derived classical style of Bukhara and Samarkand represents a highly systematic, theoretically grounded, cosmopolitan musical tradition. Lying along the medieval silk route, the Turkistani oases were open to musical cross-currents. Today's musical roots may reach back to the period in which urban Central Asian music was in vogue at T'ang dynasty courts in China (618–907). The movement of musical instruments across the caravan trail from the Near East to China via Central Asia is well documented since early times. Over the centuries, town musicians evolved an urban style patronized by the local courts, notably under Timur (Tamerlane) and his descendants (*c.* 1350–1500) in Herāt (now in Afghanistan) and Samarkand. The degree of musical eclecticism characteristic of the era is illustrated by a court historian's description of the festivities of Timur's son:

> Golden-tongued singers and sweet-sounding musicians played and sang to motives [melodic figures] in Persian style, to Arab melodies according to Turkish practice and with Mongol voices, following Chinese laws of singing and Altai meters.

By the 17th century the court style had been codified into sets of nonimprovised suites of instrumental and vocal pieces using poetic texts in classical Persian and local court Turkish (Chaghatai). In Bukhara this collection of suites was known as the *Shashmaqām,* or six *maqām*s (suites), with each *maqām* (an Arabic term, but changed in meaning) set in one of the classical Persian musical modes. (The Persian modes are melodic frameworks, each with a given scale, typical melodic figures, and accepted emotional content.) Regional courts and large towns developed their own sets of *maqām*s, performed in unison by an orchestra and a male chorus.

20th-century changes in music practice

Areas of Turkistan under Soviet rule since about 1920 have undergone far-reaching modification of traditional music practice, although the older styles such as the *Shashmaqām* are also maintained. Changes include the reconstruction of local instruments to fit the Western musical scale of 12 equally spaced half steps, establishment of music schools and conservatories, creation of orchestras of folk instruments, introduction of vocal polyphony, and the writing of works in Western forms (symphonies, operas, chamber music) by native and European Soviet composers. In Afghanistan, musical change began on a national basis in the 1950s under the influence of Radio Afghanistan, which broadcasts principally popular styles based on Pashtun folk music and songs of the Indian film industry.

TURKIC NOMADS, MONGOLS, AND SIBERIAN PEOPLES

This region includes primarily the great open spaces of Central Asia, from the Turkmen desert in the southwest to the Kazakh steppes, Mongol plains, and from the Gobi to the vast subarctic Siberian evergreen forests, or taiga, and tundra, or Arctic plains, stretching to the Pacific. The considerable mobility and often close linguistic affinity of the peoples in the area led to substantial interchange of musical terms and instruments, and to common social functions of music relating to the traditional tribal social structure of most of the groups of this region.

Social role of music. Three basic functions of music are common throughout most of the region: music as ritual, with magical connotations (shamanism), music as tribal record, aiding group solidarity (epic recitation), and music as entertainment (itinerant performers, festivals).

The shaman's music

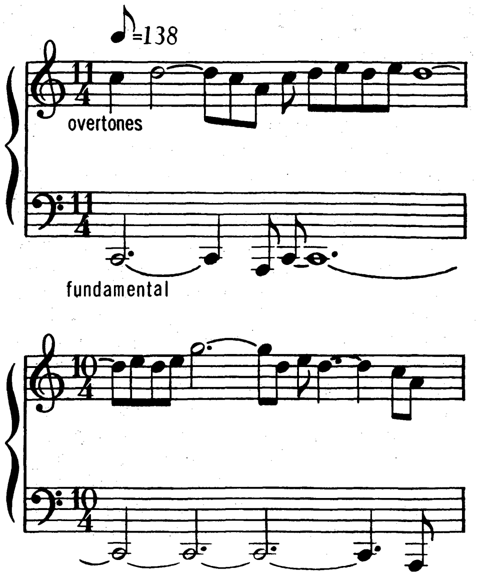
Music is the medium of the shaman, or priest-medicine man, as he performs his role as mediator between the seen, or men, and the unseen, the spirits that inhabit the spheres above and below the earth. Traditional shamanistic séances were creative, impassioned musico-dramatic scenes produced by a single performer, the shaman. Not only is music the shaman's aid in inducing the trance that enables him to contact spirits, but in Siberia his drum (a very large tambourine) may be considered a steed for the trip to other worlds. Thus great attention is given to each stage of drum construction, from selecting the wood of certain trees to the painting of symbolically charged designs on the drumhead. The metal hangings, sometimes including bells, on the shaman's costume also play a musical role. Among the Kirgiz and Kazakhs and until recently among the Turkmens, a fiddle with horsehair strings and bow performs the same function as the Siberian drum. Metal ringlets are attached to the head of the fiddle, and a niche is hollowed there for a mirror to catch the reflections of spirits. Shamans' horsehair fiddles can even be found among townspeople of northern Afghanistan. The occurrence of shamanism has sharply declined in Soviet portions of Central Asia.

Epic recitation, which may serve as tribal history, also has magical overtones. Among Turks, the same term (*bakhshi*) may be used for both shamans and bards, and both may be called to their trade by spirits to undergo a difficult period of initiation. Storytellers use a fiddle or lute as accompaniment, and tales may run through several nights of exhaustive performance; one Kirgiz bard is known to recite 300,000 verses of the *Manas,* the major Kirgiz epic. Such marathon performances are facilitated by the use of stereotyped melodic motives—standard short melodic figures—often invented by the individual performer. Local epic traditions vary widely in dramatization; *i.e.,* the proportion of dialogue, monologue, and narrative.

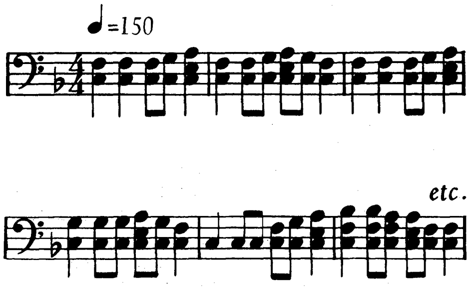
The singing contest

The third area-wide musical function, entertainment, takes many forms. One common diversion is the singing contest, in which rival minstrels compete in wit and virtuosity. Such trials of skill are most notable among the Kirgiz, Kazakhs, and Mongols. The contests follow strict rules of versification, musicality, and procedure. Often the loser must pay a forfeit to the victor, who receives acclaim from the audience and gifts from wealthy patrons; a singer's reputation may be made or broken in a single afternoon. Frequently a contestant will vilify the clan championed by the opposing singer and laud his own faction. In Siberia another type of entertainment is the widespread practice of bear festivals at specific times of the year, during which a bear is killed and his head displayed, to the accompaniment of music, dance, and games.

Instrumental and vocal styles. Across the region the principal instrument types are lutes, with two or three strings, the necks either fretted or fretless; fiddles, largely horsehair fiddles; flutes, mostly open at both ends and either end-blown or side-blown; and jews' harps, either metal or, often in Siberia, wooden. Few percussion instruments are found, except for the shaman's magic drum. Considerable instrumental polyphony is played on lutes and fiddles, particularly among the Turkic peoples. Vocal polyphony may occur in special ways: singers among the Mongols and Tuvins (a Siberian people northwest of Mongolia) can produce two parts while singing solo, as in the example below, by strongly reinforcing upper partials (overtones) while singing a very deep fundamental pitch. West of the Urals, Bashkirs may hum a basic pitch while playing solo flute pieces, and certain Siberian peoples may sing choral overlapping responsorial songs (in which group and soloist alternate, one beginning slightly before the other finishes).



The vast geographic stretch of the region produces musical links to neighbouring areas as well as highly distinctive local styles. The Turkmens live in Afghanistan and Iran as well as Turkistan and manifest some Persian influence in musical terms and instruments, yet they possess unique vocal and instrumental styles. Particularly striking is their series of guttural sounds serving as vocal ornaments. The Kirgiz and Kazakhs, closely related musically, maintain ties to Mongol and northern styles (*e.g.,* of the Bashkir and Tatar peoples, west of the Urals) as well as to Turkistan. Nevertheless, their relaxed voice quality, musical scales, and distinctive instrumental polyphony set them off. Noteworthy here is the versatile polyphonic style of the three-stringed Kirgiz *komuz* lute, based on extensive development of short melodies called kernel tunes. In the *komuz* piece shown below, the kernel tune is stated in the first two measures and is varied and developed elaborately as the piece progresses. Another Kirgiz-Kazakh specialty is programmatic music, in which instrumentalists suggest situations or tell specific stories without words, through musical images alone.



Mongolian and Siberian music

The Mongols display links to both Chinese and Tibetan music. Chinese influence is apparent in the use of certain instruments (*e.g.,* some flutes and fiddles) and perhaps in the structure of melodies; Tibetan impact occurs in the religious music and musical instruments of Tibetan Buddhism, introduced in the 16th century. Mongolian music also has its own distinctive profile, sporadically documented since the 13th-century *Secret History of the Mongols,* the first written Mongolian chronicle. Of interest is the fact that Arghūn Khān, Mongol ruler of Persia, sent a musician as emissary to Philip IV the Fair of France in 1289. Because of the focal position of Mongolia at the heart of Central Asia, some Mongol epic melodies have spread westward as far as the Kalmuks on the Volga River, and eastward to the Ainu of Sakhalin Island, north of Japan. Mongol songs may be either quick and marked rhythmically or drawn-out in free rhythm, with extensive melodic ornamentation. The Mongol horsehair fiddle accompanies a singer with simultaneous variations on the melody, a technique called heterophony.

Siberian music includes a broad spectrum of styles over a huge geographic expanse. Many unique traditions occur, such as the bridgeless, often rectangular zithers of the Khants and Mansi, Ugrian peoples along the Ob River; farther east, the solo flute-and-voice polyphony of the Tuvins and Bashkirs; and the rapid, compact songs with nonsense syllables of the Gilyaks, Chukots, and other peoples of the Far Eastern Amur River region and Pacific coast. At that northeastern shore of Siberia there is a carryover of musical style to the Ainu of northeastern Japan and possible musical ties between the Eskimos of Asia and of North America. Other links beyond Central Asia may exist at the far western end of Siberia, for example, to the music of Lapland in the Scandinavian Arctic; or the relation of tunes of certain peoples of the Volga River region, such as the Mari or Cheremis, with old Hungarian folk songs.

Outside the few written Mongol references to music, the only approach to discovery of the stylistic history of this region of Central Asia is through fragmentary information about musical instrument types. Perhaps the most remarkable instrument finds were made at Pazyryk in south central Siberia, where Soviet archaeologists found wooden objects which possibly form pieces of a harp and an artifact resembling a vase-shaped drum, both dating from the 5th century BC.

THE HIMALAYAN PEOPLES

This region, including Tibet, Bhutan, Nepal, and Sikkim (which was annexed to India in 1975), occupies an important middle ground between India and China, and its central position is reflected in the local music cultures. Of utmost importance for musical life was the introduction of Buddhism from India via Turkistan, beginning in the 7th century AD. Music became an integral part of the official creed of Tibetan Buddhism, and the considerable cultural influence of Tibet spread Tibetan religious music to the nearby areas of Nepal, Sikkim, and Bhutan and, much later, to Mongolia.

Tibetan music. Tibetan religious music is the only Central Asian repertoire that has a long history of written notation. This notation, for liturgical chant, consists of neumes; *i.e.,* symbols representing melodic contour rather than precise pitch, similar to the earliest music writing of medieval Europe. Also distinctive is the metaphysical aspect of Tibetan Buddhist music, related to Indian philosophy. Each instrument of the monastery orchestra, as well as the drawn-out tones of chant, is believed to represent an externalized form of the *mantras,* or sounds inherent in the human body, accessible otherwise only through steadfast meditation. For the monks, such music is a basic aid to devotion and prayer. Musical styles vary somewhat among the sects of Tibetan Buddhism, but the basic approach and instruments are the same.

The monastery instruments typify the crossroads position of Tibet. Some, such as the large cymbals, stem from China, while others (the majority), such as the conch-shell trumpet and handbells, can be traced to Indian influence and are found as instruments of Buddhist worship as far away as Japan. Still other instruments, such as the large oboe and the ten-foot metal trumpet, are perhaps Near Eastern in origin. One wind instrument, the short trumpet made from a human leg bone, seems to be of purely local invention. Similarly, the structure of the music seems basically Tibetan. It is founded on a principle of greatly prolonged dense, deep sounds, such as unison long and short trumpets with oboe, or the seemingly endless bass chant of groups of monks, whose long, drawn-out notes are punctuated by sharp, extended bursts of percussion. Each monk is said to be able to sing two or even three notes simultaneously.

Festival dramas

Much of this music emerges from monasteries only at festival time, when the great *'cham* (dance) dramas, which may last several days, are performed for the public's entertainment and edification. These plays, which generally show the triumph of Buddhism over Bon, the earlier shamanistic religion of Tibet, may involve hundreds of musicians in the guise of masked dancers with drums, backed by a large temple orchestra. Other types of public music also abound, such as secular, perhaps Chinese-related historical plays with an alternation of dialogue and songs with orchestral accompaniment. There is also a strong tradition of folk dance, which may include songs sung by mixed antiphonal choirs (*i.e.,* two alternating groups of singers). Minstrels ply their trade along the caravan routes and play instruments perhaps more related to general Central Asian traditions than to the Indian and Chinese background of religious music.

The music of Nepal, Bhutan, and Sikkim. Little is presently known about the music of Nepal, Bhutan, and Sikkim. Minstrels play a major role in the musical life of Nepal, where, under the influence of Indian practice, musicians are classified according to caste, and each group is distinguished by specific instruments and repertoire. There appears to be a great deal of both Indian-related and indigenous folk music in the three Himalayan kingdoms. Varieties of lute, such as the long-necked *damyan* of Nepal and its Sikkimese relative, may be linked to a similar instrument of the Pamir Mountains; while a Sikkimese flute having an outside air duct (in contrast to the inside duct of a Western recorder) seems to be a unique instrument. The Sherpas of Nepal and other Tibetan-related populations of the Himalayas, along with the thousands of Tibetan refugees now living in the area, maintain the traditions of Tibetan Buddhist religious music. The *mani-rimdu* dance-drama of the Sherpas, a variant of *'cham,* is a good case in point.

THE STUDY OF CENTRAL ASIAN MUSIC

In the West, the study of Central Asian music has until recently been restricted largely to travellers' accounts and analyses of small samples of music. By far the bulk of collection and study of Central Asian music of Turkistan and Siberia lies in the domain of Soviet scholars, who instituted systematic fieldwork as early as the 1920s; this literature remains largely inaccessible to the non-Russian reader. Mongol music was the subject of sporadic but intensive fieldwork by Scandinavian researchers in the 1920s and early 1930s, so that some of the traditional music culture was documented before Mongol society underwent the changes brought by war and the advent of socialism. Tibetan music has attracted increasing attention since the late 1950s, when large numbers of Tibetan refugees poured into the Himalayan kingdoms and northern sectors of India, thus making Tibetan music more accessible to outside observation. Afghanistan has been the object of intensive musical investigation only since the mid-1960s. Thus, outside Soviet contributions, Central Asia remains a lightly researched although quite fertile area of musical investigation. (M.S.S.)

Performing arts: dance and theatre

The performing arts have played an important role in the spiritual and social life of Central Asia, where they evolved as didactic art forms within a religious context. Performance, therefore, occurs in conjunction with some religious or special event. Two main types of performance predominate throughout Tibet, Nepal, Sikkim, Bhutan, Mongolia, and parts of the Asian U.S.S.R.: those related to shamanism and those derived from Buddhism. The performing arts of the Turkic peoples of Afghanistan and Turkistan are different from these because of the influence of the Islāmic religion and are discussed in the article ISLĀMIC ARTS. The Hindu influence found in Nepalese theatre and dance is treated in the article SOUTH ASIAN ARTS.

Although primarily intended to serve the overt purposes of religion, dance and theatre in Central Asia are performing arts with covert aesthetic values. Vocal and physical expressions of appreciation by an audience attending a performance depend on the graceful and rhythmic execution of hand gestures, body movements, and footwork. Aesthetic values are best expressed in the elaborate and artistic costumes, masks, and makeup, coupled with effective though crude stage effects and props.

Use of music in dance and theatre

Musical instruments play an important role in the performance of Central Asian dance and theatre. Usually a drum, but in some cases a string instrument, is used by the shaman to induce the ecstatic trance during which he symbolically journeys to the heavens or to the netherworld when playing the role of a psychopomp, or conductor of souls. Performances of the Buddhist monastic dance, known as *'cham,* and the Buddhist morality plays, called *a-che-lha-mo* ("older sister goddess"), were accompanied by a variety of instruments, especially drums and horns. There were large and small drums, short horns with fingering holes, and long horns, particularly the *dung-chen* (great conch shell) made of brass and extending many feet. The *dung-chen* with a deep haunting wail accentuates the macabre that is so much a part of *'cham.* The Tibetan guitar *sgra-synan* (pleasant sound) is a stringed instrument used almost exclusively by Himalayan peoples for folk song and dance.

Perhaps because of the subjectivism of their religions, it was not the custom among the peoples of Central Asia to carry out objective studies of elements in their cultures, and, therefore, no indigenous evaluation of their dance and theatre is available. Although a few manuals for the performance of shamanic rituals, music, and the *'cham* do exist, as do scripts for the *a-che-lha-mo,* much of the history and traditional staging of these forms of theatre and dance was handed down by oral tradition.

SHAMANIC RITUAL

Altaic horse-sacrifice ceremony

Teachings that spirits are responsible for unexplainable phenomena, such as disease and death, and that these spirits can be controlled by an individual with special powers, such as a shaman, evolved in many primitive societies throughout the world, including those of the nomadic peoples of Central Asia. The roles of the shaman include oracle, healer, sacrificer, and psychopomp, and each role calls for the performance of specific rituals. The earliest form of theatre and dance in Central Asia, these rituals developed into an often complex genre of the performing arts. The horse-sacrifice ceremony among the Altaic peoples of east Central Asia, for example, embraces a full range of dramatic elements despite the fact that like all shamanic ritual it is essentially a one-man performance. The ceremony, which lasts two to three days, is one in which the shaman undertakes a journey to the heavens. After having set the stage, the shaman symbolically releases the soul of a real horse and then, astride a goose-shaped device, he chases the soul of the horse, all the while imitating the noises of the goose and the horse. Capturing the soul of the horse, the shaman, with help from the audience, then kills the real horse, and the flesh is prepared. The next evening, the shaman offers pieces of the horse meat to the spirits, and, amid loud drumming and chanting, symbolically goes to the heavens on the soul of the horse while ascending a notched pole. As he ascends through the higher and higher heavenly planes, the shaman communicates to the audience important information, such as predictions about the success of the coming harvest and about epidemics and misfortunes that threaten and how to avoid them through sacrifices. The ceremony is followed by merrymaking and drinking.

Shamanism maintains that the soul of one who dies a heroic or violent death ascends to the heavens, but that the soul of one who dies from disease, which is caused by an evil spirit, must go to the underworld. The part of a psychopomp, or conductor of souls to the netherworld, was, therefore, another role commonly played by the shaman. The shaman guides the soul to its destination while narrating details of its journey to his audience. In some cultures, such as that of the Lolo, or Yi, in the mountains of southwestern China, the souls of all the dead are led in this manner to the underworld; while in others, such as that of the Tungus, a subarctic forest people of eastern Siberia, the shaman is only called upon to act as psychopomp if the soul of the deceased continues to haunt his residence.

The shaman also serves as the repository of tribal folklore and beliefs. Through dance and dialogue, he instructs the audience in the traditional teachings of their ancestors, and by passing his knowledge and techniques down to his successor, those teachings remain intact for future generations.

Rituals for curing the sick, guiding the soul of the dead to the netherworld, invoking a deity, or visiting the heavens are performed by the shaman in a state of trance induced by frenetic dancing to the music of a drum or a string instrument. Elaborate, symbolic costumes and ritual objects that are used in the ceremony provide a dramatic and mystic spectacle. The expectations of the audience are directly connected with the purpose of the shamanic performance; but whether it is the hope that the patient would be cured or that the oracular communication be auspicious, those attending the shamanic performance do so with the expectation that the ritual will be an entertaining religious experience.

Tungus shaman, detail of an engraving from Witsen's *Noord en Oost Tartarye,* 1785.

Regional variations in costumes

Before the introduction of Buddhism in shamanic Central Asia, there were no centres for the performing arts in the usual sense of the word. Each shaman performed his dramatic arts at his own residence or environs as the occasion demanded. He had his own ritual costumes and paraphernalia, which displayed regional variations, particularly in ornamentation. The representation of animals and birds is common, and metallic objects, which are thought to possess a soul and do not rust, are also important. For example, the costume of a Siberian Yakut shaman must have from 30 to 50 pounds (15 to 25 kilograms) of iron to be efficacious, while a Siberian Buryat shaman, except for

Paul Popper (Popperfoto) Ltd.

Oracle priest of Tibet in a trance.

an iron casque, or helmet, wears mostly furs. The metal ornaments represent such diverse things as the internal organs, bones, a woman's breasts, the Sun or the Moon; but the object common to all shamans is a metal mirror, in which the shaman can see the souls of the dead. Regardless of the variations in dress, the purpose and performance of the rituals remain essentially the same, whether carried out by a Buddhist monk among the Sherpas of Nepal, or by a true shaman among the Siberian Yakut.

The shamanic rituals of the steppe and desert peoples have analogies among the dramatic arts of the Himalayan kingdoms, where, because of the tolerance of local beliefs and rituals, many shamanic practices were adopted into Tibetan Buddhism. For example, the State Oracle of Tibet, a monk whose oracular powers were exercised on behalf of the government and the monastic system, was regarded as a high ranking ecclesiastic, yet his ritualistic performances were no different than those of shamanic mediums throughout Central Asia. The adaptation of the psychopompic role of the shaman into Tibetan Buddhism resulted in the recitation of the *Tibetan Book of the Dead* to an effigy of the corpse. This book describes in detail the frightening apparitions the deceased encounters day after day while in the forty-nine-day interval between death and rebirth, and its reading is analogous to the shaman's narration of his journey to the underworld.

BUDDHIST RITUAL

Buddhist monastic dance. The second major genre of the performing arts to develop in Central Asia was *'cham,* the ritualistic dance performed in Buddhist monasteries. The origins of *'cham* may well be an older form of shamanic ceremonial dance in Tibet, but centuries of evolution within a Buddhist dominated society led to the recasting of the roles and theme of the dance in keeping with Buddhist dogma. *'Cham,* which was introduced along with Tibetan Buddhism into Mongolia and parts of the southern Asian U.S.S.R. in the 16th century, became the main form of religious entertainment in eastern Central Asia.

Origins of *'cham*

The origins of *'cham* lie in Tibet's dim past, long before the introduction of Buddhism. Initially, it was performed as a ritual to drive out evil spirits and to appease the guardian spirits by means of human and animal sacrifices, thus assuring an auspicious and prosperous new year. According to Tibetan tradition, the ancient shamanic dance was adapted as a Buddhist one by Padmasambhava, the Indian tantric teacher who introduced Buddhism into Tibet in the 8th century AD. He is said to have interpreted the dance as symbolizing the victory of Buddhism over the shamanism of Tibet, and, since blood sacrifices are abhorrent to a Buddhist, these traditional elements were simulated by clever techniques using effigies and red-coloured substances.

Sectarianism developed in Tibetan Buddhism in the 11th century, primarily as a reaction to the unreformed teachings of Padmasambhava and his followers; nevertheless, each of the sects retained the monastic dance as part of their religious repertoire. The reformed Yellow Hat sect changed the time for its performance from the birthday of Padmasambhava to the end of the official year, which would coincide with the lunar month from the middle of January to the middle of February.

The acceptance and spread of Buddhism led to the eventual establishment of monastic communities throughout eastern Central Asia. These monasteries became fixed centres for the performance of *'cham.* Every monastery of adequate size and monastic population maintained its own masks, costumes, props, and musical instruments. In spite of regional and sectarian variations, the performance of *'cham* remains basically the same. The stage is set outdoors in the courtyard of the monastery called the *'cham-ra* (dance enclosure). With the exception of high lamas and members of the nobility who sit on special seats, the audience stands or sits around on the edge of the dance floor or ground. The musicians with horns and drums take their places, usually under a cloth canopy. Then, accompanied by music, the various dancers emerge from a building or from behind a stage curtain and perform. The first to appear are dancers wearing wide-brimmed black hats, topped with a simulated human skull. The costume of these dancers has led to the performance being referred to in some Western works as the Black-hat devil dance. Although of shamanic origin, the costume of the black-hat dancers is said by the Buddhists to represent the black disguise worn by Dpal-gyirdo-rje, a 9th-century Tibetan monk, who assassinated the fanatic anti-Buddhist king, Glang-dar-ma.

Black-hat dancers

The black-hat dancers are followed by a variety of performers, including those wearing monstrous masks representing a host of evil spirits that harass mankind, those costumed as skeletons and wearing skull masks, and those representing Indian teachers of Buddhism. There are also masked dancers representing the tutelary deities of Buddhism, and the most impressive of all is the Choskyi-rgyalpo (King of the Religion), who wears a mask fashioned after the head of a bull, which is emblematic of the aspect of the deity that vanquishes the Lord of the Dead. It is this dancer who dismembers an effigy of a corpse and scatters the parts in a simulation of the sacrificial and expulsional elements of the ancient shamanic dance rituals.

The dance is not all macabre. Comic relief is provided by a dancer wearing a mask with an expression of stupidity. This buffoon represents Ho-shang, the Chinese monk, who was defeated in an 8th-century debate on the merits of Indian versus Chinese Buddhism. Ho-shang is represented in the *'cham* of the Sherpas of Nepal by a dancer wearing a mask portraying a balding, bearded old man, called Mi-

tshe-ring (Long-Life Man), who delights the audience by his farcical antics and pratfalls.

The whole of the *'cham* performance, which takes two or three days, is a visual presentation of the fear of demons and monstrous creatures and the way in which Buddhism serves to alleviate that fear. The audience is reassured that the good forces of religion have neutralized the evil powers of demonic spirits, and so the new year will be a prosperous one. This religious dance is performed on varying scales of grandeur in monasteries throughout the Buddhist cultures of Central Asia, but the most magnificent of all is its performance in Lhasa for the Dalai Lama, the ruler of Tibet.

Buddhist morality plays. The last performing-arts genre to develop in Central Asia was the Buddhist morality play, called *a-che-lha-mo.* The plays are based on the lives of legendary and historical figures, and through costume and masks the ethnic origin and ethical character of the players are revealed. Folktales, as well as historical and Buddhist canonical literature, are sources for the stories presented in *a-che-lha-mo.* Most plays are about mythical heroes who prove that Buddhism and its virtues conquer all evil in the end; but there are those that tell the story of historical personages.

Origins of *a-che-lha-mo*

Although traditions among the Central Asian peoples are vague about the development of shamanic rituals and *'cham,* they are clear about the origin of *a-che-lha-mo* and even point out the historical creators of the art. Some scholars regard the plays as derivatives of Indian theatre, but Tibetan tradition claims that the first performance of a morality play was produced by Thang-stong rgyal-po, a famous bridge builder of the 15th century.

One story tells of some Tibetans who were building a bridge and found that whatever they assembled during the day, demons dismantled at night. Thang-stong rgyal-po, a holy man well versed in the capricious ways of demons, advised the Tibetans to stage a play to divert the attention of the evil spirits. By this stratagem, they were able to complete the bridge. This story would seem to indicate that the primary purpose of the play was to entertain, but another story illustrates that Thang-stong rgyal-po realized that religious teachings would have a greater influence on the people if they were dramatized, so he developed the morality play to serve this purpose. Regardless of his intent, *a-che-lha-mo* evolved as didactic entertainment, and Thang-stong rgyal-po is regarded by the Tibetans as its patron saint.

From primitive beginnings, the morality plays developed into a popular performing art, complete with stylized costumes and masks, complex scenarios and effective staging. The scripts are written in a dialogue song style called *rnam-thar.* There are at least nine traditional plays in the Tibetan repertoire.

Mythical and historical plays

The most common type of *a-che-lha-mo* is the drama based on legend and mythology which often reflects a strong influence of Indian theatrical tradition. An example is the play *'Das-log Snang-sa.* The phrase *'das-log* means to return (*log*) from the beyond (*'das*) and is used in Tibetan to refer to anyone who was believed to be dead and then returns to life and relates all that was witnessed in the netherworld. *'Das-log Snang-sa* is about a virtuous woman named Snang-sa who was unjustly accused of adultery and beaten to death by her jealous sister-in-law. When Snang-sa was led before the fierce Lord of the Dead (*gshin-rje*), he found that she was pure of heart and mind, and he allowed her therefore to return to life. Once home again, however, her husband and relatives began to mistreat her, so she became a nun. The play ends with Snang-sa flying away from the convent roof and disappearing like a rainbow in the sky.

Another type of *a-che-lha-mo* is the plays based on the lives of Tibetan holy men or pious kings. *Rgya-bza' Bal-bza'* ("Chinese-wife, Nepalese-wife"), for example, tells the story of king Srong-btsan sgam-po (died AD 649) and his two Buddhist wives: Wen-ch'eng, a Chinese princess, and Bhrikuti, a princess from Nepal. These three historical figures are believed by faithful Tibetans to have been incarnations of Buddhist deities, and their story is very popular with the audience.

The performance of a play may take more than a day. Narrative recitation is used to set scenes, delineate character, and give continuity to the songs that tell the main story. Comic sketches or dances are performed between the acts. Each character in a play has a distinctive costume or mask. Usually Tibetan male characters and the heroes wear no mask, while virtuous female characters wear flat, teardrop-shaped masks, particularly the serpentine deities. Three-dimensional masks are worn by evil foreigners, demons, and witches, and masks that cover the entire head are used to portray animals. Like the *'cham,* the morality play is performed outdoors, with the audience, except for the specially seated lamas and nobles, standing or sitting on the ground around the performing area.

The morality plays are performed for profit by groups consisting of lay men and women, and some have Buddhist monks or nuns as members. These troupes are generally associated with a given locale, such as a village or a monastery; however, they often travel to give performances on special occasions, transporting their wardrobe and stage props with them. In time, four of the most popular troupes were required by the Tibetan government to perform plays at the summer palace of the Dalai Lama. These performances were obligatory as a kind of taxation. There are still several of the *a-che-lha-mo* troupes to be found among the Tibetan refugees in Nepal and India, where their performances are in popular demand.

Mongolian plays of Noyan Hutuqtu

The *a-che-lha-mo* did not spread from Tibet into other parts of Central Asia until the 19th century. According to tradition, the Monoglian lama Noyan Hutuqtu (1803–56) studied *a-che-lha-mo* as performed in the Kokonor (Tsinghai) region of northeastern Tibet and then introduced his own adaptations of it at Tulgatu-yin keyid, his own monastery near the village of Saynshand, in Mongolia. For the first time, in 1832, he produced a repertoire of four plays, and their performance required 17 full days. The four plays were based on the textual biographies of the historical Buddha, the Indian Buddhist Teacher Atīśa, the revered Tibetan hermit-poet Mi-la Ras-pa, and the fabulous "Moon-cuckoo" (*Saran-u Kökügen-ü Namtar*), a mystical story of a pious prince who became a cuckoo bird living in the forest.

Noyan Hutuqtu's productions differed from the usual performance of *a-che-lha-mo* in certain respects. His repertoire did not include any of the plays traditional in Tibet. His actors, unlike those of *a-che-lha-mo,* wore no masks; instead they painted their faces, a makeup technique associated with Chinese opera. Whereas *a-che-lha-mo* is usually performed outdoors in the Himalayan regions, Noyan Hutuqtu had a special theatre constructed near his monastery. It was a three-sided, two-storied, mud-brick building with two stage floors; thus, two scenes could be performed at the same time. The upper stage represented the sky, the lower one the earth. There were stage exits on both sides and trap doors in the floor.

The first Mongolian actors were called *schabi,* or disciples, of the lama Noyan Hutuqtu. These men and women formed a regular troupe and were invited all over Mongolia to perform.

FOLK DANCE

Among the peoples of Central Asia, folk dancing occurs as a form of entertainment at social occasions, such as festivals, weddings, and other celebrations, and private parties. Often impromptu, folk dances are sometimes performed without the accompaniment of musical instruments, and the performers rely on singing and footwork to maintain the rhythm.

Formalized folk dance does not appear to have evolved among nomadic peoples of the steppe and desert regions, but such dances did develop among the sedentary agriculturists, particularly in the Himalayan regions, where troupes of amateur performers were formed for local entertainment. Some dances were performed by a group of men and women forming a circle; in others, the dancers faced each other in lines. The dance steps and body movement were performed according to a stylized routine, and the rhythmic beat was accented by a measured stamp of the foot. (T.V.W.)

Visual arts

PREHISTORIC CULTURES

Paleolithic cultures. The earliest artifacts discovered in the Central Asian region were found in Siberia and western Turkistan and are from around the 13th millennium BC. During the millennia that followed, migrants entered the region from various directions, regardless of the geographical obstacles they encountered. As a result, some of their artifacts correspond with those produced at a similar stage of development in more western areas; some finds from the northeastern part of Soviet Turkistan, for example, are related to certain objects made in Iran and Mesopotamia, and those from northwestern Central Asia are linked to eastern and central Europe by means of the Volga River and of Kazakhstan.

The Paleolithic (Old Stone Age) sites of western Turkistan are mainly concentrated in the Lake Baikal area. A cave in the Baysuntau Range containing the body of a Neanderthal boy aged about nine had been so carefully prepared that it is evident that the people who made his grave believed in an afterlife. The site of Malta, 50 miles (80 kilometres) to the southeast of Irkutsk, and that of Buret, 80 miles (130 kilometres) to the north, are noted for their mammoth-tusk figurines of nude women. They resemble Paleolithic statuettes of Europe and the Near East and probably served as fertility symbols or as representations of the great goddess, whose cult was widespread. Some of these figurines depict elegant, slender women, others heavy, corpulent ones. Of five found at Buret, one is unusual in that it is of a clothed woman wearing a one-piece trouser suit with a hood attached to it comparable to those still worn by present-day Eskimos. In recent years Paleolithic sites have been discovered south of Samarkand, and rock paintings have been found at Zaraut Say (Zaraut Stream) in the Babatag Range, 50 miles east of Termez, and in the Shakty Caves in the Pamirs. Executed in red ochre, they depict hunting scenes. Those in the Shakty Cave are the older and include a man disguised as a bird and other men wearing skins and shooting at wild oxen with bows and arrows.

Fertility images and rock painting

The invention of the bow is ascribed to the 10th millennium BC, the Mesolithic Period. Man's artistic development during this period is attested by a pottery fragment of a most expressive woman's face dating from the 3rd millennium BC and recovered from the site of Vosnessenovka in western Siberia.

Neolithic and Metal Age cultures. Many Neolithic sites have been discovered in the Asian U.S.S.R., and the number of Bronze Age sites is even higher. The majority were found on the middle reaches of the Yenisey River, especially in the Minusinsk Basin, where metallurgy developed early. They testify to the existence of three main, basically successive, yet often overlapping cultures: the Afanasyevskaya, Andronovo, and Karasuk, so-called after the villages near which each culture was identified.

Afanasyevskaya burials

A cemetery to the southwest of Krasnoyarsk, on the slopes of the Afanasyevskaya Mountains, contained 80 burials dating from the 2nd millennium BC. The earlier ones were flat and marked by stone circles symbolizing the Sun god; the later ones took the form of barrows, or large mounds of earth, but were also encircled by similar stone slabs. The earlier graves contained elongated, spherical pottery vessels with pointed bases decorated with herringbone patterns. In the later graves this type of ware was superseded by flat-bottomed pots usually associated with sedentary pastoralist cultures. The graves also contained numerous stone and bone objects. Although copper objects were rare, they heralded the dawn of a new cultural period, the Metal Age.

Houses of Andronovo culture

The Andronovo culture succeeded the Afanasyevskaya in the 2nd and 1st millennia BC. Although found to the southwest of Krasnoyarsk, it is more frequently encountered in western Siberia and Kazakhstan. The settlement and cemetery of Alekseevskoe (present Tenlyk), some 400 miles (600 kilometres) south of Sverdlovsk, is especially important, because its earth houses were designed for permanent habitation. Their roofs rested on logs, and each dwelling had a central hearth used for heating purposes with side hearths intended for cooking. Bronze objects were numerous, and workshops existed for working copper. The metal probably came from mines in the Minusinsk Basin, Kazakhstan, and the western Altai Mountains, the latter having been worked as early as the 14th century BC.

Dating from about 1200 to about 70 BC—the dawn of the Iron and historical age—the Karasuk culture was located in the Minusinsk Basin, on the Yenisey River and on the upper reaches of the Ob River. Its creators must have been in touch with East Asia, for certain bronze objects, notably elbow-shaped knives, are related to those used between the 14th and 11th centuries BC in China during the Shang period. Stone pillars topped either with ram's heads, stylized animal forms, or human figures have also been discovered. Dzheytun, northwest of Ashkhabad, in what is called the Kyzylkum desert, is the oldest known agricultural settlement in Central Asia. It possessed a thriving Neolithic flint industry.

Pottery in the Ashkhabad region

Annau, six miles (10 kilometres) southeast of Ashkhabad, and Namazga-Tepe, situated in the same region and occupying an area of some 145 acres (60 hectares), are important Bronze Age sites. The pottery vessels recovered from Namazga-Tepe are decorated with painted plant and animal motifs showing affinities with contemporary pottery wares from the Near East. Figurines of dogs and sheep were numerous, and a model of a house has also been found. At Karatepe, also near Ashkhabad, an agricultural society produced fine pottery from the 3rd millennium BC, but it reached its fullest development in the 2nd millennium BC in a series of vessels decorated with particularly spirited animal designs.

The main Neolithic and Bronze Age cultures produced several distinctive offshoots, which began to emerge by the early Iron Age. In Chorasmia, the Neolithic culture discovered at Dzhan-Bas-Kala is known as the Kelteminar and that of the Bronze Age, as represented by the Chorasmian level of Kokcha III, as the Tazabagyab. The Neolithic Hissar culture of southern Tadzhikistan spread across northeastern Central Asia into the Semirechiye, or foothills of the Tien Shan, while in Siberia the Bronze Age Karasuk culture was replaced in the 8th century BC by the Tagar culture. The latter endured until the 2nd century BC, producing an art of animal motifs related to that of the Scythians of southern European Russia.

The Bronze Age culture on Fergana's western border is associated with settlers living in large houses grouped to form settlements of considerable size. Some of the inhabitants worked in copper mines at the time when potters of the Chust Bronze Age culture of the Fergana Valley were producing fine-quality tableware, as well as cruder pottery articles. The best Chust pottery was very thin, covered with a red slip (liquid clay) and decorated after glazing with black triangular and scroll designs.

NOMADIC CULTURES

During the 1st millennium BC and the 1st centuries of the Christian Era, certain nomadic tribes affected the course of Central Asia's artistic history. Cyrus II the Great, the ancient Persian king who founded the Achaemenid Empire, was killed by the nomadic Massagetai when campaigning in eastern Iran in 530 BC. At the time, the Śaka tribe was pasturing its herds in the Pamirs, central Tien Shan, and in the Amu Darya Delta. Their gold belt buckles, jewelry, and harness decorations display sheep, griffins, and other animal designs that are similar in style to those used by the Scythians, a nomadic people living in the Kuban Basin of the Caucasus region and the western section of the Eurasian plain during the greater part of the 1st millennium BC. When considered together with objects of a like nature recovered from the frozen burial sites of the western Altai Mountains, it becomes evident that many of the Central Asian tribesmen commonly shared the traditions and culture that were once associated only with the Scythians.

The Pazyryk burial site

Altaic tribes. Because of a freak climatic freeze, some of the Altaic burials, notably those of the 5th century BC at Pazyryk and neighbouring sites, such as Katanda, Shibe, and Tuekt, were isolated from external climatic variations by a protective layer of ice that conserved the organic substances buried in them. At Pazyryk these included the bodies of horses and an embalmed man whose body was covered with tattoos of Scythian animal motifs. The remarkable textiles recovered from the Pazyryk burials include the oldest woollen knotted-pile carpet known, the oldest embroidered Chinese silk, and two pieces of woven Persian fabric (Hermitage Museum, Leningrad). Red and ochre predominate in the carpet, the main design of which is of riders, stags, and griffins. Many of the Pazyryk felt hangings, saddlecloths, and cushions were covered with elaborate designs executed in appliqué feltwork, dyed furs, and embroidery. Of exceptional interest are those with animal and human figural compositions, the most notable of which are the repeat design of an investiture scene on a felt hanging and that of a semihuman, semibird creature on another (both in the Hermitage Museum, Leningrad). Clothing, whether of felt, leather, or fur, was also lavishly ornamented.

Horse reins either had animal designs cut out on them or were studded with wooden ones covered in gold foil. Their tail sheaths were ornamented, as were their headpieces and breastpieces. Some horses were provided with leather or felt masks made to resemble animals, with stag antlers or rams' horns often incorporated in them. Many of the trappings took the form of iron, bronze, and gilt wood animal motifs either applied or suspended from them; and bits had animal-shaped terminal ornaments. Altaic animals frequently display muscles delineated with dot and comma markings, a formal convention that may have derived from appliqué needlework. Although such markings are sometimes included in Assyrian, Achaemenid, and even Urartian animal representations of the ancient Near East, they seldom appear on those of purely Scythian origin. Roundels containing a dot serve the same purpose on the stag and other animal renderings executed by contemporary Śaka metalworkers. Animal processions of the Assyro-Achaemenid type also appealed to many Central Asian tribesmen and are featured in their arts.

Altaic decorative motifs

Certain geometric designs and sun symbols, such as the circle and rosette, recur at Pazyryk but are completely outnumbered by animal motifs. Such specifically Scythian features as zoomorphic junctures—*i.e.,* the addition of a part of one animal to the body of another—are rarer in the Altaic region than in southern Russia. The stag and its relatives, however, figure as prominently in Altaic as in Scythian art. Combat scenes between carnivores and herbivores that occur quite often in Scythian art are exceedingly numerous in Pazyryk work; but, whereas the Scythians show the victim passively accepting its fate, as on 5th-century BC gold triangular plaques from the so-called Seven Brothers burial in the Kuban, the Pazyryk beasts are locked in such bitter fights that the victim's hindquarters become inverted.

Siberian tribes. In the virtually contemporary metal-

work of Siberian nomads, single animals of the cat family, such as panthers, carry the Altaic tendency of exaggeration further by twisting their bodies into a circle. In slightly later Siberian plaques, subtle openwork is used, a feature rarely present in Altaic or Scythian objects but frequently encountered in the more rounded versions of the animal style produced in the Ordos region of China, perhaps by Hunnish craftsmen, between the 4th century BC and the 2nd century AD. In the latter part of the 1st millennium BC, Siberian metalworkers adorned many of their gold and bronze plaques with artificial gems made of glass, as well as with jewelled inlays. They produced belt buckles shaped like the letter *B*. Two such gold prices (Hermitage Museum, Leningrad) are of particular interest because of their figural content. It has been suggested that they illustrate some ancient Central Asian epics, for one depicts a hunting scene and the other a warrior lying under a tree with his head resting on a woman's lap, while a servant holds their two horses. These subjects, possible forerunners of certain episodes in the *Shāh-nāmeh* ("Book of Kings," a work by the 10th century Persian poet Ferdowsī giving an account of ancient Iranian history), are thought to complement those on a series of openwork plaques, some of them of Ordos origin, on which either two dismounted riders are shown fighting while their horses stand passively on either side or two horses are seen locked in battle, pursuing their masters' quarrel (Hermitage Museum, Leningrad).

Mongolian Huns. In the 4th century BC the Huns started to migrate westward from the Ordos region. By the 3rd century BC, they had reached the Transbaikalia and had begun to enter Mongolia, which soon became the centre of their empire. Numerous mounds mark their progress. Those in the Zidzha Valley lie in the same latitude as the Pazyryk mounds and were subjected to similar conditions of freezing temperatures, which helped to preserve their contents. The richest of the excavated burial sites, however, are those of Noin Ula, to the north of Ulaanbaatar, on the Selenge River. Like those at Pazyryk, they included horse burials. The furnishings of one tomb were especially lavish. The prince for whom it was made must have been in contact with China, for his coffin was apparently made for him there, as were certain of his possessions buried with him (among them, a lacquer cup inscribed with the name of its Chinese maker and dated September 5, AD 13, now in the Hermitage Museum, Leningrad). His horse trappings (Hermitage Museum, Leningrad) are as elaborately decorated as many of those discovered at Pazyryk. His saddle was covered with leather threaded with black and red wool clipped to resemble velvet. The magnificent textiles in his tomb included a woven wool rug lined with thin leather (Hermitage Museum, Leningrad); the centre of the rug depicts a combat, of Scytho-Altaic character, between a griffin and an elk, executed in purple, brown, and white felt appliqué work. The animals' bodies are outlined in cord and embroidered. The design on another textile is embroidered in the form of a tiger skin with a head at each end. The animal's splayed-out body is formed of black and white embroidered stripes. Other textiles are of Greco-Bactrian and Parthian origin. In some of the Parthian fragments, Central Asian and Sāsānian Persian influences prevail over Hellenistic ones.

Chinese influences in the Noin Ula burials

Tashtyk tribe. On the Yenisey River, the Bronze Age Tagar culture was replaced by the Tashtyk culture, dating from the 1st to the 4th century AD. The physical appearance of the Tashtyk people has been preserved by a series of masks, some of them modelled; others, casts taken from the dead. They were painted with the features rendered in blue, red, and green against a yellow ground. Spirals disposed on the foreheads, temples, and cheeks of many of these masks probably represent tattoos. In many cases pearl necklaces worn by the women are also included. Although the animal motifs of the Tashtyks remained strongly Scytho-Altaic in style, the community was so much influenced by China that even its architecture was affected. Just south of Abakan, a large house made of beaten clay in the Chinese style has been discovered. Its roof had been covered with Chinese tiles, some of which carry inscriptions of the Han dynasty.

Painted masks

Fragment of a large rug from Noin Ula showing a griffin attacking an elk, 1st century AD onward. The woven woollen rug was mounted on fine leather, and then purple, brown, and white felt was appliquéd onto the rug over a cord binding, after which it was embroidered. In the Hermitage, Leningrad.

PARTHIA

The Parthian Empire came into being in Khorāsān during the reign of Seleucus I, 358–281 BC, following the absorption by the Parthians of Parni (Dahae) tribesmen. The caravans traversing their territory brought them wealth and ideas from abroad. The figural art of the Hellenistic world made an especially strong impression on them. The finest Parthian objects come from Old Nisa, a town situated on the edge of the Karakoram Range, some 11 miles (18 kilometres) south of Ashkhabad in Tadzhikistan, close to the later town of New Nisa. Old Nisa was founded around 171 BC by Mithradates I to serve as a royal Parthian residence and necropolis, as well as the kingdom's capital. It contained several fine temples and an impressive palace built around a vast central hall, the roof of which was upheld by wooden supports set in stone bases—a practice followed in the town's larger houses. Lifesize clay statues of men and women stood between these supports. The royal treasuries contained many valuables, including silver and silver gilt statuettes of local Parthian deities and of Greek gods, bronze and iron weapons, burnished and painted pottery, glass, and cast bronze animals, such as griffins. The most significant of these treasures, however, is a series of ivory horn-shaped drinking vessels, or rhytons. Some are embellished

with paste inlays and precious stones, others have a carved frieze or band encircling their open ends. One rhyton (Hermitage Museum, Leningrad) has a frieze of a procession that includes a Greek god. Conceived in the purest Hellenistic style, the frieze contrasts sharply with the rhyton's horned, lion–griffin-shaped terminal ornamentation, which is admirably modelled in the round, in accordance with the Scytho-Altaic tradition.

THE KINGDOMS OF WESTERN TURKISTAN AND AFGHANISTAN

Skill in irrigation, with the resulting expansion in agriculture, encouraged urbanism and the growth of states, changes that coincided with the rise of nomadism. While the nomadic cattle and horse breeders took over the steppelands, the culturally distinct states of Sogdiana (part of Uzbekistan and much of Tadzhikistan), Fergana (the greater part of Uzbekistan), Chorasmia (the Tashkent region), and Bactria (mainly Afghanistan) were established. At times independent, at other times reduced to vassaldom, the first three states were centred on rivers—Sogdiana around the Zeravshan and Kashkadarya, Fergana on the lower Syrdarya, and Chorasmia on the Amu Darya's basin. (The earliest references to these states are to be found in the Avesta, the principal scriptural work of the Zoroastrian religion, and in the inscription cut by order of the Persian king Darius I [reigned 522–486 BC] on the face of the rock of Bīsitūn in the Kermanshah province of Iran.) Bactria extended from the Syrdarya to the Hindu Kush (southern Tadzhikistan and Afghanistan) and is rich in unexplored mounds. Excavations at Balkh show that its first inhabitants settled there when others were doing so at Afrasiab (Samarkand) and Merv.

The political and economic changes that developed in the 4th century BC, following the Macedonian Greek king Alexander the Great's conquest of these states and their incorporation in the Seleucid Empire, and the conquests made, in turn, by the Parthians, Arabs, Turks, and Mongols are reflected in the regions' arts. The city of Alexandria-Kapisu Bagrām, founded by Alexander the Great, became the clearinghouse for India's western trade. India's religious beliefs, especially Buddhism, and the scriptural style that evolved in Gandhāra (an area situated between the Qondūz and Indus rivers in the Lower Kābul Valley of northwestern Pakistan) and Mathurā (in the Punjab region of northwestern India) followed along the trade routes and reached not only Bactria but, at times, also Kashmir, Tibet, China, and even the remote oasis towns of the Tarim Basin in Sinkiang. At the same time, Seleucid support resulted in the introduction of Greco-Roman art forms into Bactria, Kapisu, Taxila (Rāwalpindi), Gandhāra, Mathurā, and, after thirty years, even into Seistan.

Sogdiana. Sogdiana, with its capital of Afrasiab, was already noted for the sophistication and number of its towns when Alexander the Great conquered it in 328 BC and opened it up to Greek soldiers and administrators, and eventually to Roman traders. The Sogdians resented being governed by Alexander's successors, the Greek kings of the Seleucid dynasty. It is difficult to establish their relationship with their Seleucid suzerains and still more so with the later Kushans, but there is ample evidence to show that neither group of conquerors hindered the rise in both Sogdiana and Chorasmia of a local feudal nobility and class of rich farmers.

Pottery sculpture

A considerable amount of secular and religious pottery sculpture dating from the early Christian Era to the Arab invasion of the 8th century has been found at Afrasiab. The more interesting examples consist of statuettes of clothed women, some of them representing Zoroastrian deities such as Anahita. They have foreshortened bodies and large heads with a withdrawn expression on their faces and wear tiaras, hats, or hoods sewn to their cloaks. When the cloaks are sleeveless, they are worn over straight, long-sleeved robes instead of draped garments. All of the figures hold a piece of fruit, a symbol of fertility. Third-to-fourth-century statuettes from the fortified town of Tali Barsu, to the south of Samarkand, depict Syavush, the god of annual death and spring rebirth, as a musician. Statuettes of women flutists, riders, animals, and the Iranian semihuman-semianimal demi-god Shah Gopat have also been discovered there. In the 7th and 8th centuries, sculpture, whether in clay or alabaster, was highly developed at Pendzhikent, a site some 40 miles (60 kilometres) east of Samarkand, where Indian influence was often felt.

The earliest of Turkistan's mural paintings have been found in its eastern section. Those at Niy date from the 2nd century AD; those at Miran, from the 3rd. The inspiration in both stemmed from Rome, whereas Buddhism provided the impulses for the slightly later murals at Bāmiān and Kizil. In the eastern zone the paintings were designed as backgrounds to sculpture, and, as in western Turkistan, they were executed in tempera. Some very high quality murals recently discovered in western Turkistan are dated slightly later. The oldest ones, which are extremely fragmentary, are from the Varakhsha, a princely residence to the northeast of Bukhara, now lying in the desert; they date from the 3rd to the 4th century AD. Murals discovered at the beginning of the 20th century at Samarkand, which are almost contemporary with those at Varakhsha, have been lost. The importance of these murals is wholly eclipsed by the slightly later works discovered recently in Sogdiana, such as the 7th-century works at Varakhsha. Some of the rooms in the main apartments of the Varakhsha Palace (which consisted of several detached buildings) are decorated with high-relief alabaster stucco panels and carved woodwork, as well as with paintings. Benches are inserted into the walls of one room, the area above them divided into two registers, or horizontal rows, both painted red. In the upper register was a procession of animals, little of which survives, and, in the lower, splendidly attired hunters seated on elephants pursued spirited leopards and creatures of the griffin family.

Mural paintings at Varakhsha

Some 200 miles (300 kilometres) east of Samarkand, in a once fertile, now desert tract of land, the ruins of the great feudal castle of Mug survive. Among the objects excavated there was part of a wooden shield with the painted figure of a rider (Hermitage Museum, Leningrad), which foreshadows a type commonly found in Islāmic Persian book illumination. Mounted on a splendidly caparisoned horse, he wears a tunic of local cut and is equipped with a long sword, two daggers, two bows, and a quiver full of arrows. He is wasp waisted in the manner of figures depicted in murals of Varakhsha and Pendzhikent.

At Pendzhikent, a site close to Mug, and some 40 miles (60 kilometres) east of Samarkand, Sogdian architecture can be seen to advantage. The desert-engulfed city contained several large temples built of rectangular adobe

Temple architecture and decoration at Pendzhikent

bricks and blocks of beaten clay. The bricks were used for vaults and domes, while the flat sections of the roofs were made of rafters supported by wooden pillars or piers, some of which had been set in stone bases. Many of the more important houses were two storied. A square room measuring 26 by 26 feet (eight metres by eight metres) had served as a temple sanctuary. Although, in a series of rooms connected to it, some fragmentary religious paintings survived, the paintings in another temple are better preserved. They depict the death, the Sogdian burial rite, and the rebirth of a youthful Syavush. Over 50 figures of this vast composition survive, some representing Sogdian noblemen, some a group of Turks. A number of the Sogdians are seated crosslegged in the oriental manner and hold gold and silver vessels of Sāsānian shape in three fingers of one hand. The men's single, close fitting Sogdian tunics—elegant versions of the nomadic dress—resemble garments depicted in paintings of the Buddhist temples of Bāmiān and eastern Turkistan, notably at Kizil and Kuca. The style and, in some cases, the subject matter of these Sogdian scenes must have influenced the illuminators of such Islāmic Persian works as the *Shāh-nāmeh.* Another set of murals is unusual in that it is executed in high relief and then coloured. It shows human beings, sea monsters, and fish, with the waves of the sea rendered in lower relief than the figures. Yet another mural depicts a feast against a black background; a king and several priests sit crosslegged under a canopy; a woman harpist, some musicians and dice players, and a procession of elephants complete the scene. By placing light figures against dark or vivid backgrounds, Sogdian artists evolved a distinct form of perspective.

A study of the religious paintings shows that Central Asian Zoroastrianism retained elements from the earlier indigenous cult of the Sun and Moon. Some of the scenes in the secular works are linked in their subject matter (but not their style) to a small group of older Siberian gold and bronze *B*-shaped buckles and to the Siberian and Ordos plaques that are thought to illustrate local epics. Other secular scenes give full expression to Sogdian interest in the splendour of contemporary court life and prowess in hunting and warfare. The love of overall decoration and of animal motifs is as prevalent as in nomadic art. Details incorporated in Sogdian paintings proclaim the eclecticism of the society they depict and for which they were created. Sāsānian influence from Persia is seen in crowns trimmed with ribbons, veils, and bells; in the styling and trimming of hair and beards; and in many of their vessel shapes. The helmets worn by the warriors in the Pendzhikent libation scene resemble those depicted in the murals of eastern Turkistan. The clothes follow local fashions, and certain horse trappings display disks the shapes of which recall nomadic types.

Sāsānian motifs in Sogdian textiles

Sogdian textiles are known to have been in great demand among their neighbours. Sāsānian motifs must have reached Sogdian weavers by way of imports from Persia, indirectly routed through Parthia, and also from Zoroastrians seeking protection in Sogdiana from Persian persecution. These motifs often figure both on surviving textiles and on those recorded in the paintings. The murals at Varakhsha, for example, include motifs taken from textiles; and a 5th-century mural from Balalyk Tepe displays the head of a tusked, boarlike animal set in a roundel that is almost identical to that on a Sāsānian fabric found at Astana in eastern Turkistan.

Between the 5th and 7th centuries, the Sogdians made dried-brick caskets shaped like rectangular rooms to contain ossuaries, or urns for the bones of the dead. The sides and lids of the ossuaries were decorated. The ornamentation on an ossuary from Bia Naiman (Hermitage Museum, Leningrad) has so many points in common with the decorations on a series of silver vessels that were, until recently, assigned to Bactria that the latter have come to be accepted as Sogdian. Several ewers have niches containing nude women rendered in a markedly Indian style, thereby recalling many a carved ivory plaque from Bagrām. Very similar niches adorn the Bia Naiman ossuary, but these contain crowned figures. In both cases the niches owe their form to Western influence, but those on the ossuary are formed of columns surmounted by capitals upholding pearl-studded arches, while on the ewers the Central Asian rosette replaces the capitals and the pearls.

Sculpture, both in relief and in the round, was widely produced in Sogdiana. Much of the earlier work takes the form of panels or friezes made of alabaster, stucco, and, occasionally, wood. Rosettes, roundels, disks, and vegetation provide the chief motifs. Audience chambers and large reception rooms often contained statues in the round. Even the statues attached to the wall had the appearance of being worked in the round. The earliest wooden caryatids, or columns in human form, are found in western Turkistan at Pendzhikent. The caryatids in the form of women have their hair elaborately dressed, and, although nude at the waist, they wear boleros, as well as close fitting, heavily trimmed skirts and splendid necklaces of Indian appearance. Once again, these figures recall those on Bagrām's ivory plaques and Buddhist statuettes of the 1st to 5th century.

Fergana and Chorasmia. Fergana produced much pottery of quality, but, as yet, there have been no finds of comparable importance to those in Sogdiana. Its arts appear to have paralleled the developments in the more prosperous, more heavily populated, and more highly urbanized state of Chorasmia (later Khwārezm). Chorasmia's defensive architecture was particularly notable. Its great citadels and palaces were enclosed by two lines of walls strengthened by massive towers that were fitted with lookout posts and firing slits and topped by archers' galleries. Chorasmian entrance gates were labyrinthine in plan. Many of these splendid buildings have disappeared beneath the desert's encroaching sands. Toprak kala, recently excavated, near Tashauz, is thought to have served not only as a citadel but perhaps as Chorasmia's capital until about the 7th century. Defended by stout walls, the palace of sun-dried bricks was equipped

Citadels and palaces

with three lookout towers. The ground floor of this two storied building acted as a foundation for the living rooms and storerooms above. Many of the rooms were adorned with sculpture: its most impressive room, the Hall of Kings, had niches fitted with grills ranged along the tops of its walls to hold statues of Chorasmia's rulers and notables; the Alabaster Hall contained many sculptures executed both in the round and in relief; a Hall of Victories contained statues of kings seated in the presence of a goddess of victory; statues of warriors carrying shields adorned the Warriors' Hall. All of the Chorasmian figural works are so lifelike that it is evident that portraiture had reached a high state of development by the 3rd and 4th centuries AD. Surviving decorations in the fortified manorhouse of Teshik Kala display the palmette, rosette, lotus, and ace-of-spade motifs that the Seljuqs later carried westward to Anatolia and beyond in the 11th and 12th centuries.

Bactria. The most Hellenized of these states in western Turkistan and Afghanistan was Bactria. Its fine coinage, for example, was distinctly Hellenistic in style, and Bactrian silversmiths were often influenced as much by Roman as Greek Hellenistic metalwork. Alexander the Great annexed Kābul to Bactria and founded Alexandria-Kapisu, a city astride the Indian caravan route, to serve as the province's capital. The multiracialism of Kapisu's population is reflected in the origins of the objects found there. Imports included articles from India, China, and the Greco-Roman world, especially from Syria. Artistic conventions characteristic of all these countries blended with the local Central Asian ones, with the Indian conventions predominating, to create Bactria's own distinctive style in sculpture, whether in alabaster, stone, ivory, or wood. Its mural paintings are wholly Buddhist in content, but they often contain features that link them to Fundukistan in India and the Sāsānian Persian world.

Importance of the decorative arts in Bactria

The decorative arts were highly developed in Bactria. Many of their sun-dried-brick houses were large enough to include several reception rooms, which contained many luxurious decorative objects.

Potters remained attached to animal forms derived from nomadic art. The large production of votive statuettes, especially representations of Anahita and Syavush, may be partly attributed to the belief that Zoroaster was born in Balkh. This tradition was also evident at Merv until the Arab invasion of Central Asia. The Bactrians mastered the technique of working metals at an early date. A 4th-century-BC lion-griffin (British Museum) in cast bronze is descended from a Scytho-Altaic prototype and so, too, is a pair of slightly earlier gold armlets (British Museum), originally embellished with inlay, from the Oxus Treasure. A series of silver dishes (Hermitage, Leningrad) from the end of the 1st millennium BC are, on the other hand, decorated with scenes drawn from the tragedies of the Greek dramatist Euripides and Greco-Roman mythology rendered in a markedly Hellenized style. Other silver dishes employ Indian motifs such as elephants. By the 8th century, these diverse ornamental motifs had fused, as on a silver-gilt bowl (Hermitage, Leningrad), dated between the 5th and 8th centuries AD, into a Kushān style that may well have provided the basis for Persia's later Rey figural pottery style.

KUSHĀN

The Kushāns replaced the Greeks in Bactria around 130 BC. They are thought to have been of Yüeh-chih stock with a strong admixture of Hephthalites, Śaka, and Tocharian. One branch of this group migrated to the Tarim Basin and founded a short-lived empire, while the other, under the name of Kushān, gained control of Central Asia. Capturing a section of the great trade route leading from India and China to the west, the Kushāns derived much of their revenue from the transit dues they exacted from the caravans crossing their territory, which often were carrying supplies of Chinese gold, silver, and nickel from the Tarim oasis towns to the Seleucid Persians. Around 106 BC, the first caravan to carry silk from China direct to Persia passed through territory that had belonged to the Seleucids but was now divided between the Kushāns and Parthians.

Kushān art reached its fullest development in the 2nd century AD, when the great king Kaniṣka is believed to have reigned. A magnificent, almost lifesize, now headless sculpture of Kaniṣka (Archaeological Museum, Mathurā) shows him wearing an elegant version of nomadic dress. His kingdom extended from Central Asia to include Gandhāra and Mathurā, where the Seleucids had so firmly established Hellenistic art that Western influence continued to maintain its hold even in the reign of the first members of India's Gupta dynasty. When Mahāyāna Buddhism reached Gandhāra during the 4th and 5th centuries AD, its sculptors turned to the Hellenistic world as a matter of course for a visual conception of Buddha and quickly evolved several Hellenistic versions. In the popular Apollo version Buddha is long faced, long nosed, and has wavy hair. This type survived into the 5th century and penetrated as far as Kashmir and Turkistan.

The Gandhāra and Mathurā styles of Buddhist sculpture

A school of religious sculpture equal in importance to that of Gandhāra developed almost simultaneously at Mathurā. Its earliest Buddhist images are virtually contemporary with the earliest ones produced in Gandhāra but, in Mathurā, Indian influences predominate. The portrayal of Buddha in the Mathurān style is softer yet more direct. The features are more Eastern; eyebrows extend in a continuous, sinous line; hair is straight; the earlobes are elongated; and an enigmatic smile replaces the withdrawn expression of the Hellenized Buddhas of Gandhāra. While the sculptors of Mathurā used a red sandstone, the Gandhārans worked in limestone or a local gray schist. They generally chose the latter for the small, uniform-sized panels with which they faced their *stūpas* and *vishanas*, carving them with scenes of Buddha's life. On the panels, the story unfolds from left to right, each scene being framed either within trees, leaves, or Corinthian columns sometimes linked by arches. These religious narratives often include furniture and details drawn from contemporary life. The figures, which use gestures of Indian origin to convey emotion, display racial characteristics that range from Indo-European to Mongolian. Many figures are presented in the frontal position favoured by Parthian artists, while others appear three-quarter face, as in Hellenistic art. Some wear Hellenistic robes and headdresses such as those worn in Palmyra, an ancient city in Syria. The Gandhāran style of sculpture was no longer produced after this area was invaded by the White Huns, in the 6th century.

Central Afghanistan is rich in Kushān sites. Āteshkadehye Sorkh Kowtal, situated in the Qondūz Valley, close to the Kābul-Mazār-e Sharīf road, is dated by an inscription to the time of Kaniṣka's reign. The architecture of the region was very highly developed there. The town was protected by a double row of walls that ascended the hill on which it stood. The most impressive site within the wall was oc-

cupied by a dynastic fire temple, built to an Achaemenid plan in large blocks of well-dressed stone and approached by an imposing staircase. Within, columns topped by Corinthian capitals supported the roof. Numerous sculptures had originally adorned the interior, those worked with floral and animal motifs conforming to the Gandhāran tradition, while figural works followed Scytho-Parthian and, to some extent, Hellenistic traditions.

Colossal Buddha carved from the rock at Bāmiān, Afghanistan, 5th century. Height 51.8 m.

Buddhist art at Bāmiān

The Buddhist art of central Afghanistan is admirably represented at Bāmiān, where Mani, the Iranian founder of the Manichaean religion, probably lived and encouraged the growth of a religious pictorial art in the 3rd century AD. At both the eastern and western approaches to Bāmiān, a huge statue of Buddha as ruler of the world was cut into the face of the rock. The smaller statue measures 120 feet (about 40 metres) and dates from soon after the town's foundation in the 4th century AD; the other measures 170 feet (50 metres) and dates from the 5th century. In their commanding monumentality, both reflect the influence of the Mathurān image of King Kaniṣka and the portrait sculpture of Sāsānian kings and Parthian notables. Traces of painting show Sāsānian and Indian influences in the rock-hewn niche behind the earlier Buddha.

Regardless of Manichaean influence, Sāsānian elements prevailed at Bāmiān between the 4th and 6th centuries. At Dūktar-e Nowshirvān, near Bāmiān, a 4th-century painting of a Sāsānian king flanked by attendants survives. The murals in Bāmiān's 5th-century temple of Kakrak include one of a deified king of Sāsānian appearance, while others display the figure of Buddha set within a circle and wearing a costume of the Sāsānian type. Sāsānian motifs of paired birds and griffins placed in medallions or pearl circlets are common. In the murals at Imgur-Enlil, Buddha wears a close-fitting tunic resembling that worn by the Sāsānian king depicted on the rock carvings of Tāq-e Bostān. The traces of Hellenism, which are also evident in these wall paintings, began to disappear by the 5th century, when Sāsānian influence gradually gave way to the Gupta style of India.

Stemming from Gupta art is the practice adopted at Bāmiān between the 5th and 6th centuries of painting in the dome of a sanctuary a Buddha within a circle or hexagon. Gradually, these circles and hexagons became symbols of the heavenly Buddha. Many developed into rosettes and eight pointed stars—motifs that were retained in the 10th and 11th centuries by the Islāmic Seljuqs, who carried them to Persia and Asia Minor. As Gupta influence increased, sculpture gained in importance. A new style had evolved by the 8th to 9th centuries, but it did not penetrate into western Turkistan, where the Arab conquerors religiously opposed figural art. In the 9th century many Buddhists left Kashgaria, and Islām gained ground. Figural sculpture was forced underground and was primarily produced by secret shamanistic cults of an indigenous Central Asian origin. Although figural art was never to flourish in western Turkistan as gloriously as it had prior to the Arab invasion, there was a revival under the Mongols in the form of book illuminations.

EASTERN TURKISTAN

Uighurs. The figural arts found new patrons in eastern Turkistan among the Turkic Uighurs, who while living in

Buddha in a mandala preaching, a painting from the dome of a cave shrine at Bāmiān, Afghanistan, 5th–6th century.

Josephine Powell, Rome

Portraiture of the Turkic Uighurs

T'ang dynasty China had been influenced by Manichaean figurative art. The overthrow in China in 846 AD of Buddhism by official Confucianism forced the Buddhist Uighurs to migrate to eastern Turkistan. Gradually, they gained control over the Tien Shan region, Turfan, and the northeastern section of the Tarim Basin. The Turkic Uighurs especially favoured portraiture. In the 7th and 8th centuries Uighur artists already had acquired great proficiency in rendering likenesses in a style heavily influenced by Chinese portraiture of the T'ang period. These portraits were painted on silk and were frequently inscribed with the sitter's name.

Khitans. The figural style is believed to have been transmitted to the Mongols by the Khitans when the latter were living on the middle reaches of the Yenisey. The wealth of the Khitan princes is reflected in the furnishings of burial mounds discovered at Kopeni, some 200 miles (300 kilometres) to the south of Krasnoyarsk. Dating from the 7th to 8th centuries, these mounds were similar in type to those constructed by the nomads of the 1st millennium BC. One of the richest graves contained four gold jugs set on a silver dish and a number of gold, silver, and bronze ornaments (Hermitage Museum, Leningrad). Two of the jugs, although undecorated, carry Orkhon inscriptions on their bases. Two others are covered with delicate relief representations of birds and fish surrounded by flowers and vegetation, executed in a style influenced by Islāmic art. A Scytho-Altaic hunting motif of riders pursuing a tiger, a deer, and a panther appears on a bronze ornamental object.

Turkic tribes had been concentrating their numbers in Central Asia from about the 5th century AD. In the 6th century the Kul Tepe and Bilge Khan tribes established a state of their own in the Orkhon Valley. The inscriptions that they carved on the valley's rocks are of considerable historical importance. In the 7th century the Turkic Oğuz people were so numerous that they constituted 24 tribes. The Sāmānids, Ghaznavids, Ghūrids, and Seljuqs were of Oğuz extraction.

Türbe construction

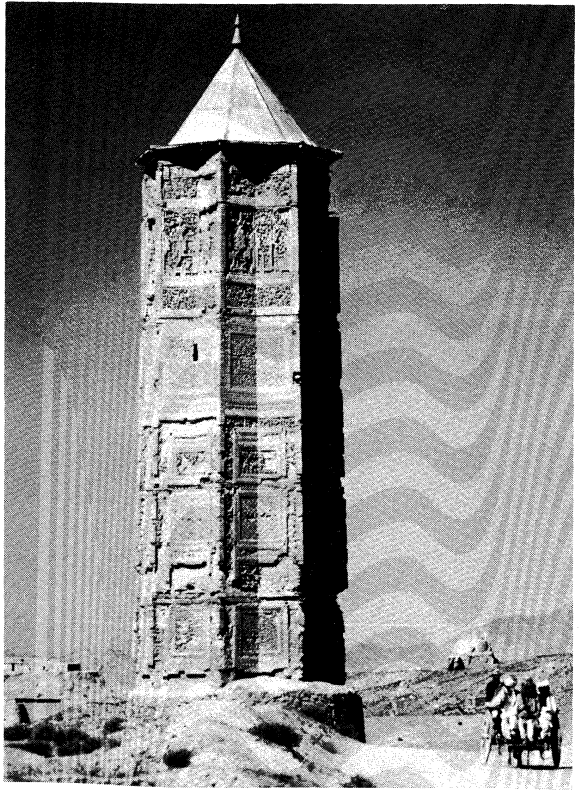
Sāmānids. The Sāmānids centred their kingdom in Khorāsān. In the 9th century, under the leadership of Esmā'il, they ruled over Transoxiana and eastern Persia from their capital of Bukhara. Esmā'il's *türbe,* or mausoleum, the oldest Islāmic monument surviving in Bukhara, reproduces the form of the Zoroastrian *chanar taq,* or fire temple. In Sāmānid and Seljuqid hands, the *türbe* generally took the form of a small circular or octagonal building, roofed with a turret shaped like the point of a pencil. Mounted on a solid or single vaulted substructure, its single chamber had a domed ceiling and a mihrab, or niche indicating the direction of Mecca. In the more elaborate *türbes*, the single door was framed with bands of geometric decoration, and the turret was sometimes ribbed.

Ghaznavids and Ghūrids. Alp Tigin, a slave of Turkic origin at the Sāmānid court, escaped in 962 AD to Kābul, where he rapidly gained control of the town. He transferred his headquarters to Ghazna in central Afghanistan and established his dynasty there. Few Ghaznavid works of art have survived, but the admirably proportioned and decorated mortuary towers at Ghazna are architectural achievements of great splendour. Still finer is the minaret of Jām, a Ghūrid structure of the 11th century. Standing alone in a desolate region, it escaped discovery until 1957. It is conjectured that the minaret may mark the position of the lost Ghūrid capital of Fīrūzkūh.

Seljuqs. The art of the Seljuqs, who founded kingdoms in Persia, eastern Byzantium, Syria, and Iraq, eclipsed that of the Sāmānids, Ghūrids, and Ghaznavids. They were great architectural patrons and constructed numerous mosques, madrasah (Islāmic religious schools), hospitals, orphanages, baths, caravanserais, bridges, and *türbes* notable for their decorative masonry, elaborately ornamented portals, and use of Kūfic script as an architectural decorative device. The Seljuqs also attained a high standard in their decorative arts, especially metalwork, wood carving, and pottery. The Mongols, who terminated the Seljuq period, adopted certain Seljuqid artistic conventions, particularly the use of ornamented portals and glazed-tile paneling.

Mongols. Genghis Khan (died 1227), the renowned Mongol conqueror, sacked and destroyed Bukhara in 1224, sparing only the 12th-century Kalyan tower, which was used for throwing criminals to their death. The 14th-century Turkic conqueror Timur, however, endowed Samarkand with new glory by building a series of religious monuments widely renowned for their splendour and decorative use of glazed tiles. In the 16th century, Bābur, prince of Fergana, coveted Samarkand. Failing to capture it, he chose Kābul as his headquarters for his conquest of India. His tomb there (he died in 1540) is the only visible testimony to the years he spent in the city.

Josephine Powell, Rome



One of the two mortuary towers at Ghazna, Afghanistan, 10th–11th century.

Emirate of Bukhara. Although fine-quality pottery decorated with animal, bird, and figural designs was being made in New Nisa in the 15th century, the artistic revival of the Mongol period that Timur had launched in western Turkistan had died out by the 16th century, when the emirate of Bukhara, incorporating much of Sogdiana, was established. Except for gold-thread embroidery and carpet making, in most of Central Asia the visual arts largely stagnated. In Mongolia the conversion of the Buryats to Lamaism in the 18th century brought into their tradition of ornamentation such Tibetan motifs as the lotus, dragon, and lion.

Revival of traditional architecture and decoration

Russian–Soviet period. In 1882 the emirate of Bukhara was incorporated as a Russian state. This political act had little cultural effect, and European art remained unknown to Central Asians. Traditional indigenous architecture of baked or unbaked brick construction was revived in the 18th century. Carved doors and screens were again produced. Old styles of Islāmic script were combined with arabesques to adorn metalwork. Zoomorphic junctures persisted in the animal designs created by metalworkers and potters alike, although the ornaments worn by nomadic women had become so stylized as to have lost all resemblance to the ancient animal motifs from which they were descended. Openwork remained a feature of much of the jewelry, notably of the necklaces formed of small openwork plaques linked by rings or chains.

Following the Russian Revolution, a new phase of art began in the Soviet-controlled regions of Central Asia. Although the Soviet authorities took steps to maintain the existing carpet and textile industries, they encouraged the inclusion of genre scenes and native animals and vegetation. They also founded schools to train artists in the traditions of European art. Pictorial arts are naturalistic in style, conforming with the principles of social realism as defined by the Soviet authorities. The first Buryat-Mongolian Turkmen painter to achieve distinction in this style was Tsyrenzhap Sampilov.

ARCTIC REGIONS

In the arctic zone of Central Asia, the prehistoric age extends from the 3rd millennium BC to the arrival of Europeans around AD 1800. Knowledge of the region's arts is still very limited, for it is wholly dependent upon the sculptures produced by Eskimos living on the shores and in the hinterland of Siberia and the Bering Strait. These sculptures are mostly in walrus tusk, though wood and reindeer horn examples also exist. The majority are small in size and worked in the round to form terminal ornaments for utilitarian or ceremonial objects or statuettes. The latter are not provided with bases and thus must have been designed to be carried about. Many of the implements are decorated with incised patterns formed chiefly of lines and dots. As in all early arts, the statuettes and terminal ornaments are largely concerned with hunting or the magical practices of shamanism. The earliest and finest statuettes of which there is knowledge are assigned to the Okvik culture, which some scholars date to the pre-Christian era, but which others assign to its early centuries. Okvik art is concerned primarily with the representation of the human figure, differing in that respect from the contemporary or slightly later Old Bering Sea culture, where interest largely centres on animals, such as reindeer, elks, bears, and seals.

Okvik sculpture

Works of the Okvik and later Arctic schools often depict women, sometimes in the nude, sometimes clothed. The nude figures seldom include more of the arms than shoulder stumps. Their bodies are short and flat, their heads large, pear-shaped, and carefully worked, as are hands when included. The faces are carved and are sometimes incised with lines, probably denoting tattooing. The so-called Okvik Madonna (University of Alaska Museum, Fairbanks) is perhaps the most expressive of these statuettes.

Some Okvik animal designs are particularly interesting because of certain stylistic details that point to a relationship with works of the Scytho-Siberian school. Reindeer are so frequently depicted that the discovery at Pazyryk of a horse's mask in the form of a reindeer's head led to the suggestion that the mask was a survival from a reindeer cult acquired by the Altaians from a northern people such as the Eskimo. That theory has been discounted, yet some Okvik works are undoubtedly related to certain slightly older examples of Siberian metalwork. Thus, the heads of some terminal ornaments bear a close resemblance to those of certain Siberian works. The lozenge-shaped muscles that appear on Eskimo carvings amid lines intended to portray the animal's skeleton are very similar to those of the Pazyryk dot and comma markings. In late- or post-Okvik times certain specifically Eskimo objects, such as masks, were decorated with stylized animal heads executed in relief and accompanied by bosses that recall the Altaic, especially those that reflect Chinese influence. Compositions such as that on an unidentifiable object (possibly a rake or comb) in the University of Alaska Museum, which includes as its central motif the head of an animal resembling a bear or a seal, display a marked affinity with west Siberian ones.

Climatic changes in the 17th century led to contacts with the outer world in the 19th century and brought the traditional Eskimo school of sculpture to an abrupt end. When, toward the end of the century, art started to revive, it did so under European influence, eventually developing a greater concern for aesthetic than religious considerations. The new style retained much of the directness of approach and formal conventions of the traditional style, but, in addition, there was a greater emphasis on naturalism. Group scenes, too, became popular, as did animal and bird compositions. There has been an extensive production of small sculptures, chiefly of fish, bird, or animal forms, in the 20th century. (T.T.R.)

HIMALAYAN CULTURES OF NEPAL AND TIBET

Nepal. The art of Nepal is centred in the Kāthmāndu Valley, in an area of less than 250 square miles (650 square kilometres). The artists are Newars, or Mongoloids, different ethnically from, though partly intermingled with, the peoples of India, whose art they made their own—whether its themes were Hindu or Buddhist.

Architecture. There is only one Nepalese architectural style, varied according to its function as private dwelling, palace, Buddhist monastery, or Buddhist or Hindu temple. The style is the protracted local flowering of an Indian architectural tradition—of brick and wood architecture with tiered, sloping roofs—other varieties of which are found in the western Himalayas and in Kerala in the southwest.

Essentially, there are two kinds of Nepalese Buddhist shrine, or *stūpa* (also called *caitya*): the large *stūpa* and the small, monolithic *stūpa.* Characteristic of the large *stūpa* like the one at Bodnath is the low base from which it rises and its crowning dome-shape. The small *stūpa* was generally set in the courtyard of a Buddhist monastery. The extant monasteries, none of which dates earlier than the 14th century, are consistent in their plans and structures. A central courtyard flanked by residential buildings is entered through a gate with a richly carved tympanum (torana) and porch. Opposite the gate and in the centre of the courtyard is the main building, the *stūpa;* with its one- to three-tiered roof, it rises higher than the buildings that surround it and forms the square of the courtyard.

Buddhist monasteries

Most Hindu temples are freestanding. The more ancient temples have two superimposed roofs; the later ones are five-roofed temples, given further height by tiered brick socles, or bases. On each story of the towerlike structure, wooden beams and struts (a structural piece designed to resist pressure in the direction of its length) support a widely projected slanting roof, the struts ascending diagonally from the central structure to the edge of the tiled roof. The majestically tapered, ascending profile of the structure, with its strong contrast of light playing on the roofs and masses of shade looming below, is peculiar to Nepal. Rich in textures and colours, the temples are embellished with carved and painted struts, carved doorframes and window frames, and embossed gilded copper sheets. Like the pantheon on the stone temples of India, the pantheon of Nepal is laid out mainly on the exterior of the temple—in contrast to Tibet, where it is displayed on the interior of the temple.

Sculpture and painting. Combinations of Hindu and Buddhist iconography came about easily, though there is something facile about them, a smoothness found also in the form of the Nepalese images, which lack the surging dynamism of Indian form. Characteristic of the Nepalese transformation of Indian styles is a loss of depth but a gain in grace. Suavity of line, temperance of modelling, tonal clarity of vivid, contrasting colours raise Nepalese works far above the merely derivative. An indigenous physiognomy, too, modifies the physical formulas for sculpture laid down in India.

While Nepalese sculpture is known to exist from the 2nd century BC (terra-cotta plaques, a stone *bodhisattva,* and a Buddha image), it was in the 5th to the 7th centuries BC that stone sculpture in Nepal came into its own. Vishnu Vikrānta (the three strides of Vishnu), dated AD 467, and 6th-century panels illustrating the Kumārasambhava ("Birth of the War-God," an epic by the 5th-century Indian poet and dramatist Kālidāsa) are masterworks of narrative relief and dramatic mythical composition. On the more intimate level of daily life, sculpture takes the form of the many fountains that adorn watering places (*pranali*) of Nepal. Water spouts forth from *makara* (Hindu water monster with the body of a crocodile and the head of an elephant) snouts sheathed in gilt copper into reservoirs laid out with architectural dignity. As far as present knowledge goes, Newari sculpture was dominated from the 8th century into the 18th by gilt-copper images. In their glowing splendour, the gilt, sometimes jewel-encrusted images embody the Buddhist quality of compassion that leads to enlightenment.

Painting in Nepal is known from the 11th century on palm leaves and wooden bookcovers of manuscripts, some of them hardly distinguishable, at first, from the Bengali prototypes. The Nepalese style, less nervous, more conscious of the beautiful line and clear, compartmental order of the surface, is fully developed in scrolls, or *prabhas* (most of them, vertical), on cotton known from the 13th century. These scrolls are of two kinds: one consists of ar-

rays of religious images with a large figure of the main deity in their midst; the other consists of a *maṇḍala,* the Hindu and Buddhist symbol of the universe—a circle enclosing a square with the deities disposed within. Narrative panels or sections in the margins of both types of scroll soften the rigour of the composition. While this Nepalese hieratic, or sacerdotal, style was at its peak, a narrative style developed in manuscript illuminations such as the *Hitopadeśa* (1594; Kāthmāndu) and horizontal scroll paintings such as the Rathayātrā Scroll (1617; Prince of Wales Museum of Western Bombay). Its planar intricacies reveal a new and vital aspect of Nepalese painting, an immediacy of emotion and action of its protagonists, the figures of which are placed on an opaque, velvety ground. The colours of these book illustrations and scrolls retain the strength and depth of those of the hieratic scrolls, which continued to be painted into the 17th century. The influence of the more realistic Indian, Rajasthani paintings, from the latter part of the 17th century, finally overwhelmed the hieratic style. Its disappearance was further hastened by a wave of Chinese-influenced Tibetan painting. (S.Kh.)

Tibet. Tibetan art comprises ancient pre-Buddhist decorative and domestic crafts and the all-pervading religious art that was gradually introduced from the 8th century onward from surrounding Buddhist countries and developed subsequently as recognizably distinct Tibetan imagery, sculpture, and decorative architectural motifs. In all its forms Tibetan art has remained subservient to special lay or religious intentions and has never become an art pursued for aesthetic ends alone. The religious art is primarily didactic and symbolic; the lay art, decorative. Therefore, while lay art may be easily appreciated, to understand the significance of the religious art requires knowledge of Tibetan religion and religious symbolism. Since the destruction of Tibetan cultural traditions by Chinese-trained Communists from 1959 onward, a greater interest has arisen in the West in the surviving Tibetan *objets d'art* preserved in museums and private collections.

Up to the 9th century AD, Tibet was open to cultural influence from Central Asia, especially Khotān, and from China. For two centuries, up to the collapse of the old Tibetan kingdom in 842, the Tibetans controlled the whole Takla Makan and the important trade routes from the Middle East to China. Stone carving and metalwork were certainly practiced in the pre-Buddhist period, and Persian, Indian, and Chinese influences, all received through Central Asia, have been noted.

The introduction of Buddhism from the 8th century onward led to the arrival in Tibet of Buddhist craftsmen from Central Asia and later from Nepal and northwest India, all of which were then Buddhist lands. Some cast images from this first Buddhist period may survive in Lhasa. After 842, central Tibet dissolved into political chaos for over 100 years, and from the 10th century onward the cultural initiative passed to a line of kings in western Tibet. For temple decorations, such as wood carving of doorways and posts, decorative painting on ceilings and woodwork, temple frescoes, and terra-cotta and stucco images, they drew heavily on the cultural resources of pre-Islāmic Kashmir. Surviving monasteries and temples, with their magnificent contents, were made known to the Western world in the 1930s. With the establishment of religious hegemonies in central Tibet from the 11th century onward, cultural contacts with Nepal and the Buddhist centres in the main Ganges Valley flourished as never before. Conversely, cultural contacts with China dwindled for several centuries, at least in central and southern Tibet. From this time until the 20th century, Tibetan religious art and Nepalese Buddhist art remained a single unified tradition. Meanwhile, eastern Tibet, where the ancient pre-Buddhist crafts of metalwork had never died out, began to develop religious styles under the influence of craftsmen from central Tibet. From that time, the spread of Tibetan culture and art became coterminous with the spread of Tibetan religion; and, thus, from the 13th century onward, when Tibetan lamas began to convert the Mongols, Mongolian religious art developed as a branch of Tibetan art. Through the Mongols, China began to extend its political influence over Tibet, and this led to a steady increase in Chinese cultural influence, especially in the east. From 1721, when the Chinese emperors became the suzerains of Tibet, Chinese influence was felt much more strongly throughout central as well as eastern Tibet, and Tibetan religious paintings and especially domestic decoration reveal distinct Chinese features.

Chinese
cultural
influence

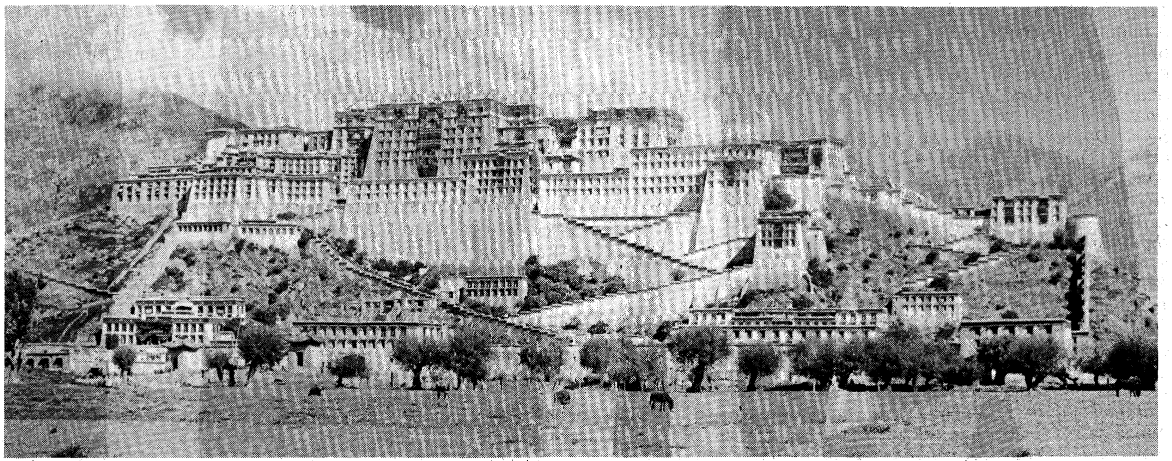
Decorative arts. In the main temple (*fo-khang*) of Lhasa there is a pre-Buddhist silver jug with a long neck surmounted by a horse's head; and there are textual references to all kinds of articles made of gold: a large golden goose holding seven gallons of wine, a wine vase, a miniature city decorated with gold lions, and golden bowls. Gold animals are mentioned as decorating the camp of King Ral-pa-can when a Chinese envoy visited him in 821. These early Tibetan skills lived on through the Buddhist period. Tibetan metalworkers have excelled in producing fine things for ritual and domestic use: ritual lamps, vases, bowls, bells, prayer wheels, decorated trumpets and horns, for the temples, and, for home use, ornamented teapots, jars, bowls, ladles, and especially beautiful stands, often in silver or gold, to hold porcelain teacups, capped by finely worked lids of precious metals. Hand-woven rugs of magnificent Central Asian and Chinese designs, always adapted to Tibetan preferences, cover low seats, and tables and cabinets of carved and painted wood were commonplace in prosperous homes.

Sculpture. From the 7th to 9th centuries there survive pre-Buddhist carved-stone pillars decorated with Chinese, Central Asian, and Indian motifs and also a stone lion showing traces of Persian influence.

Metal
casting

The art of casting images in bronze and other metals entered Tibet from Nepal and India. Having first followed foreign models, the Tibetans gradually developed their own styles and began to depict their own lamas and teachers as well as the vast pantheon of buddhas, gods, and goddesses inherited from India, each distinguished iconographically by posture, hand gestures, and accoutrements.



The Potala Palace, Lhasa, Tibet, 17th century.
Paul Popper (Popperfoto) Ltd.

(Of lesser divinities and especially of lamas, the identification is often difficult. It is rare that an image is named in an inscription and even rarer to find a date. Because of the extremely conservative nature of Tibetan art, correct dating within several centuries is often impossible.) Images of vast size, rising up through two or three stories, are quite often seen in Tibetan temples, and their construction and dedication is considered a work of vast religious merit.

Since images are mainly cast or molded, carving is restricted to decorative motifs, especially on wooden pillars and roof beams. Wood carving and terra-cotta, particularly in western and southern Tibet, were common. Papier-mâché, elaborately painted, was also used for masks of divinities. This use presumably originated in Kashmir.

Tibetan painting of Lcang-skya Rol-pa'i rdo-rje. The saint carries a book, one of the attributes of his patron, Tsong-kha-pa, founder of the Yellow Hat sect of Tibetan Buddhism. Chinese influence is shown by the architecture of the monasteries. In a private collection.

Painting: frescoes and temple banners. Temple interiors are usually covered with frescoes and often hung with painted banners, or tanka (*thang-ka*). For the preparation of the latter, a taut cotton cloth is impregnated with a mixture of chalk and glue, rubbed smooth by some suitable object; for example, a flat polished stone. A religious painter trained in the tradition draws in the outline, often using printed designs for the main figures. There is no scope for originality so far as the iconographic details of divinities are concerned, and, thus, such painting is a highly skilled craft. For decorative details—for example, flowers, cloud effects, rocks, and groups of devotees—there is wider scope. The tradition of fresco painting and temple banners certainly goes back to that of the great Buddhist monasteries of northwest India and the Ganges Valley, but these Indian origins of the 9th to 12th centuries are now entirely lost. The Indian Buddhist paintings of Ajanta are of a much earlier period (up to the 6th century AD), thus predating the great increase in the Buddhist pantheon and in occult symbolism typical of the later Indian Buddhism received by the Tibetans. Central Asian styles certainly reached central Tibet well before the 9th century, but, after that date, it was India and Nepal that were to have lasting influences on the development of Tibetan art. In more recent times, especially from the 18th century onward, Chinese influence became noticeable in the details of paintings, particularly in the freer but still balanced arrangement of the main figures and the use of Chinese-style landscapes as subsidiary decoration. With the disappearance of Buddhism from Central Asia and India from the 12th century onward, Tibetan art developed as a style exclusive to the Tibetans, the Newari Buddhists of the Nepal Valley, and the Tibetan converts of Mongolia.

Influence of Indian Buddhist painting

Decorative architectural motifs. For temples, monasteries, and official residences such as the Potala Palace of the Dalai Lama in Lhasa, the Tibetans used their own solid indigenous styles but embellished these with Indian, Nepalese, and (very much later) Chinese motifs. Tiered, ornamented temple roofs are of Indian origin, as received through Nepal and later through China. The magnificent interior carving is of Indian and Nepalese inspiration.

(T.T.R./M.S.S./T.V.W./S.Kh./D.L.S./J.R.Kr./F.I.)

Cervantes

Cervantes is the most celebrated of all Spanish writers. His novel *Don Quixote* has been translated, in whole or in part, into more than 60 languages. Editions continue regularly to be printed, and critical discussion of the work has proceeded unabated since the 18th century. At the same time, owing to their widespread representation in art, drama, and film, the figures of Don Quixote and Sancho Panza are probably familiar visually to more people than any other fictitious characters in world literature. Cervantes was a great experimenter. He tried his hand in all the major literary genres save the epic. He was a notable short-story writer, and a few of those in his collection of *Novelas exemplares* ("Exemplary Tales") attain a level close to that of *Don Quixote,* on a miniature scale.

Origins and early life

Miguel de Cervantes Saavedra was born in Alcalá de Henares, some 20 miles from Madrid, probably on Sept. 29 (the day of San Miguel), 1547. He was certainly baptized on October 9. He was the fourth of seven children in a family whose origins were of the minor gentry but which had come down in the world. Miguel's father was a barber-surgeon who set bones, performed bloodlettings, and attended lesser medical needs. The family moved from town to town, and little is known of Cervantes' early education. The supposition, based on a passage in one of the *Novelas exemplares,* that he studied for a time under the Jesuits, though not unlikely, remains conjectural. Unlike most Spanish writers of his time, including some of humble origin, he apparently did not go to a university. What is certain is that at some stage he became an avid reader of books. The head of a municipal school in Madrid, a man with Erasmist intellectual leanings named Juan López de Hoyos, refers to a Miguel de Cervantes as his "beloved pupil." This was in 1569, when the future author was 21, so—if this was the same Cervantes—he must either have been a pupil-teacher at the school or have studied earlier under López de Hoyos. His first published poem, on the death of Philip II's young queen, Elizabeth of Valois, appeared at this time.

Soldier and slave. That same year he left Spain for Italy. Whether or not this was because he was the "student" of the same name wanted by the law for involvement in a wounding incident is another mystery; the evidence is contradictory. In any event, in going to Italy Cervantes was doing what many young Spaniards of the time did to further their careers in one way or another. It seems that for a time he served as chamberlain in the household of Cardinal Giulio Acquaviva in Rome. However, by 1570 he had enlisted as a soldier in a Spanish infantry regiment stationed in Naples, a possession of the Spanish crown. He was there for about a year before he saw active service.

Confrontation at sea

Relations with the Ottoman Empire under Selim II were reaching a crisis, and the Turks occupied Cyprus in 1570. A confrontation between the Turkish fleet and the naval forces of Venice, the papacy, and Spain was inevitable. In mid-September 1571 Cervantes sailed on board the *Marquesa,* part of the large fleet under the command of Don Juan de Austria that engaged the enemy on October 7 in the Gulf of Lepanto near Corinth. The fierce battle ended in a crushing defeat for the Turks that was ultimately to break their control of the Mediterranean. There are independent accounts of Cervantes' conduct in the action, and they concur in testifying to his personal courage. Though stricken with a fever, he refused to stay below and joined the thick of the fighting. He received two gunshot wounds in the chest, and a third rendered his left hand useless for the rest of his life. He always looked back on his conduct in the battle with pride. From 1572 to 1575, based mainly in Naples, he continued his soldier's life; he was at Navarino and saw action in Tunis and La Goleta. He must also, when opportunity offered, have been familiarizing himself with Italian literature. Perhaps with a recommendation for promotion to the rank of captain, more likely just leaving the army, he set sail for Spain in September 1575 with letters of commendation to the King from the Duque de Sessa and Don Juan himself.

Treatment in captivity

On this voyage his ship was attacked and captured by Barbary corsairs, and Cervantes, together with his brother Rodrigo, was sold into slavery in Algiers, the centre of the Christian slave traffic in the Muslim world. The letters he carried magnified his importance in the eyes of his captors. This had the effect of raising his ransom price, and thus prolonging his captivity, while also, it appears, protecting his person from punishment by death, mutilation, or torture when his four daring bids to escape were frustrated. His masters, the renegade Dali Mami and later Hasan Paşa, treated him with considerable leniency in the circumstances, whatever the reason. At least two contemporary records of the life led by Christian captives in Algiers at this time mention Cervantes. He clearly made a name for himself for courage and leadership among the captive community. At long last, in September 1580, three years after Rodrigo had earned his freedom, Miguel's family, with the aid and intervention of the Trinitarian friars, raised the 500 gold escudos demanded for his release. It was only just in time before Hasan Paşa sailed for Constantinople, taking his unsold slaves with him. Not surprisingly, this, the most adventurous period of Cervantes' life, supplied subject matter for several of his literary works, notably the Captive's tale in *Don Quixote* and the two Algiers plays, *El trato de Argel* ("The Traffic of Algiers") and *Los baños de Argel* ("The Bagnios of Algiers"), as well as episodes in a number of other writings, although never in straight autobiographical form.

Economic hardships

Civil servant and writer. Back in Spain, most of the rest of his life was to be spent in complete contrast with his decade of action and danger. He would be constantly short of money and in tedious and exacting employment; it would be 25 years before he scored a major literary success with *Don Quixote.* On his return home he found that prices had risen and the standard of living for many, particularly those of the middle class like his family, had fallen. The euphoria of Lepanto was a thing of the past. Cervantes' war record did not now bring the recompense he expected. He applied unsuccessfully for several administrative posts in Spain's American empire. The most he succeeded in acquiring was a brief appointment as royal messenger to Oran in 1581. He followed Philip II and the court to Lisbon in newly annexed Portugal in vain.

First published fiction

Around this time he had an affair with a young married woman called Ana de Villafranca (or Ana Franca de Rojas), the fruit of which was a daughter. Isabel de Saavedra, Cervantes' only child, was later brought up in her father's household. Late in 1584 he married Catalina de Salazar y Palacios, 18 years his junior. She had a small property in the village of Esquivias in La Mancha. Little is known about their emotional relationship. There is no reason to suppose that the marriage did not settle down into an adequate companionableness, despite Miguel's enforced long absences from home. Neither is there any special reason to suppose that Catalina was an inspiration or a model for characters in the poetry Cervantes was now writing or in his first published fiction, *La Galatea* (1585), in the newly fashionable genre of the pastoral romance. The publisher, Blas de Robles, paid him 1,336 reales for it, a good price for a first book. The dedication of the work to Ascanio Colonna, a friend of Acquaviva, was a bid for patronage that does not seem to have been productive. Doubtless helped by a small circle of literary friends, such as the poet Luis Gálvez de Montalvo, the book did bring Cervantes' name before a sophisticated reading public. But the only later editions in Spanish to appear in the author's lifetime were those of Lisbon, 1590, and Paris, 1611. *La Galatea* breaks off in mid-narrative; judging by his repeatedly expressed hopes of writing a sequel, Cervantes evidently maintained a lasting fondness for the work.

Failure as a dramatist

He also turned his hand to the writing of drama at this time, the early dawn of the Golden Age of the Spanish theatre. He contracted to write two plays for a theatrical manager called Gaspar de Porras in 1585, one of which, *La confusa* ("Comedy of Confusion"), he later described as the best he ever wrote. Many years afterward he claimed to have written 20 or 30 plays in this period, which, he noted, were received by the public without being pelted with vegetables or booed off the stage. The number is vague; only two certainly survive from this time, the historical tragedy of *La Numancia* ("Numantia") and *El trato de Argel.* He names nine plays, the titles of a few of which sound like the originals of plays reworked and published years later in the collection *Ocho comedias, y ocho entremeses nuevos* (1615; "Eight New Plays and Eight New Interludes"). Fixed theatres were just becoming established in the major cities of Spain, and there was an expanding market geared to satisfying the demands of a public ever more hungry for entertainment. Lope de Vega was about to respond to the call, stamping his personal imprint on the Spanish *comedia* and rendering all earlier drama, including that of Cervantes, old-fashioned or inadequate by comparison. Though destined to be a disappointed dramatist, Cervantes went on trying to get managers to accept his stage works. By 1587 it was clear that he was not going to make a living from literature, and he was obliged to turn in a very different direction.

Cervantes became a commissary of provisions for the great Armada. Requisitioning corn and oil from grudging rural communities was a thankless task, but it was at least a steady job, with a certain status. It took him traveling all over Andalusia, an experience he was to put to good use in his writing. He was responsible for finances of labyrinthine complexity, and the failure to balance his books landed him in prolonged and repeated trouble with his superiors. There also was constant argument with municipal and church authorities, the latter of which more than once excommunicated him. The surviving documentation of the accountancy and negotiations involved is considerable.

After the disastrous defeat of the Armada in 1588 he gravitated to Seville, the commercial capital of Spain and one of the largest cities in Europe. In 1590 he applied to the Council of the Indies for any one of four major crown posts vacant in Central and South America. His petition was curtly rejected. Wrangles over his accounts and arrears of salary dragged on. He seems to have kept some contact with the literary world; there is a record of his buying certain books, and he must have managed to find time for reading. In 1592 he signed a contract to supply six plays to a theatrical manager, one Rodrigo Osorio. Nothing came of this. His commissary work continued, and the litigation came to a head; in September 1592 he was imprisoned for a few days in Castro del Río.

In 1594 he was in Madrid seeking a new post. He received an appointment that took him back to Andalusia to collect overdue taxes. Although it was in effect a promotion, the job was no more rewarding than the previous one and was similarly fraught with financial difficulties and confrontations. Cervantes was not by temperament a businessman. Probably by mutual agreement the appointment was terminated in 1596. The previous year he had won first prize (three silver spoons) in a poetry competition in Zaragoza. Back in Seville, it is likely that at about this time he started seriously writing stories, not to mention a wickedly satirical sonnet on the conduct of the Duque de Medina Sidonia, to be followed by one obliquely disrespectful of the recently deceased king himself. Again he met with financial troubles. In the summer of 1597 discrepancies in his accounts of three years previous landed him in the Crown Jail of Seville. He was confined until the end of April 1598 and perhaps conceived there the idea of *Don Quixote,* as a remark in the first prologue suggests.

Information about Cervantes' life over the next four or five years is sparse. He had left Seville, and, perhaps for a while in Esquivias and Madrid, later for certain in Valladolid (where the royal court established itself from 1601 to 1606), he must have been writing the first part of *Don Quixote.* Early versions of two of his stories, *Rinconete y Cortadillo* ("Rinconete and Cortadillo") and *El celoso extremeño* ("The Jealous Estremaduran"), found their way into a miscellaneous compilation, unpublished, made by one Francisco Porras de la Cámara.

Publication of *Don Quixote*

In July or August 1604 Cervantes sold the rights of *El ingenioso hidalgo Don Quixote de la Mancha* ("The Ingenious Hidalgo Don Quixote of La Mancha"; known as *Don Quixote,* Part I) to the publisher-bookseller Francisco de Robles for an unknown sum. License to publish was granted in September and the book came out in January 1605. There is some evidence of its content's being known or known about before publication—among others, to Lope de Vega, the vicissitudes of whose relations with Cervantes were then at a low point. The compositors at Juan de la Cuesta's press in Madrid are now known to have been responsible for a great many errors in the text, many of which were long attributed to the author. The novel was an immediate success, though not as sensationally so as Mateo Alemán's *Guzmán de Alfarache,* Part I, of 1599. By August 1605 there were two Madrid editions, two published in Lisbon, and one in Valencia. There followed those of Brussels, 1607; Madrid, 1608; Milan, 1610; and Brussels, 1611. Part II, *Segunda parte del ingenioso cavallero Don Quixote de la Mancha* ("Second Part of the Ingenious Knight Don Quixote of La Mancha"), came out in 1615. Thomas Shelton's English translation of the first part appeared in 1612. The name of Cervantes was soon to be as well known in England, France, and Italy as in Spain.

The sale of the publishing rights, however, meant that he made no more financial profit on Part I of his novel. He had to do the best he could with patronage. The dedication to the young duque de Béjar had been a mistake. He had better fortune with two much more influential persons: the Conde de Lemos, to whom he would dedicate Part II and no less than three other works, and Don Bernardo de Sandoval y Rojas, archbishop of Toledo. This eased his financial circumstances somewhat. However, it is apparent that he would have liked a securer place in the pantheon of the nation's writers than he ever achieved during his lifetime—he wanted a reputation comparable to that enjoyed by Lope de Vega or the poet Luis de Góngora y Argote, for example. His sense of his own marginal position may be deduced from his *Viage del Parnaso* (1614; "Voyage to Parnassus"), two or three of the later prefaces, and a few external sources. Nevertheless, relative success, still unsatisfied ambition, and a tireless urge to experiment with the forms of fiction ensured that, at the age of 57, with less than a dozen years left to him, Cervantes was just entering the most productive period of his career.

No graciousness descended on his domestic life. A stabbing incident in the street outside the house in Valladolid, in June 1605, led ridiculously to the whole household's arrest. When they later followed the court to Madrid, he continued to be plagued by litigation over money and now, too, over Isabel's unedifying marital affairs. The family lodged in various streets over the next few years before finally settling in the Calle de León. Like a number of other writers of the day, Cervantes nursed hopes of a secretarial appointment with the Conde de Lemos when, in 1610, the Conde was made viceroy of Naples. Once more he was disappointed. He had joined a fashionable religious order, the Slaves of the Most Blessed Sacrament, in 1609, and four years later he became a Franciscan tertiary, which was a more serious commitment. We know, too, of some increased involvement in the literary life of the capital in the form of his attendance at the Academia Selvaje, a kind of writers' salon, in 1612.

The *Novelas exemplares*

The next year, the 12 *Novelas exemplares* were published. The prologue contains the only known authentic portrait of the author:

> of aquiline countenance, with dark brown hair, smooth clear brow, merry eyes and hooked but well-proportioned nose; his beard is silver though it was gold not 20 years ago; large moustache, small mouth with teeth neither big nor little, since he has only six of them and they are in bad condition and

> worse positioned, for they do not correspond to each other; the body between two extremes, neither tall nor short; a bright complexion, more pale than dark, somewhat heavy in the shoulder and not very light of foot.

Cervantes' claim in this prologue to be the first to write original novellas (short stories in the Italian manner) in Castilian is substantially justified. Their precise dates of composition are in most cases uncertain. There is some variety in the collection, within the two general categories of romance-based stories and realistic ones. *El coloquio de los perros* ("Colloquy of the Dogs"), a quasi-picaresque novella, with its frame tale *El casamiento engañoso* ("The Deceitful Marriage"), is probably Cervantes' most profound and original creation next to *Don Quixote.* In the 17th century the romantic stories were the more popular; James Mabbe chose precisely these for the selective English version of 1640. Nineteenth- and 20th-century taste has preferred the realistic ones, but the others are receiving again something like their critical due.

In 1614 Cervantes published *Viage del Parnaso,* a long allegorical poem in mock-mythological and satirical vein, with a postscript in prose. It was devoted to celebrating a host of contemporary poets and satirizing a few others. The author there admitted that writing poetry did not come easily to him. But he held poetry in the highest esteem as a pure art that should never be debased. Having lost all hope of seeing any more of his plays staged, in 1615 he had eight of them published, together with eight short comic interludes, in *Ocho comedias, y ocho entremeses nuevos.* The plays show no shortage of inventiveness and originality but lack real control of the medium. The entremeses, however, are reckoned among the very best of their kind.

Don Quixote, Part II

It is not certain when Cervantes began writing Part II of *Don Quixote,* but he had probably not gotten much more than halfway through by late July 1614. Around September a spurious Part II was published in Tarragona by someone calling himself Alonso Fernández de Avellaneda, an unidentified Aragonese, who was an admirer of Lope de Vega. The book is not without merit, if crude in comparison with its model. In its prologue the author gratuitously insulted Cervantes, who not surprisingly took offense and responded, though with relative restraint if compared with the vituperation of some literary rivalries of the age. He also worked some criticism of Fernández de Avellaneda and his "pseudo" Quixote and Sancho into his own fiction from chapter 59 onward.

Don Quixote, Part II, emerged from the same press as its predecessor late in 1615. It was quickly reprinted in Brussels and Valencia, 1616, and Lisbon, 1617. Parts I and II first appeared in one edition in Barcelona, 1617. There was a French translation of Part II by 1618 and an English one by 1620. The second book capitalizes on the potential of the first, developing and diversifying without sacrificing familiarity. Most people agree that it is richer and more profound.

Last works

In his last years Cervantes mentioned several works that apparently did not get as far as the printing press, if indeed he ever actually started writing them. There was *Bernardo* (the name of a legendary Spanish epic hero), the *Semanas del jardín* ("Weeks in the Garden"; a collection of tales, perhaps like the *Decameron*), and the continuation to his *Galatea.* The one that was published, posthumously in 1617, was his last romance, *Los trabaios de Persiles y Sigismunda, historia setentrional* ("The Labours of Persiles and Sigismunda: A Northern Story"). In it Cervantes sought to renovate the heroic romance of adventure and love in the manner of the *Aethiopica* of Heliodorus (*c.* AD 230–240). It was an intellectually prestigious genre destined to be very successful in 17th-century France. Intended both to edify and to entertain, the *Persiles* is an ambitious work that exploits the mythic and symbolic potential of romance. It was very successful when it appeared; there were eight Spanish editions in two years and French and English translations in 1618 and 1619, respectively.

In the dedication, written three days before he died, Cervantes, "with a foot already in the stirrup," movingly bade farewell to the world. Clear-headed to the end, he seems to have achieved a final serenity of spirit. He died almost certainly on April 22, 1616, not on the 23rd as had been traditionally thought. The burial certificate indicates that the latter was the day he was buried, in the convent of the Discalced Trinitarians in the Calle de Cantarranas (now the Calle de Lope de Vega). The exact spot is not marked. No will is known to have survived.

Importance and influence. Cervantes' greatest creation, *Don Quixote,* appeared at the end of more than a century of remarkably innovative and diverse achievement by Spanish prose fiction writers. It was immediately preceded by the sudden efflorescence of works in the new genre of the picaresque, in which Cervantes himself participated with *Rinconete y Cortadillo. Don Quixote,* however, parodied the romances of chivalry, which in published titles had outnumbered all other kinds of fiction in the 16th century, but which were now a genre in marked decline in Spain. The parody takes an unusual form. Its protagonist, an elderly gentleman addicted to reading these romances, goes out of his mind, believes them to have been historically true, and decides to become a knight-errant, to go out into the world and live his own romance of chivalry. The story of his career is presented in the form of a basically realistic novel. The formula proved to have a remarkable potential for exploitation.

Critical interpretation

The figures of Don Quixote, Sancho Panza, and Don Quixote's horse, Rosinante, immediately gripped the popular imagination, as their recorded appearances in festive parades from Peru to Germany between 1605 and 1617 testify. Contemporaries evidently did not take the book as seriously as later generations have done, but by the end of the century its stock had greatly risen, especially abroad. It came to be seen as a mock epic in prose, and the "grave and serious air" of the author's irony was much admired. The occasional esoteric interpretation of the work as disguised political or other satire began to appear. An increasingly sympathetic view of the hidalgo signaled the start of an interpretative transformation effected by the German Romantics. The ludicrous hero of the most comical of books became the tragic hero of the saddest. However, despite some distortion, Cervantes' novel now revealed its unsuspected depths. The way was opened to modern criticism, which has been remarkable for its diversity.

In the history of the modern novel the role of *Don Quixote* is recognized as seminal. Evidence of this may be seen in Defoe, Fielding, Smollett, and Sterne. Connections have been noticed with major works by a great many of the classic novelists of the 19th century, including Scott, Dickens, Flaubert, Pérez Galdós, Melville, and Dostoyevsky. And the same is true, in different ways, in the case of many post-realist writers of the 20th century, from Joyce to Borges. The explanation would seem to have less to do with "influence" than with Cervantes' having succeeded in tapping the core of the possibilities of the novel. In addition, *Don Quixote* has proved to be a remarkable source of inspiration to creators in other genres and media. From the 17th century onward, stage adaptations, operatic versions, ballets, and musical compositions have been made in considerable number, together with cinematic, television, and cartoon versions in the 20th century. *Don Quixote* has also inspired artists such as Hogarth, Goya, Daumier, and Picasso. The illustrations by Gustave Doré are perhaps the most celebrated.

MAJOR WORKS

PROSE FICTION: *Primera parte de la Galatea* (1585; *Galatea: A Pastoral Romance,* trans. by Gordon Willoughby James Gyll, 1867); *El ingenioso hidalgo Don Qvixote de la Mancha,* and *Segunda parte del ingenioso cavallero Don Qvixote de la Mancha* (1605, 1615; *The History of the Valorous and Wittie Knight-Errant Don Quixote of the Mancha,* trans. by Thomas Shelton, 1612–20); *Novelas exemplares* (1613; *Exemplarie Novells,* trans. by Don Diego Puede-Ser [James Mabbe], 1640); *Los trabaios de Persiles y Sigismunda, historia setentrional* (1617; *The Travels of Persiles and Sigismunda: A Northern History,* 1619).

DRAMA: *La Numancia* (1784; *Numantia, A Tragedy,* trans. by Gordon Willoughby James Gyll, 1870); *Ocho comedias, y ocho entremeses nuevos* (1615; *The Interludes of Cervantes,* trans. by S. Griswold Morley, 1948).

POETRY: *Viage del Parnaso* (1614; *Voyage to Parnassus,* trans. by Gordon Willoughby James Gyll, 1870).

Recommended editions include: *The History of the Renown'd Don Quixote de la Mancha,* trans. by Peter Motteux (1700–03); *The Life and Exploits of the Ingenious Gentleman Don Quixote de la Mancha,* trans. by Charles Jarvis (1742); *The History and Adventures of the Renowned Don Quixote,* trans. by Tobias Smollett (1755, reissued 1986); *The Ingenious Gentleman Don Quixote de la Mancha,* trans. by Samuel Putnam (1949); *The Adventures of Don Quixote,* trans. by J.M. Cohen (1950); *Don Quixote: The Ormsby Translation Revised, Background and Sources, Criticism,* ed. by Joseph R. Jones and Kenneth Douglas (1981); best modern Spanish annotated edition ed. by Luis Andrés Murillo, *Don Quixote de la Mancha,* 2nd ed. (1982); *Exemplary Novels,* trans. by N. Maccoll (1902). Selections include *The Deceitful Marriage, and Other Exemplary Novels,* trans. by Walter Starkie (1963); *Exemplary Stories,* trans. by C.A. Jones (1972); *The Wanderings of Persiles and Sigismunda: A Northern Story,* trans. by L.D. Stanley (1854); *The Siege of Numantia,* trans. by Roy Campbell (1959); *Comedias y entremeses,* ed. by Rodolfo Schevill and Adolfo Bonilla (1915–22), a modern Spanish edition; *Interludes,* trans. by Edwin Honig (1964); *Journey to Parnassus,* trans. by James Y. Gibson (1883). Complete works in Spanish in 1 vol., *Obras completas,* ed. by Angel Valbuena y Prat (1943).

(E.C.R.)

Charlemagne

Charlemagne (Carolus Magnus, Charles the Great) as king of the Franks (768–814) conquered the Lombard kingdom in Italy, subdued the Saxons, annexed Bavaria to his kingdom, fought campaigns in Spain and Hungary, and, with the exception of the Kingdom of Asturias in Spain, southern Italy, and the British Isles, united in one superstate practically all the Christian lands of western Europe. In 800 he assumed the title of emperor. (He is reckoned as Charles I of the Holy Roman Empire, as well as Charles I of France.) Besides expanding its political power, he also brought about a cultural renaissance in his empire. Although this *imperium* survived its founder by only one generation, the medieval kingdoms of France and Germany derived all their constitutional traditions from Charles's monarchy. Throughout medieval Europe, the person of Charles was considered the prototype of a Christian king and emperor.

Foundation of the dynasty

Early years. Charles was born probably in 742 (on April 2), the elder son of Pepin III, also called Pepin the Short. Pepin and his older brother, Carloman, had just jointly assumed the government of the Frankish kingdom as *maior domus,* or "mayor of the palace." The dynasty, later called Carolingian after Charlemagne, had originated in the Meuse-Moselle region on the borders of modern France, Germany, Belgium, and The Netherlands. In the course of a few generations, it had, as mayors of the palace to the Merovingians, gained control of the entire Frankish kingdom. Charlemagne's grandfather, Charles Martel, reconstituted a realm that had been on the point of breaking up, and, without infringing on the royal prerogatives of the otherwise powerless Merovingians, he had in effect bequeathed the empire to his sons, Pepin and Carloman, like a family inheritance.

Alliance with the papacy

Charles grew to manhood while his father was engaged in acquiring sole sovereignty and the kingship. On Carloman's retirement to a monastery, Pepin eliminated the latter's sons from the government. Having thus prepared the way, he had himself proclaimed king in 751, after dethroning the Merovingians. An oracular response by Pope Zacharias furnished the ecclesiastical approbation for thus shunting aside the former reigning house, which had been held sacred. Zacharias' successor, Stephen II, arrived in the Frankish kingdom during the winter of 753–754, in order to seek help against the Lombards who were attacking Rome. As the reigning monarch's oldest son, Charles, then about 12 years of age, travelled ahead to welcome the Pope, who anointed him king, along with his father and his brother Carloman, thus sanctioning the new dynasty. The political alliance between the Franks and the Pope against the Lombards was affirmed on the same occasion. When his father subdued Aquitaine (France south of the Loire) in a series of yearly campaigns beginning in 760, reasserting the integrity of the Frankish kingdom all the way to the Pyrenees, Charles repeatedly accompanied the army.

These youthful experiences probably contributed to the formation of Charles's character and to the formulation of his aims. He shared with his father an unbending will to power, a readiness to fight resolutely against external enemies and to increase his domains, and the determination to rule by himself even if it meant usurping the rights of close relatives. Charles early acknowledged the close connection between temporal power and the church; he had a high regard for the church and the king's duty to spread the Christian faith and, while asserting royal suzerainty over the church, considered himself accountable to God for the Christians entrusted to him.

King of the Franks. In accordance with old Frankish custom, the kingdom was divided on Pepin's death in 768 between his two sons. It was not long, however, before a strong rivalry sprang up between the brothers: with his mother's support, Charles concluded, with the Lombard king Desiderius, whose daughter he married, and with his cousin Duke Tassilo of Bavaria, alliances directed against Carloman.

Expansion in Italy

On Carloman's sudden death in 771, Charles was able to make himself sole ruler of the kingdom, unopposed by his young nephews, whose rights he ignored. When Carloman's widow with her children and a few remaining supporters had fled to the Lombard court, and King Desiderius, breaking his alliance with Charles, put pressure on the Pope to anoint Carloman's sons as Frankish kings, Charles was forced to come to the aid of Pope Adrian I. He marched on the Lombard capital, Pavia, and after its fall made himself king of the Lombards. His brother's sons, who had fallen into his hands, disappeared. While the siege of Pavia was still in progress, Charles journeyed to Rome, where he celebrated Easter 774 with the Pope and reiterated, in St. Peter's Basilica, his father's promise to transfer to papal rule large sections of Italy. But he actually enlarged the Pope's lands only slightly, assuming for himself the sovereignty over the entire Lombard kingdom.

Charles had fought the pagan Saxons, in what is now

Lower Saxony and Westphalia, in retribution for their attacks on the lower Rhine region, as early as 772, before the first Italian campaign. From 775 on, however, it was his goal to subdue the whole Saxon tribe, converting it to Christianity and integrating it into his kingdom. This aim appeared to have been realized after several campaigns culminating in declarations of allegiance by the Saxon nobility and mass baptisms performed in 775–777. A diet held in 777 in Paderborn sealed the submission of the Saxons. Among those attending the diet had been some Arab emissaries from northern Spain who sought Charles's aid in their uprising against the Umayyad *amir* of Córdoba. In the summer of 778 Charles advanced into Spain and laid siege to Saragossa, without, however, being able to take the city. Retreating across the Pyrenees, the Frankish army was badly mauled by the Basques. Roland, warden of the Breton march, who died on this occasion, was later immortalized in legend and poetry.

This defeat marks the end of the first period of Charles's rule, the period of vigorous expansion. Within a decade he had become the sole ruler of the Franks, conquered the Lombard kingdom, visited Rome, subdued the Saxons, invaded Spain. Henceforth he was concerned with defending and safeguarding his quickly won gains (which were to be extended only on the right bank of the Rhine), while consolidating the state internally and protecting cultural life and the rule of law.

Subjugation of the Saxons

Not long after Charles's defeat in Spain, the Saxons rose up once more. The war against them became the longest and most cruel war fought by the Franks. In Charles's eyes, the resistance of this people that had undergone baptism and signed a treaty of allegiance amounted to political high treason and religious apostasy. These offenses called for severe punishment, and 4,500 Saxons were reported to have been executed en masse in 782. New outbreaks occurred after 792, and the last Saxons were not vanquished until 804. Between 772 and 804, Charles took the field against the Saxons no fewer than 18 times. In the end he carried out his aim of not only subjecting them to his rule but also incorporating them fully into his empire. Given the indissoluble tie between temporal power and the Christian faith, this meant they had to be converted. But the violent methods by which this missionary task was carried out had been unknown to the earlier Middle Ages, and the sanguinary punishment meted out to those who broke canon law or continued to engage in pagan practices called forth criticism in Charles's own circle, for example by Alcuin, his adviser and head of his palace school.

When, in 788, Charles deposed his cousin Duke Tassilo III of Bavaria, who had acknowledged the Frankish kings as feudal lords, he in effect deprived of its independence the last of the German tribes beyond the Rhine. The Bavarians, who had long been Christians, were now directly integrated into the empire. The West Germanic tribes of the Alemanni, Bavarians, Saxons, and Thuringians thus found themselves for the first time gathered into one political unit. Charles's conquests on the right bank of the Rhine were, however, not limited to the Germanic tribes. Making Ratisbon (Regensburg), the residence of the Bavarian dukes, his base, he conducted several campaigns, partly under his own command, against the Avar kingdom (in modern Hungary and Upper Austria). The remaining Avar principalities and the newly founded Slav states of the Danubian region drifted into a loose dependence on the Franks, whose sovereignty they more or less acknowledged.

The gigantic expansion of the Frankish state, raising it far above the tribal states of the early Middle Ages, entailed qualitative as well as quantitative changes. Yet the idea of bestowing on Charles the Roman title of emperor arose only at a very late stage and out of a specific political constellation. While the Eastern, or Byzantine, Empire laid claim to universal recognition, the popes, constitutionally still subjects of Byzantium, were opposed to the iconoclastic religious policies of the Eastern emperors. Moreover, under the protection of Charles, Pope Adrian sought to erect an autonomous domain over central Italy, the more so as the Byzantines, abandoning for all practical purposes Rome and Ravenna, were asserting their rule only in Sicily and the southernmost edge of Italy. The papacy's desire for independence found a significant expression in the Donation of Constantine, a forgery dating probably from the first few years of Adrian's reign and purporting to legitimize these papal aims in the name of the first Christian emperor, Constantine I the Great. Charles paid a second visit to Rome in 781, when he had the Pope crown his young sons Pepin and Louis as kings of the Lombards and Aquitanians and gained de facto recognition of his Italian position from the Byzantine empress Irene, the mother of Constantine VI. The entente that existed between Charles and Byzantium came to an end after a Frankish attack on southern Italy in 787.

Emperor of the West. In the end, local Roman conflicts brought about the clarification of the city's constitutional position. In May 799, Pope Leo III was waylaid in Rome by personal enemies. He took refuge at the court of Charles, who had him conducted back to the city and who in November 800 came to Rome himself, where he was received with imperial honours. Before Charles and a synod, Pope Leo cleared himself under oath of the charges made by his enemies. During Christmas mass in St. Peter's, the Romans acclaimed Charles emperor, whereupon the Pope crowned and perhaps anointed him.

Coronation in Rome

The imperial title was by nature a Roman dignity. While the acclamation represented the juridically conclusive act, it was the coronation at the hands of the Pope that, though of no constitutional importance, was to acquire for the Franks great significance. The Pope had been determined to make Charles emperor, deciding to a large extent the outward form; yet Charles was surely not surprised by these events. His famous statement quoted by one of his favourites, the Frankish historian Einhard, that he would not have set foot in church that Christmas if he had known the Pope's intention, implies a criticism of the ceremony initiated by the Pope, as well as a formal expression of humility. The crowning had been preceded by negotiations. While Charles's imperial rank was legally substantiated by the fact of his dominion over the western part of the old Roman Empire, the desire to counteract the petticoat rule of the empress Irene (who had dethroned and blinded her son in 797) also played a role. Residing in Rome four months and pronouncing sentence on the Pope's enemies as rebels guilty of lese majesty, Charles grasped the imperial reins with a firm hand. Likewise, after his return to Aachen (Aix-la-Chapelle), he promulgated laws in full consciousness of his rank as emperor.

Byzantium braced itself for the usurper's attack, but Charles merely wished to see his new rank and his dominion over Rome recognized in negotiations; he gained his point in 812 when the emperor Michael I acknowledged him as emperor, though not as emperor of the Romans. While the imperial title did not bring Charles any additional powers, his control of Rome was now legitimized, and the estrangement of the papacy from Byzantium and its rapprochement with the Franks, a major historical event that had been initiated in 754, was rendered incontrovertible. A significant result of this development was the tradition to which Charles's assumption of the imperial title and function gave rise: all medieval concepts of empire and all the bonds between the constitutional traditions of the Franks and the later Holy Roman Empire with the Roman Empire founded by Augustus were based on the precedent of Charles's imperial title and position.

Court and administration. The creation of the empire was chiefly legitimized by Charles's efforts to raise its cultural level internally. When Charles came to power, the Frankish kingdom's cultural, administrative, and legal institutions were still relatively undeveloped. The Frankish king, for example, possessed no permanent residence. In the summer months he travelled about, deciding political issues and dispensing justice in assemblies of spiritual and temporal lords; above all, summer was the season for military campaigns. During the winter, from Christmas to Easter and sometimes longer, the king lived and held court at one of the imperial palaces. Charles especially favoured those situated in the Frankish heartland: only rarely did he spend the winter in one of the newly won territories, in encampment in Saxony, in Ratisbon, or in Rome. Not

Charles's peripatetic court

until 794 did Aachen, which the aging monarch liked because of its warm springs, become the court's abode, indeed almost a residence, during every winter and often even in summer. Here Charles built, partially with materials imported from Rome and Ravenna, the court church that is still standing, as well as the palace whose walls were incorporated into the 14th-century city hall.

Charles's court consisted of his family, of the clergy in his personal service, who were called the king's *capella,* and of temporal officials, among them the count palatine, the seneschal, and the master of the royal household. These men were occasionally joined, on an informal basis, by other spiritual or temporal men of rank who spent some time in the ruler's presence. For Charles had the ambition to make his court the intellectual, as well as the political and administrative, centre of the realm and accordingly summoned prominent scholars from all parts of the empire and even from abroad. Among these the most important were Einhard and Alcuin.

With the help of these and other literary men, Charles established a court library containing the works of the Church Fathers and those of ancient authors, and he founded a court academy for the education of young Frankish knights. Last but not least, he himself took part with his family and the learned and lay members of his entourage in a cultivated social life that afforded him entertainment no less than instruction. His mother tongue was an Old High German idiom, besides which he presumably understood the Old French dialect spoken by many Franks; as a grown man, he also learned Latin and some Greek, had historical and theological writings, including St. Augustine's *City of God,* read aloud to him, and acquired a rudimentary knowledge of mathematics and astronomy.

The Carolingian renaissance

The court's cultural interests, however, extended beyond the intellectual gratification of a small circle, such as the exchange of verses and letters. Efforts were also made to raise the level of religious observance, morality, and the process of justice throughout the empire. The clearest and most famous instance of this was the *Epistula de litteris colendis,* dating presumably from 784 to 785 and compiled in Charles's name by Alcuin. Its main argument lies in the assertion that the right faith—indeed, every right thought—must be clothed in the appropriate form and language, lest it be falsified; hence, the prescription of intensive study of Latin language and literature for all monastic and cathedral schools. The spiritual and literary movement called the "Carolingian renaissance" had many centres, especially in the empire's monasteries; but it cannot be evaluated without reference to Charles's court and to his endeavour to call on the best minds of the whole world, setting them to work in the education of the clergy and, in the final instance, of the whole people. The court's theological knowledge and intellectual self-confidence are reflected in the *Libri Carolini,* a comprehensive treatise written about 791 in Charles's name and directed against the Council of Nicaea (787), at which Greeks and papal plenipotentiaries had countenanced the practice of iconolatry; at the same time, the *Libri Carolini* did not spare the iconoclasts.

Through this court, Charles ruled and administered his empire and dispensed justice. Once or twice a year at least, the court and the chief magistrates and nobles from all parts of the empire joined in a general assembly held either in the Frankish heartland or in one of the conquered territories. It is indicative of the unique structure of the Carolingian Empire that one cannot draw clear distinctions between an assembly of the armed forces, a constitutional assembly of the nobility, and a church synod: juridical, military, and ecclesiastical affairs were invariably discussed at one and the same time by the representatives of the nobility and the clergy. Above them all towered the figure of Charlemagne.

Internal administration

On the local level the ruler was represented in every region by counts and bishops. Liaison between these personages and the court was maintained through royal messengers who travelled about at Charles's command, usually in pairs made up of a civil servant and a clerical dignitary. Royal commands did not have to be written out, although Charles's decrees (capitularies) increasingly came to be recorded in writing, at first rather imprecisely, in the last two decades of his reign; the forms coined by the "renaissance" gained ground only with time. Charles respected the traditional rights of the various peoples and tribes under his dominion as a matter of principle, and, after he became emperor, he had many of them recorded. The capitularies served partly as complements to tribal laws, partly as regulations applying to the most disparate aspects of public and private life, and in part also as specific instructions issued to royal messengers, counts, bishops, and others. Punitive decrees against highwaymen, dispositions concerning military levies, orders for the people to take an oath of allegiance to the emperor or to teach all Christians to recite the Lord's Prayer, are found intermingled in the capitularies with jurisdictional dispositions and regulations about the internal organization of monasteries; temporal and spiritual problems are rarely treated separately. Taken as a whole, the legal documents of Charles's reign bear witness to a great concern, born of profound moral and religious convictions, with the administration of justice and with public enlightenment, but they also show discrepancies between the ideal and reality.

Conspiracies

Limitations of his rule. Charles's organization of the empire was, however, not without its defects and limitations. The sovereign's power was restricted only by theoretical principles of law and custom, not by institutions or countervailing forces. Significantly, the records report little about opposition movements and conspiracies, which, in fact, did exist. A rebellion that Thuringian counts launched against Charles in 786 can perhaps be explained as ethnic opposition to the centralism of the Franks. More ominous was an aristocratic conspiracy that in 792 attempted to place on the throne the hunchback Pepin, Charles's only son from his first marriage, which was later declared invalid; yet here, too, the political concepts and motives remain unknown. These events and, more clearly still, the history of the empire under Charles's successor, Louis, show the extent to which the political system had been designed for one person on whose outstanding abilities everything depended and with whose disappearance it threatened to collapse. Their self-confidence enhanced by Charles's educational policy, the clergy could not accept for all time his theocracy without opposing it with their own political and religious principles. The temporal nobility that had built the empire with the Carolingians could be firmly tied to the dynasty only as long as new conquests held out the prospect of new spoils and fiefs; if these failed to materialize, there remained only the care of one's properties in the different regions and the hope of gaining advantages from party strife. External expansion, however, could not advance substantially beyond the borders reached by 800; in fact, economic and technical resources were insufficient to hold together and administer what had already been won and to defend it against foreign enemies. Charles's empire lacked the means by which the Romans had preserved theirs: a money economy, a paid civil service, a standing army, a properly maintained network of roads and communications, a navy for coastal defense. Already in Charles's lifetime, the coasts were being threatened by the Normans. In 806 Charles planned a division of the empire between his sons, but after the death of the elder two he crowned Louis of Aquitaine his coemperor and sole successor at Aachen in 813. It was only a few months later that Charles himself died there on January 28, 814.

Personality and influence. Charlemagne's posthumous fame shone the more brightly as the following generations were unable to preserve the empire's internal peace, its unity, and its international position. Even after the Carolingian dynasty had become extinct, political tradition in the East Frankish (German) kingdom and empire, as well as in the West Frankish (French) kingdom, drew sustenance from the example set by Charlemagne. Under Otto I, Aachen became the city in which the rulers of Germany were crowned, and, at Frederick I Barbarossa's request, the antipope Paschal III canonized Charlemagne in 1165. In France the Capetians, beginning with Philip II Augustus, revived the traditions that had grown up around Charlemagne. The controversial question whether the Germans or the French were the true successors of Charlemagne was kept alive through the Middle Ages and into modern times. Napoleon called himself Charlemagne's successor; after the end of World War II, discussions of a united, Christian, "occidental" Europe invoked his model. Hand in hand with these political traditions went those in popular legend and poetry, culminating in the Roland epics. Nor did Charlemagne's fame stop at the boundaries of what was once his empire; some Slavic languages derived their term for "king" from his name (Czech *král,* Polish *król,* etc.).

Charles left no biographical document; his personality can be constructed only from his deeds and the reports left by contemporaries. This is how Einhard, who lived at the court from about 795 on, described Charlemagne's character and appearance in his famous *Vita Karoli Magni:* "He had a broad and strong body of unusual height, but well-proportioned; for his height measured seven times his feet. His skull was round, the eyes were lively and rather large, the nose of more than average length, the hair gray but full, the face friendly and cheerful. Seated or standing, he thus made a dignified and stately impression even though he had a thick, short neck and a belly that protruded somewhat; but this was hidden by the good proportions of the rest of his figure. He strode with firm step and held himself like a man; he spoke with a higher voice than one would have expected of someone of his build. He enjoyed good health except for being repeatedly plagued by fevers four years before his death. Toward the end he dragged one foot."

Character and appearance

The strength of Charlemagne's personality was evidently rooted in the unbroken conviction of being at one with the divine will. Without inward contradiction, he was able to combine personal piety with enjoyment of life, a religious sense of mission with a strong will to power, rough manners with a striving for intellectual growth, and intransigence against his enemies with rectitude. In his politically conditioned religiosity, the empire and the church grew into an institutional and spiritual unit. Although his empire survived him by only one generation, it contributed decisively to the eventual reconstitution, in the mind of a western Europe fragmented since the end of the Roman Empire, of a common intellectual, religious, and political inheritance on which later centuries could draw. Charlemagne did not create this inheritance single-handedly, but one would be hard put to imagine it without him. One of the poets at his court called him *rex pater Europae*—"King father of Europe." In truth, there is no other man who similarly left his mark on European history during the centuries of the Middle Ages. (P.Cla.)

ZEYDEL (1972, reissued 1985), the famous biography of one of Charlemagne's closest collaborators—a character analysis rather than an account of events; DONALD A. BULLOUGH, *The Age of Charlemagne,* 2nd ed. (1973, reissued 1980), a modern presentation for the general reader by a good specialist; "Europae Pater: Charlemagne and His Achievement in the Light of Recent Scholarship," *English Historical Review,* 85:59–105 (1970), a report on contemporary scholarship; HEINRICH FICHTENAU, *The Carolingian Empire* (1957, reprinted 1978; originally published in German, 1949); *Karl der Grosse: Lebenswerk und Nachleben,* ed. by WOLFGANG BRAUNFELS, 3rd ed., 5 vol. (1967–68), an international compendium of 74 contributions by various experts (mostly in German with some articles in French, English, and Italian); FRIEDRICH HEER, *Charlemagne and His World* (1975), a well-illustrated life for the general reader; and ROBERT FOLZ, *Coronation of Charlemagne* (1974; originally published in French, 1964), a history of his antecedents and a study of his influence on both contemporaries and successors.

Chaucer

Geoffrey Chaucer, the outstanding English writer before Shakespeare, is among England's greatest poets. He contributed importantly in the second half of the 14th century to the management of public affairs as courtier, diplomat, and civil servant. In that career he was trusted and aided by three successive kings—Edward III, Richard II, and Henry IV. But it is his avocation—the writing of poetry—for which he is remembered. Perhaps the chief characteristics of Chaucer's works are their variety in subject matter, genre, tone, style, and in the complexities presented concerning man's pursuit of a sensible existence. Yet his writings also consistently reflect an all-pervasive humour, combined with serious and tolerant consideration of important philosophical questions. From his writings Chaucer emerges as poet of love, both earthly and divine, whose presentations range from lustful cuckoldry to spiritual union with God. Thereby, they regularly lead the reader to speculation about man's relation both to his fellows and to his Maker, while simultaneously providing delightfully entertaining views of the frailties and follies, as well as the nobility, of mankind.

Chaucer, portrait miniature painted after the poet's death. In the British Museum (Harley Ms. 4866).

Forebears and early years. Chaucer's forebears for at least four generations were middle-class English people whose connection with London and the court had steadily increased. John Chaucer, his father, was an important London vintner and a deputy to the king's butler; in 1338 he was a member of Edward III's expedition to Antwerp, in Flanders, now part of Belgium, and he owned property in Ipswich, in the county of Suffolk, and in London. He died in 1366 or 1367 at the age of 53. The name Chaucer is derived from the French word *chaussier,* meaning a maker of footwear. The family's financial success derived from wine and leather.

Although *c.* 1340 is customarily given as Chaucer's birth date, 1342 or 1343 is probably a closer guess. No information exists concerning his early education, although doubtless he would have been as fluent in French as in the Middle English of his time. He also became competent in Latin and Italian. His writings show his close familiarity with many important books of his time and of earlier times.

Chaucer first appears in the records in 1357, as a member of the household of Elizabeth, countess of Ulster, wife of Lionel, third son of Edward III. Geoffrey's father presumably had been able to place him among the group of young men and women serving in that royal household, a customary arrangement whereby families who could do so provided their children with opportunity for the necessary courtly education and connections to advance their careers. By 1359 Chaucer was a member of Edward III's army in France and was captured during the unsuccessful siege of Reims. The King contributed to his ransom, and Chaucer served as messenger from Calais to England during the peace negotiations of 1360. Chaucer does not appear in any contemporary record during 1361–65. He was probably in the King's service, but he may have been studying law—a not unusual preparation for public service, then as now—since a 16th-century report implies that, while so engaged, he was fined for beating a Franciscan friar in a London street. On February 22, 1366, the King of Navarre issued a certificate of safe-conduct for Chaucer, three companions, and their servants to enter Spain. This occasion is the first of a number of diplomatic missions to the continent of Europe over the succeeding 10 years, and the wording of the document suggests that here Chaucer served as "chief of mission."

Capture at the siege of Reims

By 1366 Chaucer had married. Probably his wife was Philippa Pan, who had been in the service of the Countess of Ulster, and who entered the service of Philippa of Hainaut, queen consort of Edward III, when Elizabeth died in 1363. In 1366 Philippa Chaucer received an annuity, and later annuities were frequently paid to her through her husband. These and other facts indicate that Chaucer married well.

In 1367 Chaucer received an annuity for life as yeoman of the king, and in the next year he was listed among the King's esquires. Such officers lived at court and performed staff duties of considerable importance. In 1368 Chaucer was abroad on a diplomatic mission, and in 1369 he was on military service in France. Also in 1369 he and his wife were official mourners for the death of Queen Philippa. Obviously, Chaucer's career was prospering, and his first important poem—*Book of the Duchess*—seems further evidence of his connection with persons in high place.

First important poem

That poem of more than 1,300 lines, probably written in late 1369 or early 1370, is an elegy for Blanche, duchess of Lancaster, John of Gaunt's first wife, who died of plague in September 1369. Chaucer's close relationship with John, which continued through most of his life, may have commenced as early as Christmas 1357 when they, both about the same age, were present at the Countess of Ulster's residence in Yorkshire. For this first of his important poems, Chaucer used the dream-vision form, a genre made popular by the highly influential 13th-century French poem of courtly love, the *Roman de la rose.* Chaucer translated that poem, at least in part, probably as one of his first literary efforts, and he borrowed from it throughout his poetic career. The *Duchess* is also indebted to contemporary French poetry and to Ovid, Chaucer's favourite Roman poet. Nothing in these borrowings, however, will account for his originality in combining dream-vision with elegy and eulogy of Blanche with consolation for John. Also noteworthy here—as it increasingly became in his later poetry—is the tactful and subtle use of a first-person narrator, who both is and is not the poet himself. The device had obvious advantages for the minor courtier delivering such a poem orally before the high-ranking court group. In addition, the *Duchess* foreshadows Chaucer's skill at presenting the rhythms of natural conversation within the confines of Middle English verse and at creating realistic characters within courtly poetic conventions. Also, Chaucer here begins, with the Black Knight's account of his love for Good Fair White, his career as a love poet, examining in late medieval fashion the important philosophic and religious questions concerning the human condition as they relate to both temporal and eternal aspects of love.

Diplomat and civil servant. During the decade of the 1370s, Chaucer was at various times on diplomatic missions in Flanders, France, and Italy. Probably his first Italian journey (December 1372 to May 1373) was for negotiations with the Genoese concerning an English port for their commerce, and with the Florentines concerning loans for Edward III. His next Italian journey occupied May 28 to September 19, 1378, when he was a member of a mission to Milan concerning military matters. Several times during the 1370s, Chaucer and his wife received generous monetary grants from the King and from John of Gaunt. On May 10, 1374, he obtained rent free a dwelling above Aldgate, in London, and on June 8 of that year he was appointed comptroller of the customs and subsidy of wools, skins, and tanned hides for the Port of London. Now, for the first time, Chaucer had a position away from the court, and he and his wife had a home of their own, about a 10-minute walk from his office. In 1375 he was granted two wardships, which paid well, and in 1376 he received a sizable sum from a fine. When Richard II became king in June 1377, he confirmed Chaucer's comptrollership and, later, the annuities granted by Edward III to both Geoffrey and Philippa. Certainly during the 1370s fortune smiled upon the Chaucers.

Appointment as comptroller of the customs

So much responsibility and activity in public matters appears to have left Chaucer little time for writing during this decade. The great literary event for him was that, during his missions to Italy, he encountered the work of Dante, Petrarch, and Boccaccio, which was later to have profound influence upon his own writing. Chaucer's most important work of the 1370s was *Hous of Fame,* a poem of more than 2,000 lines, also in dream-vision form. In some ways it is a failure: it is unfinished, its theme is unclear, and the diversity of its parts seems to overshadow any unity of purpose; but it gives considerable evidence of Chaucer's advancing skill as a poet. The eight-syllable metre is handled with great flexibility; the light, bantering, somewhat ironic tone—later to become one of Chaucer's chief effects—is established; and a wide variety of subject matter is included. Further, the later mastery in creation of memorable characters is here foreshadowed by the marvellous golden eagle who carries the frightened narrator, "Geoffrey," high above the Earth to the houses of Fame and Rumour, so that as a reward for his writing and studying he can learn "tydings" to make into love poems. Here, too, Chaucer's standard picture of his own fictional character emerges: the poet, somewhat dull-witted, dedicated to writing about love but without successful personal experience of it. The comedy of the poem reaches its high point when the pedantic eagle delivers for Geoffrey's edification a learned lecture on the properties of sound. In addition to its comic aspects, however, the poem seems to convey a serious note: like all earthly things, fame is transitory and capricious.

The middle years: political and personal anxieties. In a deed of May 1, 1380, one Cecily Chaumpaigne released Chaucer from legal action: "both of my rape and of any other matter or cause." Rape (*raptus*) could at the time mean either sexual assault or abduction; scholars have not been able to establish which meaning applies here, but, in either case, the release suggests that Chaucer was not guilty as charged. He continued to work at the Customs House and in 1382 was additionally appointed comptroller of the petty customs for wine and other merchandise; but in October 1386 his dwelling in London was leased to another man, and, in December of that year, successors were named for both of his comptrollerships in the customs—whether he resigned or was removed from office is not clear. Between 1382 and 1386 he had arranged for deputies—permanent in two instances and temporary in others—in his work at the customs. In October 1385 he was appointed a justice of the peace for Kent, and in August 1386 he became knight of the shire for Kent, to attend Parliament in October. Further, in 1385 he probably moved to Greenwich, then in Kent, to live. These circumstances suggest that, for some time before 1386, he was planning to move from London and to leave the Customs House. Philippa Chaucer apparently died in 1387; if she had suffered poor health for some time previously, that situation could have influenced a decision to move. On the other hand, political circumstances during this period were not favourable for Chaucer and may have caused his removal. By 1386 a baronial group led by Thomas of Woodstock, duke of Gloucester, had bested both Richard II and John of Gaunt—with whose parties Chaucer had long been associated—and usurped the King's authority and administration. Numerous other officeholders—like Chaucer, appointed by the King—were discharged, and Chaucer may have suffered similarly. Perhaps the best view of the matter is that Chaucer saw which way the political wind was blowing and began early to prepare to move when the necessity arrived.

The period 1386–89 was clearly difficult for Chaucer. Although he was reappointed justice of the peace for 1387, he was not returned to Parliament after 1386. In 1387 he was granted protection for a year to go to Calais, in France, but seems not to have gone, perhaps because of his wife's death. In 1388 a series of suits against him for debts began, and he sold his royal pension for a lump sum. Also, from February 3 to June 4, 1388, the Merciless Parliament, controlled by the barons, caused many leading members of the court party—some of them Chaucer's close friends—to be executed. In May 1389, however, the 23-year-old King Richard II regained control, ousted his enemies, and began appointing his supporters to office. Almost certainly, Chaucer owed his next public office to that political change. On July 12, 1389, he was appointed clerk of the king's works, with executive responsibility for repair and maintenance of royal buildings, such as the Tower of London and Westminster Palace, and with a comfortable salary.

Although political events of the 1380s, from the Peasants' Revolt of 1381 through the Merciless Parliament of 1388, must have kept Chaucer steadily anxious, he produced a sizable body of writings during this decade, some of very high order. Surprisingly, these works do not in any way reflect the tense political scene. Indeed, one is tempted to speculate that during this period Chaucer turned to his reading and writing as escape from the difficulties of his public life. The *Parlement of Foules,* a poem of 699 lines, is a dream-vision for St. Valentine's Day, making use of the myth that each year on that day the birds gathered before the goddess Nature to choose their mates. Beneath its playfully humorous tone, it seems to examine the value of various kinds of love within the context of "common profit" as set forth in the introductory abstract from the *Somnium Scipionis* (*Dream of Scipio*) of Cicero. The narrator searches unsuccessfully for an answer and concludes that he must continue his search in other books. For this poem Chaucer also borrowed extensively from Boccaccio and Dante, but the lively bird debate from which the poem takes its title is for the most part original. The poem has often been taken as connected with events at court, particularly the marriage, in 1382, of Richard II and Anne of Bohemia. But no such connection has ever been firmly established. The *Parlement* is clearly the best of Chaucer's earlier works.

Composition of the *Parlement of Foules*

The Consolation of Philosophy, written by the Roman philosopher Boethius (early 6th century), a Christian, was one of the most influential of medieval books. Its discussion of free will, God's foreknowledge, destiny, fortune, and true and false happiness—in effect, all aspects of the manner in which the right-minded individual should direct his thinking and action to gain eternal salvation—had a deep and lasting effect upon Chaucer's thought and art. His prose translation of the *Consolation* is carefully done, and in his next poem—*Troilus and Criseyde*—the influence of Boethius' book is pervasive. Chaucer took the basic plot for this 8,239-line poem from Boccaccio's *Filostrato.*

Some critics consider *Troilus and Criseyde* Chaucer's finest work, greater even than the far more widely read *Canterbury Tales.* But the two works are so different that comparative evaluation seems fruitless. The state of the surviving manuscripts of *Troilus* shows Chaucer's detailed effort in revising this poem. Against the background of the legendary Trojan War, the love story of Troilus, son

Theme of *Troilus and Criseyde*

of the Trojan king Priam, and Criseyde, widowed daughter of the deserter priest Calkas, is recounted. The poem moves in leisurely fashion, with introspection and much of what would now be called psychological insight dominating many sections. Aided by Criseyde's uncle Pandarus, Troilus and Criseyde are united in love about halfway through the poem; but then she is sent to join her father in the Greek camp outside Troy. Despite her promise to return, she gives her love to the Greek Diomede, and Troilus, left in despair, is killed in the war. These events are interspersed with Boethian discussion of free will and determinism. At the end of the poem, when Troilus' soul rises into the heavens, the folly of complete immersion in sexual love is viewed in relation to the eternal love of God. The effect of the poem is controlled throughout by the direct comments of the narrator, whose sympathy for the lovers—especially for Criseyde—is ever present.

Failure of the *Legend of Good Women*

Also in the 1380s Chaucer produced his fourth and final dream-vision poem, the *Legend of Good Women,* which is not a success. It presents a "Prologue," existing in two versions, and nine stories. In the "Prologue" the god of love is angry because Chaucer had earlier written about so many women who betrayed men. As penance, Chaucer must now write about good women. The "Prologue" is noteworthy for the delightful humour of the narrator's self-mockery and for the passages in praise of books and of the spring. The stories—concerning such women of antiquity as Cleopatra, Dido, and Lucrece—are brief and rather mechanical, with the betrayal of women by wicked men as a regular theme; as a result, the whole becomes more a legend of bad men than of good women. Perhaps the most important fact about the *Legend,* however, is that it shows Chaucer structuring a long poem as a collection of stories within a framework. Seemingly the static nature of the framing device for the *Legend* and the repetitive aspect of the series of stories with a single theme led him to give up this attempt as a poor job. But the failure here must have contributed to his brilliant choice, probably about this same time, of a pilgrimage as the framing device for the stories in *The Canterbury Tales.*

Last years. Chaucer's service as clerk of the king's works lasted only from July 1389 to June 1391. During that tenure he was robbed several times and once beaten, sufficient reason for seeking a change of jobs. In June 1391 he was appointed subforester of the king's park in North Petherton, Somerset, an office that he held until his death. He retained his home in Kent and continued in favour at court, receiving royal grants and gifts during 1393–97. The records show his close relationship during 1395–96 with John of Gaunt's son the Earl of Derby, later King Henry IV. When John died in February 1399, King Richard confiscated John's Lancastrian inheritance; then in May he set forth to crush the Irish revolt. In so doing, he left his country ready to rebel. Henry, exiled in 1398 but now duke of Lancaster, returned to England to claim his rights. The people flocked to him, and he was crowned on September 30, 1399. He confirmed Chaucer's grants from Richard II and in October added an additional generous annuity. In December 1399 Chaucer took a lease on a house in the garden of Westminster Abbey. But on October 25, 1400, he died. He was buried in the Abbey, a signal honour for a commoner.

The Canterbury Tales

Chaucer's great literary accomplishment of the 1390s was *The Canterbury Tales.* In it a group of about 30 pilgrims gather at the Tabard Inn in Southwark, across the Thames from London, and agree to engage in a storytelling contest as they travel on horseback to the shrine of Thomas à Becket in Canterbury, Kent, and back. Harry Bailly, host of the Tabard, serves as master of ceremonies for the contest. The pilgrims are introduced by vivid brief sketches in the "General Prologue." Interspersed between the 24 tales told by the pilgrims are short dramatic scenes presenting lively exchanges, called links and usually involving the host and one or more of the pilgrims. Chaucer did not complete the full plan for his book: the return journey from Canterbury is not included, and some of the pilgrims do not tell stories. Further, the surviving manuscripts leave room for doubt at some points as to Chaucer's intent for arranging the material. The work is, nevertheless, sufficiently complete to be considered a unified book rather than a collection of unfinished fragments. Use of a pilgrimage as a framing device for the collection of stories enabled Chaucer to bring together people from many walks of life: knight, prioress, monk; merchant, man of law, franklin, scholarly clerk; miller, reeve, pardoner; wife of Bath and many others. Also, the pilgrimage and the storytelling contest allowed presentation of a highly varied collection of literary genres: courtly romance, racy fabliau, saint's life, allegorical tale, beast fable, medieval sermon, alchemical account, and, at times, mixtures of these genres. Because of this structure, the sketches, the links, and the tales all fuse as complex presentations of the pilgrims, while, at the same time, the tales present remarkable examples of short stories in verse, plus two expositions in prose. In addition, the pilgrimage, combining a fundamentally religious purpose with its secular aspect of vacation in the spring, made possible extended consideration of the relationship between the pleasures and vices of this world and the spiritual aspirations for the next, that seeming dichotomy with which Chaucer, like Boethius and many other medieval writers, was so steadily concerned.

For this crowning glory of his 30 years of literary composition, Chaucer used his wide and deep study of medieval books of many sorts and his acute observation of daily life at many levels. He also employed his detailed knowledge of medieval astrology and subsidiary sciences as they were thought to influence and dictate human behaviour. Over the whole expanse of this intricate dramatic narrative, he presides as Chaucer the poet, Chaucer the civil servant, and Chaucer the pilgrim: somewhat slow-witted in his pose and always intrigued by human frailty but always questioning the complexity of the human condition, always seeing both the humour and the tragedy in that condition, and always trying to discover the right way for existence on this Earth. At the end, in the "Retractation" with which *The Canterbury Tales* closes, Chaucer as poet and pilgrim states his conclusion that the concern for this world fades into insignificance before the prospect for the next; in view of the admonitions in "The Parson's Tale," he asks forgiveness for his writings that concern "worldly vanities" and remembrance for his translation of the *Consolation* and his other works of morality and religious devotion. On that note he ends his finest work and his career as poet.

Descendants and posthumous reputation. Information concerning Chaucer's children is not fully clear. The probability is that he and Philippa had two sons and two daughters. One son, Thomas Chaucer, who died in 1434, owned large tracts of land and held important offices in the 1420s, including the forestership of North Petherton. He later leased Chaucer's house in Westminster, and his twice-widowed daughter Alice became duchess of Suffolk. In 1391 Chaucer had written *Treatise on the Astrolabe* for "little Lewis," probably his younger son, then 10 years old. Elizabeth "Chaucy," probably the poet's daughter, was a nun at Barking in 1381. A second probable daughter, Agnes Chaucer, was a lady-in-waiting at Henry IV's coronation in 1399. The records lend some support to speculation that John of Gaunt fathered one or more of these children. Chaucer seems to have had no descendants living after the 15th century.

For Chaucer's writings the subsequent record is clearer. His contemporaries praised his artistry, and a "school" of 15th-century Chaucerians imitated his poetry. Over the succeeding centuries, his poems, particularly *The Canterbury Tales,* have been widely read, translated into modern English, and, since about the middle of the 19th century, the number of scholars and critics who devote themselves to the study and teaching of his life and works has steadily increased. (R.M.Lu.)

MAJOR WORKS

Information concerning dates of composition of the extant manuscripts, and of the first printings of the works can be found in the book by Hammond cited in the Bibliography.

LONGER POEMS (in probable order of composition): *Book of the Duchess; Hous of Fame* (unfinished); *Parlement of Foules; Troilus and Criseyde; Legend of Good Women;* prologue, two versions; *The Canterbury Tales;* consisting of The Prologue

(The General Prologue), "The Knight's Tale," "The Miller's Tale," "The Reeve's Tale," "The Cook's Tale," "The Man of Law's Tale," "The Wife of Bath's Tale," "The Friar's Tale," "The Summoner's Tale," "The Clerk's Tale," "The Merchant's Tale," "The Squire's Tale," "The Franklin's Tale," "The Second Nun's Tale," "The Canon's Yeoman's Tale," "The Physician's Tale," "The Pardoner's Tale," "The Shipman's Tale," "The Prioress's Tale," "The Tale of Sir Thopas" and "The Tale of Melibeus" (Chaucer's contributions to the tales told by his fellow-pilgrims, the latter in prose), "The Monk's Tale," "The Nun's Priest's Tale," "The Manciple's Tale," and "The Parson's Tale" (in prose), and ending with Chaucer's "Retractation."

Not all the tales are complete; several contain their own prologues.

SHORTER POEMS: *Anelida and Arcite* (unfinished); *Complaint of Chaucer to his Empty Purse; Lines to Adam Scriven,* his scribe; *Truth, Fortune,* and *Gentilesse;* and letters in verse to Henry Scogan and to Buxton.

PROSE: *The Consolation of Philosophy (Boethius)* (trans. from Boethius' *De consolatione philosophiae); Treatise on the Astrolabe.*

BIBLIOGRAPHY. Complete reference to publications concerning Chaucer and his works is provided by the following: ELEANOR P. HAMMOND, *Chaucer: A Bibliographical Manual* (1908, reprinted 1933); DUDLEY D. GRIFFITH, *Bibliography of Chaucer, 1908–1953* (1955); WILLIAM R. CRAWFORD, *Bibliography of Chaucer, 1954–63* (1967); in the Modern Language Association's *MLA International Bibliography of Books and Articles on the Modern Languages and Literatures* (annual); and in *The Chaucer Review* (quarterly), with even wider coverage than in *MLA.* An excellent selective bibliography is ALBERT C. BAUGH (comp.), *Chaucer,* 2nd ed. (1977). Manuscripts of Chaucer's works are described in the book by Hammond listed above; and their locations are given in both Hammond and in JOHN E. WELLS, *A Manual of the Writings in Middle English 1050–1500* (1967–). From 1868 to 1926 the Chaucer Society in England published 155 volumes of important Chaucerian texts and commentaries. In the United States the Chaucer Group of the MLA sponsors *The Chaucer Review,* as well as the Chaucer Library, editions of his sourcebooks as he probably knew them.

Editions: The early printed editions of the *Works* are by PYNSON (1526), THYNNE (1532, 1542, and 1545?), STOW (1561), SPEGHT (1598, 1602, and 1687), and URRY (1721); those of the *Canterbury Tales* alone are by CAXTON (*c.* 1478 and *c.* 1484), PYNSON (*c.* 1492), WYNKYN DE WORDE (1495? and 1498), MORELL (1737), and TYRWHITT (1775–78). The most important 19th-century edition is WALTER W. SKEAT, *The Complete Works of Geoffrey Chaucer,* 7 vol. (1894–97). Student editions are FRED N. ROBINSON, *The Works of Geoffrey Chaucer,* 2nd ed. (1957, reissued 1974); ETHELBERT T. DONALDSON, *Chaucer's Poetry: An Anthology for the Modern Reader,* 2nd ed. (1975, reissued 1983); and ALBERT C. BAUGH, *Chaucer's Major Poetry* (1963). Scholarly editions, based on all manuscripts, are JOHN M. MANLY and EDITH RICKERT, *The Text of the Canterbury Tales,* 8 vol. (1940, reissued 1967); and ROBERT K. ROOT, *The Book of Troilus and Criseyde* (1926). Modern editions of the *Tales* include A.C. CAWLEY, *The Canterbury Tales* ("Everyman's Library," 1958, reissued 1975); and ROBERT A. PRATT, *Selections from the Tales of Canterbury, and Short Poems* ("Riverside Editions," 1966).

Modernizations: JOHN S.P. TATLOCK and PERCY MACKAYE, *The Complete Poetical Works of Geoffrey Chaucer* (1912; reprinted as *The Modern Reader's Chaucer,* 1966), expurgated, in prose; THEODORE MORRISON, *The Portable Chaucer,* rev. ed. (1975, reissued 1978), major selections in verse; NEVILL COGHILL, *The Canterbury Tales* (1952), in verse; ROBERT M. LUMIANSKY, *The Canterbury Tales* (1948, reissued 1972), and *Troilus and Criseyde* (1952), both in prose.

Biography and criticism: ALFRED A. KERN, *The Ancestry of Chaucer* (1906, reprinted 1973); JAMES R. HULBERT, *Chaucer's Official Life* (1912, reprinted 1970); MARTIN M. CROW and C.C. OLSON (eds.), *Chaucer Life-Records* (1966); S.S. HUSSEY, *Chaucer: An Introduction,* 2nd ed. (1981), including the literary and political background of his times; DEREK S. BREWER, *Chaucer,* 3rd ed. rev. (1973), a brief treatment of Chaucer's life and works, and (ed.), *Geoffrey Chaucer* (1974), an anthology of critical essays that place Chaucer within his literary, political, religious, and philosophical context; MARTIN B. RUUD, *Thomas Chaucer* (1926, reprinted 1972); MARION H. SPIELMANN, *The Portraits of Chaucer* (1900); GEORGE G. COULTON, *Chaucer and His England,* 8th ed. (1950, reprinted 1968), the 14th-century historical background; CAROLINE F.E. SPURGEON, *Five Hundred Years of Chaucer Criticism and Allusion, 1357–1900,* 7 vol. (1914–25; 3 vol., 1925, reprinted 1960); W.L. ALDERSON, "A Check-List of Supplements to Spurgeon's Chaucer Allusions," *Philological Quarterly,* 32:418–427 (1953). GEORGE L. KITTREDGE, *Chaucer and His Poetry* (1915, reissued 1970), essays on aspects of the poetry; ROBERT K. ROOT, *The Poetry of Chaucer,* rev. ed. (1922, reissued 1957), a detailed treatment of the life and works; WALTER C. CURRY, *Chaucer and the Mediaeval Sciences,* rev. ed. (1960); JOHN M. MANLY, *Some New Light on Chaucer* (1926, reissued 1959), contemporaries seen as possible models for some of Chaucer's characters; JOHN L. LOWES, *Geoffrey Chaucer and the Development of His Genius* (1934), essays on Chaucer's poetic career; PERCY V.D. SHELLY, *The Living Chaucer* (1940, reissued 1968), a critical assessment of the poetry; CHARLES MUSCATINE, *Chaucer and the French Tradition* (1957, reissued 1965); D.W. ROBERTSON, *A Preface to Chaucer* (1962), essays on aspects of Chaucer's thought; BERYL ROWLAND (ed.), *Companion to Chaucer Studies,* rev. ed. (1979), essays on the life and works; ALFRED DAVID, *The Strumpet Muse: Art and Morals in Chaucer's Poetry* (1977), an exploration of Chaucer's desire to provide moral instruction through his writings; ALICE S. MISKIMIN, *The Renaissance Chaucer* (1975), a study of the evolution of Chaucer interpretation from his time through the Renaissance; DONALD R. HOWARD, *The Idea of the Canterbury Tales* (1976), a scholarly study; WILLIAM F. BRYAN and GERMAINE DEMPSTER (eds.), *Sources and Analogues of Chaucer's Canterbury Tales* (1941, reissued 1958); MURIEL A. BOWDEN, *A Commentary on the General Prologue to the Canterbury Tales,* 2nd ed. (1967, reissued 1973); RALPH BALDWIN, *The Unity of the Canterbury Tales* (1955, reprinted 1977); ROBERT M. LUMIANSKY, *Of Sondry Folk: The Dramatic Principle in The Canterbury Tales* (1955, reissued 1980); SANFORD B. MEECH, *Design in Chaucer's Troilus* (1959, reissued 1969); HELGE KÖKERITZ, *A Guide to Chaucer's Pronunciation* (1954, reprinted 1978).

(R.M.Lu./Ed.)

Chemical Compounds

A chemical compound is a substance made up of identical molecules containing atoms of two or more elements. Millions of chemical compounds are known; millions more probably exist in nature; and still other millions may be synthesized in the laboratory. The known compounds differ from one another in almost every conceivable way. Some, such as water, are colourless; others, the dyes and pigments, embody every colour of the rainbow. Some are light gases at ordinary temperatures; others, dense solids. Some are chemically inert; others, so unstable that they exist for only fractions of a second. In order to deal with the bewildering mass of diverse information about this multitude of substances, chemists have devised a number of classification schemes. These provide rational ways of organizing all chemical compounds, known or still to be discovered, into related groups of similar and dissimilar substances.

In any systematic classification, of course, chemical compounds must themselves be distinguished from other forms of matter. Most matter encountered in everyday life consists of mixtures of two or more substances. Generally, such mixtures can be separated by physical means—as, for example, salt is separated from seawater when the water is evaporated. The pure substances themselves are either atoms, or aggregates of atoms, of elements or molecules of compounds. Because the molecules of compounds contain atoms of several elements, compounds can be broken down into their elements by chemical reactions.

Molecular formulas represent the compositions of compounds in terms of the specific elements that constitute them—that is, in terms of what is called their elemental composition. Such formulas consist of the chemical symbols of the elements involved, along with numerical subscripts that indicate the numbers of atoms of each kind in the molecules. Thus, the formula for water, H_2O, indicates that a molecule of water contains two atoms of hydrogen and one of oxygen.

Among the most useful schemes for the classification of chemical compounds are those based on (1) the elemental composition of the compound, (2) the types of bonds that exist between the atoms in their molecules, and (3) the varieties of chemical reactions they undergo. Several other, less important classification methods are used for certain special purposes. (W.F.K.)

Organic compounds

Classification by elemental composition. *Organic compounds.* Early in the 19th century, chemists began to classify chemical compounds found in or produced by living organisms as organic. By contrast, compounds from nonliving sources, such as minerals, were classified as inorganic. Like the biological materials from which they come, organic compounds, such as sugar or alcohol, either burn or char when heated in air; inorganic compounds, such as limestone or table salt, either are inert toward heating or undergo specific characteristic transformations not associated with decomposition. Although it has been known since 1828 that typical organic compounds can be synthesized in the laboratory from inorganic compounds without the involvement of living organisms, the name organic still is used to refer to this group of compounds. Generally, organic compounds are compounds of carbon—except for simple compounds containing only carbon and oxygen and minerals, such as limestone or marble. Compounds involving elements other than carbon are classed as inorganic.

Aliphatic and aromatic compounds

Though carbon is only one element among more than 100, it is thought that the number of carbon compounds is larger than the number of compounds of all other elements put together. Carbon atoms form strong bonds with the atoms of nonmetals, such as hydrogen, oxygen, nitrogen, and chlorine, but the large number of carbon compounds is due to the fact that carbon atoms also are able to form strong bonds with other carbon atoms. The atoms of no other element bond to one another to the same extent or in the same variety of ways as carbon atoms do. Carbon atoms join together in chains or rings that function as molecular backbones to which atoms of other elements are attached. These chains can vary in length from two carbon atoms, as in ethane (symbolized by the formula C_2H_6), a component of natural gas, to hundreds of thousands of carbon atoms, as in polyethylene, a manufactured polymer used to make household utensils and fibres. Each carbon atom in any chain has attached to it a variety of atoms or groups of atoms, which may also be other carbon chains. Molecules consisting of simple carbon chains have been called aliphatic ever since the early discovery that they occurred in fatty substances (Greek *aleiphar-*, "fat"). In contrast, certain compounds consisting of chains of carbon atoms whose ends are joined to form rings, of which a prototype molecule is benzene, C_6H_6, are called aromatic compounds, a name originally chosen because of the odour associated with coal tar, in which such molecules typically are found. The discovery that benzene is a ring of six carbon atoms, rather than a chain, was one of the dramatic breakthroughs in 19th-century science. Generally, aliphatic and aromatic compounds behave quite differently, and the subclassification of organic compounds into these two large families, aliphatic and aromatic, is a natural one. Ring compounds are also called cyclic compounds.

Organic compounds often contain special groups of atoms called functional groups, which readily undergo chemical reaction. Because these functional groups dominate the chemistry of the compounds that contain them, they provide a convenient way of classifying organic compounds. Alcohols, ethers, aldehydes, ketones, and carboxylic acids are typical examples of organic compounds classified by the functional groups they contain.

Inorganic compounds. The periodic table provides the chemist with his most comprehensive scheme for classification of the elements. Consequently, it also serves as a starting point for the classification of inorganic compounds, which, as mentioned above, are compounds of elements other than carbon. One convenient way to classify inorganic compounds is by grouping together all of the compounds of a particular element. This is especially useful with compounds containing atoms of only two elements (binary compounds), which are designated commonly by the suffix -ide. Thus, the compound sodium chloride (symbolized by the formula NaCl), or table salt, is formed by the combination of the metallic element sodium (Na) with the nonmetallic element chlorine (Cl). Chlorides of other metallic elements are known, and the definition of chlorides as a group is useful in certain classification schemes. This type of classification can easily be extended to other elements of the chlorine family in the periodic table, which form compounds similar to the chlorides. Members of this family are known as halogens (salt formers). Consequently, the binary compounds formed by this family of elements are called by the generic name halides. Familiar examples of halides are sodium fluoride (NaF), the material added to drinking water to prevent tooth decay, and silver iodide (AgI), a substance used in making photographic films.

Hydrides, oxides, and sulfides

Other examples of classifying together the binary compounds of a single element are the binary compounds of hydrogen, known as hydrides, those of oxygen, called oxides; and those of sulfur, called sulfides. Like the halogen elements, most elements within a single vertical file, or group, of the periodic table form similar compounds. For example, all of the elements of the family known as the alkali metals form similar chlorine compounds, which are known collectively as the alkali chlorides. Similarly, the elements of the family known as the alkaline-earth metals form oxygen compounds known as the alkaline-earth oxides.

Similar principles apply to the classification of inorganic compounds composed of more than two elements. In naming these compounds, suffixes and prefixes are employed along with roots. The suffix -ate, for example, often is used to indicate that an element contains a number of oxygen atoms bound to it. Thus, sodium sulfate is the name of the compound with the formula Na_2SO_4 (consisting of sodium, sulfur, and oxygen), and calcium silicate is $CaSiO_3$ (calcium, silicon, and oxygen). Sulfates and silicates are recognizable classes of compounds, and, again, classes such as the alkali sulfates and the alkaline-earth silicates often are discussed.

Hemoglobin and chlorophyll

Organometallic compounds. The great number and variety of potential combinations among the atoms of the elements make it impossible for any classification scheme to put all possible compounds into mutually exclusive categories. Thus, it is found that many metal atoms, most frequently encountered in inorganic substances, can also combine with compounds generally classed as organic. The resulting organometallic, or metallo-organic, compounds are widespread among substances essential to living systems. Hemoglobin, the vital oxygen-carrying constituent in the blood of higher animals, is a large, carbon-containing molecule in which an iron atom is combined. Chlorophyll, similarly essential to green plants, has a magnesium atom imbedded in a large organic molecule. Vitamin B_{12} is an organometallic compound containing cobalt. But organometallics are not restricted to compounds found in nature. Many new synthetic varieties are produced each year. The compound tetraethyllead, formula $Pb(C_2H_5)_4$ (one atom of lead bonded to four groups, each consisting of two atoms of carbon and five of hydrogen), is a synthetic organometallic compound that has found wide use as an additive to gasoline.

Variation in ratios of elements

Nonstoichiometric compounds. One of the tenets of the atomic theory, on which much of chemistry is based, is that, when elements combine, they do so in such a manner that the ratio of the numbers of atoms of elements is integral. This rule is implied in typical molecular formulas. For example, the formula Al_2O_3 for the substance aluminum oxide means that atoms of aluminum combine with atoms of oxygen in the exact ratio of 2:3 to form this compound. The ratio of elements in a compound is revealed by the analysis of any pure sample of it. Any compound found to contain atoms of elements in whole-number ratios is said to be a stoichiometric (Greek: "element measuring") compound. A great majority of compounds, including nearly all organic compounds, fall into this class. There is, however, another class of compounds, nonstoichiometric compounds, in which the relative numbers of elemental atoms are not integral. The class includes, particularly, the oxides and sulfides of certain metals. For example, accurate analyses have shown that the number of zinc atoms relative to sulfur atoms in zinc sulfide, ZnS, can actually exceed the predicted 1:1 ratio of the formula by 0.03 percent. Similarly, the analysis of a sulfide of cerium suggests a formula $Ce_{2{\cdot}7}S_4$, which means that the ratio of cerium to sulfur is in the proportion of 2.7:4. The electricity-conducting properties of such nonstoichiometric substances make them increasingly important as components of solid-state devices used in the electronics industry.

Classification by bond type. *Ionic compounds.* In the chemical reaction by which sodium chloride is formed from sodium atoms and chlorine atoms, the sodium atoms each lose an electron (the basic, negatively charged particle present in all atoms and also free in space), and the chlorine atoms each gain one. The consequence of this kind of electron transfer is that the compound formed exists as an aggregate of particles of matter bearing electrical charges, or ions. Forces of electrical attraction hold, or bond, the positively charged sodium ions in a matrix of negatively charged chloride ions, and vice versa. This form of bonding, ionic bonding, is characteristic of all salts. Certain hydrides (*e.g.,* sodium hydride) and oxides (*e.g.,* magnesium oxide) also have properties—such as high melting point and electrical conductivity in solution—that classify them as saltlike, or ionic, compounds.

Covalent compounds. An alternative, nonionic process, however, is involved in the combination of certain atoms to form compounds. In this process, electrons are shared between atoms, producing bonds, which are referred to as covalent bonds, between them. Covalent bonding occurs when carbon atoms combine in organic compounds and between nonmetal atoms when they combine into molecules. Such bonding results in the formation of covalent molecules, typical examples of which are methane (CH_4), a constituent of natural gas, and water (H_2O). Covalent molecules are complete entities, not electrically charged fragments like ions, and their aggregation into large samples is the consequence of the attractive forces between molecules, rather than electrostatic attraction. Generally speaking, intermolecular forces are weaker than electrostatic forces. As a result, the molecules of covalent compounds are pulled apart more easily than ions are and therefore the melting points of covalent compounds are lower than those of ionic compounds.

Macro-
molecules

The mechanism of covalent-bond formation leads in some cases to the formation of huge, extended molecules involving thousands to millions of atoms. These macromolecules (macro-, "large") are also referred to as polymers (poly-, "many"; -mers, "parts"). The familiar plastics encountered in thousands of everyday uses are polymers. Polyethylene, Plexiglas, and nylon are examples. These are huge organic molecules formed by the combination of many small units. Varieties of macromolecules important to living organisms are proteins, carbohydrates, and nucleic acids, such as deoxyribonucleic acid (DNA). All of these are polymers held together by covalent bonds. There are also some inorganic materials that properly can be classed as covalent macromolecules. Quartz (SiO_2) and other silicon-containing minerals, such as clays, have many chemically identical small units bonded together in two- and three-dimensional networks.

Coordination compounds. There are many stable compounds the structures of which are such that they can form even more stable compounds by adding other molecules. Such addition compounds are called coordination compounds. An example is expressed by the equation

$$CuSO_4 + 4NH_3 \rightarrow Cu(NH_3)_4SO_4,$$

which indicates that one molecule of cupric sulfate ($CuSO_4$), also written copper(II) sulfate, and four molecules of ammonia (NH_3) combine to produce the coordination compound tetramminecopper(II) sulfate. In the process, four covalent bonds are formed between the four ammonia molecules and the copper ion. In each of these bonds, a pair of electrons on the ammonia molecule is shared with the copper ion. In such bonds, the electrons are donated by only one of the two atoms, rather than coming from both atoms, as in typical covalent bonds. A great variety of coordination compounds is formed by the so-called transition elements—*i.e.,* metallic elements found in the central portion of the periodic table. An important example of a coordination compound is the one formed when carbon monoxide attaches to the iron atom in hemoglobin of the blood. The stability of this compound robs hemoglobin of its oxygen-carrying ability. For an organism in which a major percentage of the hemoglobin molecules have combined with carbon monoxide, the consequence is death.

Donation
of electrons

Classification by chemical reactivity. A natural consequence of the accumulation of information about the behaviour of chemical compounds is the recognition of similarities in their chemical properties. This recognition leads to classification on the basis of chemical reactivity, a classification that generally correlates well with classifications based on chemical structure.

Acids, bases, and salts. Very early in the development of chemistry, it was recognized that a type of reaction common to many substances is their ability to act as acids. Vinegar, for example, is a natural product that behaves as it does because it contains an organic acid, acetic acid. Acids generally have the property of imparting a characteristic colour to certain dyestuffs used as indicators. The indicator litmus, for instance, turns from blue to pink in acidic solutions. Acids also have a corrosive effect on many metals and produce hydrogen gas as a result of the action. This observation suggests that acids are hydrogen-containing compounds, as, indeed, most of them are. The so-called mineral acids are aqueous solutions of compounds derived from inorganic materials; typical mineral acids are hydrochloric acid (HCl), sulfuric acid (H_2SO_4), and nitric acid (HNO_3).

Bases, on the other hand, are a class of compounds capable of reacting with acids to neutralize their acidity. They, too, impart a characteristic colour to indicator dyes; litmus turns from pink to blue in solutions of bases. Alkali hydroxides—*e.g.,* sodium hydroxide, (NaOH), commonly called lye—and alkaline-earth oxides—*e.g.,* calcium oxide (CaO), familiarly called lime—are typical bases. Two neutralization reactions are shown in the following equations:

$$HCl + NaOH \rightarrow HOH + NaCl;$$

$$H_2SO_4 + CaO \rightarrow HOH + CaSO_4.$$

In the first equation, hydrochloric acid is neutralized with sodium hydroxide to give water and sodium chloride, common table salt. In the second reaction, sulfuric acid comes together with calcium oxide to form, again, water and a salt, in this case, calcium sulfate. From these reactions and many others like them, it can be generalized that acids as a class react with bases as a class to produce water and a third class of substances, salts.

Some substances, however—ammonia, for example—are capable of neutralizing acids without giving water as a product. The reaction of ammonia with nitric acid can be written

$$NH_3 + HNO_3 \rightarrow NH_4NO_3.$$

In this reaction, a molecule of ammonia is seen to combine with a hydrogen ion (H^+) from the acid in a manner similar to the way in which oxygen (or an oxygen–hydrogen group) combines with hydrogen in the above examples. One definition of bases, then, calls them the class of compounds capable of accepting hydrogen from acids. Ammonium nitrate (NH_4NO_3) is another example of a salt, the product of the neutralization of an acid by a base.

To enlarge the classification, there are compounds containing no hydrogen that are also capable of reacting with bases. Boron trifluoride (BF_3) is such a compound. It reacts with ammonia to produce a neutral compound, much like a salt: $NH_3 + BF_3 \rightarrow H_3NBF_3$. The structural interpretation of this reaction is that the boron atom accepts a share in a pair of electrons from the nitrogen atom of ammonia. A covalent bond is formed between boron and nitrogen. This reaction suggests another definition of acids and bases: acids are compounds capable of accepting a pair of electrons; bases are compounds capable of donating a pair of electrons.

Acids as
electron
recipients

Oxidizing and reducing agents. Another frequently employed classification of chemical compounds is based upon their behaviour in so-called oxidation–reduction reactions. Such reactions are ones in which the combining capacity (valence) of several of the components is changed by the reaction. A simple example is:

$2Cu$ (copper) $+ O_2$ (oxygen) $\rightarrow 2CuO$ (copper[II] oxide).

In this reaction, two atoms of copper are said to be oxidized to two molecules of copper(II) oxide by a molecule of oxygen. In the process, the valence of the copper atoms has been changed from 0 in the uncombined element to +2 in the compound. At the same time, the valence of oxygen has been reduced from 0 in the elemental form to −2 in the compound. A comparable result can be accomplished by treating copper with sulfuric acid:

$$Cu + H_2SO_4 \rightarrow CuO + SO_2 + H_2O.$$

In this reaction, copper again is oxidized; and sulfuric acid is the oxidizing agent, being reduced to sulfur dioxide in the process. (The valence of sulfur changes from +6 in sulfuric acid to +4 in sulfur dioxide.) There is a complementarity in this classification scheme: in oxidation–reduction reactions, oxidizing agents always are reduced; reducing agents invariably are oxidized.

Because examples of oxidation and reduction are so numerous in all branches of chemistry, the classification of substances as oxidizing or reducing agents is important. The results of many reactions can be anticipated by recognizing the degree to which the compounds involved exhibit oxidizing or reducing tendencies.

Nonchemical (trivial) classification schemes. It is hardly surprising that, in any study as vast as the examination of all kinds of matter, there are a great many classification schemes based simply on convenience. Thus, for example, classification based upon the physical state of a pure substance divides all substances into the categories gases, liquids, and solids. Although such a classification may be useful, it reflects little about the essential structure or reactivity of a material. For example, the familiar forms of the compound H_2O are solid ice, liquid water, and gaseous steam. The compound itself, however, is chemically identical in all three forms.

Natural and synthetic compounds

Another nonchemical basis for a classification scheme may be the source of a compound. Thus, natural compounds are found in nature; synthetic compounds are produced in laboratories or factories. Natural compounds may be further classified as terrestrial, meteoric, or lunar, depending on their place of origin. Again, however, it is important to recognize that a pure compound isolated from any one source is chemically identical with the same compound from any other source. It is in this sense that the chemist considers all such nonchemical classification schemes as trivial. (W.F.K.)

INORGANIC CHEMICAL COMPOUNDS

In the early stages of the development of chemistry, considerable emphasis was placed on the origins of the various substances. As noted earlier, those substances clearly derived from living organisms were referred to as organic, whereas those that had in no known way been associated with living organisms were described as inorganic. Since the common substances derived from living matter are composed predominantly of the elements carbon, nitrogen, oxygen, and hydrogen—especially carbon—much of the chemistry of those elements was reserved for the field of organic chemistry, organic compounds being chiefly those substances in which varying amounts of hydrogen, oxygen, or nitrogen are combined with carbon. Inorganic chemistry, then, encompasses the bulk of the chemistry of all the remaining elements; see Figure 1. In addition, there exist compounds of carbon, hydrogen, oxygen, and nitrogen that are strictly inorganic, and there are many inorganic compounds formed by combination of various of these elements with other known elements.

Figure 1: The periodic table of the elements.

CHEMICAL BONDING IN INORGANIC COMPOUNDS

The atoms of the elements that are combined in an inorganic compound may be bound to each other by a variety of kinds of chemical bonds, as the attractive forces that hold atoms together are called. These are most broadly separable into three categories: covalent bonds, electrovalent bonds, and metallic bonds. Within certain of these categories, there are also a few other bond types that must also be recognized.

Sharing of electron pairs

Covalent bonding. A covalent bond involves the binding together of two atoms of either the same element or of two different elements by the sharing of two electrons (an electron pair). This type of bond is illustrated by the formation of the compound hydrogen fluoride from its constituent atoms of hydrogen and fluorine, as shown in the following chemical equation:

$$H\cdot \quad + \quad \cdot\ddot{\underset{\cdot\cdot}{F}}: \quad \longrightarrow \quad H:\ddot{\underset{\cdot\cdot}{F}}:.$$

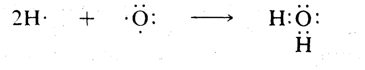
hydrogen atom — fluorine atom — hydrogen fluoride molecule

where atoms of hydrogen and fluorine are represented (as is customary) by their chemical symbols, H and F, respectively; the dots represent electrons in the outermost shells of the atoms of the elements (every atom being made up of electrons in concentric shells around a central nucleus). As is generally true in chemical equations, the starting materials are written to the left of an arrow (which points in the direction of the reaction) and the products to the right.

Since every atom has a definite electron capacity in its outermost shell of electrons (also called the valence shell), each of the combining atoms must be able to accommodate the shared electrons within its valence shell. Very commonly, the number of electrons that can be accommodated is eight. This is the so-called rule of eight (or octet rule), and it comes about because the two lowest energy subshells in any major electron shell are the *s* (electron capacity of two) and *p* (electron capacity, six) subshells (with the letters serving only to designate the subshells and having no other pertinent meaning).

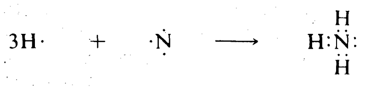
The rule of eight

The formulas of the covalent compounds water (H_2O, O being an atom of oxygen) and ammonia (NH_3, N being an atom of nitrogen) reflect the rule of eight (as does that of hydrogen fluoride, above). This circumstance is shown in the equations below, in which the numbers of electrons in the free atoms reflect the electronic structures of the free elements, whereas the number of electrons assigned



$$2H\cdot \quad + \quad \cdot\ddot{\underset{\cdot}{O}}: \quad \longrightarrow \quad H:\underset{H}{\ddot{\underset{\cdot\cdot}{O}}}:$$

hydrogen atoms — oxygen atom — water molecule



$$3H\cdot \quad + \quad \cdot\dot{\underset{\cdot}{N}}: \quad \longrightarrow \quad H:\underset{H}{\overset{H}{\dot{\underset{\cdot\cdot}{N}}}}:$$

hydrogen atoms — nitrogen atom — ammonia molecule to each element in the compounds includes those not involved in bonds as well as those utilized by that element in covalent bonding.

Electron configuration. A free hydrogen atom has the electronic configuration designated $1s^1$, in which the first number indicates the number of the shell proceeding outward, the letter designates the type of subshell, and the superscript represents the number of electrons involved. The valence-shell configuration for oxygen is $2s^22p^4$ and that for nitrogen is $2s^22p^3$. In its covalent compounds, hydrogen effectively has the configuration $1s^2$, whereas the configurations of both oxygen and nitrogen in covalent compounds are $2s^22p^6$.

The closed-shell configuration of hydrogen

The closed-shell configuration of bonded hydrogen ($1s^2$) thus contains only two electrons, rather than eight; there is one important respect, however, in which this closed-shell configuration closely resembles those of such other covalently bonded elements as oxygen and nitrogen in their compounds water and ammonia ($2s^22p^6$). In each case, the bonded element has gained a share in a sufficient number of electrons to have the same configuration as the nearest noble gas (or Group 0 element) in the periodic table (see Figure 1). With hydrogen, this element is helium (configuration $1s^2$), whereas with oxygen and nitrogen it is neon ($2s^22p^6$). One may conclude that when an element obeys the rule of eight, it has assumed a noble gas configuration.

For elements having atomic numbers greater than 10 (the elements customarily being arranged in order of increasing atomic number—a value equivalent to the number of electrons in the neutral atom), the valence shell contains a d subshell in addition to the s and p subshells. Many compounds of these elements reflect the fact that more than eight electrons can be accommodated in the outermost shells.

Electronegativity. The ability of two atoms to share electrons depends on their having comparable relative abilities to attract electrons. This affinity for electrons depends ultimately on the charge on the nucleus of the atom as moderated by the other electrons in the atom. It is commonly estimated by a quantity called the electronegativity, which increases from left to right and from bottom to top in the periodic table (Figure 1). If two covalently bonded atoms have identical electronegativities, they share the electron pair equally. The bond is then said to be nonpolar, and the molecule is described as being homopolar (or nonpolar). If the electronegativities of the two atoms are not equal, the electron pair of the covalent bond is shared unequally. This causes one of the atoms to have a slight excess of negative charge and the other a slight excess of positive charge. Such a bond is called polar, and the molecule is described as being heteropolar (or simply polar). Polar and nonpolar molecules have different properties.

Polarity

Formation of ions

Electrovalent bonding. Electrovalent bonding occurs when the electronegativity difference between two atoms (elements) is so great that electron sharing is not possible. In this case, one atom takes electrons away from the other, and the two atoms are converted to charged particles called ions. The resulting ions have opposite charges, and they are attracted to each other by the resulting electrostatic force (positive–negative attraction). An example of how ions can be considered to be formed from neutral atoms is shown below in the reaction of sodium with fluorine:

$$\begin{array}{ccccccc} \mathrm{Na}\cdot & + & \cdot\overset{\cdot\cdot}{\underset{\cdot\cdot}{\mathrm{F}}}: & \longrightarrow & \mathrm{Na}^{+} & + & :\overset{\cdot\cdot}{\underset{\cdot\cdot}{\mathrm{F}}}:^{-}. \\ (3s^1) & & (2s^22p^5) & & (2s^22p^6) & & (2s^22p^6) \\ \text{sodium atom} & & \text{fluorine atom} & & \text{sodium ion} & & \text{fluoride ion} \end{array}$$

A great difference between such ion–ion bonds and ordinary covalent (non-ionic) bonds is the fact that the electrostatic bond is not restricted to a single pair of atoms. Every negative ion attracts every other positive ion in its vicinity, and vice versa. This generalized attraction results in the formation of ionic crystal lattices (extended structures built up of positive and negative ions) by solid electrovalent compounds. For an example see Figure 2, representing the structure of sodium chloride (NaCl) crystal.

The number of electrons transferred between atoms is usually in accord with the rule of eight, as illustrated in the examples below:

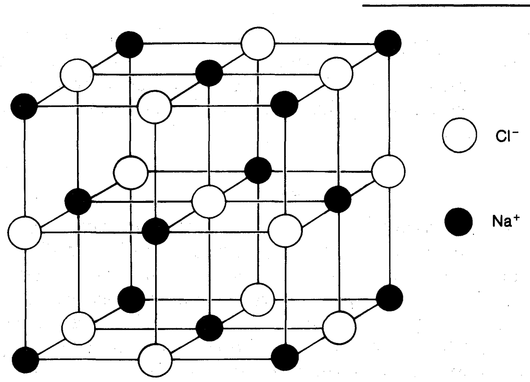


Figure 2: Ionic structure of sodium chloride in a three-dimensional array.

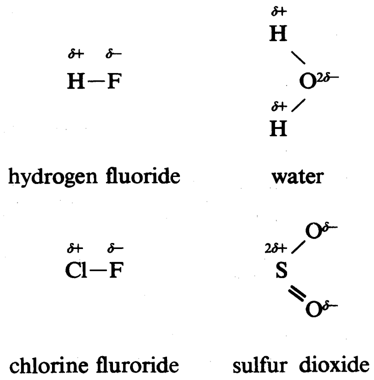
$$\begin{array}{ccccccc} \cdot\mathrm{Ca}\cdot & + & \cdot\overset{\cdot\cdot}{\underset{\cdot}{\mathrm{O}}}: & \longrightarrow & \mathrm{Ca}^{2+} & + & :\overset{\cdot\cdot}{\underset{\cdot\cdot}{\mathrm{O}}}:^{2-} \\ (4s^2) & & (2s^22p^4) & & (3s^23p^6) & & (2s^22p^6) \\ \text{calcium atom} & & \text{oxygen atom} & & \text{calcium ion} & & \text{oxygen ion} \end{array}$$

$$\begin{array}{ccccccc} 3\mathrm{Li}\cdot & + & \cdot\overset{\cdot\cdot}{\underset{\cdot}{\mathrm{N}}}\cdot & \longrightarrow & 3\mathrm{Li}^{+} & + & :\overset{\cdot\cdot}{\underset{\cdot\cdot}{\mathrm{N}}}:^{3-}. \\ (2s^1) & & (2s^22p^3) & & (2s^2) & & (2s^22p^6) \\ \text{lithium atom} & & \text{nitrogen atom} & & \text{lithium ion} & & \text{nitrogen ion} \end{array}$$

Polar molecules, such as those of water, bind to ions by attractive forces between the partially separated charges (dipoles) of the polar molecules and the free charges of the ions. When sodium chloride and other salts dissolve in water, their ions interact with the molecules of solvent by means of ion–dipole forces, as shown in Figure 3 (Left).

Molecules that have unsymmetrical electronic arrangements (dipoles) are commonly referred to as polar because their extremities bear opposite charges, which are indicated by the symbols $\delta+$ and $\delta-$. Various examples of polar molecules and their respective dipoles are provided below:



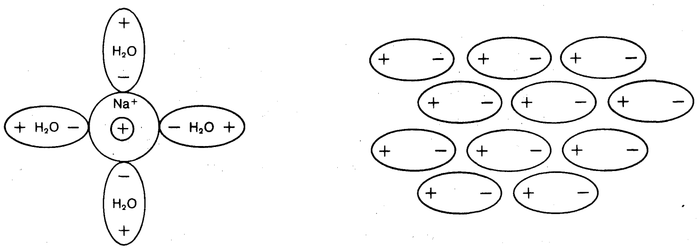


Figure 3: (Left) Attraction of water molecules to a sodium cation by ion–dipole forces. (Right) Alignment of dipoles in a liquid or solid phase containing polar molecules.

Polar molecules attract each other by aligning their charges so that those of opposite sign are adjacent. Dipole–dipole forces provide the intermolecular attractions that hold the molecules of many solids and liquids together, as shown in Figure 3 (Right). Certain molecules with polar bonds do not have dipole moments because of the cancelling of dipoles. Carbon dioxide, CO_2, provides an example:

$$\overset{\delta-}{:\ddot{O}} = \overset{2\delta+}{C} = \overset{\delta-}{\ddot{O}:}\ .$$

Hydrogen bonds

Polar molecules with hydrogen atoms at their positive extremities often form very strong ion–dipole and dipole–dipole bonds. This is particularly true when the second element in the compound is strongly electronegative, as are fluorine, oxygen, and nitrogen. These linkages are called hydrogen bonds and are responsible for the unusually large mutual attractions of the molecules of such compounds as hydrogen fluoride, water, and ammonia (when compared to their higher molecular weight analogues: hydrogen chloride, hydrogen sulfide, and phosphine, respectively). Comparisons of the heat of vaporization (the amount of heat needed to vaporize a standard quantity) of the hydrogen halides and of water and its heavier analogues show that more heat is needed to vaporize the lightest member of each series, and hence the strength of the dipole–dipole attractions is markedly greater for these compounds (more heat being required to overcome stronger attractions).

The nature of the forces holding the particles together in solids determines the physical and chemical properties of those substances, as shown in Table 1. Ion–ion forces and metallic bonding (the attractive force between atoms in metals) are usually extremely strong. Ion–dipole and dipole–dipole forces are not so strong, and the so-called van der Waals forces (weak attractions between nonpolar molecules) are weakest of all.

More subtle variations in properties than are implied in Table 1 are illustrated by the melting points of the fluorides for the horizontal series (period) of elements in the periodic table, beginning with sodium: 988° C (1,810° F), sodium fluoride; 1,266° C (2,311° F), magnesium fluoride; 1,291° C (2,356° F), aluminum fluoride; −90.2° C (−130.4° F), silicon tetrafluoride; −83° C (−117° F), phosphorus pentafluoride; −50.5° C (−58.9° F), sulfur hexafluoride. In this series of compounds, the covalent nature of the molecular structures increases in proceeding to the right.

Table 1: Binding Forces and Properties of Solids

class of solid	nature of bonds	physical properties	example
Ionic	ion–ion (electrovalent)	hard, brittle, high mp and bp, melt conducts electricity	$NaCl$, CaF_2, LaF_3
Giant molecular	covalent	very hard, high mp, and bp, nonconductor	diamond, boron nitride, carborundum
Polar molecular	dipole–dipole	moderately soft, intermediate mp, nonconductor	water, ammonia, ether
Metallic	metallic bonds	great variety in hardness, mp, and bp, malleable, ductile, electrical conductors	elemental metals; *e.g.*, Ag, Cu, Fe, Na, Hg, W
Nonpolar molecular	van der Waals	very soft, low mp and bp, nonconductor	naphthalene, CCl_4, N_2, Ar

NOMENCLATURE OF INORGANIC COMPOUNDS

Binary compounds. There are several acceptable ways of naming binary compounds (compounds of only two elements). The choice of which is used depends on the complexity of the chemistry of the elements in the particular compound and the complexity of the structure of the compound itself.

Order of names

For compounds of electropositive elements (that is, those with only positive oxidation states) that do not have variable valences, such as the alkali and alkaline-earth elements, the name is composed of the unmodified name of the electropositive element followed by that of the electronegative element (the element with negative oxidation state), the latter having its name modified in a phonetically useful way to end in "-ide." The simple compound of sodium and chlorine (NaCl), for example, is called sodium chloride; that between calcium and sulfur (CaS) is calcium sulfide; that between magnesium and nitrogen (Mg_3N_2) is magnesium nitride; and the compound formed between aluminum and boron (AlB_{12}) is known as aluminum boride.

Names incorporating oxidation states

In cases in which several oxidation states are possible for the electropositive element in a binary compound, a roman numeral is added in parentheses after the name of the electropositive element. Thus, the compound with the molecular formula $FeCl_2$ is known as iron(II) chloride, whereas the compound with the formula $FeCl_3$ is referred to as iron(III) chloride. Similarly, CuCl is copper(I) chloride; $SnBr_4$ is tin(IV) bromide; NO_2 is nitrogen(IV) oxide; and SF_6 is sulfur(VI) fluoride. This system replaces an older system in which electropositive elements were given different suffixes to indicate the oxidation state. In the older system, for example, iron(II) chloride was called ferrous chloride and iron(III) chloride was known as ferric chloride.

Alternatively, when compounds incorporating different combinations of the same two elements are known, Latin and Greek prefixes are used to indicate the proportions of elements present in a given compound. A series of compounds named by this method are given in Table 2.

Table 2: Some Compounds Named Using Prefixes To Indicate Proportions

molecular formula	name
N_2O	dinitrogen oxide
N_2O_3	dinitrogen trioxide
N_2O_4	dinitrogen tetroxide
N_2S_5	dinitrogen pentasulfide
S_2Cl_2	disulfur dichloride
Al_2Cl_6	dialuminum hexachloride
ClO_3	chlorine trioxide

Names indicating ratios

This system is also often used more loosely to indicate the ratios of elements combined in a substance rather than its exact molecular formula. Thus the name aluminum trichloride (and the formula $AlCl_3$) indicates the composition of the substance but not its true molecular formula (which is generally thought to be Al_2Cl_6). Furthermore, manganese dioxide, MnO_2, exists in a saltlike lattice (see below *Structural classification of inorganic compounds*) rather than as discrete molecules as the name suggests.

The binary acids may either be named as typical binary compounds (hydrogen chloride for HCl, hydrogen sulfide for H_2S) or they may be given the prefix hydro- and the suffix -ic acid (thus hydrochloric acid for HCl, and hydrosulfuric acid for H_2S).

Certain classes of binary compounds have systems of nomenclature based on common names. This is especially true of hydrogen derivatives, both neutral and charged, as shown in Table 3.

Table 3: Common Names of Hydrogen Compounds

neutral compound		cation		anion	
formula	name	formula	name	formula	name
H_2O	water	H_3O^+	hydronium	OH^-	hydroxide
NH_3	ammonia	NH_4^+	ammonium	NH_2^-	amide
N_2H_4	hydrazine	$N_2H_5^+$	hydrazinium	—	—
B_2H_6	diborane	—	—	BH_4^-	tetrahydridoborate
SiH_4	silane	—	—	—	—

Compounds with common names

The hydrides of boron are named as boranes by indicating the number of boron atoms with a Latin or Greek prefix and the number of hydrogens with a numerical suffix. Examples are given in Table 4.

Ternary compounds. Many ternary compounds (compounds of three elements) can be considered as oxygen acids or their salts. The names of most common oxygen acids are nomenclature systems. Familiarity, however, requires retention of these names. Systematic names can be assigned on the basis of coordination-compound nomenclature (see below *Coordination compounds*); these, however, often are so cumbersome that the common names are preferred. A list of common names of well-known

Table 4: Names and Formulas of Some Boranes

formula	name
B_2H_6	diborane-6
B_5H_9	pentaborane-9
B_5H_{11}	pentaborane-11
$B_{18}H_{22}$	octadecaborane-22

ternary acids—and the related anions (negative ions)—is included in Table 5.

Salts—ternary compounds involving other elements in place of the hydrogen of the parent acids—are named according to the rules for binary compounds, with the anion from the acid playing the role of the more electronegative constituent. If one or more atoms of hydrogen remains, hydrogen is named as a second electropositive constituent. Examples of such salts are given in Table 6.

The occurrence of water, or similar molecules, in the composition of a material is indicated by adding to the end of the name the word hydrate for water (or, for example, ammoniate for ammonia) with a Latin or Greek prefix to indicate the number of molecules present. Examples of names of materials of this kind are given in Table 7.

Table 5: Common Names of Acids and Their Anions

formula	name of acid	name of anion	formula of anion
H_3BO_3	orthoboric acid*	borate	BO_3^{3-}
H_2CO_3	carbonic acid	carbonate	CO_3^{2-}
HNO_3	nitric acid	nitrate	NO_3^-
HNO_2	nitrous acid	nitrite	NO_2^-
H_3PO_4	orthophosphoric acid*	phosphate	PO_4^{3-}
$H_4P_2O_7$	pyrophosphoric acid	pyrophosphate	$P_2O_7^{4-}$
$H_5P_3O_{10}$	triphosphoric acid	triphosphate	$P_3O_{10}^{5-}$
$(HPO_3)_n$	metaphosphoric acid	metaphosphate	$(PO_3^-)_n$
$(HPO_3)_3$	trimetaphosphoric acid	trimetaphosphate	$(PO_3^-)_3$
H_3PO_3	phosphorous acid	phosphite	HPO_3^{2-}
H_3PO_2	hypophosphorous acid	hypophosphite	$H_2PO_2^-$
H_2SO_5	peroxosulfuric acid	peroxysulfate	SO_5^{2-}
$H_2S_2O_6$	dithionic acid	dithionate	$S_2O_6^{2-}$
H_2SO_4	sulfuric acid	sulfate	SO_4^{2-}
H_2SO_3	sulfurous acid	sulfite	SO_3^{2-}
$H_2S_2O_3$	thiosulfuric acid	thiosulfate	$S_2O_3^{2-}$
$HClO_4$	perchloric acid	perchlorate	ClO_4^-
$HClO_3$	chloric acid	chlorate	ClO_3^-
$HClO_2$	chlorous acid	chlorite	ClO_2^-
$HClO$	hypochlorous acid	hypochlorite	ClO^-
$HMnO_4$	permanganic acid	permanganate	MnO_4^-

*Prefix often omitted.

Table 6: Names and Formulas of Salts Based on Ternary Acids

formula	name
KNO_3	potassium nitrate
$NiSO_3$	nickel(II) sulfite
$KHSO_4$	potassium hydrogen sulfate
$Na_2H_2P_2O_7$	disodium dihydrogen pyrophosphate

Table 7: Names of Hydrated and Ammoniated Compounds

formula	name
$Na_2SO_4 \cdot 10H_2O$	sodium sulfate decahydrate
$NiSO_4 \cdot 7H_2O$	nickel(II) sulfate heptahydrate
$PtCl_4 \cdot 2NH_3$	platinum(IV) chloride diammoniate

Coordination compounds. A coordination compound is composed of one or more complex structural units, each of which has a central atom bound directly to a surrounding set of groups called ligands. Nomenclature of coordination compounds requires a knowledge of these structural relationships; this topic is covered below in the section *Coordination compounds.*

STRUCTURAL CLASSIFICATION OF INORGANIC COMPOUNDS

Salts. The compounds formed by the chemical union of strong metals (elements at the left-hand side of the periodic table, of which the most metallic are the alkali metals, Group Ia) with strong nonmetals (elements at the right-hand side of the table, of which the most nonmetallic are the halogens, Group VIIa) provide the simplest examples of salts. These include sodium chloride (common table salt) and all the other compounds of alkali metals and halogens, called halides, such as lithium fluoride, potassium bromide, rubidium chloride, and cesium iodide, as well as the halides of many other elements—for example, magnesium fluoride, calcium chloride, and lanthanum fluoride. These halides are most clearly electrovalent in nature. The oxides of these elements (binary compounds with oxygen), the sulfides (binary compounds with sulfur), and the nitrides (binary compounds with nitrogen) are also electrovalent.

Most other binary compounds (compounds made of two elements) are either clearly composed of molecules (rather than ions) or else the character of their bonding is open to question. Commonly such materials are partially covalent in nature.

From F. Cotton and G. Wilkinson, *Advanced Inorganic Chemistry* (© 1966); John Wiley & Sons, Inc.

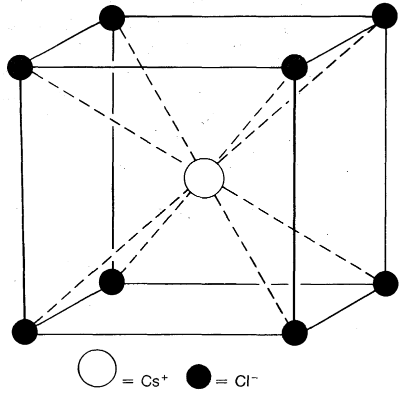

Figure 4: Cesium chloride structure.

Ionic crystal lattices

Electrovalent substances form solid crystals that are described in terms of ionic lattices. In these lattices, the positive ions are surrounded by negative ions, and the negative ions, in turn, are surrounded by positive ions. In any particular ionic lattice, a definite number of ions of one kind is arrayed about those of the second kind, and vice versa. This number is called the coordination number. In the sodium chloride lattice, the coordination number of both the cation (positive ion), the sodium ion, and the anion (negative ion), the chloride ion, is 6. The halide salts of most of the alkali metals crystallize in this same lattice form. The main exceptions are the cesium salts (*e.g.,* cesium chloride), which have a lattice in which the coordination number of both ions is 8 (see Figure 4).

The anions and cations have the same coordination numbers only in structures in which the same numbers of the two kinds of ions are present. In the lattice of calcium fluoride (CaF_2), the coordination number of the calcium cation is 8, whereas that of the fluoride anion is 4 (see Figure 5).

When salts melt, the geometric constraint of the crystal lattice is overcome, with the result that the individual ions become relatively free to move. The fact that the ultimate particles of the molten salt are charged makes it possible to pass an electric current through such melts. When such conduction occurs, the ions migrate through the liquid toward the electrode of opposite charge, thereby constituting an electric current. In water solutions, the covalent water molecules separate the ions so that they can move independently. Consequently, such solutions are also electric conductors.

Oxides, anhydrides, acids, and bases. The physical properties and chemical behaviour of the oxides of the elements provide a scheme for systematizing much of the chemistry of inorganic compounds. The gases of low atomic number—helium, neon, and argon—do not form stable oxides. The oxides of the early elements in any period of the table (such as sodium and calcium) are typically electrovalent, or saltlike, as evidenced by their high

From F. Cotton and G. Wilkinson, *Advanced Inorganic Chemistry* (© 1966); John Wiley & Sons, Inc.

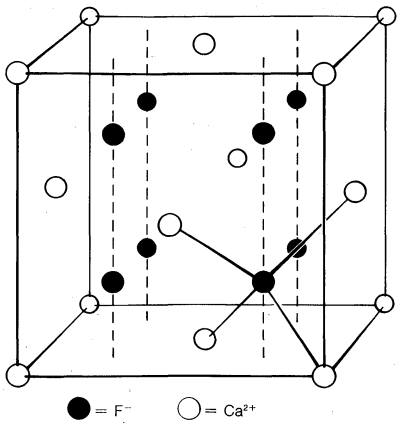

Figure 5: Calcium fluoride (fluorite) structure.

melting and boiling points. In contrast, the oxides of the last members of a given period in the table are characteristically discrete molecular structures held together by covalent bonds and with only weak forces between the molecules, as evidenced by their low melting points and high volatilities (for example, phosphoric anhydride and sulfur trioxide). The oxides of the elements in the centre of a period are intermediate in bond type and physical properties.

The contrast in physical properties of the oxides of the elements extends also to their chemical behaviour. Oxides of the alkali and alkaline-earth elements (and of a few other metals, the ions of which have low valences—that is, few charges) are basic in character and react with water to form ionic hydroxides. A good example of this behaviour is the action of sodium oxide on water to give sodium hydroxide:

$$\underset{\text{sodium oxide}}{Na_2O} + \underset{\text{water}}{H_2O} \longrightarrow \underset{\text{sodium hydroxide}}{2NaOH}.$$

asic
xides

Sodium hydroxide is composed of sodium (Na^+) and hydroxide (OH^-) ions. Basic (the chemical opposite of acidic) character is associated with the presence of hydroxide ions in aqueous solutions. Bases neutralize acids, change the colours of certain dyes (red litmus turns blue in bases), and absorb gaseous carbon dioxide to form carbonates. The reaction of sodium hydroxide with carbon dioxide to give sodium carbonate is shown below:

$$\underset{\text{sodium hydroxide}}{2NaOH} + \underset{\text{carbon dioxide}}{CO_2} \longrightarrow \underset{\text{sodium carbonate}}{Na_2CO_3} + \underset{\text{water}}{H_2O}.$$

Solutions of bases are slick to the touch because of the destructive action of bases on skin tissue; and they taste bitter (although, of course, tasting is not advisable).

cidic
xides

The oxides of the last members of a period, especially in high oxidation states (that is, high valence), are acidic in character. Aqueous solutions of acids contain hydronium ions (H_3O^+). They neutralize bases, turn blue litmus red, liberate carbon dioxide from carbonates, and react with active metals, forming salts and evolving hydrogen. They also have a sour taste. The reaction of a typical strong acid, sulfuric acid, with metallic zinc to give a salt, zinc sulfate, and hydrogen is shown below:

$$\underset{\text{zinc}}{Zn} + \underset{\text{sulfuric acid}}{H_2SO_4} \longrightarrow \underset{\text{zinc sulfate}}{ZnSO_4} + \underset{\text{hydrogen}}{H_2}.$$

Standard definitions of acids and bases recognize the typical behaviour mentioned above and characterize the neutralization reaction as the production of a salt and water. In fact, sodium hydroxide exists in solution as sodium and hydroxide ions, and nitric acid exists as hydronium and nitrate ions; the neutralization process involves the reaction of hydronium ions and hydroxide ions to form water molecules.

In addition to the oxides mentioned above, binary hydrides of strong nonmetals are also acids. In a solution of hydrogen chloride in water, for example, almost all of the hydrogen chloride has reacted with water to form the hydronium and chloride ions:

$$\underset{\text{water}}{H_2O} + \underset{\text{hydrogen chloride}}{HCl} \longrightarrow \underset{\text{hydronium ion}}{H_3O^+} + \underset{\text{chloride ion}}{Cl^-}.$$

Hydrochloric acid is a strong acid because of its almost complete dissociation to the ionic form. In solutions of acetic acid (vinegar), however, most of the acid is present as discrete molecules of acetic acid rather than as ions, and this substance is, therefore, a weak acid. Some acids have more than one replaceable—or acidic—proton (hydrogen ion): phosphoric acid (H_3PO_4), for example, has three, and sulfuric acid (H_2SO_4) has two.

Acid–base
theories

According to the more general Brønsted acid–base theory (which is named after its first proponent, the Danish chemist Johannes Nicolaus Brønsted), an acid is defined as a proton donor, whereas a base is a proton acceptor. Neutralization is then the transfer of a proton from an acid to a base. In the reaction of gaseous ammonia (NH_3)—a base—with gaseous hydrogen chloride (HCL)—an acid—to form electrovalent ammonium chloride (NH_4Cl), neutralization has produced a new acid, NH_4^+, and a new base, Cl^-:

$$\underset{\text{ammonia}}{NH_3} + \underset{\text{hydrogen chloride}}{HCl} \longrightarrow \underset{\text{ammonium ion}}{NH_4^+} + \underset{\text{chloride ion}}{Cl^-}.$$

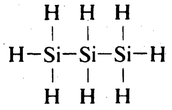
The new acid and base are both weaker than were the original reactants. Because of neutralization, the strongest acid that can exist in water is the hydronium ion (H_3O^+); similarly, the strongest base that can exist in water is the hydroxide ion (OH^-).

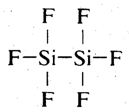
Another useful theory of acids and bases is the Lewis theory (named for the U.S. chemist Gilbert Newton Lewis), which specifies that a base is an electron-pair donor and an acid is an electron-pair acceptor. The "donated" electron pair is shared by the donor and the acceptor. According to this definition, water ($H_2\ddot{O}:$), hydroxide ion ($H\underset{\cdot\cdot}{\ddot{O}}:^-$), ammonia ($:NH_3$), and chloride ion ($:\underset{\cdot\cdot}{\ddot{Cl}}:^-$) are all Lewis bases. The most obvious Lewis acids (other than the proton H^+) are ions and atoms that have fewer electrons than required by the rule of eight. Boron trifluoride (BF_3), for example, has only six valence electrons and is capable of combining with a fluoride ion ($:\underset{\cdot\cdot}{\ddot{F}}:^-$) to form the tetrafluoroborate ion (BF_4^-). The boron atom in this ion obeys the rule of eight.

The oxides that form acids in aqueous solutions traditionally have been called acid anhydrides. The reaction of such an anhydride with water produces an acid, as in the following example with sulfur trioxide, SO_3:

$$\underset{\text{sulfur trioxide}}{SO_3} + \underset{\text{water}}{H_2O} \longrightarrow \underset{\text{sulfuric acid}}{H_2SO_4}.$$

Catenates. The ideal covalent bond is a nonpolar one between two atoms of the same element; in this case, the electron pair is equally attracted to both atoms. The phenomenon of like atoms joining together by covalent bonds is called catenation (Latin *catena,* "chain"), and it reaches a maximum with carbon, giving rise to a great many compounds of this type. The other elements of Group IVa in the table show increasingly diminished abilities to undergo catenation (silicon much less than carbon, germanium and tin somewhat less than silicon, and lead least of all). Silicon forms the series of compounds denoted by the general formulas Si_nH_{2n+2} and Si_nX_{2n+2+} (in which n is any integer and X = Cl, F). The structures below represent low-molecular-weight examples of the two series:





Catenation in Groups Va and VIa

The elements of Group Va of the table show relatively little tendency to catenate. Hydrazine ($NH_2{-}NH_2$) is the only hydride of nitrogen containing only nitrogen—nitrogen single bonds. Among Group VIa elements, sulfur is unique in its ability to self-link; it forms several series of linear covalent molecules of the types represented by the following general formulas: HS_nH, ClS_nCl, and $HO_3SS_nSO_3H$. Salts of polysulfide anions (S_n^{2-}) are also well characterized. Structures are given below for representative compounds in these various classes:

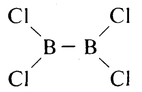
dihydrogen disulfide

polysulfide anion

tetrathionic acid

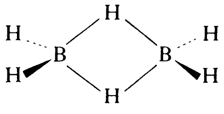
Some of the polysulfide ions are able to form chelate rings in which the sulfur atoms at each end of the chain are coordinated to one metal ion.

Boron is unique among Group IIIa elements in its ability to form catenates; the self-linkage of boron, however, is not restricted to typical boron–boron covalent binding. A few such compounds do exist, including diboron tetrachloride:



diboron tetrachloride

Although the simple hydride diborane (B_2H_6) was once thought to have a similar structure, it actually involves a distinctive three-centre, electron-deficient bond, in which one electron pair is shared between three atoms, two borons and one hydrogen atom:



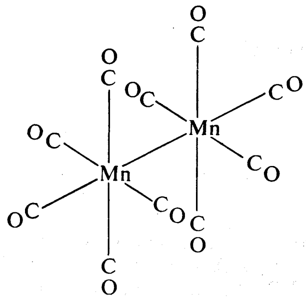
diborane

The ability of boron to form three-centre bonds in addition to normal covalent linkages leads to the formation of a number of boron hydrides with complicated structures. Although the simplest boron hydrides (for example, diborane) are extremely reactive toward oxygen and all solvents containing replaceable protons (such as water and alcohols), certain of the anions with cagelike structures (such as $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$) are remarkably unreactive.

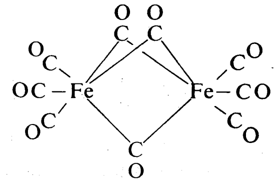
The carboranes are compounds similar to these anions except that two carbon atoms have replaced two of the boron atoms. Several of the carboranes with basket-like structures form pi complexes with metal ions that are very similar to the organometallic compounds with pi bonds described above.

Cluster compounds

Compounds in which the self-linking of elements has produced compact structures are referred to as cluster compounds. Catenation of metallic elements can yield both simple linear units and clusters. Though a number of representative metals apparently can produce metal–metal bonds under the right conditions, only mercury forms such species in aqueous mediums. The diatomic mercurous ion (Hg_2^{2+}) is unique in this regard. Given the right ligands (attached groups), however, most transition elements (those in the centre of the periodic table) can form metal–metal bonds. The carbonyls of iron and manganese provide examples of metal–metal bonds that are, respectively, accompanied by, and not accompanied by, bridging groups, as shown below:



decacarbonyldimanganese

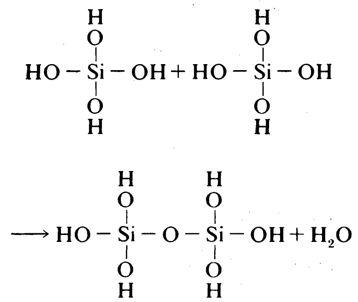


tri-μ-carbonylbis(tricarbonyliron)

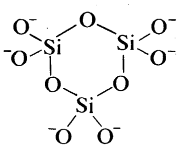
In the case of the rhenium halides with the formula $Re_2X_8^{2-}$, molecular orbital theory has been used to explain the unusually short rhenium–rhenium-bond distance in terms of a quadruple bond between the two rhenium atoms. Clusters occur with mutual bonding of three metal atoms [$Os_3(CO)_{12}$, Nb_3Cl_8], four metal atoms [$Co_4(CO)_{12}$], and six metal atoms [$Rh_6(CO)_{16}$ and $Mo_6X_8^{4+}$].

Polymeric silicates

Inorganic polymers. A polymer is a substance with a molecular structure containing repeating units; commonly, molecules with varying numbers of the repeating units are present, with the result that most polymer samples exist as a distribution of molecules having different molecular weights. Whereas the repeating methylene unit (CH_2) is the simplest and most familiar among organic polymers, the unit $-O{-}SiY_2-$ (in which $Y = O^-$ or OH) is the parent of many inorganic structures, especially certain minerals. Orthosilicic acid, $Si(OH)_4$, polymerizes by the elimination of water to form a vast array of structures, known as polymeric silicates, as shown by the following equation for the formation of a double molecule, or dimer; repetition of the process leads to progressively longer molecules.



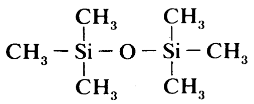
These polymers are best known in certain minerals (see the *Macropædia* article MINERALS AND ROCKS: *Silicates*). Long chains of $-SiO_3-$ units, for example, are found in the minerals enstatite, which conforms to the general formula $MgSiO_3$, and in spodumene, $LiAl(SiO_3)_2$. Other minerals, called amphiboles, and including such substances as tremolite, $Ca_2Mg_5(Si_4O_{11})_2(OH)_2$, contain double-stranded long chains in which the repeated unit is $S_4O_{11}^{6-}$. These substances are fibrous in character (asbestos being a good example), and the chains are held together by the cations. Mica and talc are two-dimensional sheet polymers of silicon and oxygen, whereas feldspar and zeolites are rigid, three-dimensional ploymers of similar type. Silicates also form such cyclic materials as $Si_3O_9^{6-}$, the structure of which is shown below:



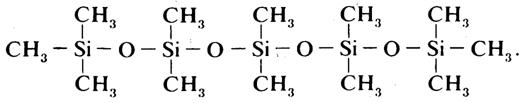
cyclic silicate anion

The most useful of man-made inorganic polymers are the siloxanes (also known as silicones), which use the basic structural unit of the silicate minerals, $-OSiY_2-$, with—

however—the Y's being methyl groups. Simple examples of these structures are:



$$CH_3-\underset{CH_3}{\overset{CH_3}{Si}}-O-\underset{CH_3}{\overset{CH_3}{Si}}-CH_3$$



$$CH_3-\underset{CH_3}{\overset{CH_3}{Si}}-O-\underset{CH_3}{\overset{CH_3}{Si}}-O-\underset{CH_3}{\overset{CH_3}{Si}}-O-\underset{CH_3}{\overset{CH_3}{Si}}-O-\underset{CH_3}{\overset{CH_3}{Si}}-CH_3.$$

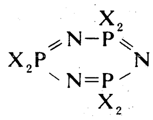
Siloxanes are chemically unreactive and thermally stable.

Phosphoric acid (H_3PO_4) and sulfuric acid (H_2SO_4) resemble orthosilicic acid (H_4SiO_4) in undergoing polymerization reactions, but the polymers designated by the formulas $H_2S_2O_7$ and $H_2S_3O_{10}$ are extremely sensitive to moisture. Sulfur trioxide, SO_3, exists in trimeric cyclic and linear polymeric forms.

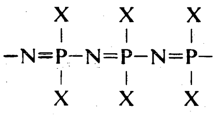
Polyphosphates and polysulfates

The polyphosphates are somewhat more stable than polysulfates, and long chain structures similar to the single-stranded silicates are known. The lower molecular weight anions, $(O_3P-O-PO_3)^{4-}$ and $(O_3P-O-PO_2O-PO_3)^{5-}$, are the most important. Cyclic phosphates are also known. Tungsten and molybdenum form a remarkable series of polyacids in which cluster-type polymerization occurs through oxygen bridges.

Phosphorus forms a series of compounds of the formula $(PNX_2)_n$, which can exist in both cyclic and linear polymeric forms, as shown below:



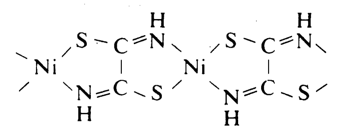
cyclic form



$$-N=\underset{X}{\overset{X}{P}}-N=\underset{X}{\overset{X}{P}}-N=\underset{X}{\overset{X}{P}}-$$

linear polymeric form

Polymers held together by coordination have also been prepared. A substance that found early use in producing coated polarizing lenses had the structures shown:



Unusual valence states. Oxygen forms metal salts containing the peroxide ion O_2^{2-}, the superoxide ion O_2^{-}, or the ozonide ion O_3^{-}. The last two are powerful oxidizing agents, whereas the peroxide ion can act either as an oxidizing or as a reducing agent.

Oxygen fluorides

Oxygen is assigned positive oxidation states only when it is combined with fluorine, the most electronegative of all elements. The compounds formulated as OF_2, O_2F_2, O_3F_2, and O_4F_2 are all strong oxidizing agents, and all are likely to react violently with most other substances. Trioxygen difluoride, O_3F_2, for example, is even more reactive than elemental fluorine. The great oxidizing strengths of these materials has led to interest in them as potential oxidizers for rocket fuels.

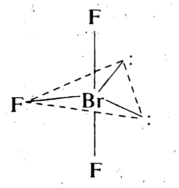
The binary compounds of hydrogen with elements at the right of the periodic table (Group IVa to VIIa) have already been discussed. The hydrides of the strong metallic elements are typical salts containing the hydride ion, H^-. The alkali-metal hydrides (*e.g.*, lithium and sodium hydride) have the same crystal structure as sodium chloride. The hydride ion also forms many complexes, especially with the electron-deficient hydrides of the Group IIIa elements. The formation of lithium borohydride is shown below:

$$\underset{\text{lithium hydride}}{2LiH} + \underset{\text{diborane}}{B_2H_6} \longrightarrow \underset{\text{lithium borohydride}}{2LiBH_4} .$$

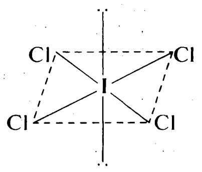
The complex hydride lithium aluminum hydride is an especially important reducing agent (that is, one that provides electrons) in chemical syntheses.

Interhalogen compounds

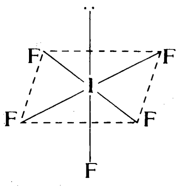
The halogens react among themselves to form a remarkable series of molecular interhalogen compounds (such as iodine chloride, bromine trifluoride, and iodine pentafluoride) and interhalogen ions (such as those formulated as I_3^-, ICl_4^-, BrF_4^-). The structures of these substances have been of theoretical importance because unshared pairs of electrons on the central atoms play a part in determining the geometries of the molecules, as shown in the following diagrams:



bromine trifluoride



iodine tetrachloride



iodine pentafluoride

The fluorides of sulfur contrast strongly with those of oxygen. Sulfur tetrafluoride is a moderate fluorinating agent, and the hexafluoride can be used effectively as a dielectric material (one that does not conduct electricity) because of its great thermal stability and chemical inertness.

Boron and nitrogen are on opposite sides of carbon in the periodic table, and they occur in one-to-one ratios in a series of materials that resemble elemental forms of carbon (diamond and graphite) and certain hydrocarbons (see Figure 6).

The compounds of sulfur and phosphorus, tetraphosphorus trisulfide (P_4S_3), tetraphosphorus pentasulfide (P_4S_5), tetraphosphorus heptasulfide (P_4S_7), and tetraphosphorus decasulfide (P_4S_{10}), appear to have strange formulas; they can all be understood, however, on the basis of a single structural principle. White phosphorus is composed of discrete P_4 tetrahedra, and the various sulfides are derived from these by the addition of sulfur atoms either along the edges or at the apexes of the structure (as shown below), all such locations being filled in tetraphosphorus decasulfide:

The anhydride of phosphoric acid, P_4O_{10}, has the same type of structure as tetraphosphorus decasulfide (with oxygen atoms replacing sulfur atoms). (D.H.B./Ed.)

WATER

Water is an extraordinary substance, anomalous in nearly all of its physical–chemical properties and easily the most complex of all the familiar substances that are single chemical compounds.

Ancient man, who clearly sensed the importance of water, made it a central feature of a great many mythological and religious cosmogonies, including that of Genesis. For the Greeks, the Titans Oceanus and Tethys were the parents of creation; and Western scientific tradition began in Greece when the Ionian philosopher-scientist Thales of Miletus, who flourished in the 6th and 7th centuries BC, substituted natural forces for gods as the causes of natural phenomena but retained water as the central principle, or "element," of his cosmology. His successors added other primal "elements"—fire, earth, and air—and the influence of Aristotle, who taught the doctrine of the four elements, adding a fifth element of his own (quintessence), dominated Islāmic and Christian thought. For many centuries the elements as qualities formed the basis of alchemical beliefs. Even Newton, an avid alchemist, set forth in *De Natura Acidorum* the view that all substances can be reduced to water. Eventually, hydrogen, one of the components of water, was considered to be the primal element, largely because it was found to be the lightest of all elements. The hypothesis that all the chemical elements were merely different aggregates of hydrogen was not abandoned until the 19th century, when precise determination of the atomic weights of the other chemical elements showed that they were not simple multiples of that of hydrogen.

Water as one of the alchemical elements

Structure of water. The formula for water, consisting of two atoms of hydrogen (H) and one atom of oxygen (O), is, thus, H_2O. The three atoms (*i.e.,* these three nuclei and their attendant electrons) are covalently bonded and form a specific structure, with the oxygen atom between the two hydrogen atoms.

The three atoms do not lie in a straight line, however, but, rather, with the hydrogen atoms bent toward each other. The three-dimensional structure of the water molecule, therefore, is unsymmetrical and can be shown with four uneven arms contained by a not quite perfect cube (Figure 7A). The angle formed by the two hydrogens and the central oxygen atom is about 105°, whether in the gaseous, liquid, or solid states, and the distance between the oxygen and each hydrogen nucleus—*i.e.,* the oxygen–hydrogen bond distance—is 0.96 angstrom (Å; one angstrom equals 10^{-8} centimetre). Opposite the hydrogen atoms and directed to the opposite corners of the containing cube are two electronic clouds of negative electrification, which are the keys to water's peculiar behaviour: they attract the hydrogen nucleus of an adjacent water molecule to form what is called a hydrogen bond. These bonds are not especially strong, but, since they orient the water molecules into a specific configuration, they significantly affect the properties of water. Water is not the only substance capable of hydrogen bonding. Ammonia, hydrogen fluoride, and alcohols also form hydrogen bonds; *i.e.,* hydrogen nuclei in these compounds are enough exposed to be attracted by the concentration of negative charges on adjacent molecules. Such molecules, so structured that one part has an excess of positive and the other an excess of negative charges, act somewhat like minute magnets and are called polar molecules. Polarity can also sometimes be induced in a molecule by the environment. The uniqueness of water appears to lie, however, in the ease with which its molecules form extended, three-dimensional, polymorphic hydrogen-bonded aggregates.

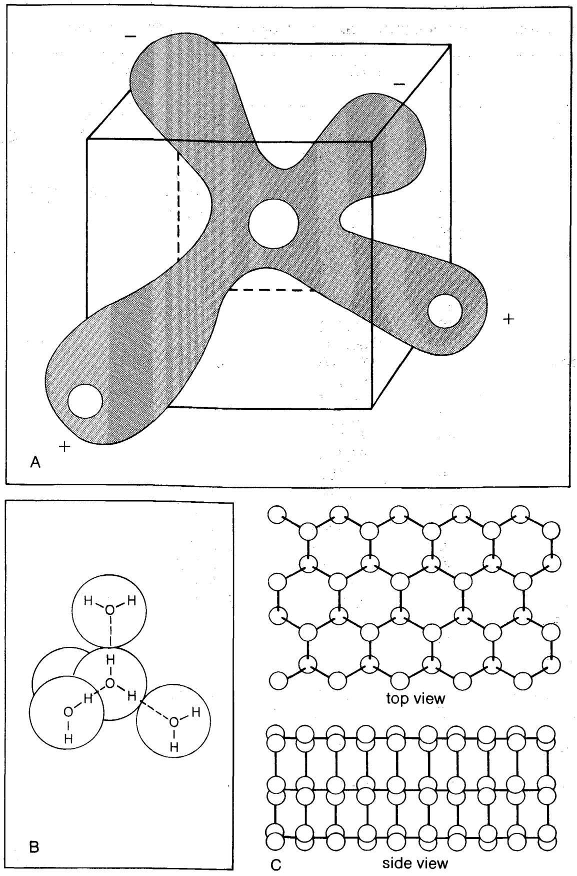

Figure 7: *The effect of the electronic structure of individual water molecules on the pattern of their organization in the crystalline state.*
(A) Electronic cloud of a single water molecule. (B) Tetrahedral arrangement of water molecules in the ice I lattice. (C) The structure of ice I.

Effects of hydrogen bonds. In the gaseous state, whether steam or water vapour, water molecules are largely independent of one another; and, apart from collisions, interactions between them are slight. Gaseous water, then, is largely monomeric; *i.e.,* it consists of single molecules, signified by a subscript, $(H_2O)_1$, with an occasional water dimer—*i.e.,* molecule formed by the union of two simple molecules, $(H_2O)_2$—and, perhaps, some even rarer trimers, consisting of molecules formed by the combination of three simple molecules, $(H_2O)_3$. In the solid state, at the other extreme, the water molecules interact with one another strongly enough to form an ordered structural lattice. A water molecule collects the four nearest of its neighbours and arranges them about itself in a tetrahedral configuration (Figure 7B). When the water freezes, this results in a lattice that can be schematically represented as sheets of puckered hexagonal rings (Figure 7C). Since the molecules in such a lattice are not crowded closely together, water is one of the few substances that is less dense in solid than in liquid state, and, for this reason, lakes and ponds develop a surface ice sheet in winter rather than freezing solid from bottom to top, as does a liquid that is less dense than its solid form (*i.e.,* normal liquids become more dense [they shrink] as the temperature is lowered, and the coldest layers will sink to the bottom, where they will be the first to freeze).

Ice

A variety of structures are formed when water freezes, and they are identified by roman numerals. The structure represented in Figure 7C is that of ice I, the familiar ice that forms and is stable at ordinary atmospheric pressure. Nine different forms of ice are known, each definable by

its lattice structure. Changes in temperature and pressure transform one kind of ice into another. The changes are specific and have been charted in phase diagrams.

Liquid water

Although ice has many baffling aspects, the full implications of water's eccentricities are revealed by the liquid. Far from being a simple, or "normal," fluid with undissociated molecules moving randomly and more or less independent of one another, water exhibits a short-range ordering reminiscent of the long-range ordering in the ice lattice, because the hydrogen bond makes water molecules stick tenaciously to one another. This results in anomalously high values for viscosity, surface tension, and the temperatures and heats of melting and boiling, which involve separation of molecules (Table 8). By analogy with hydrogen sulfide, H_2S (a molecule similar to water chemically), water should be a gas rather than a liquid at room temperature.

The stickiness of water molecules was recognized in the 19th century, and early attempts to explain it were in terms of association to form small aggregates called dihydrol and trihydrol. Water is an associated liquid best represented by the formula $(H_2O)_n$, in which n represents the number of H_2O molecules included in the aggregate. At present, despite intensive research for many years, there is uncertainty about the exact value of n—it seems dependent on temperature and pressure and the type and concentration of solute present, and its value may depend on where the water sample has been taken; there is a difference between n at a surface and n deep in the bulk.

Many theories have been developed to explain the structure of pure liquid water; some can account for most of water's peculiar properties, but none can account for all. Certain theories envision the liquid as consisting of a partially broken-down ice I lattice; others define a continuum model, and still others project a mixture model. A popular example of the latter postulates the liquid as a mixture of clusters (or polymers) with an average value

Flickering clusters

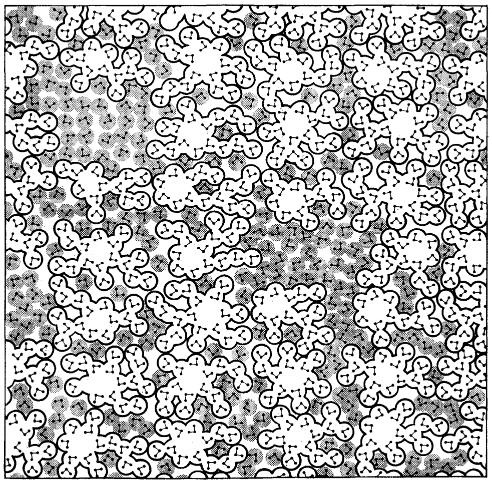

Figure 8: The "flickering cluster" model of liquid water showing a mixture of aggregates (outlined) and monomeric water (shaded).

for n of about 40 (at 20° C [68° F] and one atmosphere of pressure) and of monomeric ($n = 1$) water (Figure 8). The different groupings are in constant change, or flux, and are called flickering clusters. The average cluster size, n, decreases with increasing temperature or pressure, thus accounting for such properties as the maximum in the temperature dependence of the density and the minimum in the pressure dependence of the relative viscosity. The exact nature of the aggregates, if indeed there are clusters, is a subject of controversy.

The thermodynamics (*i.e.,* the study of heat and related energy changes) of the dissolution of nonpolar (molecules with no effective concentrations of charges—*i.e.,* no opposite poles) solutes in water indicate that they tend to order the water about themselves to form what has been described as an iceberg, the implication being that the structure is more or less analogous to that of ordinary ice. The implication, however, is unwarranted, and it is preferable to be less explicit and to describe this phenomenon as hydrophobic hydration. In some instances the crystalline hydrates (compounds or atoms that have combined with or added water molecules to themselves) of inert gases and other hydrophobic (water-repelling) solutes have actually been isolated and their structure determined. These gas hydrates (belonging to a class of molecules called clathrates) consist of a "guest" solute molecule enclosed in a polygonal cage of water molecules.

Hydration effects

Some ionic and polar solutes appear to make the water about them more structured, whereas others appear to be water-structure breakers. In order to account for this diverse behaviour, a process called Coulombic hydration is envisioned as producing the complex structure of what may be called a hydration envelope. First, there is an inner sphere of strongly bound molecules (called primary hydration); this forms part of a region of enhanced water structure, which in turn is surrounded by a zone of disrupted water structure (Figure 9). Depending on which zone is the more important, the solute will be a structure maker or breaker. So strongly held are the innermost water molecules that they may stick to the solute even when it is crystallized out of solution—the so-called water of hydration. It is possible to speak of hydration numbers, but there is little agreement in the values obtained by the different experimental techniques in use (Table 9). Recently, a Soviet school of physical chemists tried to circumvent this difficulty by thinking instead in terms of the time a water molecule will remain in a position near the solute species compared with the length of time a water molecule will remain in a position that is a great distance from the solute.

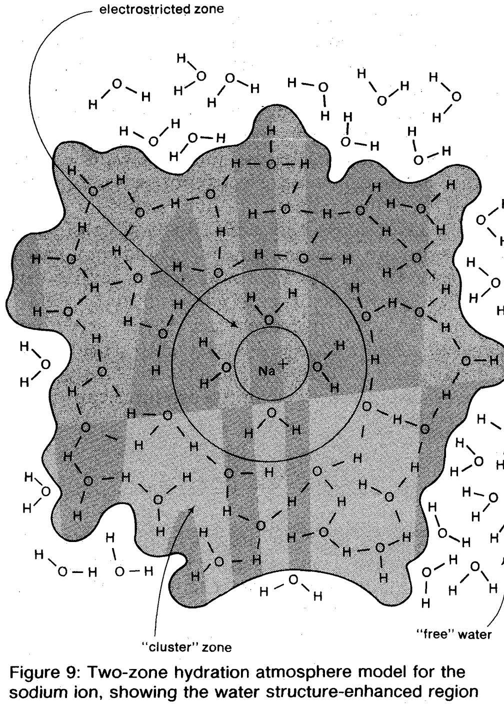

Figure 9: Two-zone hydration atmosphere model for the sodium ion, showing the water structure-enhanced region (the electrostricted zone plus the "cluster" zone) and the structure-broken region ("free" water).

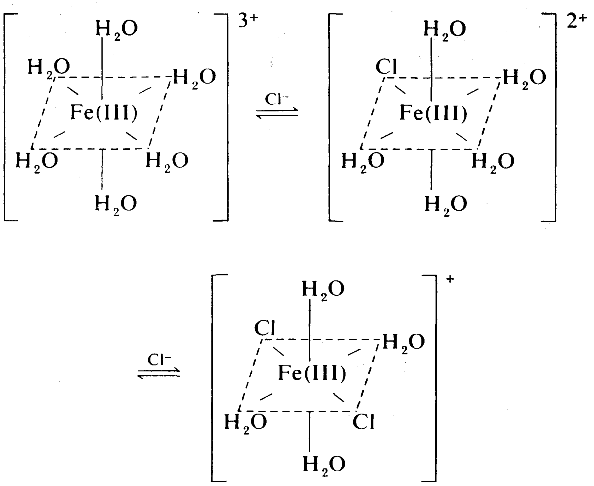
Table 9: Hydration Numbers of a Few Common Ions

ion	range of reported values	not unlikely value
Na^+	2–70	4
K^+	0.6–20	4
Mg^{2+}	6–36	12
Ca^{2+}	4–29	8
Br^-	2–5	2
SO_4^{2-}	1–12	12

Coordination in hydrates

Although it is an oversimplification to equate an ion's hydration number (number of water molecules associated with the ion) with its coordination number (the number of molecules, atoms, or ions, collectively called ligands, bonded to a central atom in a complex molecular structure), the hydration of an ion is closely related to its coordination chemistry. The water molecules can occupy the coordination positions around the central ion and be replaced with other ligands, either neutral molecules or ions.

The ion of iron(III), Fe^{3+}, has grouped around it six water molecules in a coordination compound that can be represented in a three-dimensional sketch:



Chlorine ions can replace the water, and, particularly if the ligands are organic groups, such replacement can result in drastic changes in chemical properties. If, for example, four of the six water molecules in the iron coordination compound are replaced by protoporphyrin, an organic compound, as is the case in heme (a portion of hemoglobin), the ability of the iron ion to act as a catalyst for the decomposition of hydrogen peroxide is increased 1,000-fold; if the remaining two water molecules are replaced by a protein compound to form the oxidizing enzyme catalase (which occurs in the blood and tissues), the catalytic activity is further increased 10,000,000-fold. The iron in heme, with two coordinated water molecules, is rapidly oxidized by molecular oxygen, but, if one of the two water molecules is replaced by protein, as in hemoglobin, the resulting compound can combine with oxygen reversibly and transport molecular oxygen from the lungs to distant cells without oxidation of the ferrous iron.

Generally speaking, the greater the charge density—*i.e.,* the ratio of charge to surface area—of an ion, the more heavily hydrated it will be, and as a rule negative ions (anions) are less heavily hydrated than positive ions (cations) because of the greater difficulty of crowding water molecules about the anions with the positive charges of the water protons oriented inward; *i.e.,* it is easier to orient the water with the protons outward and the negative end inward toward the positively charged cations.

Effects of interfaces

The structure of liquid water is also perturbed by the presence of an interface, but just how deep this layer of water (called vicinal) extends and what its structure might be are even less clear and more controversial than the structure of the bulk liquid. Vicinal water is suspected to have properties quite different from those of ordinary bulk water, a higher viscosity for example; this could be important since, if the layer is indeed thick, then most of the water in droplets in the atmosphere, most of the interstitial water in marine and other sediments, and most of the water in living cells and tissues would be vicinal water. The situation was complicated by the announcement of the discovery of a new form of water, orthowater (or polywater); however, the bulk of the present evidence points in the direction of vicinal water contaminated with various levels of impurities, rather than a new liquid form.

Physical properties of water. The physical–chemical properties of water are of great importance. Not only is the terrestrial environment largely aqueous, but also, because life originated in the oceans and evolved in Earth's hydrosphere, the basic processes of the life function are inextricably dependent upon water's peculiar properties.

Table 8 lists selected properties, at one atmosphere of pressure, of pure ordinary water, $(H_2O)_n$; pure heavy water, $(D_2O)_n$ (one isotope of hydrogen has a proton and a neutron in the nucleus, with resulting mass number 2, and is called deuterium; water composed of this heavier isotope of hydrogen is called heavy water); water's sister compound, H_2S; a "normal liquid, *n*-pentane; 35 parts per thousand salinity seawater; ice I; and water vapour. As has been indicated, the relatively high melting and boiling points, surface tension, and heats of fusion and vaporization are all the consequence of the disinclination of the hydrogen-bonded molecules to separate. The high viscosity also is a reflection of the extensively structured nature of liquid water; the very high dielectric constant (a dielectric substance acts as a nonconductor of electricity; the more insulating the substance, the higher is its dielectric constant), one property that makes water such a good solvent, is in part the result of the molecule being bent,

rather than linear, H—O—H, so that there is a strong dipole moment (measure of the tendency of a molecule with oppositely charged parts to be affected by an electrical, or magnetic field). Heavy water, D_2O, is slightly more structured than ordinary water; that is to say, the deuterium bond is slightly stronger than the hydrogen bond, so that many of its properties tend to have somewhat higher numerical values.

Chemical properties of water. Water is a highly reactive chemical substance, but, because it is recoverable from so many familiar chemical and physical processes, it was long thought to be elemental—*i.e.,* not a compound. Its compound nature was not demonstrated until quite late, and it was not directly synthesized from its elements until 1781. Because of early confusion between the atomic and molecular weights of gases, the formula of water was for some time erroneously thought to be HO rather than H_2O. Thermally, water is very stable; at 2,700° C (4,900° F) it is still only about 11 percent dissociated into hydrogen and oxygen molecules according to the equation (in which the number of each molecule involved is given before its formula and two arrows indicate that the reaction can go in either direction—*i.e.,* that it is reversible): $2H_2O \rightleftharpoons 2H_2 + O_2$.

Ionization of water

The self-ionization of water is small but extremely important. One molecule of water breaks up into a positive hydrogen ion, H^+, and a negative hydroxyl ion, OH^-, and again the reaction is reversible; *i.e.,* the ions recombine to form a water molecule: $H_2O \rightleftharpoons H^+ + OH^-$. According to the law of mass action, which pertains to reversible reaction in a system, when the two opposite reactions proceed at equal rates (when the production of ions equals the production of water)—*i.e.,* when the system is in a state called equilibrium—and the actual concentrations of the constituents (in this case H_2O, H^+, OH^-) are not changing, even though reactions among them are taking place, the ratio of the concentrations of the constituents equals a constant. If brackets are taken to indicate concentration, then the product of ion concentrations divided by the concentration of water equals a constant:

$$\frac{[H^+]\,[OH^-]}{[H_2O]} = \text{constant.}$$

Because so few molecules dissociate, so that the concentration of water molecules is always enormous, relative to its ions, it, $[H_2O]$ in the denominator, can also be considered a constant, K. Thus, $[H^+]\,[OH^-] = \text{constant} \times [H_2O] = K$. Measurements show that K equals 10^{-14}, which means that at room temperature pure water contains 55 moles (one mole is the weight in grams of the molecular weight—*e.g.,* 18 grams of water) of H_2O molecules per litre but only about 10^{-7} moles each of H^+ and OH^- ions. If the hydroxyl ion concentration $[OH^-]$ is changed, the hydrogen ion concentration $[H^+]$ always changes automatically to maintain the equation. It is thought that it is the hydrogen ion that gives an acid its acidic characteristics, while the properties of the hydroxyl ion are those of bases. Acidity is thus defined in terms of concentration of hydrogen ion and is expressed as the pH of a solution. The pH is 7 in a neutral solution or in pure water. This concentration of hydrogen ions is taken as the base for the chemical acidity scale. Systems with a pH less than 7 are said to be acidic; those with a pH greater than 7 are alkaline or basic. At one time, the proton, H^+, in solution was represented as associated with a water molecule in what was called hydronium ion, a complex resulting from the H^+ ion bonding with a water molecule and giving it a positive charge: H_3O^+. More recent evidence indicates that the proton in aqueous solution is more heavily hydrated and should be represented as bonded to four water molecules: $H_9O_4{}^+$ or $H(H_2O)^+{}_4$, which is to say that the primary hydration number of the proton is 4.

Acidity and pH

Acid–base reactions comprise a major class of chemical reactions. Another important class of chemical reactions is oxidation–reduction: a substance is oxidized when it loses electrons and is reduced when it gains electrons. Just as no acid can react as an acid unless a base is present, so no oxidation of one reactant can take place without the presence of a reactant that can be reduced. Hydrogen gas, H_2, is a reducing agent; *i.e.,* it is oxidized to hydrogen ion, H^+, and electron, e^-, according to the equation $H_2 \rightarrow 2H^+ + 2e^-$. The potential for any substance to be reduced or oxidized can be compared with the potential of any other, and therefore such substances can be arranged in a list according to increasing potential to be oxidized. The standard against which the potential of any substance can be measured is hydrogen gas, and thus water forms the basis of what is called the electromotive series, with the oxidation–reduction potential of hydrogen set at 0 (by international convention). Very active metals high in the series (such as sodium, Na) spontaneously (and sometimes violently) displace hydrogen gas (indicated by suffixed *g*) from water at room temperature to give sodium ion, Na^+, hydroxyl ion OH^-, and hydrogen gas, $H_2(g)$, according to the equation: $2Na + H_2O \rightarrow Na^+ + OH^- + H_2(g)$. Less reactive metals such as iron (Fe), react very slowly with water but more rapidly with steam to produce iron oxide and hydrogen gas:

$$3Fe + 4H_2O\ (\text{steam}) \overset{600^\circ\,C}{\rightleftharpoons} Fe_3O_4 + 4H_2(g).$$

Metals, such as silver, below hydrogen in the series, will not displace hydrogen from water. The importance of acid-base and oxidation–reduction reactions in the study of water lies in the fact that, with few exceptions, the acidity and oxidative ranges—that is to say, the proton and electron concentration ranges—in the natural environment are those set by water and its reactions. Life has evolved within these ranges, and values of pH and E_H (oxidation potential) outside them rapidly prove fatal to most

Oxidation and reduction reactions

living things. The tolerance of organisms to temperature may also be set, at least in part, by water properties.

Water as a solvent

Although exotic chemicals are being synthesized constantly, water remains one of the best solvents known, perhaps closest to being the "universal solvent" of which alchemists dreamed. All chemical substances have a finite solubility in water ranging from compounds like ethanol (ethyl alcohol), which is miscible with water in all proportions, to so-called insoluble substances like mercuric sulfide, saturated solutions of which contain less than 10^{-25} dissolved ions per litre. The high dielectric constant (a measure of nonconductivity) of water greatly facilitates the dissolution of ionizable species. Equally important is the strength with which water molecules solvate (react with and take into solution) ionic and other solutes. The coexistence of oppositely charged species, such as sodium ion (Na^+) and chlorine ion (Cl^-), in water without recombination is testimony to the strength and stability of the hydration atmospheres (the molecules of water surrounding the solute) of solutes in aqueous solution. In addition to hydration, represented by the equation

$$Na^+ + (n + 4)\,H_2O \leftrightharpoons Na\,(H_2O)_4\,(H_2O)_n{}^+,$$

there is also the hydrolysis of metallic species, a reaction in which the metal ion displaces the proton of water to form basic substances. The following equations illustrate the step by step hydrolysis of iron(III) ion to iron(III) hydroxide and hydrogen ion:

$$Fe^{3+} + H_2O \leftrightharpoons [FeOH]^{2+} + H^+$$

$$[FeOH]^{2} + H_2O \leftrightharpoons [Fe(OH)_2]^+ + H^+;$$

$$[Fe(OH)_2]^+ + H_2O \leftrightharpoons Fe(OH)_3 + H^+.$$

When these successive reactions are summed, the result can be stated as: $Fe^{3+} + 3H_2O \rightleftharpoons Fe(OH)_3 + 3H^+$. The hydroxides of iron are all bases.

Nonmetallic species, on the other hand, on being hydrolyzed, form acids, of which carbon dioxide is a common example. Ignoring the step by step process, the final result of the hydrolysis is hydrogen ion and the bicarbonate ion, HCO_3^-, according to the equation

$$CO_2 + H_2O \leftrightharpoons H^+ + HCO_3^-.$$

Some of these reactions have profound environmental significance. The hydrolysis of iron is intimately mixed with the chemistry of trace metals, including heavy metal pollutants such as mercury in natural waters, and forms the chemical basis for the production of the troublesome, highly acidic waters that often drain from old mining operations. As another example, if the rate of any of the steps for the dissolution of carbon dioxide gas in the oceans is slow enough, the accumulation of carbon dioxide in the atmosphere from the combustion of fossil fuels could result in a general warming up of the earth's surface in what is called the greenhouse effect. Theoretically, then, the polar ice cover could melt, and all the coastal cities disappear beneath the rising surface of the seas.

Water as a medium and a catalyst for chemical

Dissolution generally greatly enhances the chemical reactivity of substances; it is not surprising that, in part due to its good solvent properties, water is the medium and also a catalyst for countless chemical reactions. With the exception of petrochemical and combustion reactions, there are few chemical processes in our environment that do not occur in aqueous systems, including man's own respiratory and metabolic functions. Even the cooking of food takes place in water or involves dehydration and subsequent changes of proteinous material.

The rates of the fastest chemical processes in aqueous mediums are determined simply by the encounter frequency (frequency of collision) of the reactants. Consequently, the speed with which solute and solvent species can move through liquid water is a question of some interest. All the major transport processes in water—that is to say, processes that involve the movement of species within the liquid, such as electrical conduction, diffusion, viscous flow, and dielectric relaxation—require about the same energy, thereby implying that they all take place by the same mechanism, and the slow, rate-determining step of that mechanism is now believed to be the formation of a vacancy, or "hole," in the liquid water. Hole formation is then followed by the jump of a nearby solute or solvent species into the hole. The observed energy associated with this process is presumably that necessary to break hydrogen bonds and form the hole. These various movements take place in liquid water at great speeds, ranging from about 10^{-12} to 10^{-10} second. The average lifetime of the aforementioned flickering clusters falls in the same range.

(R.A.Ho.)

ORGANIC CHEMICAL COMPOUNDS

As previously observed, organic chemical compounds can be defined roughly as compounds of carbon. They are of great importance to mankind—indeed, to all forms of life on Earth—if only because most of the substances of which living things are composed fall into this category. The chief foodstuffs—namely, fats, proteins, and carbohydrates—are organic compounds, as are such vital materials as hemoglobin, chlorophyll, enzymes, hormones, and vitamins. Other materials that add to the comfort, health, or convenience of man are composed of organic compounds: clothing of cotton, wool, silk, and synthetic fibres; common fuels, such as wood, coal, petroleum, and natural gas; components of protective coatings, including varnishes, paints, lacquers, and enamels; antibiotics and synthetic drugs; natural and synthetic rubber; dyes; plastics; and pesticides.

Many of these synthetic organic compounds, as well as many waste compounds produced during their manufacture, are dumped eventually on the land and into the rivers, where they resist the chemical reactions that break down naturally produced organic structures. In addition, many noxious synthetic compounds, designed for the control of plants and insects, also are impervious to natural agents, and even low concentrations of these compounds threaten all forms of life. Thus, an increasing problem in organic chemistry is the ultimate disposal of synthetic products.

A recent trend in organic chemistry has emphasized greater knowledge of the mechanisms of reactions, a field dominated by the methods of physical chemistry. A trend in biology depends upon increasing use of knowledge concerning molecular structure. Thus, organic chemistry is now a field in which knowledge of physics and knowledge of biological processes meet.

Uniqueness of the carbon atom

The carbon atom is unique among elements in its tendency to form covalent bonds, not only with other elements but also with itself. Because of its position midway in the second horizontal row, or period, of the table, carbon is neither an electropositive nor an electronegative element; it therefore is more likely to share electrons than to gain or lose them. Moreover, for elements in its period, carbon has the maximum number of outer shell electrons (four) capable of forming covalent bonds. (Other elements, such as phosphorus and cobalt, are able to form five and six covalent bonds, respectively, with other elements, but they lack carbon's ability to bond indefinitely with itself.) The four bonds of the carbon atom are directed to the corners of a tetrahedron (a solid figure with four corners) and make angles of about 109.5° with each other. The result is that carbon atoms not only can combine with one another indefinitely to give compounds of extremely high molecular weight, but the molecules formed have a three-dimensional structure that leads potentially to an infinite variety of different molecules. It is the abundance of the covalent compounds of carbon, as well as their unique character, that justifies their characterization as a separate group, called organic compounds, whereas the compounds of all other elements are classed together as the inorganic compounds.

The elements other than carbon that usually are present in organic compounds, in the order of decreasing frequency, are hydrogen, oxygen, nitrogen, chlorine, and sulfur; in addition, many compounds are known that contain other elements.

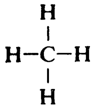
CLASSIFICATION AND NOMENCLATURE

Fortunately, despite the large number of organic compounds, a relatively simple systematic nomenclature has been adopted internationally that can be applied to the less complex—and hence the great majority of—organic compounds. This system was inaugurated by an international congress held in Geneva in 1892 and modified and extended at a meeting of the International Union of Chemistry held at Liège, Belgium, in 1930; since 1949, further development of the system has been continued under the auspices of the International Union of Pure and Applied Chemistry (IUPAC).

The IUPAC system

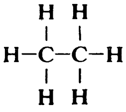
Hydrocarbons. Fundamentally, the IUPAC system is based on a nomenclature for the hydrocarbons (compounds containing only the two elements carbon and hydrogen).

The structures of organic compounds commonly are represented by structural formulas, which show not only the kinds and numbers of atoms present in the molecule but also the way in which the atoms are linked by the covalent bonds—information that is not given by simple molecular formulas. (With most inorganic compounds, the use of structural formulas is not necessary, because only a few atoms are involved, and only a single arrangement of the atoms is possible.) In the structural formulas of organic compounds, dashes are used to represent the covalent bonds. Atoms of the individual elements are represented by their chemical symbols as in molecular formulas. Examples of structural formulas of simple hydrocarbons are given below:



$$\begin{array}{c} H \\ | \\ H-C-H \\ | \\ H \end{array}$$

methane



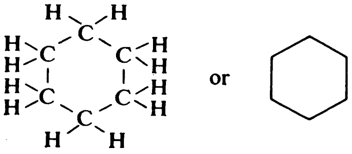
$$\begin{array}{c} H\ H \\ |\ \ | \\ H-C-C-H \\ |\ \ | \\ H\ H \end{array}$$

ethane

 or $CH_3CH_2CH_2CH_2CH_3$

$$\begin{array}{c} H\ H\ H\ H\ H \\ |\ \ |\ \ |\ \ |\ \ | \\ H-C-C-C-C-C-H \\ |\ \ |\ \ |\ \ |\ \ | \\ H\ H\ H\ H\ H \end{array}$$

pentane



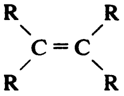
cyclohexane

Because so many hydrogen atoms appear in the various formulas when they are fully written out, it is customary to indicate simply the order of the carbon atoms with the number of hydrogens attached to each carbon indicated by a subscript as in molecular formulas, as shown in the alternate formula of pentane (above). Moreover, with cyclic compounds the rings are often indicated merely by polygons, each apex of which is considered to be a carbon atom bearing as many hydrogen atoms as needed for saturation.

In order to facilitate the naming of more complicated compounds, hydrocarbon groups that have one less hydrogen atom than the alkane are called alkyl groups, and their names have the same root as the corresponding alkane but end in the suffix -yl. Thus, CH_{3-} is known as a methyl group, and CH_3CH_{2-}, or simply C_2H_{5-}, is ethyl. The structure and nomenclature of the hydrocarbons are fully covered in the major section *Hydrocarbons* below.

Compounds with functional groups. Atomic groupings within molecules that are responsible for the varying chemical properties of organic compounds, such as double and triple bonds, are known as functional groups. The further classification and nomenclature of organic compounds is based on these groups.

If the symbol R is used to represent either hydrogen or an alkyl group, the general classes of organic compounds can be represented by attaching the proper number of R groups to the functional groups that distinguish the various classes. Alkenes, for example, can be represented by the general formula shown below:



(If one of the R groups in a class must be hydrogen, it is so indicated.) The functional group is indicated by either a suffix or a prefix added to the name of the corresponding alkane, as shown in Table 10. Before a vowel, the terminal *e* of the alkane is elided. For simpler compounds, common names generally are used.

Polyfunctional compounds

Polyfunctional compounds have more than one functional group. Hydroxycarboxylic acids, ketocarboxylic acids, and aminocarboxylic acids are common natural products. More complicated compounds with numerous mixed functions frequently are encountered.

Major categories of organic compounds—as defined by the functional groups present in their molecules—are treated in the following major sections of this article: *Alcohols, phenols, and ethers; Aldehydes and ketones; Carboxylic acids and their derivatives; Organic halogen compounds; Organic nitrogen compounds; Organic phosphorus compounds;* and *Organic sulfur compounds.* Other large groups of organic compounds—traditionally identified on the basis of other criteria—are dealt with in the sections *Alkaloids; Isoprenoids; Steroids; Dyestuffs and pigments; Heterocyclic compounds;* and *Polymers.*

PREPARATION AND PURIFICATION

Sources of organic compounds

Organic compounds are either derived from natural products or prepared by synthesis. The natural sources of organic compounds are plants and animals or fossilized materials, such as coal and petroleum. Synthesis is the use of chemical reactions to build larger molecules from smaller ones or to rearrange the atoms in a molecule to give new molecules.

The destructive distillation of coal to produce coke yields a liquid mixture called coal tar, which once was the chief source of aromatic compounds. Thermal decomposition of ethane, propane, and higher petroleum products is used to give alkenes of lower molecular weight; and the catalytic reforming of gasoline and kerosene fractions (which results in cyclization and the removal of hydrogen) now also yields aromatic hydrocarbons.

Fats, carbohydrates, and proteins not only are important as food substances but also yield fatty acids, sugars, and amino acids. Cellulose from cotton or wood can be converted to synthetic fibres, plastics, and explosives. Many important medicinals, such as the alkaloids and vitamins, as well as some dyes, flavours, and perfumes, are extracted from plants. Synthesis, however, accounts for most organic compounds, the initial starting points for which are chiefly the alkenes and the aromatic hydrocarbons. The chemical reactions of the various classes of organic compounds, many of which are of synthetic utility, are described below (see below *Chemical reactions*).

Separation methods

Most natural products and the products of synthetic reactions are mixtures that must be separated into the pure components. The procedures most commonly used are distillation, crystallization, and extraction with solvents. For the more difficult separations, selective adsorption and the various types of chromatography, a separation procedure based on differential adsorption of substances on various solid supporting materials, are used. Electrophoresis and ionophoresis, two processes that depend on the relative rates of migration in an electric field, can be used for charged particles.

It probably is fair to say that no ordinary compound is ever entirely free of foreign molecules as impurities. The

Table 10: Some Classifications of Organic Compounds According to Functional Group

class	function and name	general formula	suffix	prefix	examples
Alcohols	$-OH$, hydroxyl	$R-OH$	-ol	hydroxy-	C_2H_5OH, ethanol; C_6H_5OH, phenol; $HOCH_2CH_2OH$, 1,2-dihydroxyethane
Halogen compounds	$-X=$chlorine, bromine, or iodine	$R-X$		chloro-, bromo-, or iodo-	$CH_3CH_2CHClCH_3$, 2-chlorobutane (*sec*-butyl chloride)
Ethers	$RO-$, alkoxyl	$R-O-R$		alkoxy-	$C_2H_5OCH_3$, methoxyethane (ethyl methyl ether)
Carboxylic acids	$-COOH$, carboxyl	$R-COOH$	-oic acid		CH_3COOH, ethanoic acid (acetic acid)
Ketones	$>C=O$, carbonyl	$R-CO-R$	-one	oxo- (keto-)	$CH_3CH_2CH_2COCH_3$, 2-pentanone $CH_3COCH_2CH_2COOH$, 4-oxopentanoic acid
Aldehydes	$-\overset{\overset{H}{\vert}}{C}=O$, aldehyde	RCHO	-al	formyl-	$CH_3CH_2CH_2CHO$, butanal (*n*-butyraldehyde) $HCOCH_2CH_2COOH$, 3-formylpropanoic acid
Esters	$-\overset{\overset{O}{\Vert}}{C}-OR$, alkoxycarbonyl	$R-COOR'$	alkyl... -oate		$CH_3COOC_2H_5$, ethyl ethanoate (ethyl acetate)
Amines	—NH_2, amino	RNH_2	-amine	amino-	$CH_3\underset{\underset{NH_2}{\vert}}{C}HCH_3$, 2-aminopropane (isopropylamine)
Thiols (mercaptans)	$-SH$, sulfhydryl	RSH	-thiol	mercapto-	C_2H_5SH, ethanethiol (ethyl mercaptan) $HSCH_2CH_2COOH$, 3-mercaptopropanoic acid
Sulfonic acids	$-SO_3H$, sulfonic acid	RSO_3H	-sulfonic acid		$CH_3CH_2CH_2SO_3H$, propanesulfonic acid

degree of purity of any particular substance depends on the effort that is made to remove the last traces of impurities, and the effort expended generally depends on the use to be made of the compound. Compounds prepared for use as food additives or medicinal agents, for example, may need more extensive purification than those intended merely for industrial use. Once a compound is obtained as homomolecular (that is, in a form in which all the molecules present are identical) as is reasonably possible, it may be analyzed qualitatively for the elements present and then quantitatively for each element to determine the relative amounts of it in the molecule. The final step in establishing the molecular formula of the compound in question is the determination of the molecular weight. Today, in modern chemical laboratories, all of these analytical operations are carried out by specialists in microanalysis rather than by organic chemists.

Determination of structure

Once the molecular formula of a compound is established, the structure of the compound—that is, the order in which the atoms are attached to each other—must be elucidated. First, the kind and number of functional groups are determined. Then the molecule is broken down stepwise by known chemical reactions to smaller molecules of known structure. From the various bits of evidence, a structure is postulated in much the same way as a jigsaw puzzle is put together. This process has been greatly accelerated since about 1940, due to the development of physical procedures that use sophisticated electronic apparatus to secure information concerning molecular structure. Therefore, the determinations of ultraviolet and infrared spectra (light-absorption patterns), nuclear-magnetic-resonance spectra (patterns produced by magnetic effects on atomic nuclei), and mass spectra (separations of compounds—and fragments produced from them—on the basis of their relative mass) all play an important role in investigating the structures of relatively complex molecules. The use of radioactive isotopes of the various elements is fairly common, particularly in the study of organic reactions and in biochemical research on the way in which organic compounds are synthesized by living organisms.

The final proof of structure of a new organic compound is the synthesis of the supposed structure by known reactions from smaller molecules of known structure. Chemists have been able to arrive at the structure and configuration of substances with extraordinarily complex molecules, such as cholesterol, $C_{27}H_{46}O$, penicillin G, $C_{16}H_{18}N_2SO_4$, and chlorophyll *a*, $C_{55}H_{72}N_4O_5Mg$, by investigating their chemical and physical properties—and those of their degradation products. They also have been able to rebuild these molecules step by step from smaller molecules and in the end obtain compounds identical in all respects with the original product. This fact is the most convincing evidence of the soundness of the theories concerning the ways in which the various atoms are attached to one another in organic molecules.

PHYSICAL PROPERTIES

Since all compounds with a given functional group have approximately the same chemical properties, the differences among members of a given class of organic compound are largely differences in their physical properties. Boiling points, melting points, and solubility in various solvents are used most frequently to characterize a particular compound. Density, vapour pressure, and viscosity also often are measured. The most characteristic physical property of an organic compound, however, is its infrared absorption spectrum—that is, the particular pattern of wavelengths of light absorbed in the infrared region of the electromagnetic spectrum. If two samples have identical infrared spectra, they almost certainly are the same compound.

Factors that raise boiling points

Boiling point. In general, the boiling points of compounds with similar structures increase with increasing molecular weight. For simple, monofunctional, straight-chain compounds, the boiling point increases by about 20° C (36° F) for each additional carbon atom. Alkanes with four carbon atoms or fewer are gases at room temperature. For the higher molecular weight compounds, the boiling point rises from 36° C (97° F) for pentane, C_5H_{12}, to 287° C (548° F) for hexadecane, $C_{16}H_{34}$. Branching of the carbon chain lowers the boiling point. Thus, 2-methylbutane boils at 28° C (82° F) and 2,2-dimethylpropane at 9.5° C (49° F).

With the exception of double bonds, functional groups in a compound cause the boiling point to be higher. The chief factors that raise the boiling points of compounds above those of the corresponding alkanes are hydrogen bonding (attraction through secondary bonds involving hydrogen atoms attached to oxygen or nitrogen) and dipole–dipole interaction (attraction between polarized molecules). Both of these factors cause a degree of adhesion between individual molecules, hence making it more difficult to separate them. Table 11 lists the boiling points of some simple compounds of approximately the same molecular weight in the order of increasing boiling points.

Table 11: Boiling Points and Specific Gravities of Some Simple Organic Compounds

common name	formula	molecular weight	boiling point (°C)	specific gravity at 20° C
n-Butane	$CH_3CH_2CH_2CH_3$	58	−0.5	0.58
Methyl ethyl ether	$CH_3OCH_2CH_3$	60	10.8	0.73
Ethyl chloride	CH_3CH_2Cl	64	12.3	0.90
Ethyl mercaptan	CH_3CH_2SH	62	35.0	0.84
n-Propylamine	$CH_3CH_2CH_2NH_2$	59	49.0	0.72
Propionaldehyde	CH_3CH_2CHO	58	49.0	0.81
Acetone	CH_3COCH_3	58	56.0	0.79
n-Propyl alcohol	$CH_3CH_2CH_2OH$	60	98.0	0.80

Melting point. The melting points of solids increase with an increase of the forces holding the molecules in the crystal lattice. These forces depend on how readily the molecules fit together, a process that is influenced by the functional groups present and by the size and shape of the molecules. Usually, the more symmetrical the molecule, the higher the melting point of the compounds. Other generalizations have been made for certain types of compounds, but few predictions can be made concerning the melting points of most compounds.

Solubility. The solubility of one organic compound in another is the result of the intermingling of like and unlike molecules, whether they be gases, liquids, or solids. The extent to which compounds are mutually soluble depends on how nearly the attractive forces between like molecules match the attractive forces between unlike molecules. Thus, gases are all miscible with each other, because there is little in the way of attractive force even between the like molecules of a particular gaseous substance. The liquid alkanes are miscible in all proportions because the attractive forces between the like alkane molecules are much the same as between the unlike molecules. The liquid alkanes dissolve solid alkanes of lower molecular weights, but the solubility of the solid compounds decreases with increasing molecular weight, chiefly because the force with which the molecules are held in the crystal lattice increases with increasing molecular weight.

At the other extreme, water molecules are practically insoluble in liquid alkanes, and alkanes in water. In these cases, hydrogen bonding (secondary attraction by way of hydrogen atoms) of the water molecules to each other is many times stronger than the attractive forces between water molecules and alkane molecules, and there is little tendency to intermingle.

On the other hand, the lower alcohols, amines, and carboxylic acids are soluble in water for much the same reason that sodium chloride is soluble in water. Water molecules form hydrogen bonds not only with themselves but also with the hydroxyl group of alcohols and the amino group of amines and can hydrate the carboxylic-acid group and its ions, thus tending to equalize the attractive forces between the different molecules. For straight-chain alcohols with more than four carbon atoms and carboxylic acids with more than six carbon atoms, hydration is less effective in equalizing the attractive forces, and solubility of these compounds in water rapidly decreases. These considerations give rise to the old rule of thumb that "like dissolves like"; that is, the more closely organic compounds resemble one another in composition and structure, the greater is their mutual solubility.

Density and viscosity. The density of alkanes is lower than that of all other organic compounds, all alkanes being lighter than water. For liquids, a commonly cited datum is the specific gravity at 20° C (68° F); that is, the density of the substance at 20° C compared to that of water at 4° C (39° F); among the alkanes, the specific gravity varies from 0.63 for pentane (C_5H_{12}) to 0.77 for hexadecane ($C_{16}H_{34}$). The specific gravity increases with the introduction of atoms of elements that have a higher atomic weight than carbon (see Table 11) and with the increase of the ratio of the mass of such atoms to the mass of the rest of the molecule. Thus, ethyl chloride (C_2H_5Cl, $Cl/C_2H_5 = 1.2$) has a higher specific gravity, 0.90, than ethyl alcohol, 0.80 (C_2H_5OH, $OH/C_2H_5 = 0.6$); and 1,2-dichloroethane, at 1.26 (ClC_2H_4Cl, $Cl/CH_2 = 2.5$), is denser than water.

The viscosity of liquids depends on the ease with which molecules can slip past each other. Viscosity usually increases with increasing chain length of organic molecules because of the increased attraction between the molecules and the increased possibility of mutual entanglement.

CHEMICAL REACTIONS

Equilibria and rates of reaction

Most organic reactions are reversible to a greater or lesser extent; that is, the products of the reaction react with one another to regenerate the original reactants. In equilibrium reactions, the most important features are (1) the position of equilibrium, namely the ratio of products to reactants when chemical equilibrium is reached, and (2) the rate of reaction, or the speed at which the reaction takes place. The position of equilibrium is governed by the relative concentrations of reactants, the temperature, and the free energy change for the reaction —that is, the relative energy content of the reactants and products. The rate of reaction is influenced by the nature of the reactants, their concentrations, the temperature, the presence of catalysts or inhibitors, and the type of solvent used (if the reaction is carried out in solution). Acid–base reactions that involve readily ionized acids, for example, are extremely fast. When covalent bonds must be broken, however, the rate of the reaction at room temperature usually is very slow.

Since the rates of chemical processes approximately double for each 10° C (18° F) rise in temperature, organic reactions usually are carried out at elevated temperatures. In those instances in which high temperatures adversely affect the position of equilibrium, catalysts are sought that will make it possible for the reaction to proceed at reasonable rates and at as low a temperature as possible. Because both the forward and reverse reactions depend on the concentrations of the reactants, a desired reaction often can be made to go to completion by removing one of the products of the reaction; water, for example, may be removed by distillation or by the addition of a dehydrating agent. Since about 1940, chemists have become increasingly aware of the effect of solvents on the rates of reactions. Rate increases of more than 1,000,000-fold have been produced merely by changing the solvent.

Types of reactions

Because of the large number of different parent organic compounds and different functional groups, many types of organic reactions are possible. Some of the more important types are acid–base, addition, substitution, displacement, hydrolysis, pyrolysis, condensation, polymerization, and molecular-rearrangement reactions.

Acid–base reactions. Acids may be defined as compounds that can transfer a proton (a hydrogen atom that lacks an electron) to a base and a base as any entity with an unshared pair of electrons (and therefore capable of accepting a proton). In acid–base reactions a proton is transferred from an acid to a base, as shown in the following equation

$$H{:}A + {:}B \rightleftharpoons H{:}B^+ + {:}A^-,$$

in which HA represents any acid and B any base.

If HA and B are neutral molecules, the product is a positive ion and a negative ion and is known as a salt. A specific example is shown below, in which acetic acid is the acid involved, ethylamine is the base, and ethylammonium acetate is the resulting salt.

$$\underset{\text{acetic acid}}{CH_3COOH} + \underset{\text{ethylamine}}{{:}NH_2C_2H_5} \longrightarrow \underset{\text{ethylammonium acetate}}{CH_3COO^- + {}^+NH_3C_2H_5}$$

Varying degrees of acidity—that is, variations in the ease of removal of the proton—are possible, ranging from the extremely strong sulfonic acids to the virtually nonacidic alkanes; and varying degrees of basicity—or attraction for the proton—ranging from the extremely strongly basic alkide ion, R^-, to the extremely weakly basic sulfonate ion, RSO_2O^-, are also possible.

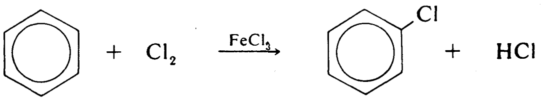
Degrees of acidity and basicity

Addition reactions. The addition of one molecule to another to give a single new molecule is an important class of reactions. Illustrative is the addition of bromine to ethylene.

$$H_2C=CH_2 + Br_2 \longrightarrow H_2CBrCH_2Br$$

ethylene bromine 1,2-dibromoethane

Substitution reactions. The replacement of hydrogen on carbon by another group generally is referred to as substitution. A typical substitution reaction is the synthesis of chlorobenzene from benzene and chlorine using ferric chloride as catalyst, as shown below:



benzene chlorine ferric chloride chlorobenzene hydrogen chloride

Displacement reactions. The direct replacement of one functional group by another generally is classed as a displacement reaction. A simple displacement of one halogen atom (chlorine) by another (iodine) in acetone as solvent is shown below:

$$CH_3CH_2CH_2Cl + Na^+I^- \longrightarrow CH_3CH_2CH_2I + Na^+Cl^-.$$

propyl chloride sodium iodide propyl iodide sodium chloride

Hydrolysis. The scission (or cleavage) of a molecule by reaction with water, with insertion of the elements of water into the final products, is called hydrolysis. An example is the acid-catalyzed hydrolysis of ethyl acetate:

$$CH_3COOC_2H_5 + H_2O \overset{H^+}{\rightleftharpoons} CH_3COOH + HOC_2H_5.$$

ethyl acetate water acetic acid ethyl alcohol

This reaction is typical of reversible reactions that do not go to completion. When one mole (the quantity with a weight in grams numerically equal to the molecular weight) of ethyl acetate and one mole of water react, only about one-third of the ethyl acetate is converted to acetic acid and ethyl alcohol. A greater degree of conversion may be produced by using an excess of water. However, a more practical procedure is to promote the reaction by a strong base, which reacts irreversibly with the acetic acid formed and, therefore, forces the reaction to completion.

Pyrolysis. Pyrolysis is the decomposition of a molecule by heat. The pyrolysis of carbon tetrachloride is a good example:

$$2CCl_4 \xrightarrow{800-900^\circ C} Cl_2C=CCl_2 + 2Cl_2\,.$$

carbon tetrachloride tetrachloroethylene chlorine

Condensation. The formation of a carbon–carbon bond between two molecules, with the elimination of a small molecule such as water or alcohol, generally is called a condensation reaction. An example follows:

$$CH_3COOC_2H_5 + CH_3COOC_2H_5$$

ethyl acetate ethyl acetate

$$\overset{^-OC_2H_5}{\rightleftharpoons} CH_3COCH_2COOC_2H_5 + C_2H_5OH.$$

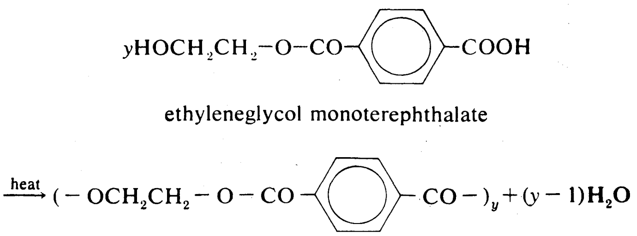
ethyl acetoacetate

Polymerization. Polymerization refers to the formation of compounds of high molecular weight—that is, polymers—from many smaller molecules (monomers) by addition or condensation reactions. Examples of both types are given below:

$$xCH_2=CH_2 \xrightarrow[\text{titanium tetrachloride, trialkyl-aluminum}]{TiCl_4,\ AlR_3} (-CH_2CH_2-)_x$$

ethylene polyethylene

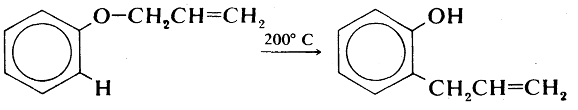
Condensation polymerization:



ethyleneglycol monoterephthalate

Dacron $y = 80$ to 130
molecular weight = 15,000 to 25,000

Molecular rearrangement. Molecular rearrangements are redistributions of atoms or groups within molecules. An example is the heat-induced rearrangement of allyl phenyl ether to 2-allylphenol, as shown:



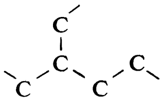
allyl phenyl ether 2-allylphenol

Numerous subclassifications of the above reactions, such as alkylation, acylation, esterification, ammonolysis, oxidation–reduction, nitration, chlorination, sulfonation, and disproportionation, also are used by chemists. See also the article CHEMICAL REACTIONS. (C.R.No./Ed.)

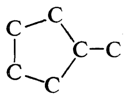
Hydrocarbons

Chemical substances containing only the elements hydrogen (H) and carbon (C) generally are called hydrocarbons. In hydrocarbon molecules the carbon atoms make up the skeleton or framework that gives the molecules their general shape, and the hydrogen atoms are attached to the carbon atoms, completing the molecular structure. The carbon atoms may be arranged in chains that are consecutive or branched, in rings, or in complex three-dimensional frameworks.

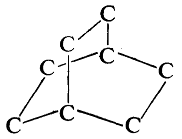
consecutive chain



branched chain



ring with one branch



a three-dimensional framework

The number of carbon atoms per molecule has no apparent upper limit: hydrocarbons with as many as 110 carbon atoms in a consecutive chain have been synthesized.

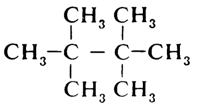
Occurrence. Many hydrocarbons occur in nature. As constituents of petroleum and natural gas, they are important energy sources. Because petroleum and natural gas are available in large supply, these hydrocarbons also serve as raw materials for the manufacture of plastics, synthetic rubber, solvents, explosives, lubricants, alcohols, synthetic fabrics, and many other useful products.

Certain hydrocarbons are present in trees and other plants. A hydrocarbon known as α-pinene (alpha-pinene), for example, with the empirical formula $C_{10}H_{16}$ (that is, with molecules each composed of ten carbon atoms and 16 hydrogen atoms), is the major component of turpentine, which is obtained from pine trees; and n-heptane, with the formula C_7H_{16}, can be obtained in pure form and in large

Hydrocarbons in foods, tobacco, and rubber

quantities from the Jeffrey pine. Hydrocarbons also are present in plant and insect waxes: beeswax contains 10–14 percent hydrocarbons (mainly $C_{31}H_{64}$).Hydrocarbons with fairly long carbon chains (up to C_{29}) have been isolated from cabbage and tobacco leaves, and from the cuticle (waxy film) of apples. Lycopene ($C_{40}H_{56}$) is the red pigment in ripe tomatoes and watermelon, and the carotenes (also with the formula $C_{40}H_{56}$ but with different arrangements of the atoms in the molecule) are important pigments in carrots and green leaves. Over 98 percent of crude plantation rubber is a hydrocarbon polymer, a chainlike molecule made of many small units joined together, with the formula $(C_5H_8)_n$, with n being a number averaging approximately 20,000.

Chemical and physical properties. Regardless of their diverse molecular structures, all hydrocarbons have a number of properties in common. They are virtually insoluble in water and, being less dense, float on its surface. Hydrocarbons are, however, usually soluble in one another as well as in certain organic solvents such as ether. Hydrocarbons may be gases, liquids, or solids at room temperature, their physical state depending mainly on their molecular weight. Those with four carbon atoms or fewer are gases. It is more difficult, however, to generalize about the demarcation between liquids and solids because crystallinity depends on molecular shape as well as on molecular weight. Some hydrocarbons, despite comparatively low molecular weights, are crystalline because their structures are highly symmetrical or compact. An example is hexamethylethane, the only hydrocarbon out of a total of 18, all of which have the formula C_8H_{18}, that is a solid at room temperature. It has the remarkably high melting point of 104° C (219° F), only 3° C (5.4° F) below its boiling point.



$$(CH_3)_3C-C(CH_3)_3$$

hexamethylethane

All hydrocarbons are combustible. If burned completely with sufficient oxygen, they produce carbon dioxide (CO_2) and water (H_2O). For example, the combustion of methane, the main component of natural gas, can be expressed:

$$\underset{\text{methane}}{CH_4} + \underset{\text{oxygen}}{2O_2} \longrightarrow \underset{\text{carbon dioxide}}{CO_2} + \underset{\text{water}}{2H_2O} + \text{heat}\,.$$

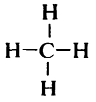
Such reactions are exothermic (that is, they give off heat), a fact that accounts for the widespread use of hydrocarbons as fuels. If insufficient oxygen is present, the hydrocarbon may be incompletely oxidized, producing carbon monoxide or carbon. Such incomplete combustion explains the presence of carbon monoxide in automobile exhaust, and carbon in the form of soot in chimneys.

$$\underset{\text{methane}}{CH_4} + \underset{\text{oxygen}}{\tfrac{3}{2}O_2} \longrightarrow \underset{\text{carbon monoxide}}{CO} + \underset{\text{water}}{2H_2O}$$

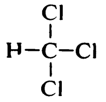
$$\underset{\text{methane}}{CH_4} + \underset{\text{oxygen}}{O_2} \longrightarrow \underset{\text{carbon}}{C} + \underset{\text{water}}{2H_2O}$$

Varieties of carbon–carbon bonds

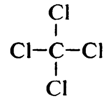
Classification. Hydrocarbons are in a sense the parent compounds from which can be derived all other organic compounds, as the large class of compounds containing carbon is called. In addition, the hydrocarbons illustrate several types of chemical bonding between carbon atoms, and their nomenclature forms the basis for the names of other organic compounds. More complicated molecules can be related structurally in a systematic way to hydrocarbons by the replacement of one or more of the hydrogens by other atoms or groups of atoms. Some examples are:



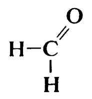
methane



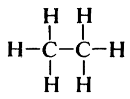
chloroform or trichloromethane



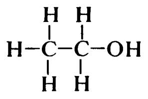
carbon tetrachloride or tetrachloromethane



formaldehyde or methanal

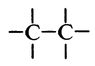


ethane

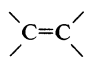


ethyl alcohol or ethanol

The structures of particular hydrocarbons and their chemistry depend in large measure upon the types of chemical bonds that the carbon atoms of the hydrocarbon molecules form with one another. Carbon atoms have a maximum valence, or chemical binding power, of four; this is a consequence of the fact that each carbon atom has four valence electrons, which it can share with other atoms including, of course, other carbon atoms. A single carbon atom, however, can share more than one of these electrons with another atom, again including carbon, thereby forming double or triple bonds, as shown in the following diagram. Thus, carbon atoms may be attached to four, three, or two other atoms.



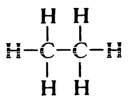
single



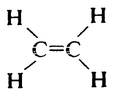
double

triple

If each of the remaining bonds in the structures shown above is to a hydrogen atom, the structures of the following hydrocarbons are obtained:



ethane



ethylene

acetylene

In each case there are four bonds to each carbon atom and one bond to each hydrogen atom, hydrogen atoms always having a valence of one. The type of bonding present, whether single or multiple, affects the molecular structure and chemical behaviour of the hydrocarbon in characteristic ways, which will be discussed as each class of hydrocarbons is considered below.

In order to group together compounds with similar chemical behaviour, hydrocarbons are divided into several major classes according to their structure:

- Aliphatic hydrocarbons
  - Saturated (alkanes, cycloalkanes)
  - Unsaturated
    - Alkenes, dienes, polyenes; related cycloalkenes, etc.
    - Alkynes, cycloalkynes
- Aromatic hydrocarbons
  - Benzenoid (mono-, di-, and polycyclic)
  - Nonbenzenoid

The two major categories are aliphatic (Greek *aleiphar,* "fat") and aromatic (Greek *arōmatikos,* "aromatic"). The aliphatic hydrocarbons can be defined most simply as all those hydrocarbons that are not aromatic. The chemical sense of the word aromatic no longer has any relation to the term aroma from which it was originally derived. Rather, aromatic compounds are now loosely defined as those substances the molecules of which have closed rings of atoms joined by a type of bond regarded as a hybrid of the single bond and the double bond. (For further treatment of this special bond, see below *Aromatic hydrocarbons.*) Aliphatic substances include all hydrocarbons of which the molecules contain chains but no rings of carbon atoms, called acyclic, as well as those with carbon rings, called alicyclic, or carbocyclic, except for those classed as aromatic. Aliphatic hydrocarbons may be further cat-

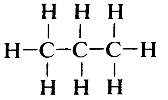
Saturated and unsaturated hydrocarbons

egorized according to the types of carbon–carbon bonds present. If all the bonds are single, the compound is said to be saturated. The systematic names for such classes of compounds are alkanes and cycloalkanes (or cyclanes). If a multiple bond connects any two carbon atoms, the hydrocarbon is referred to as unsaturated; the bonds may be double, as in alkenes or alkadienes, or triple, as in alkynes; some substances contain both types of multiple bonds in the same molecule. Aromatic compounds are classed as benzenoid if they contain six-membered aromatic rings, as in the parent compound benzene, or nonbenzenoid if they do not. They are further classified according to the number of rings they contain.

The nomenclature, structure, physical properties, synthesis, and chemical reactions of each of these classes of hydrocarbons are discussed below.

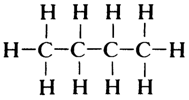
ALIPHATIC HYDROCARBONS

Alkanes. Alkanes have the general formula C_nH_{2n+2}, n being an integer and signifying the number of carbon atoms; each member of the class differs from the next higher and lower member, called homologues, by one carbon and two hydrogens. Formulas for the first two members of the series, methane, CH_4, and ethane, C_2H_6, have been given above. Only one structure is possible for each of these, and for the compound propane, C_3H_8, in which $n = 3$, but when $n = 4$, giving butane, C_4H_{10}, two structural formulas consistent with the valence rules can be written, depending on whether the carbon chain is consecutive or branched. In fact, substances corresponding to each butane structure can be prepared, as shown below. (The prefix "*n*-" refers to a normal, or consecutive, chain of atoms; "iso-" in this case implies a branched structure.)



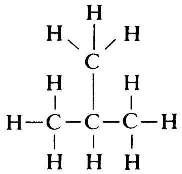
$H-\overset{H}{\underset{H}{C}}-\overset{H}{\underset{H}{C}}-\overset{H}{\underset{H}{C}}-H$

propane, C_3H_8



$H-\overset{H}{\underset{H}{C}}-\overset{H}{\underset{H}{C}}-\overset{H}{\underset{H}{C}}-\overset{H}{\underset{H}{C}}-H$

n-butane, C_4H_{10}



isobutane, C_4H_{10}

This phenomenon—called isomerism—is a general one, perhaps one of the most important in organic chemistry. Molecules are said to be isomers if they have the same molecular formula, as in the case of the butanes, C_4H_{10}, but different structural formulas (*i.e.*, different arrangements of the atoms in the molecule, as in *n*-butane and isobutane). Isomers usually have similar but not identical properties; both butanes, for example, are colourless gases, but *n*-butane boils at a slightly higher temperature (−0.5° C [32.9° F]) than does isobutane (−12° C [10.4° F]).

The number of possible isomers rises sharply with increasing *n*, as shown in Table 12. All alkanes up to and including the 75 isomers corresponding to formula $C_{10}H_{22}$ have been synthesized, and in each case the number of isomers found corresponded with that predicted. Of the groups containing more than 10 carbons, only a few isomers have been prepared, chiefly because there has been no practical incentive for chemists to synthesize them.

Table 12: Number of Possible Isomeric Alkanes

n	number of isomers	*n*	number of isomers
5	3	10	75
6	5	15	4,347
7	9	20	366,319
8	18	30	4,111,846,763
9	35	40	6.25×10^{13}

IUPAC nomenclature

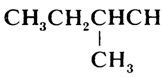
Nomenclature. Because of the existence of numerous isomers corresponding to each formula, the need for a systematic way of naming hydrocarbons quickly became apparent to chemists. A system originally devised by an international congress of chemists held in 1892 in Geneva, Switzerland, and later revised by the International Union of Pure and Applied Chemistry (IUPAC), is now used universally by organic chemists. In this system the saturated hydrocarbons are known as alkanes, the "*-ane*" ending being reserved for saturated compounds. After the first four members of the series, whose names have already been given, the normal (straight or consecutive chain) alkanes are named using Greek or Latin prefixes to indicate the number of carbon atoms in the chain:

C_5 *pent*ane	C_9 *non*ane	C_{13} *tridec*ane
C_6 *hex*ane	C_{10} *dec*ane	C_{14} *tetradec*ane
C_7 *hept*ane	C_{11} *undec*ane	C_{15} *pentadec*ane
C_8 *oct*ane	C_{12} *dodec*ane	C_{20} *eicos*ane

Branched-chain hydrocarbons are regarded as derivatives of normal hydrocarbons, the longest consecutive chain being considered the parent. The carbon atoms of this longest chain are then numbered from the end that gives the branches the lowest possible numbers. The names of the branches are attached as prefixes to the parent name, and their position is indicated by giving the number of the atom to which they are attached. If there are two branches on the same carbon, the number is repeated. The numbers precede the groups and are separated from them by hyphens. Finally, groups are named by changing the "-ane" ending to "-yl." For example:

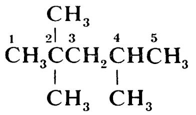
CH_4	CH_3-	CH_3CH_3	CH_3CH_2-
methane	methyl group	ethane	ethyl group

The system is illustrated by the following examples:



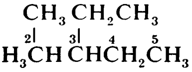
$CH_3CH_2\underset{CH_3}{CH}CH_3$

2-methylbutane



$\overset{1}{C}H_3\underset{CH_3}{\overset{CH_3}{\overset{2}{C}}}\overset{3}{C}H_2\underset{CH_3}{\overset{4}{C}}H\overset{5}{C}H_3$

2,2,4-trimethylpentane



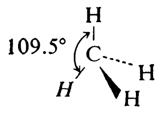
$\overset{1}{C}H_3\overset{CH_3}{\overset{2}{C}}H\,\overset{CH_2CH_3}{\overset{3}{C}}H\overset{4}{C}H_2\overset{5}{C}H_3$

3-ethyl-2-methylpentane
(alphabetic order for substituents)

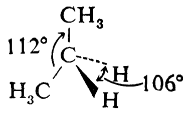
Special rules have been provided to handle unusually complex structures.

Tetrahedral structure of the carbon atom

Three-dimensional structures. Although flat, or two-dimensional, formulas are customarily used to represent the structures of organic compounds, the molecules themselves are in fact three-dimensional. The electron pairs making up chemical bonds usually adopt positions that keep them as far from one another as possible, since electrons carry like charges and repel one another. When the carbon atom has four groups attached to it (all with single bonds), the most stable arrangement is for the atom itself to be at the centre of a regular tetrahedron with the bonds extending toward its corners. Thus in methane, all H—C—H bond angles are equal to 109.5° (if the methane molecule were flat, the average angle between bonds would be only 90°.) The tetrahedral structure, with slight angle variations (106–112°) if the tetrahedron is not entirely symmetric, is common to all alkanes.



methane

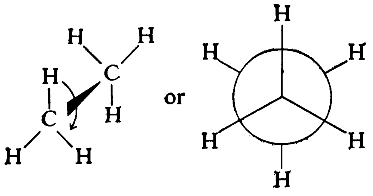


propane

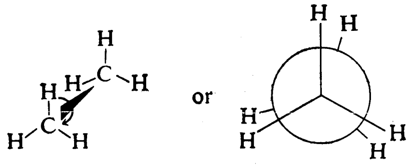
The carbon–carbon bond distance in alkanes is almost always 1.54 angstroms, and the carbon–hydrogen bond distance is 1.09 Å. The distance between hydrogens on adjacent carbons varies, however, because of rotation of the atoms about the carbon–carbon single bond. This phenomenon can be observed in the structure of ethane, in which the hydrogen–hydrogen distances are greatest in the so-called staggered conformation—that is, the shape the molecule assumes by rotation about the carbon–carbon bond; conversely, the hydrogen–hydrogen distances are smallest in another conformation, called the eclipsed conformation. Because of energy considerations, the staggered arrangement is more stable, and at room temperature most ethane molecules have this conformation.

Conformational analysis

Conformational analysis, the analysis of physical properties and chemical reactions as a function of molecular shape, was first developed during the 1950s by D.H.R. Barton of England and Odd Hassel of Norway, who shared a Nobel Prize in 1969 for their work.



ethane
(staggered conformation)

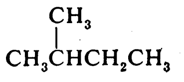


ethane
(eclipsed conformation)

Physical properties. The boiling points, melting points, and specific gravities of the normal alkanes increase with increasing molecular weight (Table 13). There is an enhanced attractive force between molecules as the number of atoms making them up increases, and this force affects melting and boiling points by making it more difficult to separate individual molecules (a prerequisite for either melting or boiling), and it increases specific gravities by pulling the molecules closer together. The viscosity, or "stickiness," also increases with increasing chain length, partly because of the same attractive force, and also because the greater lengths of the larger molecules increases the possibilities for entanglement and decreases the ability of the molecules to slip past one another. Branched-chain isomers almost always have lower boiling points than do the straight-chain isomers of the same compounds. This is clearly demonstrated by the three isomers of the hydrocarbon C_5H_{12} as shown below:

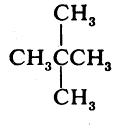
$CH_3CH_2CH_2CH_2CH_3$

pentane, 36.1° C



$$CH_3\overset{\displaystyle CH_3}{\overset{|}{C}}HCH_2CH_3$$

isopentane
or 2-methylbutane,
28° C



$$CH_3\underset{\displaystyle CH_3}{\underset{|}{\overset{\displaystyle CH_3}{\overset{|}{C}}}}CH_3$$

neopentane
or 2,2-dimethylpropane,
9.5° C

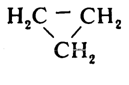
This effect stems from the fact that branching forces the molecules to remain farther apart and consequently decreases their mutual attraction.

Cycloalkanes. The general formula for cycloalkanes with one ring is C_nH_{2n}, where n is an integer equal to or greater than three. Thus, there are two fewer hydrogen atoms in the molecule of a cycloalkane than there are in the molecule of the corresponding alkane.

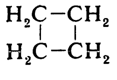
This condition exists because a valence bond from each of two carbon atoms is used in forming the ring. Rings are classified generally as small ($n = 3$ or 4), ordinary ($n = 5$ or 6), medium ($n = 7$ to 10), and large (n greater than 10). They are named with the same roots as alkanes, but with the prefix "cyclo-":

Table 13: Physical Properties of *n*-Alkanes

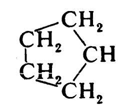
name	formula	boiling point (°C)	melting point (°C)	specific gravity
Methane	CH_4	−164	−182.5	.466
Ethane	C_2H_6	−88.6	−183.3	.572
Propane	C_3H_8	−42	−189.7	.501
Butane	C_4H_{10}	−0.5	−138.35	.601
Pentane	C_5H_{12}	+36.1	−129.7	.626
Hexane	C_6H_{14}	+68.9	−95.0	.660
Heptane	C_7H_{16}	+98.4	−90.6	.684
Octane	C_8H_{18}	+125.6	−56.8	.703
Nonane	C_9H_{20}	+150.8	−51.0	.718
Decane	$C_{10}H_{22}$	+174.1	−29.7	.730
Pentadecane	$C_{15}H_{32}$	+270	+10	.769
Octadecane	$C_{18}H_{38}$	+316.1	+28.2	.777
Eicosane	$C_{20}H_{42}$	+343	+36.8	.778
Triacontane	$C_{30}H_{62}$	+449.7	+65.8	.775
Tetracontane	$C_{40}H_{82}$	—	+81	—
Pentacontane	$C_{50}H_{102}$	—	+92	.794



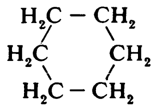
cyclopropane
(bp −33° C)



cyclobutane
(bp +12° C)



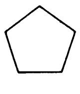
cyclopentane
(bp + 49.3° C)



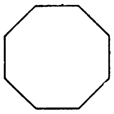
cyclohexane
(bp +80.7° C)

Frequently the formulas for cycloalkanes are represented by geometric figures that correspond to the rings. Each corner of the figure stands for a carbon atom with the appropriate number of hydrogen atoms to complete the valence of four. If substituents other than carbon are present they are shown explicitly, and the ring is numbered to assign them the lowest possible values. The "-ane" ending is retained when no multiple carbon–carbon bonds are present.

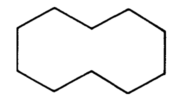
cyclopropane



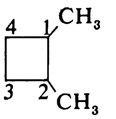
cyclopentane



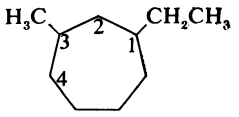
cyclooctane
(bp 147° C)



cyclodecane
(bp 201° C)

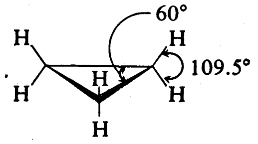


1,2-dimethylcyclobutane

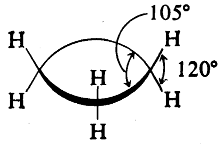


1-ethyl-3-methylcycloheptane

The three carbon atoms of cyclopropane necessarily define a plane, and the six hydrogen atoms are oriented above and below this plane. Since the carbons are at the corners of an equilateral triangle, the angles between the carbon–carbon bonds should be 60°. This small angle imposes considerable strain on the molecule, however, because the normal angle between carbon–carbon bonds (with the tetrahedral structure) is 109.5°. The molecule accommodates to this situation in two ways: (1) the angles between carbon–hydrogen bonds spread to 120° (larger than usual), allowing the angles between carbon–carbon bonds to contract, and (2) the electrons that constitute the carbon–carbon bonds do not lie along the direct lines



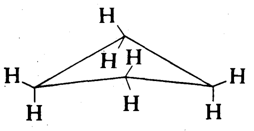
equilateral triangle
structure for cyclopropane



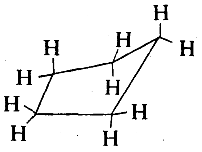
bent bond structure
for cyclopropane

between the centres of the carbon atoms, but rather they bulge outward in the plane of the ring, so that the actual bond angle becomes 105°. The chemical consequence of this "bending" of the bonds is that the electrons of the bond are more accessible than usual to attacking reagents. The cyclopropane ring, therefore, can be broken more easily than can larger rings.

Cyclobutane molecules also are strained. If the molecule were planar, each angle between carbon–carbon bonds would be 90°, and all hydrogens on adjacent carbons would be eclipsed. The ring puckers to decrease the interaction between hydrogens, even at the expense of some further decrease in the carbon–carbon bond angles. A puckered conformation is also adopted by cyclopentane, even though the internal angles of a regular pentagon are very close (108°) to the tetrahedral angle preferred by saturated carbon atoms. The puckered conformation in this case is assumed almost solely to avoid eclipsing of hydrogens.



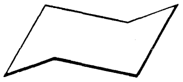
cyclobutane



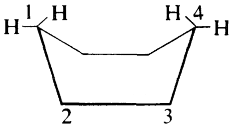
cyclopentane

Cyclohexane conformations

The conformations of cyclohexane, in particular, have been carefully studied because of the common occurrence of six-membered rings in many natural products, especially the steroids (*e.g.,* cholesterol). Three distinct conformations can be defined, the two rigid forms, chair and boat, and the flexible skew, or twist, form. In each, the angle between carbon–carbon bonds is 109.5° and strainless, and the forms are interconvertible by simple rotations about the C—C bonds. Since the angles are identical, the three conformations might be expected to be equally stable, but this is not the case. The chair conformation is much more stable, for in it all the hydrogen atoms on adjacent carbons are completely staggered, as in the staggered conformation of ethane. In the skew form several hydrogens are partially eclipsed, and in the boat form, which is the least stable, there are eclipsed hydrogens on C_2 and C_3, and again on C_5 and C_6, and in addition two of the hydrogens on C_1 and C_4 point in toward one another and are badly crowded. Because of these interactions, 999 of every 1,000 cyclohexane molecules will be in the chair form (the other being skew) at room temperature.



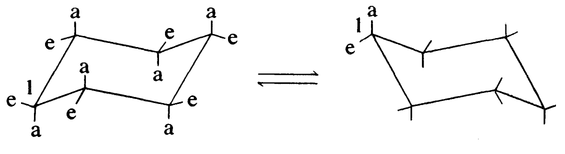
chair



boat

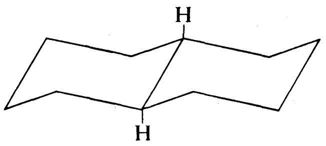
skew (twist)

There are two types of carbon–hydrogen bonds in the chair conformation of cyclohexane; these are called axial (*a*) or equatorial (*e*), depending on whether they are perpendicular or parallel to the mean molecular plane. The three axial hydrogens on each side of the molecule come close to one another in space. The two types (axial and equatorial) are interchangeable if the ring "flips" (this cannot be done directly; the skew forms are intermediates in the process). Any substituent other than hydrogen, the smallest atom, prefers an equatorial position since it avoids interaction with the axial hydrogens, and where "flipping" is possible this is the conformation observed. Conformational effects are important in explaining subtle differences in the chemical behaviour of cyclic molecules.

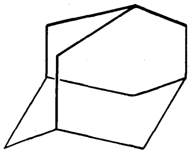


All larger rings also are puckered and free of angle strain, but those with seven to 12 carbons suffer unfavourable interactions between nonbonded hydrogens (hydrogens on different carbon atoms). The molecules adopt conformations that minimize these strains. Rings with more than 12 carbons are sufficiently flexible to adopt essentially strain-free conformations, analogous to those of the open-chain alkanes.

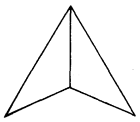
Many hydrocarbons with more than one ring are known. Among these are *trans*-decalin and adamantane, both having essentially strain-free molecules and both being substances found in petroleum. Three highly strained small-ring structures, bicyclobutane, spiropentane, and cubane, are examples of the unusual cyclic hydrocarbon molecules created by organic chemists in their laboratories.



trans-decalin, $C_{10}H_{18}$

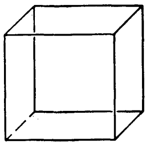


adamantane, $C_{10}H_{16}$



bicyclobutane, C_4H_6

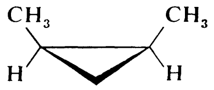
spiropentane, C_5H_8



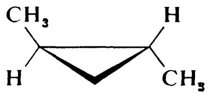
cubane, C_8H_8

Geometric isomerism

Certain cyclic structures show a type of isomerism in which two molecules differ only in the arrangement of substituent groups in space. For example, in 1,2-dimethylcyclopropane, the methyl groups may be on the same (*cis*) or on opposite (*trans*) sides of the ring plane. The resulting two substances are different, each having its own properties. *Cis–trans* isomers normally cannot be interconverted at room temperature, because to do so requires the breaking and remaking of chemical bonds. Alkenes, incidentally, also exhibit *cis–trans* isomerism (see below *Alkenes*). Biological reactions, controlled by enzymes, frequently are so sensitive to molecular structure that they can readily distinguish between a pair of geometric (*cis–trans*) isomers.



cis-1,2-dimethylcyclopropane
(bp 37°C)



trans-1,2-dimethylcyclopropane
(bp 29°C)

Sources and synthesis. The main commercial sources of alkanes are petroleum and natural gas. The latter contains 60–80 percent methane, 5–9 percent ethane, 3–18 percent propane, and 2–14 percent higher hydrocarbons. More than 150 pure hydrocarbons have been isolated from petroleum; about half are alkanes or cycloalkanes (the latter with C_5 or C_6 rings). Thermal and catalytic cracking (see below *Chemical reactions*) of petroleum and hydrogenation of coal are other alkane sources. Lower members of the series (through C_4) can be obtained in pure form by distillation. Annual production of each lower alkane is in the billion-pound range.

Individual higher alkanes and cycloalkanes usually are synthesized by reactions designed to give a unique product, since the number of possible isomers corresponding to each molecular formula is so large that separation of mixtures becomes impractical. One of the oldest but still useful laboratory methods involves electrolysis of organic acid salts (that is, passage of an electric current through a solution of the salt). Carbon dioxide is lost in the process, and the resulting organic radicals combine in pairs to form an alkane. For example,

$$2CH_3CH_2CH_2CO_2^-Na^+ - 2e$$

sodium butanoate

$$\xrightarrow[H_2O]{\text{electrolysis}} CH_3CH_2CH_2CH_2CH_2CH_3 + 2CO_2 + 2Na^+.$$

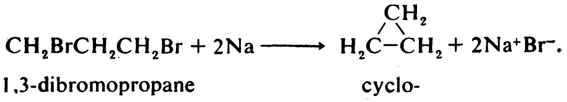
hexane

The reaction is quite general, the structure of the product depending upon the particular acid salt used. In a formally related reaction, the French chemist Charles-Adolphe Wurtz found in 1855 that organic halides couple when treated with sodium:

$$2CH_3CH_2CH_2Br + 2Na \longrightarrow CH_3CH_2CH_2CH_2CH_2CH_3 + 2Na^+Br^- .$$

1-bromopropane hexane

A modification of the Wurtz reaction has been used to prepare cyclopropane:



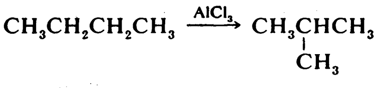
1,3-dibromopropane cyclopropane

In the current commercial process, zinc replaces sodium, and the cheaper 1-bromo-3-chloropropane is used. The product, cyclopropane, is a gas used in medicine as a general anesthetic.

Saturated hydrocarbons are also synthesized from corresponding unsaturated molecules, by the process of hydrogenation (see below *Alkenes; physical and chemical properties*).

Chemical reactions. Saturated hydrocarbons are unaffected at room temperature by most acids, alkalies, or oxidizing or reducing agents. This relative inertness gave rise to the name paraffins (Latin *parum,* "little"; *affinitas,* "affinity") sometimes applied to these substances, but it is now known that alkanes and cycloalkanes are more reactive than was once supposed. Methane, for example, will exchange its hydrogens for deuterium (a heavy isotope of hydrogen with chemical symbol, D) when placed in the extremely strong acid, deuterofluorosulfuric acid–antimony pentafluoride, FSO_3 D–SbF_5, at 80° C (176° F). Also, certain alkanes can be isomerized to highly branched structures. This isomerization reaction, carried out with the aid of an aluminum chloride catalyst, is used commercially to convert *n*-butane to isobutane, which is an important raw material for high-octane fuels.

Isomerization reactions



$$CH_3CH_2CH_2CH_3 \xrightarrow{AlCl_3} CH_3\underset{\substack{|\\ CH_3}}{C}HCH_3$$

n-butane isobutane

The most common reactions of saturated hydrocarbons involve replacement of one or more of the hydrogens by other atoms or groups of atoms. The reaction was discovered in a curious way. At a ball in France in 1830 guests were driven from the ballroom by choking fumes given off by the burning candles. It was found that the candles had been bleached by a process using chlorine; some hydrogen atoms in the hydrocarbon molecules of the wax were replaced by chlorine atoms and, on heating gave off hydrogen chloride fumes. The reaction was investigated systematically and found to be useful synthetically. When an alkane, or cycloalkane, is treated with chlorine or bromine at elevated temperature or in the presence of ultraviolet light, substitution occurs in the following manner:

$$RH + Cl_2 \xrightarrow[\text{light}]{\text{heat or}} RCl + HCl.$$

(R = an organic radical or group of atoms.) More than one hydrogen on a given carbon can be replaced, as in the sequence:

$$CH_4 \xrightarrow[-HCl]{Cl_2} CH_3Cl \xrightarrow[-HCl]{Cl_2} CH_2Cl_2 \xrightarrow[-HCl]{Cl_2} CHCl_3 \xrightarrow[-HCl]{Cl_2} CCl_4 .$$

methane methyl chloride dichloromethane chloroform carbon tetrachloride

The reaction conditions can be modified to give predominant mono- or poly- substitution, as desired.

Cracking

At high temperatures (500–700° C [932–1,292° F]) higher alkanes undergo rupture, or cracking, to give a mixture of smaller organic molecules and hydrogen gas. It is clear that if a given alkane, such as $C_{20}H_{42}$, is cracked to furnish another acyclic alkane, perhaps $C_{10}H_{22}$, along with a molecule of hydrogen (H_2), some of the remaining fragments must be unsaturated since, in the example chosen, only 18 hydrogen atoms are available to be distributed among the remaining ten carbon atoms. Cracking is therefore an important commercial source of unsaturated hydrocarbons.

Finally, of course, all alkanes are fuels, which can be burned to carbon dioxide and water. Partial oxidation occurs spontaneously at a considerably lower temperature than that required for combustion. This process, called autoxidation, causes the formation of organic acids and other corrosive materials during the use of hydrocarbon lubricating oils. Various antioxidants and inhibitors are added to automotive oils to slow down this undesirable reaction.

Alkenes. Alkenes, also called olefins, have two fewer hydrogens per molecule than do alkanes. They are unsaturated, with the general formula C_nH_{2n}, and their most characteristic structural feature is a carbon–carbon double bond. The first two members of the series are ethylene, C_2H_4, and

$CH_2{=}CH_2$	$CH_3CH{=}CH_2$
ethylene (ethene) (bp −102.4° C)	propylene (propene) (bp −47.7° C)

propylene, C_3H_6. The number of possible isomers increases more rapidly than with alkanes; whereas there are only two butanes, there are three isomeric butenes (see below *Geometry of the double bond,* however, for other, geometric isomers). The double bond may occupy any of several positions along the chain. If the bond is at the end of the chain, it is called terminal; otherwise, internal.

isobutylene (2-methylpropene) (bp −6.6° C)

Nomenclature. The general name is alkene, the "-ene" ending standing for a carbon–carbon double bond. (Older names include an "-yl-" after the root, as in ethylene, but the IUPAC names omit this syllable, as in ethene.) The longest chain incorporating the double bond determines the root of the name, which is the same as that of the alkane with the same number of carbon atoms. The position of the double bond is designated by the lower number of the two carbons involved in the bond, and the chain is numbered so as to give the double bond the lowest possible number (as in the formulas of 1- and 2-butene, above). The number that refers to the position of the double bond is sometimes omitted if this causes no ambiguity, as is often the case with cycloalkenes. Substituents are named in the same way as with alkanes, the numbering being determined, however, by the position of the double bond. These rules are illustrated by the examples at the end of this section.

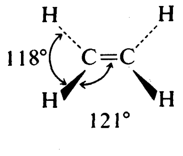
3-methyl-cyclopentene

Vinyl and allyl groups

Two unsaturated groups have useful common names, the vinyl and allyl groups. The vinyl group is $CH_2{=}CH-$, forming, *e.g.*, $CH_2{=}CHCl$, vinyl chloride, or chloroethene. The allyl group is $CH_2{=}CH-CH_2-$, forming $CH_2{=}CHCH_2Br$, allyl bromide, or 3-bromopropene.

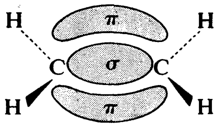
Geometry of the double bond. Each of the carbon atoms involved in a double bond is attached to only two other atoms or groups, because the total number of bonds to carbon can be no greater than its normal valence of four. In principle, the best geometric arrangement, which minimizes the repulsion between the electrons in the bonds, has all four atoms (carbon and the three atoms attached to it) in a single plane, with three equal bond angles of 120°. In practice the planar geometry is observed but the angles vary slightly from 120°, as shown for ethylene.



The average carbon–carbon double-bond distance is 1.34 Å, appreciably shorter (by 0.2 Å) than that of the carbon–carbon single bond. This decrease results from the fact that two electron pairs, rather than only one, bind the two carbon nuclei to one another.

Sigma and pi bonds

The position of the two electron pairs is of some significance in explaining the reactions of alkenes. One pair, as in a single bond, occupies the space directly between the two carbon nuclei, in an orbital (region of space within which the electrons are localized) that is symmetric about an axis drawn between the two nuclei. Bonds with this symmetry are referred to as σ (sigma) bonds. The second electron pair, in order that it not occupy the same space as the first, cannot lie directly between the nuclei that it binds together. It lies instead in an orbital that is both immediately above and immediately below the plane formed by the two carbons and the atoms attached to them; this is called a π (pi) bond. The π bond is somewhat weaker and more easily broken than the σ bond. The π electrons, not being buried between two atomic nuclei, are quite accessible to chemical reagents. For this reason, alkenes and cycloalkenes are much more reactive than alkanes, and most of the reactions involve breaking the π bond or adding to it.



Cis and trans isomers

The presence of two bonds between adjacent carbon atoms imposes some geometric restrictions on the molecule. Sigma bonds, being centrosymmetric about the C-C axis, permit relatively free rotation of one carbon with respect to another, as in ethane. But the π bond has no such symmetry; to rotate one carbon of a double bond 180° with respect to the other carbon would require that the π bond be broken and eventually reformed. This process usually requires considerably more energy than is available at room temperature. Consequently, rotation about double bonds is ordinarily not possible except at high temperatures, or in the presence of other energy sources, or during chemical reactions in which the π bond is temporarily broken anyway. Restricted rotation around double bonds leads to geometric, or *cis–trans,* isomers, like those found in cycloalkanes (see above *Cycloalkanes*), when the two groups attached to each carbon of the double bond are different. Thus there are two 2-butenes, *cis* and *trans.* In all small and ordinary sized ring compounds with a double bond (cycloalkenes), the geometry is necessarily *cis;* the smallest stable ring structure with a *trans* double bond has eight carbon atoms.

Geometric isomers may differ rather drastically in molecular shape. The carbon chain in *cis*-2-butene, for example, is approximately U-shaped, whereas that of the *trans* isomer is Z-shaped. In biological systems such drastic structural changes can be very significant, because they affect the way in which an unsaturated molecule interacts with enzymes. The chemistry of vision constitutes a particularly important example. A visual pigment called retinene contains a number of double bonds, and the conversion of one of these from the *cis* to the *trans* form occurs when the pigment is exposed to light. This isomerization alters the degree of attachment of retinene to a protein molecule and brings about other changes in the chemicals of the retina.

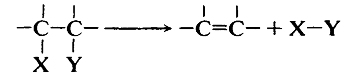
trans-cyclooctene

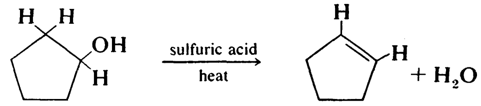
Sources and synthesis. The lower alkenes (through C_4) are produced commercially by cracking natural gas or petroleum or mixtures of hydrocarbons derived from them. The largest percentage of the ethylene produced each year in the United States is used as a raw material for making the plastic polyethylene. Another sizable percentage goes to make ethylene oxide, which in turn is used to manufacture glycol antifreeze and other products. Substantial amounts also are converted into ethyl alcohol. Propylene and the butenes, also manufactured on a large scale, are sources of other chemicals that are used as solvents or as starting materials for the manufacture of plastics, detergents, synthetic rubber, food preservatives, and numerous other products.

Individual higher alkenes and cycloalkenes may be synthesized by reactions in which a double bond is introduced into a saturated precursor. The principle behind most of these methods is expressed by the equation:

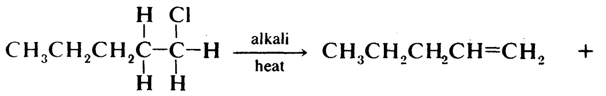


$$-\underset{X}{\overset{|}{\underset{|}{C}}}-\underset{Y}{\overset{|}{\underset{|}{C}}}- \longrightarrow -\overset{|}{C}{=}\overset{|}{C}- + X{-}Y$$

in which X and Y are two atoms or groups attached to adjacent carbon atoms and capable of forming some small molecule X—Y. The process is called an elimination reaction (X and Y being eliminated from the starting compound). Examples include the dehydration of alcohols and the removal of a halogen acid from an alkyl halide.



cyclopentanol, an alcohol — cyclopentene



$$CH_3CH_2CH_2\underset{H}{\overset{H}{C}}-\underset{H}{\overset{Cl}{C}}-H \xrightarrow[\text{heat}]{\text{alkali}} CH_3CH_2CH_2CH{=}CH_2 \quad + \quad HCl$$

an alkyl halide — an alkene — hydrochloric acid

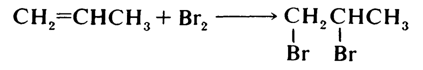
These usually are laboratory rather than commercial methods. Alkenes also can be prepared by partial hydrogenation of alkynes (see below *Alkynes; reactions*).

Physical and chemical properties. The physical properties of the alkenes are generally similar to those of alkanes or cycloalkanes with equal numbers of carbon atoms.

Addition reactions

In contrast with the alkanes, however, which react predominantly by substitution, alkenes react mainly by addition; various reagents add to the carbon–carbon double bond by reactions that are the reverse of elimination. These reactions are frequently very rapid, even at room temperature.

Halogens, such as bromine, add rapidly to most alkenes. The product is saturated since the carbon–carbon double bond in the reactant is replaced entirely by single bonds in the product. The π electrons originally present are used to form single (σ) bonds to the bromine atoms. One bromine adds to each carbon of the double bond (note that the only product from propene is 1,2-dibromopropane; no 1,1- or 1,3- or 2,2-isomer is formed).

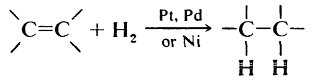


$$CH_2{=}CHCH_3 + Br_2 \longrightarrow \underset{Br}{C}H_2\underset{Br}{C}HCH_3$$

propene 1,2-dibromopropane

The reaction with bromine is frequently used as a test for unsaturation in a molecule. Alkenes are colourless, bromine is a reddish-brown liquid, and the product, an organic dibromide, is colourless. When a reddish-brown solution of bromine in some inert solvent (*e.g.,* carbon tetrachloride) is added to an alkene, the bromine reacts instantly to form the colourless product. The bromine solution is "decolourized." If the substance being tested has no carbon–carbon double bonds, the bromine does not react, or reacts only slowly by substitution, and the colour of the bromine solution remains essentially unchanged. The reaction can be modified and used to determine the percentage of alkenes present in an unknown mixture; bromine is added until it is no longer decolourized, and the amount required for a given sample weight is measured.

Alkenes can be converted to alkanes by hydrogen, usually under pressure and in the presence of a finely divided metal catalyst, such as platinum, palladium, or nickel. The generality of this reaction, called catalytic hydrogenation, was first appreciated by the French chemist Paul Sabatier (Nobel Prize, 1912). Hydrogenation is used commercially not only to make alkanes or cycloalkanes, but in general to produce more saturated molecules from less saturated ones (for example, oleomargarine from soybean oil).

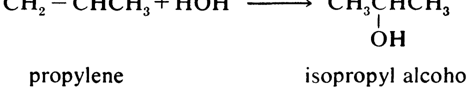


Alkenes are converted to alcohols by hydration; the reaction requires an acid catalyst. Most of the ethanol produced for industrial use is obtained from ethylene.

$$CH_2{=}CH_2 + HOH \xrightarrow[\text{acid}]{\text{sulfuric}} CH_3CH_2OH$$

ethyl alcohol
(ethanol)

The following similar reaction gives isopropyl alcohol from propylene.



$$CH_2 = CHCH_3 + HOH \xrightarrow{\text{acid}} CH_3\underset{OH}{C}HCH_3$$

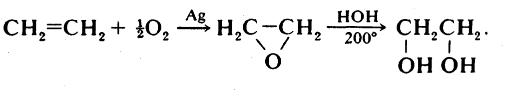
propylene isopropyl alcohol

Alcohols also add to alkenes in the presence of acid. Ether (more correctly, diethyl ether), the widely used solvent and anesthetic, is made from ethylene in this way.

$$CH_2{=}CH_2 + HOCH_2CH_3 \xrightarrow{\text{acid}} CH_3CH_2OCH_2CH_3$$

ethylene ethyl alcohol diethyl ether

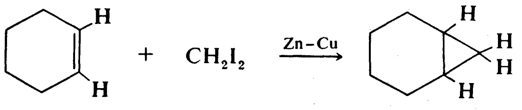
Ethylene oxide is produced by passing a mixture of ethylene and air (or oxygen) over a heated silver catalyst:



ethylene oxide (oxirane) ethylene glycol

Most of the ethylene oxide produced is converted (with water) to ethylene glycol, the main component of permanent automotive antifreeze.

Alkenes may be converted to cyclopropanes by reaction with dihalomethanes (CH_2X_2) and a metal; in effect, a $-CH_2-$ group is added to the double bond, as for example:



diiodomethane norcarane

Alkenes and cycloalkenes react rapidly with ozone. Although ozone first adds to the double bond, the net reaction is cleavage of the molecule, a process called ozonolysis; two fragments with C=O (carbonyl) groups are produced.

ozone

When the position of the carbon–carbon double bond in the molecule is unknown, the ozonolysis reaction can be used to locate it, if the carbonyl products can be identified. For example, on ozonolysis 2-butene gives a single product, acetaldehyde, $CH_3CH{=}O$, whereas 1-butene gives two products, formaldehyde, $CH_2{=}O$, and propionaldehyde, $O{=}CHCH_2CH_3$.

Polymerization

One alkene molecule can add to the double bond of another; each is said to be a monomer, and the product is a dimer. If the process is repeated, trimers, and eventually polymers, substances composed of a great many monomer units, are obtained. Polymerization is one of the most important reactions used by the chemical industry.

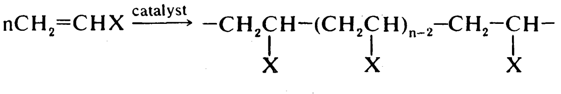
Ethylene can be converted to polyethylene by several processes:

$$nCH_2{=}CH_2 \xrightarrow{\text{catalyst}} -CH_2CH_2{-}(CH_2CH_2)_{n-2}{-}CH_2CH_2-$$

polyethylene

the product is essentially an alkane and therefore is chemically inert. The ends of the chain may have catalyst molecules attached, or the chain may terminate by loss of one hydrogen, leaving a double bond at the end. Depending on the catalyst used, the chain may be almost entirely consecutive as shown, or it may have occasional branches of smaller chains. The more nearly linear the chain, the greater the density of the polymer. Because of its high molecular weight (n often exceeds 1,000), polyethylene is insoluble in most solvents. But it is thermoplastic (softens and flows on heating), and it can be extruded into sheets or films and molded into various shapes that are retained on cooling.

Substituted ethylenes also form polymers according to the reaction

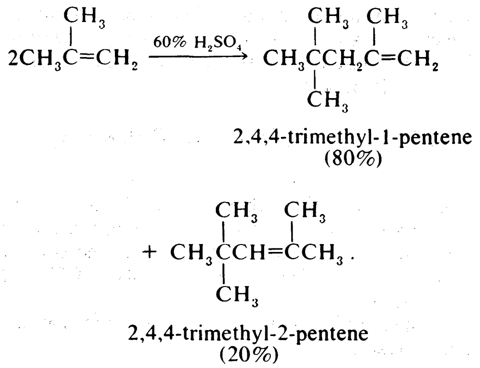


$$nCH_2{=}CHX \xrightarrow{\text{catalyst}} -CH_2\underset{X}{C}H{-}(CH_2\underset{X}{C}H)_{n-2}{-}CH_2{-}\underset{X}{C}H-$$

a vinyl compound a vinyl polymer

If X = Cl the product is polyvinyl chloride, over a billion pounds of which are used annually to make floor tiles, shoe soles, raincoats, phonograph records, and textile fibres. If X = C_6H_5 (a phenyl group, derived from benzene: see below *Aromatic hydrocarbons*), the product is polystyrene, often foamed and used as a lightweight structural and insulating material. If X = CH_3, the product is polypropylene, used to make films, molded articles, and fibres.

Some alkenes form useful dimers or other lower polymers. For example, if isobutylene is treated with aqueous sulfuric acid, the products are mainly the two dimers shown in the equation



$$2CH_3\overset{CH_3}{\overset{|}{C}}{=}CH_2 \xrightarrow{60\%\ H_2SO_4} CH_3\underset{CH_3}{\overset{CH_3}{C}}CH_2\overset{CH_3}{C}{=}CH_2$$

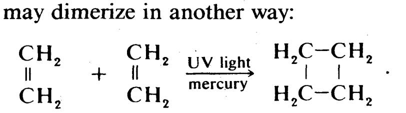
2,4,4-trimethyl-1-pentene
(80%)

$$+\ CH_3\underset{CH_3}{\overset{CH_3}{C}}CH{=}\overset{CH_3}{C}CH_3\,.$$

2,4,4-trimethyl-2-pentene
(20%)

Although isobutylene is a gas, with too low a boiling point for effective use as gasoline, the dimers fall nicely within the gasoline boiling range, and their highly branched structures are particularly desirable in preventing engine knock. Hydrogenation of the dimer mixture produces 2,2,-4-trimethylpentane, the hydrocarbon used as a standard for 100 octane number. Both reactions, dimerization and hydrogenation, are carried out in most petroleum refineries to produce high-octane gasolines.

In the presence of ultraviolet light and a sensitizer, alkenes may dimerize in another way:



$$\begin{matrix}CH_2\\ \|\\ CH_2\end{matrix} + \begin{matrix}CH_2\\ \|\\ CH_2\end{matrix} \xrightarrow[\text{mercury}]{\text{UV light}} \begin{matrix}H_2C-CH_2\\ |\qquad |\\ H_2C-CH_2\end{matrix}\,.$$

The reaction, called a cycloaddition, is useful for laboratory synthesis of cyclobutanes.

Alkynes. A carbon–carbon triple bond is the characteristic structural feature of alkynes, or acetylenes. The simplest and commercially most important of the series, acetylene itself, was first prepared as long ago as 1836, though its name was coined some 25 years later. The general formula for the class is C_nH_{2n-2}.

Nomenclature and structure. Alkynes are named in the same way as alkenes, except that the ending that designates the triple bond is "-yne." Acetylene is almost always called by that name, though its IUPAC name is ethyne:

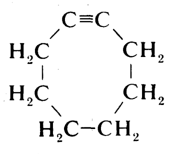
$$HC{\equiv}CH \qquad CH_3C{\equiv}CH \qquad \overset{1}{C}H_3\overset{2}{C}{\equiv}\overset{3}{C}\overset{4}{C}H_3\,.$$

ethyne (acetylene)	propyne (methylacetylene)	2-butyne (dimethylacetylene)

Other alkynes usually are named systematically, but they also may be named as derivatives of acetylene (examples of these names are given above in parentheses).

Only one other atom or group can be attached to a carbon atom of a triple bond. The molecule is linear:

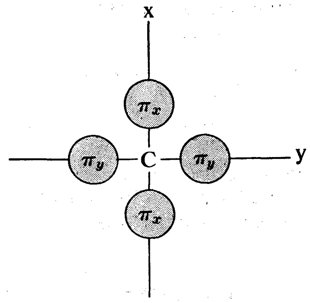
Because of this linearity, small rings incorporating a triple bond are not stable. Cyclooctyne is the smallest cyclic acetylene of which synthesis has been reported, though evidence has been obtained for smaller cycloalkynes as reaction intermediates (which are not actually isolated).



cyclooctyne

The C≡C distance is 1.20 Å, appreciably shorter than both the C═C and C—C distances (see above *Geometry of the double bond*), because three electron pairs bind the two carbon atoms in the first case. The triple bond consists of one sigma (σ) bond along the C—C internuclear axis, and two pi (π) bonds lying in mutually perpendicular planes. A view down the carbon–carbon axis (the z axis) shows only the π bonds, the σ bond being symmetric along the z axis. The two groups attached to the triple bond also lie along the z axis, so that no geometric (*cis–trans*) isomerism is possible.

The carbon–carbon triple bond



Physical properties. In general, alkynes boil 10°–20° C (18°–36° F) higher than do the corresponding alkenes and alkanes. They are slightly more dense than alkenes, and more soluble in water. Owing to its symmetric structure, acetylene has an unusually high melting point, within a few degrees of its boiling point (−83.4° C [−118.1° F]). When liquefied, acetylene is sensitive to shock and may explode, forming its elements: $C_2H_2 \rightarrow 2C + 2H_2$ + heat. For this reason the gas cannot be liquefied safely under pressure for shipping. Acetylene gas, however, is remarkably soluble in acetone, and at a pressure of 12 atmospheres (180 pounds per square inch) one volume of acetone will dissolve 300 volumes of acetylene. Since this solution is stable, acetylene usually is transported under pressure in tanks filled with porous material, such as asbestos, that is saturated with acetone.

Other alkynes, especially those with an internal triple bond, are less sensitive than is acetylene itself. Internal alkynes generally boil higher than the isomeric terminal alkynes, as shown by the last two pairs of entries in Table 14.

Commercial production of acetylene

Sources and synthesis. Acetylene is the only alkyne produced commercially in large amounts. It is made by the reaction of water with calcium carbide, which, in turn, comes from coke and lime, as represented in the following reactions:

Table 14: Boiling Points of Alkynes

name	carbon skeleton	boiling point (°C)
Acetylene	C≡C	−84.0
Propyne	C≡C—C	−23.2
1-Butyne	C≡C—C—C	+8.1
2-Butyne	C—C≡C—C	+27.0
1-Pentyne	C≡C—C—C—C	+40.2
2-Pentyne	C—C≡C—C—C	+56.1

$$3C + CaO \xrightarrow{2{,}500^\circ} CaC_2 + CO$$

coke	lime	calcium carbide	carbon monoxide

$$CaC_2 + 2H_2O \xrightarrow[\text{temperature}]{\text{room}} HC{\equiv}CH + Ca(OH)_2\,.$$

acetylene	calcium hydroxide

Acetylene also is a major product from high-temperature cracking of methane:

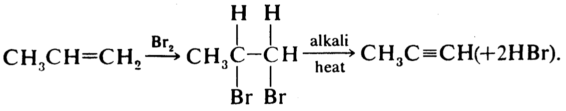
$$2CH_4 \xrightarrow{1{,}600^\circ} C_2H_2 + 3H_2;$$

a considerable fraction of commercial acetylene comes from this source.

Before the era of electricity, acetylene was used as a component of illuminating gas, for it burns with a colourless flame. Now about half the acetylene produced is consumed in oxyacetylene torches for welding and cutting metals; the oxyacetylene flame is intensely hot (about

2,800° C [5,000° F]). The remaining acetylene produced is used as a raw material for other organic chemicals (see below *Reactions*).

Other alkynes can be made from acetylene (see below *Reactions*) or by extensions of the methods used for introducing double bonds, as, for example:



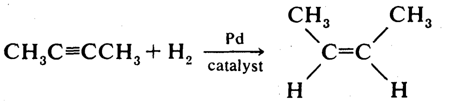
$$CH_3CH{=}CH_2 \xrightarrow{Br_2} CH_3\underset{Br}{\overset{H}{C}}{-}\underset{Br}{\overset{H}{C}}H \xrightarrow[\text{heat}]{\text{alkali}} CH_3C{\equiv}CH(+2HBr).$$

Reactions. Many of the same reagents that add to alkenes also add to alkynes, but because of the triple bond the latter are capable of adding two molecules of reagent rather than one:

$$HC\equiv CH \xrightarrow{Br_2} CHBr{=}CHBr \xrightarrow{Br_2} CHBr_2CHBr_2.$$

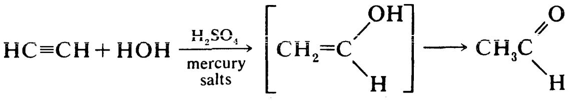
acetylene 1,2-dibromoethene 1,1,2,2-tetrabromoethane

When hydrogen and a special palladium catalyst are used, hydrogenation can be stopped readily at the alkene stage. Since both of the hydrogen atoms are delivered to the same side of the triple bond from the catalyst surface, this reaction provides a good method for obtaining *cis*-alkenes:



cis-2-butene

Perhaps the most important commercial reaction of acetylene is its hydration. The initial product (vinyl alcohol) is unstable and rearranges to the carbonyl compound acetaldehyde, an important precursor of many other industrial organic chemicals.



vinyl alcohol acetaldehyde

Hydrogen cyanide also adds to acetylene. The product, acrylonitrile, is a valuable monomer used to make synthetic fibres (Acrilan, Orlon, Dynel).

$$HC{\equiv}CH + HC{\equiv}N \xrightarrow[\text{heat}]{\text{catalyst}} CH_2{=}CHC{\equiv}N$$

acrylonitrile

Terminal alkynes are very weak acids, and the hydrogen attached to the triple bond may be replaced by metals, producing salts called acetylides, although the calcium salt is almost always called the carbide. This process is accomplished most commonly by reaction in liquid ammonia with sodium amide, a very strong base:

$$RC{\equiv}CH + Na^+NH_2^- \xrightarrow[\text{ammonia}]{\text{liquid}} RC{\equiv}C^-Na^+ + NH_3.$$

a sodium acetylide

Acetylides are reactive, and can be used to introduce triple bonds into other molecules. Sodium acetylide, for example, reacts with ethyl bromide, to produce 1-butyne, in a reaction somewhat reminiscent of the Wurtz reaction (see above *Alkanes; Sources and synthesis*):

$$HC\equiv C^-Na^+ + BrCH_3 \longrightarrow HC\equiv CCH_3 + Na^+Br^-$$

propyne

In principle any higher alkyne can be made from acetylene itself by judicious use of this reaction.

Silver, copper, and other heavy metal acetylides, when dry, explode under the influence of heat or shock, and hence they are used in detonators. In suspension, however, copper acetylides are useful in synthesis as, for example, in oxidative coupling of two alkynes to produce a product having two triple bonds:

$$2RC{\equiv}CH + \tfrac{1}{2}O_2 \xrightarrow[\text{salt}]{\text{cuprous}} RC{\equiv}C{-}C{\equiv}CR + H_2O.$$

Some hydrocarbons in which triple bonds are separated by single bonds have been found to be present in certain fungi and higher plants; an example is the substance $CH_3{-}C{\equiv}C{-}C{\equiv}C{-}C{\equiv}C{-}C{\equiv}C{-}C{\equiv}C{-}CH{=}CH_2$, present in Asteraceae.

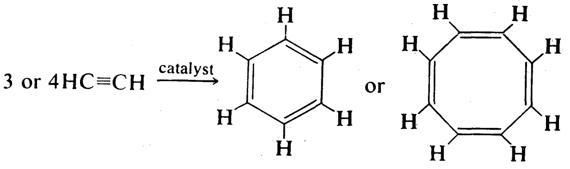
Acetylenes also undergo another type of dimerization, or self-addition, reaction:

Dimerization of acetylenes

$$HC{\equiv}CH + HC{\equiv}CH \xrightarrow[\substack{\text{ammonium chloride}\\ \text{hydrochloric acid}}]{\text{cuprous chloride}} CH_2{=}CHC{\equiv}CH.$$

vinylacetylene

Vinylacetylene is employed in the synthesis of neoprene, a synthetic rubber. With still other catalysts acetylenes undergo cyclic trimerization or tetramerization:



benzene cyclooctatetraene

In a strong base they may be isomerized to other alkynes or to compounds with two double bonds on the same carbon atom, allenes:

$$CH_3CH_2C{\equiv}CH \underset{\text{base}}{\overset{\text{strong}}{\rightleftharpoons}} CH_3CH{=}C{=}CH_2 \underset{\text{base}}{\overset{\text{strong}}{\rightleftharpoons}} CH_3C{\equiv}CCH_3.$$

1-butyne 1,2-butadiene (an allene) 2-butyne

From the variety of reactions they undergo, it is understandable that alkynes are particularly useful synthetic intermediates in organic chemistry.
