According to the literary critic Rosemarie Battaglia, the emotion-arousing words cold, cruel, loveless, dead, lost, and barren resonate with a sense of Stephen's withdrawal from his social world.

Other modern writers have made frank use of psychological concepts of emotion and emotion-related processes, particularly those introduced by Sigmund Freud. Thus, for example, the author's characters may be motivated by unconscious processes, feelings they cannot label and articulate because the fundamental underlying ideation associated with the feelings has been repressed.

Philosophy. Using Aristotle's system of causal explanation, the 16th-century British philosopher John Rainolds defined emotion as follows: the efficient cause of emotions is God, who implanted them; the material cause is good and evil human things; the formal cause is a commotion of the soul, impelled by the sight of things; and the final cause is seeking good and fleeing evil. The American philosopher L.D. Green's commentary on Rainolds' thesis indicates that Rainolds was not faithful to Aristotle's own discussions of emotion.

One thing that Aristotle did advocate was moderation of emotions, allowing them to have an effect only at the right time and in the right manner. Rainolds noted that the Aristotelian thinker Cicero saw emotions as beneficial—fear making humans careful, compassion and sadness leading to mercy, and anger whetting courage. These thoughts about emotion are similar to those of some modern theorists.

For Rainolds, the emotions are the active, energizing aspects of human nature. Although the intellect exercises control over emotions, intellect can have no impact without emotion. Rainolds was specifically concerned with the effects of emotion on rhetoric, but he saw rhetoric as a principal means of influencing human behaviour and affairs. He believed that

> the passions [emotions] must be excited, not for the harm they do but for the good, not so they twist the straight but that they straighten the crooked; so they ward off vice, iniquity, and disgrace; so that they defend virtue, justice, and probity.

Spinoza's idea of emotion and bodily change

Benedict de Spinoza in the 17th century described emotions in much the same way as Rainolds did, but he discussed them in relation to action rather than to language. He saw emotions as bodily changes that result in the amplification or attenuation of action and as processes that can facilitate or impede action. For Spinoza, emotion also included the ideas, or mental representations, of the bodily changes in emotion.

Blaise Pascal and David Hume reversed Rainolds' position by assuming the primacy of emotion in human behaviour. Hume said that reason is the slave of the passions (emotions), and Pascal observed in *Pensées* that "the heart has reasons that reason does not know." Although Hume believed that passions (emotions) rule reason or intellect, he thought the dominant passion should be moral sentiment. Some contemporary psychologists trace morality to empathy and empathy to discrete emotions including sadness, sorrow, compassion, and guilt.

Since Rainolds lectured on emotions at Oxford, philosophers have considered many questions related to emotions: Are they active or passive? Can they be explained by neurophysiological processes and reduced to material phenomena? Are they rational or nonrational? Are they voluntary or involuntary? Characterizing or categorizing emotions according to these dichotomies has resulted in yet other classifications or distinctions.

Ultimately, emotion concepts resist definition by way of dichotomous distinctions. Emotions are generally active and tend to generate action and cognition, but extreme fear may cause behavioral freezing and mental rigidity. Emotion can be explained on one level in terms of neurochemical processes and on another level in terms of phenomenology. Emotions are rational in the sense that they serve adaptive functions and make sense in terms of the individual's perception of the situation. They are nonrational in the sense that they can exist in the brain at the neurochemical level and in consciousness as unlabeled feelings that may be independent of cognitive-rational processes. Emotions are voluntary in that their expression in older children and adults is subject to considerable modification and control via cognition and action, and willful regulation of expression may result in regulation of emotion experience. Emotions are involuntary in that an effective stimulus elicits them automatically, without deliberation and conscious choice. Nowhere is this more evident than in infants and young children, who have little capacity to modulate or inhibit emotion by means of cognitive processes.

Rational and nonrational emotions

One contemporary American philosopher, Amélie O. Rorty, espouses a three-part causal history for emotions, which includes (1) the formative events in a person's past, including the development of habits of thought, (2) sociocultural factors, and (3) genetically determined sensitivities and patterns of response. These are essentially the same factors that are recognized by psychologists, who frequently reduce the list to two: (1) experience as mediated by culture and learning and (2) genetic determinants that unfold with ontogenetic development. The first of these two causal factors indicates that individual differences in interpretations of an event or situation lead to different emotions in different persons.

Some philosophers are concerned with the question of the rationality of emotion as judged on the basis of causes and consequences. One resolution is in terms of appropriateness: an emotion is appropriate if the reasons for it are adequate, regardless of the reasons against it. There may be a sense, however, in which emotions are intrinsically nonrational because they can come into a person's consciousness without that person having considered all of the relevant reasons for them. In the final analysis, caution should be used in judging the rationality of emotions.

James Hillman's conception

Another contemporary philosopher, James Hillman, has been notably effective in using classical philosophical principles to explain emotions. He has delineated 12 ways that emotion has been conceptualized in philosophy and psychology. These include conceptions of emotion as a distinct entity or trait, an accompaniment of instinct, energy for thought and action, a neurophysiological mechanism and process, mental representation, signal, conflict, disorder, and creative organization. This philosopher found each of these conceptions incomplete or incorrect and returned to Aristotle's system of four causes in an effort to integrate the information from each of the foregoing approaches to defining and studying emotions.

For Hillman, the efficient cause of emotion, described psychologically, consists of conscious or unconscious mental representations (perceptions, images, or thoughts) and conflicts between physiological or psychological systems or between a person and the environment. The efficient cause described physiologically includes genetic endowment and the neurochemical and hormonal processes involved in emotion activation. Hillman stated that the material cause of emotion is energy. He argued that matter, the ultimate source of energy, is relative and that emotion, as the psychological aspect of general energy, is going on all the time and is a two-way bridge uniting subject and object.

In considering the formal cause, one may see emotion as a pattern of neurophysiological and expressive behaviours and subject–object relations. Hillman concluded that, in a formal sense, emotion is a total pattern of the soul:

> Emotion is the soul as a complex whole, involving constitution, gross physiology, facial expression in its social context as well as actions aimed at the environment.

The final cause, or purpose, of emotion, according to Hillman, can be thought of in terms of what it achieves: survival (energy release, homeostatic regulation, and action on the stimulus and environment), signification (qualification of experience, expression, communication, and values), and improvement (emergence of energy into consciousness, facilitation of creative activity, and strengthening of the organization of self and behaviour). Hillman integrated these various descriptions of final cause in the concept of change. Emotion occurs in order to actualize change; "emotion itself is change."

HOW PSYCHOLOGY CONCEIVES EMOTIONS

In 1872, emotion studies received a boost in scientific status when Charles Darwin published his seminal treatise *The Expressions of the Emotions in Man and Animals.* Twelve years later, the American philosopher and psychologist William James, one of the pioneers of psychology in the United States, published what was to become a famous and controversial theory of emotions. In it James proposed that an arousing stimulus (such as a poignant memory or a physical threat) triggers internal physiological processes as well as external expressive and motor actions and that the feeling of these physiological and behavioral processes constitutes the emotion. Thus, people are happy because they smile, sad because they cry, angry because they frown, and afraid because they run from danger.

A few years later the Danish physician Carl Lange published a more constricted theory, maintaining that emotion is a function of the perception of changes in the visceral organs innervated by the autonomic nervous system. Although there were distinctively individual components in the theories of James and Lange, the theories became linked in the minds of psychologists and the combination became known as the James–Lange theory.

The James–Lange theory

The James–Lange theory was seriously challenged by the American physiologist Walter B. Cannon, who showed that, among other things, animals whose viscera were separated from the central nervous system still displayed emotion expression. Cannon contended that bodily changes were similar for most kinds of emotions, whereas the James–Lange theory implied a different bodily pattern of response for different emotions. The James–Lange theory has remained a more or less permanent fixture in behavioral science nevertheless, and most psychology textbooks summarize the theory and Cannon's criticisms of it. Some theories of emotion are classified as neo-Jamesian, and most theories can be identified or classified on the basis of their similarities and differences with the landmark James–Lange theory.

Psychological theories of emotion can be grouped into two broad categories—biosocial and constructivist. Although this system of categorization is an oversimplification, it provides a way for the student of emotion to get a perspective on a particular theory. A contemporary textbook, for example, describes 20 psychological theories of emotion, and there are many others that it does not consider.

Many of the differences between the two categories of emotion theory stem from different assumptions regarding the relative importance of genetics and life experiences. Biosocial theories assume that emotions are rooted in biological makeup and that genes are significant determinants of the threshold and characteristic intensity level of each basic emotion. In this view, emotional life is a function of the interaction of genetic tendencies and the evaluative systems, beliefs, and roles acquired through experience. Constructivist theories assume that genetic factors are inconsequential and that emotions are cognitively constructed and derived from experience, especially from social learning. The constructivists' crucible for emotions is formed by the interactions of the person with the environment, especially the social environment. Thus, according to the constructivists, emotions are a function of appraisals, or evaluations, of the world of culture, and of what is learned. (For examples of both types of theory and some of the research generated by each, see below *Contemporary approaches to emotion.*)

Biosocial and constructivist theories

The importance of emotions

The use of emotion concepts is common in literature and philosophy, as was discussed above, and there is widespread agreement among scientists that emotions are important in individual development, physical and mental health, and human relations. Experts in different disciplines emphasize different reasons for the importance of emotions.

EVOLUTIONARY-BIOLOGICAL PERSPECTIVES

Darwin and emotion expressions

Darwin included emotions, in particular emotion expressions, in his studies of evolution. He considered continuity or similarity of expression in animals and human beings as further evidence of human evolution from lower forms. His finding that certain emotion expressions are innate and universal was seen as evidence of the "unity of the several races." Thus, the expressions, or the language of the emotions, provide a means of communication among all human beings, regardless of culture or ethnic origin.

In his work *The Expression of the Emotions in Man and Animals,* Darwin made an explicit value judgment regarding the significance of emotion expressions:

> The movements of expression in the face and body, whatever their origin may have been, are in themselves of much importance for our welfare. They serve as the first means of communication between the mother and infant; she smiles approval, and thus encourages her child on the right path, or frowns disapproval. We readily perceive sympathy in others by their expression; our sufferings are thus mitigated and our pleasures increased; and mutual good feeling is thus strengthened. The movements of expression give vividness and energy to our spoken words. They reveal the thoughts and intentions of others more truly than do words, which may be falsified.

From his studies of emotion expressions, Darwin concluded that some emotion expressions were due to the "constitution of the nervous system," or our biological endowment. The implication is that these expressive movements are part of human nature and have played a role in survival and adaptation. Darwin thought other expressions were derived from actions that originally served biologically adaptive functions (*e.g.,* preparation for biting became the bared teeth of the anger expression). Although he noted that expressive movements may no longer serve biological functions, he made it quite clear that they serve critical social and communicative functions.

PSYCHOLOGICAL VIEWS

Significance of emotions

From the very beginning of scientific psychology, there were voices that spoke of the significance of emotions for human life. James believed that "individuality is founded in feeling" and that only through feeling is it possible "directly to perceive how events happen, and how work is actually done." The Swiss psychiatrist Carl Gustav Jung recognized emotion as the primal force in life:

> But on the other hand, emotion is the moment when steel meets flint and a spark is struck forth, for emotion is the chief source of consciousness. There is no change from darkness to light or from inertia to movement without emotion.

Psychologists did not rally to the Darwinian thesis on the evolutionary-adaptive functions of emotions in significant numbers until the 1960s. Several influential volumes following this theme were published in the 1960s and '70s. For example, the American psychologist Robert Plutchik echoed Darwinian principles in several of the postulates of his theory: emotions are present at all levels of animal life, and they serve an adaptive role in relation to survival issues posed by the environment.

The American psychologist Silvin Tomkins believed that the emotions constitute the primary motivational system for human beings. He held that even physiological drives such as hunger and sex obtain their power from emotions and that the energizing effects of emotion are necessary to sustain drive-related actions. In this way, he argued that emotions are essential to survival and adaptation.

Other theorists and researchers that follow the Darwinian principles of the survival value and adaptive value of emotions have emphasized their role in human development and in the development of social bonds, particularly mother–infant or parent–child attachment. These researchers have shown that even the very young infant has a repertoire of emotion expressions translatable into messages calling for nourishment and affection, both essential ingredients of healthy development. The distress expression is the infant's all-out cry for help, the sadness expression an appeal for empathy, and the smile an invitation to stimulating face-to-face interactions. (For discussion of empirical evidence of the importance of emotions in child development, social relations, cognitive processes, and mental health, see below *The functions of emotion.*)

Infant emotions

Contemporary approaches to emotion

Contemporary psychologists are concerned with the activation, or causes, of emotion, its structure, or components, and its functions or consequences. Each of these aspects can be considered from both a biosocial and a constructivist view. On the whole, biosocial theories have been relatively more concerned with the neurophysiological aspects of emotions and their roles as motivators and organizers of cognition and action. Constructivists have been relatively more concerned with explaining the causes of emotion at the experiential level and cognition-emotion relations in terms of cognitive–linguistic processes.

STRUCTURES AND PROCESSES OF EMOTION ACTIVATION

The question of precisely how an emotion is triggered has been one of the most captivating and controversial topics in the field. To address the question properly, one must break it down into more precise parts. Emotion activation can be divided into three parts: neural processes, bodily (physiological) changes, and mental (cognitive) activity.

While it is easy for people to think of things that make them happy or sad, it is not yet possible to explain precisely how the feelings of joy and sadness occur. Neuroscience has produced far more information about the processes leading to the physiological responses and expressive behaviour of emotion than about those that generate the conscious experience of emotion.

Neural processes. An emotion can be activated by causes and processes within the individual or by a combination of internal and external causes and processes. For example, within the individual, an infection can cause pain, and pain can activate anger.

The findings of neuroscience indicate that stimuli are evaluated for emotional significance when information from primary receptors (in the visual, tactual, auditory, or other sensory systems) travels along certain neural pathways to the limbic forebrain. Scientific data developed by Joseph E. LeDoux show that auditory fear conditioning involves the transmission of sound signals through the auditory pathway to the thalamus (which relays information) in the lower forebrain and thence to the dorsal amygdala (which evaluates information).

The brain's involvement

Evidence from neuroscience suggests that emotion activated by way of the thalamo-amygdala (subcortical) pathway results from rapid, minimal, automatic, evaluative processing. Emotion activated in this way need not involve the neocortex. Emotion activated by discrimination of stimulus features, thoughts, or memories requires that the information be relayed from the thalamus to the neocortex. Such a circuit is thought to be the neural basis for cognitive appraisal and evaluation of events.

This two-circuit model of the neural pathways in emotion activation has several important theoretical implications. The neurological evidence indicating that emotion can be activated via the thalamo-amygdala pathway is consistent with the behavioral evidence that very young infants respond emotionally to pain and that adults can develop preferences or make affective judgments in responding to objects before they demonstrate recognition memory for them. This suggests that in some instances humans may experience emotion before they reason why.

It might be expected that in early human development most emotion expressions derive from automatic, subcortical processing, with minimal cortical involvement. As cognitive capacities increase with maturation and learning, the neocortex and the cortico-amygdala pathway become more and more involved. By the time children acquire language and the capacity for long-term memory, they may process events in either or both pathways, with the subcortical pathway specializing in events requiring rapid response and the cortico-amygdala pathway providing evaluative information necessary for cognitive judgment and more complex coping strategies.

Physiological processes. Many theorists agree that feedback from physiological activity contributes to emotion activation. There is disagreement over the kind of feedback that is important. Some think that it is a visceral feedback—coming from the activity of the smooth-muscle organs such as the heart and stomach, which are innervated by the autonomic nervous system. Others believe that it is feedback from the voluntary, striated muscles, especially of the face, which are innervated by the somatic nervous system.

Cognitive processes. Constructivist theorists and researchers have been concerned with the causes of emotion at the cognitive-experiential level and with the relations between cognitive processes and emotion. This research has focused on two topics: the relations between appraisals, or evaluations, and emotions and the relations between causal attributions and emotions.

Magda B. Arnold was the first contemporary psychologist to propose that all emotions are a function of one's cognitive appraisal of the stimulus or situation. She maintained that before a stimulus can elicit emotion it has to be appraised as good or bad by the perceiver. She described the appraisal that arouses emotion as concrete, immediate, undeliberate, and not the result of reflection. Her position was adopted and elaborated by others, some of whom assumed that cognitive activity, whether in the form of primitive evaluative perception or symbolic processes, is a necessary precondition of emotion. Biosocial and constructivist theorists agree that cognition is an important determinant of emotion and that emotion–cognition relations merit continued research.

Emotion appraisal

Research by the American psychologists Phoebe C. Ellsworth and Craig A. Smith on the relations between appraisals and specific emotions show that people tend to appraise situations in terms of elements such as pleasantness, anticipated effort, certainty, responsibility, control, legitimacy, and perceived obstacle. Researchers have found that each discrete emotion tends to be associated with a distinctive combination of appraisals. For example, a perceived obstacle (barrier to a goal) that is due to

someone else's responsibility is associated with anger, a perceived obstacle that is the person's own responsibility is associated with guilt, and a perceived obstacle characterized by uncertainty is associated with fear. This study was based on subjects' retrospective accounts of emotion-eliciting situations, and therefore the data cannot confirm the view that appraisal causes emotion. However, the assumption that emotion and appraisal are causally related seems reasonable.

Another approach to explaining the causes of emotions is that of attribution theory. The central idea of this theory, according to the American psychologist Bernard Weiner, is that the perceptions of the causes of events can be characterized in three principal ways which affect many emotional experiences. The perceived causes of events (*e.g.,* success and failure) are characterized by their locus (internal or external to the person), stability (a trait of the person or a temporary condition), and controllability (under the person's control or not).

Attribution theory

Research has shown that different patterns of causal attribution are associated with different emotions, including anger, guilt, shame, and the more complex phenomena of pity, pride, gratitude, and hopelessness. Pity is attributed to the perception of uncontrollable and stable causes—people feel pity for a person who has an affliction due to a genetic defect or accident. Anger is attributed to external and controllable events—people feel anger when an affront or injury is caused by someone's lack of concern or thoughtlessness. Guilt is attributed to the perception of internal and controllable causes—people feel guilt for wrongdoing they could have avoided. Children aged five to 12 understand the emotional consequences of revealing the causes of their actions; they know that their teachers might be angry at their failure if they have not tried hard enough and that teachers might feel pity for students who lack the ability to learn efficiently and perform well.

Coping with emotions

Psychologists researching cognitive activation have studied the relations between the ways people cope with stressful encounters and the emotions they experience after their efforts to resolve the problems. In one study emotions were assessed by asking subjects to indicate the extent to which they experienced emotions on four scales: worried/fearful, disgusted/angry, confident, and pleased/happy. Coping was assessed by subjective ratings on eight scales: confrontive coping ("stood my ground and fought"), distancing ("didn't let it get to me"), self-control ("tried to keep my feelings to myself"), seeking social support ("talked to someone"), accepting responsibility ("criticized myself"), escape-avoidance ("wished the situation would go away"), planful problem solving ("changed or grew as a person"), and positive reappraisal. Four of these ways of coping were associated with the quality of emotion that followed the effort to cope. Planful problem solving and positive reappraisal tended to increase happiness and confidence and to decrease disgust and anger. Obversely, the subjects reported that confrontation and distancing techniques increased their disgust and anger and decreased their happiness and confidence. Because these data were retrospective, there can be no firm conclusion that a particular way of coping causes a particular emotion experience. Nevertheless, the observed relations among ways of coping and subsequent emotion experiences are reasonable and in line with theoretical expectations.

The controversy as to whether some cognitive process is a necessary antecedent of emotion may hinge on the definition of terms, particularly the definition of cognition. If cognition is defined so broadly that it includes all levels or types of information processing, then cognition may confidently be said to precede emotion activation. If those mental processes that do not involve mental representation based on learning or experience are excluded from the concept of cognition, then cognition so defined does not necessarily precede the three-week-old infant's smile to the high-pitched human voice, the two-month-old's anger expression to pain, or the formation of the affective preferences (likes or dislikes) in adults.

Multimodal theory. Evidence suggests that a satisfactory model of emotion activation must be multimodal. Emotions can, as indicated above, be activated by such pre-cognitive processes as physiological states, motor mimicry (imitation of another's movements), and sensory processes and by numerous cognitive processes, including comparison, matching, appraisal, categorization, imagery, memory, attribution, and anticipation. Further, all emotion activation processes are influenced by a variety of internal and external factors.

THE STRUCTURE OF EMOTIONS

In the discussion of the structure of emotions it is not always possible to ignore the function of emotions, which is discussed in the following section. The separation, however, is conducive to sorting out the complex field of emotions.

Both biosocial and constructivist theories of emotions acknowledge that an emotion is a complex phenomenon. They generally agree that an emotion includes physiological functions, expressive behaviour, and subjective experience and that each of these components is based on activity in the brain and nervous system. As noted above, some theorists, particularly those of the constructivist persuasion, hold that an emotion also involves cognition, an appraisal or cognitive-evaluative process that triggers the emotion and determines or contributes to the subjective experience of the emotion.

Biosocial and constructivist views

The physiological component. The physiological component of emotion has been a lively topic of research since Cannon challenged the James–Lange theory by showing that feedback from the viscera has little effect on emotional expression in animals. Cannon's studies and criticisms were regarded by many as too narrow, failing to, among other things, consider the possible role of feedback from striated muscle systems of the face and body.

Role of the nervous system. Since the popularization of the James–Lange theory of emotion, the physiological component of emotion has been traditionally identified as activity in the autonomic nervous system and the visceral organs (*e.g.,* the heart and lungs) that it innervates. However, some contemporary theorists hold that the neural basis of emotions resides in the central nervous system and that the autonomic nervous system is recruited by emotion to fulfill certain functions related to sustaining and regulating emotion experience and emotion-related behaviour. Several findings from neuroscience support this idea. Neuroanatomical studies have shown that the central nervous system structures involved in emotion activation can exert direct influences on the autonomic nervous system. For example, efferents from the amygdala to the hypothalamus may influence activity in the autonomic nervous system that is involved in defensive reactions. Further, there are connections between pathways innervating facial expression and the autonomic nervous system. Studies have shown that patterns of activity in this system vary with the type of emotion being expressed.

Findings of neuroscience

Roles of the brain hemispheres. There is some evidence that the two hemispheres of the brain are related differently to emotion processes. Early evidence suggested that the right (or dominant) hemisphere may be more adept than the left at discriminating among emotional expressions. Later research using electroencephalography elaborated this initial conclusion, suggesting that the right hemisphere may be more involved in processing negative emotions and the left hemisphere more involved in processing positive emotions.

The expressive component. The expressive component of emotion includes facial, vocal, postural, and gestural activity. Expressive behaviour is mediated by phylogenetically old structures of the brain, which is consistent with the notion that they served survival functions in the course of evolution.

Involvement of brain structures. Emotion expressions involve limbic forebrain structures and aspects of the peripheral nervous system. The facial and trigeminal nerves and receptors in facial muscles and skin are required in expressing emotion and in facilitating sensory feedback from expressive movements.

Early studies of the neural basis of emotion expression showed that aggressive behaviour can be elicited from a cat after its neocortex has been removed and suggested

that the hypothalamus is a critical subcortical structure mediating aggression. Later research indicated that, rather than the hypothalamus, the central gray region of the midbrain and the substantia nigra may be the key structures mediating aggressive behaviour in animals.

Importance of facial expression

Neural pathways of facial expression. Of the various types of expressive behaviour, facial expression has received the most attention. In human beings and in many nonhuman primates, patterns of facial movements constitute the chief means of displaying emotion-specific signals. Whereas research has provided much information on the neural basis of emotional behaviours (*e.g.*, aggression) in animals, little is known about the brain structures that control facial expression.

The peripheral pathways of facial emotion expression consist of the seventh and fifth cranial nerves. The seventh, or facial, nerve is the efferent (outward) pathway; it conveys motor messages from the brain to facial muscles. The fifth, or trigeminal, nerve is the afferent (inward) pathway that provides sensory data from movements of facial muscles and skin. According to some theorists, it is the trigeminal nerve that transmits the facial feedback which contributes to the activation and regulation of emotion experience. The impulses for this sensory feedback originate when movement stimulates the mechanoreceptors in facial skin. The skin is richly supplied with such receptors, and the many branches of the trigeminal nerve detect and convey the sensory impulses to the brain.

The innateness and universality of emotion expressions. More than a century ago Darwin's observations and correspondence with friends living in different parts of the world led him to conclude that certain emotion expressions are innate and universal, part of the basic structure of emotions. Contemporary cross-cultural and developmental research has given strong support to Darwin's conclusion, showing that people in literate and preliterate cultures have a common understanding of the expressions of joy, surprise, sadness, anger, disgust, contempt, and fear. Other studies have suggested that the expressions of interest and shyness and the feelings of shame and guilt may also be innate and universal.

The experiential component. There is general agreement that various stimuli and neural processes leading to an emotion result not only in physiological reactions and expressive behaviour but also in subjective experience. Some biosocial theorists restrict the definition of an emotion experience to a feeling state and argue that it can be activated independently of cognition. Constructivist theorists view the experiential component of emotion as having a cognitive aspect. The issue regarding the relation between emotion feeling states and cognition remains unresolved, but it is widely agreed that emotion feeling states and cognitive processes are typically highly interactive.

Emotion experiences, the actual feelings of joy, sadness, anger, shame, fear, and the like, do not lend themselves to objective measurement. All research on emotion experience ultimately depends on self-reports, which are imprecise. There are few instances where feelings and words are perfectly matched. Yet, most students of emotions, whether philosopher or neuroscientist, ultimately want to explain emotion experience.

Neural basis of emotion experience

The physiological structure of emotion experience. Little is known about the neural basis of emotion experience. Critical reviews have shown that there is little evidence to support the position that activity in the autonomic nervous system provides the physiological basis for emotion experience. However, there is some evidence to support the hypothesis that sensory feedback from facial expression contributes to emotion experience.

Cognitive models of emotion experience have influenced conceptions of the underlying neural processes. Explanations of emotions in terms of appraisal and attributional processes led some researchers to suggest that conscious experiences of emotions derive from the cognitive processes that underlie language. This led to the hypothesis that emotion experiences involve interactions between limbic forebrain areas and the areas of the neocortex that mediate language and language-based cognitive systems. However, this view does not take into account the possibility that emotions occur in preverbal infants and may be mediated in adults by unconscious or nonlinguistic mental processes, such as imagery.

Action tendencies in emotion experiences. Both constructivist and biosocial theorists have emphasized that emotions include action tendencies. The experience, or feeling, of a given emotion generates a tendency to act in a certain way. For example, in anger the tendency is to attack and in fear to flee. Whether a person actually attacks in anger or flees in fear depends on the individual's methods of emotion regulation and the circumstances.

THE FUNCTIONS OF EMOTIONS

In academic discussions of the functions of emotions the focus is usually on the phenomenological, or experiential, aspect of emotions. For purposes of this discussion, however, the functions of emotions are examined in terms of the three structural components—physiological, expressive, and experiential.

Structural components of functions

Physiological functions. The functions of physiological activity that is mediated by the autonomic nervous system and that accompanies states of emotion can be considered as part of the individual's effort to adapt and cope, but, of course, physiological as well as cognitive reactions in extreme emotion usually require regulation (expressed through cognitive processes and expressive behaviour) in order for coping activities to be effective. For example, adaptation to situations that elicit a less extreme emotion such as interest require a quite different physiological and behavioral activity than do situations that elicit intense anger or fear. The heart-rate deceleration and quieting of internal organs that occur in interest facilitate the intake and processing of information, whereas heart-rate acceleration in intense anger and fear prepares the individual to cope by more active means, whether through shouting, physical actions, or various combinations of the two.

Functions of emotion expressions. Emotion expressions have three major functions: they contribute to the activation and regulation of emotion experiences; they communicate something about internal states and intentions to others; and they activate emotions in others, a process that can help account for empathy and altruistic behaviour.

Feedback of facial expression

Role of expressions in emotion experiences. In *The Expression of the Emotions in Man and Animals* Darwin clearly revealed his belief that even voluntary emotion expression evoked emotion feeling. He wrote: "Even the simulation [expression] of an emotion tends to arouse it in our minds." Thus, Darwin's idea suggested that facial feedback (sensations created by the movements of expressive behaviour) activate, or contribute to the activation of, emotion feelings. A number of experiments have provided substantial evidence that intentional management of facial expression contributes to the regulation (and perhaps activation) of emotion experiences. Most evidence is related not to specific emotion feelings but to the broad classes of positive and negative states of emotion. There is, therefore, some scientific support for the old advice to "smile when you feel blue" and "whistle a happy tune when you're afraid."

Darwin was even more persuasive when speaking specifically of the regulation of emotion experience by self-initiated expressive behaviour. He wrote:

> The free expression by outward signs of an emotion intensifies it. On the other hand, the repression, as far as this is possible, of all outward signs softens our emotions.

Experiments by more contemporary researchers on motivated, self-initiated expressive behaviours have shown that, if people can control their facial expression during moments of pain, there will be less arousal of the autonomic nervous system and a diminution of the pain experience.

Role of expressions in communicating internal states. The social communication function of emotion expressions is most evident in infancy. Long before infants have command of language or are capable of reasoning, they can send a wide variety of messages through their facial expressions. Virtually all the muscles necessary for facial expression of basic emotions are present before birth. Through the use of an objective, anatomically based system for coding the separate facial muscle movements, it

has been found that the ability to smile and to facially express pain, interest, and disgust are present at birth; the social smile can be expressed by three or four weeks; sadness and anger by about two months; and fear by six or seven months. Informal observations suggest that expressions indicative of shyness appear by about four months and expressions of guilt by about two years.

The expressive behaviours are infants' primary means of signaling their internal states and of becoming engaged in the family and larger human community. Emotion expressions help form the foundation for social relationships and social development. They also provide stimulation that appears to be necessary for physical and mental health.

Mother–infant relations through emotion expression

Role of expressions in motivating response. One- and three-day-old infants cry in response to other infants' cries but not to a computer-generated sound that simulates crying. Infants as young as two or three months of age respond differently to different expressions by the mother. The information an infant obtains from the mother's facial expressions mediates or regulates a variety of infant behaviours. For example, most infants cross a modified "visual cliff" (an apparatus that was originally used in depth perception study, consisting of a glass floor that gives the illusion of a drop-off) if their mother stands on the opposite side and smiles, but none cross if she expresses fear.

Facial expressions, particularly of sadness, may facilitate empathy and altruistic behaviour. Darwin thought facial expressions evoked empathy and concluded that expression-induced empathy was inborn. Research has shown that, when mothers display sadness expressions, their infants also demonstrate more sadness expressions and decrease their exploratory play. Infants under two years of age respond to their mother's real or simulated expressions of sadness or distress by making efforts to show sympathy and provide help.

Functions of emotion experiences. Psychologists who adopt a strong behaviourist position deny that emotion experiences are matters for scientific inquiry. In contrast, some biosocial theories hold that emotion feelings must be studied because they are the primary factors in organizing and motivating human behaviour. According to these theories, most of the functions attributed to emotion expressions, such as empathy and altruism, are dependent on the organizing and motivating properties of underlying emotion feelings. Emotion experiences have several other functions.

Commonality of emotion experience

Research has shown that people in widely different literate and preliterate cultures not only recognize basic emotion expressions but also characterize and label them with semantically equivalent terms. It seems reasonable to assume that the common feeling state of a given emotion generates the cues for the cognitive processes that result in universal emotion concepts. Of course, if researchers include contextual factors, such as societal taboos, in their description of an emotion experience, they then find differences across cultures. In any case, although the feeling of a given emotion, say fear, may be constant, people within and across cultures learn to be afraid of quite different things and to cope with fear in different ways.

Experiential influence on cognitive processes. Several lines of research have shown that induced emotion affects perception, learning, and memory. In one study, conducted by Carroll E. Izard and his students, subjects were made happy or angry and then shown happy and angry faces and friendly and hostile interpersonal scenes in a stereoscope. Happy subjects perceived more happy faces and friendly interpersonal scenes, and angry subjects perceived more angry faces and hostile interpersonal scenes. In this case, emotion apparently altered the basic perceptual process. In another study subjects were made happy or sad and then given happy and sad information about fictional persons and later asked to give their impressions and make judgments about the fictional characters. Overall, happy subjects reported more favourable impressions and positive judgments than did sad subjects. These studies provide evidence for the common wisdom that happy people are more likely to see the world through rose-coloured glasses.

Experiential facilitation of empathy and altruism. An extensive series of studies indicated that positive emotion feelings enhance empathy and altruism. It was shown by the American psychologist Alice M. Isen that relatively small favours or bits of good luck (like finding money in a coin telephone or getting an unexpected gift) induced positive emotion in people and that such emotion regularly increased the subjects' inclination to sympathize or provide help.

Effects of positive emotion

Experiential relation to increased creativity. Several studies have demonstrated that positive emotion facilitates creative problem solving. One of these studies showed that positive emotion enabled subjects to name more uses for common objects. Another showed that positive emotion enhanced creative problem solving by enabling subjects to see relations among objects that would otherwise go unnoticed. A number of studies have demonstrated the beneficial effects of positive emotion on thinking, memory, and action in preschool and older children.

Explanation of the functions of emotion experiences. There are two kinds of factors that contribute to the enhancing effects of positive emotion on perception, learning, creative problem solving, and social behaviour. Two factors, emphasized by cognitive-social theorists, are related to cognitive processes. First, positive emotion cues positive material in memory, and, second, positive material in memory is more extensive than neutral and negative material. The second set of factors, emphasized by biosocial theorists, are related to the intrinsic motivational and organizational influences of emotion and to the particular characteristics of the subjective experience of positive emotion. For example, these theorists maintain that the experience of joy is characterized by heightened self-esteem and self-confidence. These qualities of consciousness increase the receptibility to information and the flexibility of mental processes. Biosocial theorists consider that the positive emotion induced by experimental manipulations and experimental tasks includes the emotion of interest, which is characterized by curiosity and the desire to explore and learn. The concepts emphasized by biosocial and cognitive-social theories may be seen as complementary.

EMOTIONS AND ADAPTATION

The results of many of the experiments discussed above indicate that emotions have motivational and adaptive properties. Perhaps the most convincing demonstrations of this come from studies showing that emotions influence perception, learning, and memory and empathic, altruistic, and creative actions.

Some theorists have viewed emotions more negatively, seeing them as disorganizing and disrupting influences. Researchers in this tradition have also viewed emotions as transient, episodic states. These ideas were fueled by a research emphasis on "emergency emotions," such as rage and panic. These researchers might agree that, although such emotions may serve an adaptive function under certain circumstances, in many situations they can lead to behaviours that prove to be maladaptive and even fatal. As was indicated above, however, emotion expressions can serve critical functions in mother–infant communication and attachment, and emotion experiences, or feeling states, facilitate learning and empathic, altruistic, and creative behaviour.

Biological adaptations

Although psychologists generally favour viewing emotions as having motivating, organizing, and adaptive functions, the conditions under which emotions become maladaptive warrant further research. Extreme anger and fear can bring about large changes in the activities of internal organs innervated by the autonomic nervous system. When such arousal repeatedly involves the sympathetic nervous system and the hormones of the medulla of the adrenal gland, the individual may develop resistance to mental and physical disorders. When there is repeated arousal involving the sympathetic nervous system and the hormones of the cortex of the adrenal gland, the individual may experience adverse effects.

Problems of adaptation and mental health can also be conceived as attributable not to the emotions but to the

way a person thinks and acts. For example, if a person decides to break a moral code and consequently feels guilty, the guilt may be adaptive in that it can provide motivation for making amends. In this framework psychological problems or disorders arise because the individual fails to respond appropriately to the emotion's motivational cues while the emotion is still at low or moderate intensity.

THE REGULATION OF EMOTIONS

Several beliefs and attitudes have contributed to the idea that emotions should be brought under rather tight control. Historically, some religious and philosophical literature has treated human passion, a concept which included emotions, as an evil force that could contaminate or even destroy the mind or soul. In this tradition passions became associated with sin and wrongdoing, and their rigorous control was thus a sign of goodness. Even in this tradition, however, some negative emotions were exempt from tight control—guilt as a result of wrongdoing and righteous indignation toward moral transgressions.

Changing views of emotion regulation. Traditionally, scientists have given far more attention to negative emotions and their control than to positive ones. The focus on negative emotions has continued among clinical psychologists and psychiatrists, who are concerned with relieving depression and anxiety. However, as parents have long recognized, there is also a need to regulate positive emotions when, for example, children are having fun at someone else's expense or while neglecting chores and homework.

Developmental processes in emotion regulation. Of central importance in emotion regulation are developmental processes that enable children, as they mature, to exercise an increasingly greater control over affective responses. For example, before an infant can regulate the innate affective behaviour patterns elicited by acute pain, maturation of neural inhibitory mechanisms is required. Further control is realized through techniques that result from cognitive development and socialization, processes involving both maturation and learning.

Regulation in infants

In a study of responses of two- to 19-month-old infants to the pain of diphtheria-tetanus-pertussis (DTP) inoculation, it was found that the physical distress expression occurred as the initial response in all infants at the ages of two, four, and seven months (the ages at which the first three DTPs were administered). The physical distress expression is an all-out emergency response, a cry for help that dominates the physical and mental capacities of the infant. Beginning at the age of four months and accelerating rapidly between seven and 19 months, the infants became capable of greatly reducing the duration of the physical distress expression. As the duration of the physical distress expression decreased, that for anger expression increased. By 19 months of age, 25 percent of the infants were able to inhibit the distress expression completely. It was inferred that these developmental changes are adaptive for the relatively more capable toddler: whereas the physical distress expression in the younger subjects is all-consuming, anger mobilizes energy for defense or escape.

Other factors in emotion regulation. Several other factors are observable in emotion or mood regulation. First, there is neurochemical regulation by means of naturally occurring hormones and neurotransmitters. Regulation is also attained through psychoactive drugs, many of which were developed to control the prevalent psychological disorders of anxiety and depression. A substantial body of research has shown that anxiety and depression are associated with chemical imbalances in the brain and nervous system. Psychoactive drugs help to correct these imbalances.

Neurochemical regulation

Socialization processes, especially child-rearing practices, influence emotion regulation. Attempts by parents, teachers, and other adults to control emotions may be aimed either at the level of expression or experience or both. Parents may try to control their child's anger expressions before they culminate in "temper tantrums." A father may try to control his son's expressions of fear of bodily injury because he anticipates the shame of his son being seen as a coward. In considering the net effect of socialization on emotion regulation, it is necessary to weigh the effects that the child's unique genetic makeup may contribute to the process.

Cognitive-social theories point to cognitive processes as means of controlling emotion. According to this approach, if it is possible for people to change the way they make appraisals and attributions about the nature and cause of events, their emotion experiences can be changed. This could be manifested, for instance, in a reduction in self-blame and an alteration in negative concepts and outlooks. That cognitive therapy and cognitive techniques for controlling depressive and aggressive behaviour have achieved some success is testimony to the validity of the idea of cognitive control of emotion. That they sometimes fail indicates that it is no panacea and that other factors may be necessary for emotion regulation. As discussed above, theory and empirical data support the notion that expressive behaviour, which is under voluntary control, can be used to regulate emotions.

EMOTIONS, TEMPERAMENT, AND PERSONALITY

Most theorists agree that emotion thresholds and emotion responsiveness are part of the infrastructure of temperament and personality. There has, however, been little empirical research on the relations among measures of emotions, dimensions of temperament, and personality traits.

Emotions and temperament. Most theories of temperament define at least one dimension of temperament in terms of emotion. Two theories maintain that negative emotions form the core of one of the basic and stable dimensions of temperament. Another suggests that each of the dimensions of temperament is rooted in a particular discrete emotion and that these dimensions form the emotional substrate of personality characteristics. For example, proneness to anger would influence the development of aggressiveness, and the emotion of interest would account for the temperament trait of persistence.

Dimensions of temperament

Emotions and personality. A number of major personality theories, such as theories of temperament, identify dimensions or traits of personality in terms of emotions. For example, the German-born British psychologist Hans J. Eysenck has proposed three fundamental dimensions of personality: extroversion–introversion, neuroticism, and psychoticism. Extroversion–introversion includes the trait of sociability, which can also be related to emotion (*e.g.*, interest, as expressed toward people, versus shyness). Neuroticism includes emotionality defined, as in temperament theory, as nonspecific negative emotional responsiveness. Psychoticism may represent emotions gone awry or the absence of emotions appropriate to the circumstances.

Eysenck's fundamental dimensions

Several studies have shown that measures of positive emotionality and negative emotionality are independent, are not inversely related, and have stability over time. Further, it has been shown that positive and negative emotionality have different relations with symptoms of psychological disorders. For example, negative emotionality correlates positively with panic attack, panic-associated symptoms and obsessive-compulsive symptoms; that is, the higher the degree of negative emotion, the more likely that the attack or symptoms will occur. Conversely, positive emotionality correlates negatively with these phenomena. Although several of the same negative emotions characterize both the anxiety and depressive disorders, a lack of positive emotion experiences is more characteristic of depression than of anxiety.

Continuity of emotion expressiveness. Some studies have shown that specific emotions, identified in terms of expressive behaviour and physiological functions, have stability. One study showed that a child's expression of positive and negative emotion was consistent during the first two years of life. Other studies have shown stability of wariness or fear responses, indicating that a child who is fearful at one age is likely to be fearful in comparable situations at a later age. In a study of infants' responses to the pain of DTP inoculation, it was found that the child's anger expression indexes at ages two, four, and six months accurately predicted his or her anger expression in the inoculations at 19 months of age. Similar results were obtained for the sadness expression.

A study of mother–infant interaction and separation found that infants' expression at three to six months of age were accurate predictors of infant emotion expressive patterns at nine to 12 months of age. Emotion expression patterns have also shown continuity from 13 to 18 months of age during brief mother–infant separation.

Conclusion

The emotions are central to the issues of modern times, but perhaps they have been critical to the issues of every era. Poets, prophets, and philosophers of all ages have recognized the significance of emotions in individual life and human affairs, and the meaning of a specific emotion, at least in the context of verbal expression, seems to be timeless. Although art, literature, and philosophy have contributed to the understanding of emotion experiences throughout the ages, modern science has provided a substantial increase in the knowledge of the neurophysiological basis of emotions and their structure and functions.

Research in neuroscience and developmental psychology suggests that emotions can be activated automatically and unconsciously in subcortical pathways. This suggests that humans often experience emotions without reasoning why. Such precognitive information processing may be continuous, and the resulting emotion states may influence the many perceptual-cognitive and behavioral processes (such as perceiving, thinking, judging, remembering, imagining, and coping) that activate emotions through pathways involving the neocortex.

The two recognized types of emotion activation have important implications for the role of emotions in cognition and action. Subcortical, automatic information processing may provide the primitive data for immediate emotional response, whereas higher-order cognitive information processing involving the neocortex yields the evaluations and attributions necessary for the appropriate emotions and coping strategy in a complex situation.

Biosocial and constructivist theories agree that perception, thought, imagery, and memory are important causes of emotions. They also agree that once emotion is activated, emotion and cognition influence each other. How people feel affects what they perceive, think, and do, and vice versa.

Emotions have physiological, expressive, and experiential components, and each component can be studied in terms of its structure and functions. The physiological component influences the intensity and duration of felt emotion, expressions serve communicative and sociomotivational functions, and emotion experiences (feeling states) influence cognition and action.

Research has shown that certain emotion expressions are innate and universal and have significant functions in infant development and in infant–parent relations and that there are stable individual differences in emotion expressiveness. Emotion states influence what people perceive, learn, and remember, and they are involved in the development of empathic, altruistic, and moral behaviour and in basic personality traits.

BIBLIOGRAPHY. Studies of philosophical and cultural views on emotion include JAMES HILLMAN, *Emotion: A Comprehensive Phenomenology of Theories and Their Meanings for Therapy* (1960), a contemporary philosopher's explanation of emotions in terms of Aristotle's system of causes and a review of other approaches; AMÉLIE OKSENBERG RORTY (ed.), *Explaining Emotions* (1980), a collection of philosophical essays on the causes, meaning, and consequences of emotions; and ROM HARRÉ (ed.), *The Social Construction of Emotions* (1986), a collection of studies on the role of language and culture in the cognitive construction, *i.e.,* learning, of emotions.

The significance of emotions is the subject of many analyses, beginning with CHARLES DARWIN, *The Expression of the Emotions in Man and Animals* (1872, reprinted 1979), a classical work that placed human emotions in evolutionary perspective and presented the first evidence for their innateness and universality in human beings; CARROLL E. IZARD, *Human Emotions* (1977), a discussion of each of the fundamental emotions of human experience in terms of their unique organizing and motivational influence on cognition and action; SUSANNE K. LANGER, *Mind: An Essay on Human Feeling,* 3 vol. (1967–72), a philosopher's view of the significance of feelings in the evolution of human mentality; GEORGE MANDLER, *Mind and Body: Psychology of Emotion and Stress* (1984), a cognitive, or constructivist, view of the role of emotions in mental and bodily processes; ROBERT PLUTCHIK, *Emotion, a Psychoevolutionary Synthesis* (1980), a look at emotions in evolutionary perspective; and SILVAN S. TOMKINS, *Affect, Imagery, Consciousness,* vol. 1, *The Positive Affects* (1962), a brilliant essay on emotions as the primary motivational system of human beings.

The following works reflect some contemporary approaches to the study of emotions: MAGDA B. ARNOLD, *Emotion and Personality,* vol. 1, *Psychological Aspects* (1960), emphasizes the role of cognitive appraisal in emotion and sets the stage for later cognitive-social, or constructivist, theories of emotion; NICO H. FRIJDA, *The Emotions* (1986), is a comprehensive cognitive-social view of emotions; JOSEPH J. CAMPOS *et al.,* "Socioemotional Development," chapter 10 in MARSHALL M. HAITH and JOSEPH J. CAMPOS (eds.), *Infancy and Developmental Psychobiology,* 4th ed. (1983), pp. 783–915, provides a comprehensive review of theory and research on emotional development; ROBERT N. EMDE, THEODORE J. GAENSBAUER, and ROBERT J. HARMON, *Emotional Expression in Infancy: A Biobehavioral Study* (1976), is an influential contribution to the study of expressions; NATHAN A. FOX and RICHARD J. DAVIDSON (eds.), *The Psychobiology of Affective Development* (1984), presents a collection of reviews of theory and research papers on the biological aspects of emotional development; CARROLL E. IZARD, JEROME KAGAN, and ROBERT B. ZAJONC (eds.), *Emotions, Cognition, and Behavior* (1984), is a collection of research papers by leading psychologists on the relations between emotions, cognition, and actions; CARROLL E. IZARD and C.Z. MALATESTA, "Perspectives on Emotional Development I: Differential Emotions Theory of Early Emotional Development," chapter 9A in JOY DONIGER OSOFSKY (ed.), *Handbook of Infant Development,* 2nd ed. (1987), pp. 494–554, provides a detailed theory of emotional development and a review of related research; JOSEPH E. LEDOUX, "Emotion," chapter 10 in FRED PLUM (ed.), *Higher Functions of the Brain* (1987), pp. 419–59, in *Handbook of Physiology,* section 1, vol. 5, discusses brain mechanisms and neural pathways involved in the activation, expression, and experience of emotion; MICHAEL LEWIS and LINDA MICHALSON, *Children's Emotions and Moods: Developmental Theory and Measurement* (1983), explores a cognitive-social view of the development of emotions; PHOEBE C. ELLSWORTH and CRAIG A. SMITH, "From Appraisal to Emotion: Differences Among Unpleasant Feelings," *Motivation and Emotion,* 12(3):271–302 (September 1988), surveys research on the relations between appraisal processes and emotions and presents a new theory of cognition–emotion relations; H. HILL GOLDSMITH *et al.,* "What Is Temperament? Four Approaches," *Child Development,* 58(2):505–29 (April 1987), reviews theories of temperament with attention to temperament–emotion relations; ALICE M. ISEN, KIMBERLY A. DAUBMAN, and GARY P. NOWICKI, "Positive Affect Facilitates Creative Problem Solving," *Journal of Personality and Social Psychology,* 52(6):1122–31 (June 1987), exemplifies research showing how positive emotion facilitates creative thinking, empathy, and altruism; CARROLL E. IZARD, ELIZABETH A. HEMBREE, and ROBIN R. HUEBNER, "Infants' Emotion Expressions to Acute Pain: Developmental Change and Stability of Individual Differences," *Developmental Psychology,* 23(1):105–13 (January 1987), studies change and continuity in children's emotion expressions; WILLIAM JAMES, "What Is an Emotion?" *Mind,* 9:188–205 (1884), provides a classic definition of emotion that remains influential today; JEROME KAGAN, J. STEVEN REZNICK, and NANCY SNIDMAN, "Biological Bases of Childhood Shyness," *Science,* 240:167–71 (April 1988), summarizes a series of studies on biological bases and the continuity of shyness; and ROGER SPERRY, "Some Effects of Disconnecting the Cerebral Hemispheres," *Science,* 217:1223–26 (September 1982), discusses the effects of disconnecting cerebral hemispheres on mental and emotional experience.

(C.E.I.)

Encyclopaedias and Dictionaries

For more than 2,000 years encyclopaedias have existed as summaries of extant scholarship in forms comprehensible to their readers. The word encyclopaedia, of Greek origin (*enkyklopaideia*), at first meant a circle or a complete system of learning—that is, an all-around education. When Rabelais used the term in French for the first time in *Pantagruel* (chapter 20), he was still talking of education. It was Paul Scalich, a German writer and compiler, who was the first to use the word to describe a book in the title of his *Encyclopaedia; seu, orbis disciplinarum, tam sacrarum quam prophanum epistemon* . . . ("Encyclopaedia; or Knowledge of the World of Disciplines, Not Only Sacred but Profane . . . "), issued at Basel in 1559. The many encyclopaedias that had been published prior to this time either had been given fanciful titles (*Hortus deliciarum,* "Garden of Delights") or had been simply called "dictionary." The word dictionary has been widely used as a name for encyclopaedias, and Scalich's pioneer use of encyclopaedia did not find general acceptance until Denis Diderot made it fashionable with his historic French encyclopaedia, although cyclopaedia was then becoming fairly popular as an alternative term.

An outline of the scope and history of encyclopaedias is essentially a guide to the story of the development of scholarship, for encyclopaedias stand out as landmarks throughout the centuries, recording much of what was known at the time of publication. Many homes have no encyclopaedia at all, very few have more than one, yet in the past 2,000 years at least 2,000 encyclopaedias have been issued in various parts of the world, and some of these have had many editions. No library has copies of them all; if it were possible to collect them they would occupy some two miles of shelf space. But they are worth preserving—even those that appear to be hopelessly out-of-date—for they contain many contributions by a large number of the world's leaders and scholars.

"Dictionary" is used to describe a wide variety of reference works. Basically, a dictionary lists a set of words with information about them. The list may attempt to be a complete inventory of a language or may be only a small segment of it. A short list, sometimes at the back of a book, is often called a glossary. When a word list is an index to a limited body of writing, with references to each passage, it is called a concordance. Theoretically, a good dictionary could be compiled by organizing into one list a large number of concordances. A word list that consists of geographic names only is called a gazetteer.

The word lexicon designates a wordbook, but it also has a special abstract meaning among linguists, referring to the body of separable structural units of which the language is made up. In this sense, a preliterate culture has a lexicon long before its units are written in a dictionary. Scholars in England sometimes use "lexis" to designate this lexical element of language.

The compilation of a dictionary is lexicography; lexicology is a branch of linguistics in which, with the utmost scientific rigour, the theories that lexicographers use in the solution of their problems are developed.

The common phrase "dictionary order" takes for granted that the alphabetical order will be followed, and yet the alphabetical order has been called a tyranny that makes dictionaries less useful than they might be if compiled in some other order. The assembling of words into groups related by some principle, as by their meanings, can be done, and such a work is often called a thesaurus or synonymy. Such works, however, need an index for ease of reference, and it is unlikely that alphabetical order will be superseded except in specialized works. A monolingual dictionary has both the word list and the explanations in the same language, whereas bilingual or multilingual (polyglot) dictionaries have the explanations in another language or different languages. The word dictionary is also extended, in a loose sense, to reference books with entries in alphabetical order, such as a dictionary of biography, a dictionary of heraldry, or a dictionary of plastics.

For coverage of related topics in the *Macropædia* and the *Micropædia,* see the *Propædia,* section 735, and the *Index.*

The article is divided into the following sections:

ENCYCLOPAEDIAS

The meaning of the word encyclopaedia has changed considerably during its long history. Today most people think of an encyclopaedia as a multivolume compendium of all available knowledge, complete with maps and a detailed index, as well as numerous adjuncts such as bibliographies, illustrations, lists of abbreviations and foreign expressions, gazetteers, and so on. They expect it to include biographies of the great men and women of the present as well as those of the past, and they take it for granted that the alphabetically arranged contents will have been written in their own language by many people and will have been edited by a highly skilled and scholarly staff; nevertheless, not one of these ingredients has remained the same throughout the ages. Encyclopaedias have come in all sizes from a single 200-page volume written by one man to giant sets of 100 volumes or more. The degree of coverage of knowledge has varied according to the time and country of publication. Illustrations, atlases, and bibliographies have been omitted from many encyclopaedias, and for a long time it was not thought fitting to include biographies of living persons. Indexes are a late addition, and most of the early ones were useless. Alphabetical arrangement was as strongly opposed as the use of any language but Latin, at least in the first 1,000 years of publication in the West, and skilled group editorship has a history of scarcely 200 years.

In this article the word encyclopaedia has been taken to include not only the great general encyclopaedias of the past and the present but all types of works that claim to provide in an orderly arrangement the essence of "all that is known" on a subject or a group of subjects. This includes dictionaries of philosophy and of American history as well as volumes such as *The World Almanac and Book of Facts,* which is really a kind of encyclopaedia of current information.

The nature of encyclopaedias

In the *Speculum majus* ("The Greater Mirror"; completed 1244), one of the most important of all encyclopaedias, the French medieval scholar Vincent of Beauvais maintained not only that his work should be perused but that the ideas it recorded should be taken to heart and imitated. Alluding to a secondary sense of the word *speculum* ("mirror"), he implied that his book showed the world what it is and what it should become. This theme, that encyclopaedias can contribute significantly to the improvement of mankind, recurs constantly throughout their long history. A Catalan ecclesiastic and scholastic philosopher, Ramon Llull, regarded the 13th-century encyclopaedias, together with language and grammar, as instruments for the pursuit of truth. Domenico Bandini, an Italian humanist, planned his *Fons memorabilium universi* ("The Source of Noteworthy Facts of the Universe") at the beginning of the 15th century to provide accurate information on any subject to educated men who lacked books and to give edifying lessons to guide them in their lives. Francis Bacon believed that the intellect of the 17th-century individual could be refined by contact with the intellect of the ideal man. Another Englishman, the poet and critic Samuel Taylor Coleridge, was well aware of this point of view and said in his "Preliminary Treatise on Method" (1817) that in the *Encyclopædia Metropolitana,* which he was proposing to create, "our great objects are to exhibit the Arts and Sciences in their Philosophical harmony; to teach Philosophy in union with Morals; and to sustain Morality by Revealed Religion." He added that he intended to convey methodically "the pure and unsophisticated knowledge of the past . . . to aid the progress of the future." The Society for the Diffusion of Useful Knowledge declared in *The Penny Cyclopædia* (1833–43) that, although most encyclopaedias attempted to form systems of knowledge, their own would in addition endeavour to "give such general views of all great branches of knowledge, as may help to the formation of just ideas on their extent and relative importance, and to point out the best sources of complete information."

In *De disciplinis* ("On the Disciplines"; 1531) the Spanish humanist Juan Luis Vives emphasized the encyclopaedia's role in the pursuit of truth. In Germany of the early 19th century the encyclopaedia was expected to provide the right or necessary knowledge for good society. Probably the boldest claim was that of Alexander Aitchison, who said that his new *Encyclopædia Perthensis* (1796–1806) was intended to supersede the use of all other English books of reference.

Greek and Roman concepts

All these ideas were a far cry from the Greek concept, deriving from Plato, that in order to think better it is necessary to know all, and from the Roman attitude of the advisability of acquiring all useful knowledge in order to carry out one's tasks in life competently. The present concept of the encyclopaedia as an essential starting point from which one can embark on a voyage of discovery, or as a point of basic reference on which one can always rely, is little more than two centuries old.

The prose form has usually been accepted as the only suitable vehicle for the presentation of the text of an encyclopaedia, though *L'Image du monde* ("The Image of the World"; 1245?)—attributed by some to Gautier de Metz, a French poet and priest, and by others to a Flemish theologian, Gossuin—was written in French octosyllabic verse. It has also been generally accepted that an encyclopaedia should adopt a straightforward, factual approach. Even so, the Spanish writer Alfonso de la Torre, in his *Visio delectable* ("Delightful Vision"; *c.* 1484), adopted the allegorical approach of a child receiving instruction from a series of maidens named Grammar, Logic, Rhetoric, and so on.

The alphabetically arranged encyclopaedia has a history of less than 1,000 years, most of the encyclopaedias issued before the introduction of printing into Europe having been arranged in a methodical or classified form. The early compilers of encyclopaedias held, as Coleridge was to hold, that "to call a huge unconnected miscellany of the *omne scibile,* in an arrangement determined by the accident of initial letters, an encyclopaedia, is the impudent ignorance of your Presbyterian bookmakers!" Today several encyclopaedias still retain the classified form of arrangement.

There has never been any general agreement on the way in which the contents of an encyclopaedia should be arranged. In Roman times the approach was usually practical, with everyday topics such as astronomy and geography coming first, while the fine arts were relegated to the end of the work. The Roman statesman and writer Cassiodorus, however, in his 6th-century *Institutiones,* began with the Scriptures and the church and gave only brief attention to such subjects as arithmetic and geometry. St. Isidore of Seville, educated in the classical tradition, redressed the balance in the next century in his *Etymologiarum sive originum libri XX* ("Twenty Books on Origins, or Etymologies"), commonly called *Etymologiae,* giving pride of place to the liberal arts and medicine, the Bible and the church coming later, but still preceding such subjects as agriculture and warfare, shipping and furniture. The earliest recorded Arabic encyclopaedia, compiled by the Arab philologist and historian Ibn Qutayba, had a completely different approach, beginning with power, war, and nobility, and ending with food and women. A later Persian encyclopaedia, compiled in 975–997 by the Persian scholar and statesman al-Khwārizmī, started with jurisprudence and scholastic philosophy, the more practical matters of medicine, geometry, and mechanics being relegated to a second group labelled "foreign knowledge." The general trend in classification in the Middle Ages is exemplified by Vincent of Beauvais's *Speculum majus,* which was arranged in three sections: "Naturale"—God, the creation, man; "Doctrinale"—language, ethics, crafts, medicine; "Historiale"—world history. The encyclopaedists were, however, still uncertain

of the logical sequence of subjects, and although there were many who started with theological matters, there were just as many who preferred to put practical topics first.

A turning point came with Francis Bacon's plan for his uncompleted *Instauratio magna* ("Great Instauration"; 1620) in which he eschewed the endless controversies in favour of a three-section structure, including "External Nature" (covering such topics as astronomy, meteorology, geography, and species of minerals, vegetables, and animals), "Man" (covering anatomy, physiology, structure and powers, and actions), and "Man's Action on Nature" (including medicine, chemistry, the visual arts, the senses, the emotions, the intellectual faculties, architecture, transport, printing, agriculture, navigation, arithmetic, and numerous other subjects).

Various arrangements of the contents of encyclopaedias

In his plan Bacon had achieved more than a thoroughly scientific and acceptable arrangement of the contents of an encyclopaedia; he had ensured that the encyclopaedists would have a comprehensive outline of the scope of human knowledge that would operate as a checklist to prevent the omission of whole fields of human thought and endeavour. Bacon so profoundly altered the editorial policy of encyclopaedists that even 130 years later Diderot gratefully acknowledged his debt in the prospectus (1750) of the *Encyclopédie.* Because every later encyclopaedia was influenced by Diderot's work, the guidance of Bacon still plays its part today.

Engraved title page from the first edition of Francis Bacon's *Instauratio magna,* published in London, 1620.

Coleridge, who was very much impressed by Bacon's scheme, in 1817 drew up a rather different table of arrangement for the *Encyclopaedia Metropolitana.* It comprised five main classes: Pure Sciences—Formal (philology, logic, mathematics) and Real (metaphysics, morals, theology); Mixed and Applied Sciences—Mixed (mechanics, hydrostatics, pneumatics, optics, astronomy) and Applied (experimental philosophy, the fine arts, the useful arts, natural history, application of natural history); Biographical and Historical, chronologically arranged; Miscellaneous and Lexicographical, a gazetteer, and a philosophical and etymological lexicon. The fifth class was to be an analytical index.

Influence of Coleridge's classification

Although Coleridge's classification was altered by the publisher, and although the *Metropolitana* was an impressive failure, the ideas for it had a lasting influence. Even though nearly all encyclopaedias today are arranged alphabetically, the classifications of Bacon and Coleridge still enable editors to plan their work with regard to an assumed hierarchy of the various branches of human knowledge.

The concept of alphabetical order was well known to both the Greeks and Romans, but the latter made little use of it. Neither the Greeks nor the Romans employed it for encyclopaedia arrangement, with the exception of Sextus Pompeius Festus in his 2nd-century *De verborum significatu* ("On the Meaning of Words"). St. Isidore's encyclopaedia was classified, but it included an alphabetically arranged etymological dictionary. The 10th- or 11th-century encyclopaedic dictionary known as *Suidas* was the first such work to be completely arranged alphabetically, but it had no influence on succeeding encyclopaedias, although glossaries, when included, were so arranged. Bandini's *Fons memorabilium universi* ("The Source of Noteworthy Facts of the Universe"), though classified, used separate alphabetical orders for more than a quarter of its sections, and the Italian Domenico Nani Mirabelli's *Polyanthea nova* ("The New Polyanthea"; 1503) was arranged in one alphabetical sequence. These were rare exceptions, however; the real breakthrough came only with the considerable number of encyclopaedic Latin-language dictionaries that appeared in the early 16th century, the best known of which is a series of publications by the French printer Charles Estienne. The last of the great Latin-language encyclopaedias arranged in alphabetical order was *Encyclopaedia* (1630) by the German Protestant theologian and philosopher Johann Heinrich Alsted. The publication of *Le Grand Dictionnaire historique* ("The Great Historical Dictionary"; 1674) of Louis Moréri, a French Roman Catholic priest and scholar, confirmed public preference both for the vernacular and the alphabetically arranged encyclopaedia; this choice was emphasized by the success of the posthumous *Dictionnaire universel* (1690) by the French lexicographer Antoine Furetière.

From time to time important attempts have been made to reestablish the idea of the superiority of the classified encyclopaedia. Coleridge saw the encyclopaedia as a vehicle for enabling man to think methodically. He felt that his philosophical arrangement would "present the circle of knowledge in its harmony" and give a "unity of design and of elucidation." He did agree that his appended gazetteer and English dictionary would best be arranged alphabetically for ease of reference. By then, however, alphabetical arrangement had too strong a hold, and it was not until 1935 that a new major classified encyclopaedia began to appear—the *Encyclopédie française* ("French Encyclopaedia"), founded by Anatole de Monzie. The Dutch *Eerste nederlandse systematisch ingerichte encyclopaedie* ("First Dutch Systematic and Comprehensive Encyclopaedia"; 1946–52) has a classification that is in almost reverse order of that of the *Encyclopédie française,* but it is clear that behind both works lies a philosophical concept of the order and main divisions of knowledge that is influenced by both Bacon and Coleridge. The Spanish *Enciclopedia labor* (1955–60) and the *Oxford Junior Encyclopaedia* (1948–56) follow systems of arrangement that are closer to the French than to the Dutch example.

Role of the trivium and quadrivium

From earliest times it had been held that the trivium (grammar, logic, rhetoric) and the quadrivium (geometry, arithmetic, astronomy, music) were essential ingredients in any encyclopaedia. Even as late as 1435 Alfonso de la Torre began his *Visiõ delectable* in almost that exact order, and only when he had laid these foundations did he proceed to the problems of science, philosophy, theology, law, and politics. Thus the seven liberal arts were regarded by the early encyclopaedists as the very mathematics of human knowledge, without a knowledge of which it would be foolish to proceed. This idea survived to a certain extent in Coleridge's classification; he stated that grammar and logic provide the rules of speech and reasoning, while

mathematics opens mankind to truths that are applicable to external existence.

When Louis Shores became editor in chief of *Collier's Encyclopedia* in 1962, he said that he considered the encyclopaedia to be "one of the few generalizing influences in a world of overspecialization. It serves to recall that knowledge has unity." This echoes the view of the English novelist H.G. Wells, that the encyclopaedia should not be "a miscellany, but a concentration, a clarification and a synthesis." The Austrian sociologist Otto Neurath in the same year suggested that a proposed new international encyclopaedia of unified science should be constructed like an onion, the different layers enclosing the "heart"—comprising in this case the foundations of the unity of science.

Even a brief survey of contemporary encyclopaedia publishing is enough to make clear that, as the trivium and quadrivium and the topically classified encyclopaedias that they influenced receded further and further into history, there arose a number of modern encyclopaedists concerned with the importance of making a restatement of the unity of knowledge and of the consequent interdependence of its parts. Though most encyclopaedists were willing to accept the essential reference-book function of encyclopaedias and the role of an alphabetical organization in carrying out that function, they became increasingly disturbed about the emphasis on the fragmentation of knowledge that such a function and such an organization encouraged. A number looked for ways of enhancing the educational function of encyclopaedias by reclaiming for them some of the values of the classified or topical organizations of earlier history.

Notable among the results of such activities was the 15th edition of *Encyclopædia Britannica* (1974), which was designed in large part to enhance the role of an encyclopaedia in education and understanding without detracting from its role as a reference book. Its three parts (*Propædia,* or *Outline of Knowledge; Micropædia,* or *Ready Reference and Index;* and *Macropædia,* or *Knowledge in Depth*) represented an effort to design an entire set on the understanding that there is a circle of learning and that an encyclopaedia's short informational articles on the details of matter within that circle as well as its long articles on general topics must all be planned and prepared in such a way as to reflect their relation to one another and to the whole of knowledge. The *Propædia* specifically was a reader's version of the circle of learning on which the set had been based and was organized in such a way that a reader might reassemble in meaningful ways material that the accident of alphabetization had dispersed.

Encyclopaedias in general

THE ROLE OF ENCYCLOPAEDIAS

Of the various types of reference works—who's whos, dictionaries, atlases, gazetteers, directories, and so forth—the encyclopaedia is the only one that can be termed self-contained. Each of the others conveys some information concerning every item it deals with; only the encyclopaedia attempts to provide coverage over the whole range of knowledge, and only the encyclopaedia attempts to offer a comprehensive summary of what is known of each topic considered. To this end it employs many features that can help in its task, including pictures, maps, diagrams, charts, and statistical tables. It also frequently incorporates other types of reference works. Several modern encyclopaedias, from the time of Abraham Rees's *New Cyclopaedia* (1802–20) and the *Encyclopédie méthodique* ("Systematic Encyclopaedia"; 1782–1832) onward, have included a world atlas and a gazetteer, and language dictionaries have been an intermittent feature of encyclopaedias for most of their history.

Treatment of biographical material

Most modern encyclopaedias since the *Universal-Lexicon* (1732–50) of the Leipzig bookseller Johann Heinrich Zedler have included biographical material concerning living persons, though the first edition of *Encyclopædia Britannica* (1768–71) had no biographical material at all. In their treatment of this kind of information they differ, however, from the form of reference work that limits itself to the provision of salient facts without comment. Similarly, with dictionary material, some encyclopaedias—such as the great Spanish "Espasa" (1905 to date)—provide foreign-language equivalents as well.

An English lexicographer, Henry Watson Fowler, wrote in the preface to the first edition (1911) of *The Concise Oxford Dictionary of Current English* that a dictionary is concerned with the uses of words and phrases and with giving information about the things for which they stand only so far as current use of the words depends upon knowledge of those things. The emphasis in an encyclopaedia is much more on the nature of the things for which the words and phrases stand. Thus the encyclopaedic dictionary, whose history extends as far back as the 10th- or 11th-century *Suidas,* forms a convenient bridge between the dictionary and the encyclopaedia, in that it combines the essential features of both, embellishing them where necessary with pictures or diagrams, at the same time that it reduces most entries to a few lines that can provide a rapid but accurate introduction to the subject.

Interrelations. An encyclopaedia does not come into being by itself. Each new work builds on the experience and contents of its predecessors. In many cases the debt is acknowledged: the German publisher Friedrich Arnold Brockhaus bought up the bankrupt encyclopaedia of Gotthelf Renatus Löbel in 1808 and converted it into his famous *Conversations-Lexikon;* but Jesuits adapted Antoine Furetière's *Dictionnaire universel* without acknowledgment in their *Dictionnaire de Trévoux* (1704). Classical writers made many references to their predecessors' efforts and often incorporated whole passages from other encyclopaedias. Of all the many examples, the *Cyclopaedia* (1728) of the English encyclopaedist Ephraim Chambers has been outstanding in its influence, for Diderot's and Rees's encyclopaedias would have been very different if Chambers had not demonstrated what a modern encyclopaedia could be. In turn, the publication of *Encyclopædia Britannica* was stimulated by the issue of the *Encyclopédie.* Almost every subsequent move in encyclopaedia making is thus directly traceable to Chambers' pioneer work.

The intended audience

Readership. Encyclopaedia makers have usually envisaged the particular public they addressed. Cassiodorus wrote for the "instruction of simple and unpolished brothers"; the Roman statesman Cato wrote for the guidance of his son; Gregor Reisch, prior of the Carthusian monastery of Freiburg, addressed himself to "Ingenuous Youth"; the Franciscan encyclopaedist Bartholomaeus Anglicus wrote for *ordinary* people; the German professor Johann Christoph Wagenseil wrote for children; and Herrad of Landsberg, abbess of Hohenburg, wrote for her nuns. *Encyclopædia Britannica* is designed for the use of the curious and intelligent layman. The editor of *The Columbia Encyclopedia* in 1935 tried to provide a work compact enough and simply enough written to serve as a guide to the "young Abraham Lincoln." The Jesuit Michael Pexenfelder (1670) made his intended audience clear enough by writing his *Apparatus Eruditionis* ("Apparatus of Learning") in the form of a series of conversations between teacher and pupil. St. Isidore addressed himself to the needs not only of his former pupils in the episcopal school but also to all the priests and monks for whom he was responsible. At the same time, he tried to provide the newly converted population of Spain with a national culture that would enable it to hold its own in the Byzantine world.

Contributors. In sympathy with many of their various ends, many scholars have contributed to encyclopaedias. Not all their contributions are known because, until recently, it was not the custom to sign articles. Even today there is what amounts to partial concealment in that articles are often initialled only, and, although a key is provided, few readers look up the writer's identity. It is known, however, that the English encyclopaedist John Harris enlisted the help of such scientists as John Ray and Sir Isaac Newton for his *Lexicon Technicum* (1704) and that Rees's *New Cyclopaedia* (1802–20) included articles on music by the English organist and music historian Charles Burney and on botany by the English botanist Sir J.E. Smith. Illustrious Frenchmen such as Voltaire, Rousseau, Condorcet, Montesquieu, and Georges Boulanger contributed to the *Encyclopédie;* the writer and statesman Thomas

Macaulay, the Russian-born jurist and medieval historian Sir Paul Vinogradoff, and the Czech statesman Tomáš Masaryk to the *Britannica;* the Scottish physicist Sir David Brewster and the Danish physicist Hans Christian Ørsted to *The Edinburgh Encyclopaedia* (1808–30); the English astronomer Sir William Herschel and the English mathematician and mechanical genius Charles Babbage to the *Metropolitana;* the Russian Communist leader Lenin to the "Granat" encyclopaedia; and the dictator Benito Mussolini to the *Enciclopedia italiana.*

Language. The language of Western encyclopaedias was almost exclusively Latin up to the time of the first printed works. As with most scholarly writings, the use of Latin was advantageous because it made works available internationally on a wide scale and thus promoted unlimited sharing of information. On the other hand, it made the contents of encyclopaedias inaccessible to the great majority of people. Consequently, there was from the early days on a movement to translate the more important encyclopaedias into various vernaculars. Honorius Inclusus' *Imago mundi* ("Image of the World"; *c.* 1122) was rendered into French, Italian, and Spanish; Bartholomaeus Anglicus' *De proprietatibus rerum* ("On the Characteristics of Things"; 1220–40) into English; the Dominican friar Thomas de Cantimpré's *De natura rerum* ("On the Nature of Things"; *c.* 1228–44) into Flemish and German; and Vincent of Beauvais's *Speculum majus* ("The Greater Mirror") into French, Spanish, German, Dutch, and Catalan. In later years the more successful encyclopaedias were translated from one vernacular into another. Moréri's encyclopaedia, *Le Grand Dictionnaire historique,* was translated into both English and German. The German *Brockhaus* appeared in a Russian translation (1890–1907), and the French *Petit Larousse* had several foreign-language editions. Nevertheless, an encyclopaedia, however successful in its own country, may find acceptance in another country far from easy, because each nation appears to have its own very individual concept of what an encyclopaedia should comprise.

Translations of Latin encyclopaedias

The contemporary world. Encyclopaedias have often reflected fairly accurately the civilization in which they appeared; that this was deliberate is shown by the frequency with which the earlier compilers included such words as *speculum* ("mirror"), *imago* ("image"), and so forth in their titles. Thus as early as the 2nd century the Greek sophist Julius Pollux was already defining current technical terms in his *Onomastikon.* In the 13th century Vincent of Beauvais quoted the ideas of both pagan and Christian philosophers freely and without differentiation, for their statements often agreed on questions of morals. In doing so, he reflected the rapidly widening horizons of a period that saw the founding of so many universities. Bartholomaeus Anglicus devoted a considerable part of his work to psychology and medicine. "Theophilus" (thought to be Roger of Helmarshausen, a Benedictine monk) as early as the 12th century gave a clear and practical account in his *De diversis artibus* ("On Diverse Arts") of contemporary processes used in painting, glassmaking and decoration, metalworking, bone carving, and the working of precious stones, even listing the necessary tools and conditions for successful operations. Pierre Bayle, a French philosopher and critic, showed in his *Dictionnaire historique et critique* ("Historical and Critical Dictionary"; 1697) how the scientific renaissance of the previous 40 years had revolutionized contemporary thought. To every detail he applied a mercilessly scientific and inquiring mind that challenged the assumptions and blind reverence for authority that had characterized most of his predecessors.

At that point in history, much attention was being paid to practical matters: the statesman Jean-Baptiste Colbert himself directed the French Académie des Sciences (1675) to produce a work that eventually appeared as the *Description et perfection des arts et métiers* ("Description and Perfection of the Arts and Crafts"; 1761). The German Meyer's *Grosses Conversations-Lexicon* from the first edition (1840–55) onward paid particular attention to scientific and technical developments, and the *Encyclopedia Americana,* aided by the *Scientific American,* strengthened its coverage in this area from 1911 onward. In its very first edition the *Encyclopædia Britannica* included lengthy articles containing detailed instructions on such topics as surgery, bookkeeping, and many aspects of farming. Similarly, Abraham Rees had been including articles on subjects such as candle making and coachbuilding earlier in the century. The outstanding example of a completely contemporary encyclopaedia was, of course, the *Encyclopédie,* in which the philosopher Denis Diderot and the mathematician and philosopher Jean Le Rond d'Alembert and their friends set out to reject much of the heritage of the past in favour of the scientific discoveries and the more advanced thought of their own age. Their decision in this respect was both intellectually and commercially successful; since that time every edition of any good encyclopaedia has the additional merit of being a valuable source for the thought and attitudes of the world for which it was published.

Treatment of practical matters in encyclopaedias

Encyclopaedias and politics. All great encyclopaedia makers have tried to be truthful and to present a balanced picture of civilization as they knew it, although it is probable that no encyclopaedia is totally unbiassed. A great encyclopaedia is inevitably a sign of national maturity and, as such, will pay tribute to the ideals of its country and its times. The first Hungarian encyclopaedia, János Apáczai Csere's *Magyar encyclopaedia* (1653–55), was mostly a summary of what was available in foreign works, but the *Révai nagy lexikona* ("Révai's Great Lexicon"; 1911–35) was a handsome tribute to Hungary's emergence as a country in its own right, just as the *Enciklopedija Jugoslavije* (1955–) is a prestige work that does full justice to the advances made by Yugoslavia in the mid-20th century. The supreme example of an encyclopaedia that set out to present the best possible image of its people and the wealth and stature of their culture is undoubtedly the *Enciclopedia italiana* (1929–36). Mussolini's contribution of an article on Fascism indicates the extent to which the work might be regarded as an ideological tool, but, in fact, the bulk of its contents is admirably international and objective in approach. The various Soviet encyclopaedias already occupy many feet of shelf space, and the later editions each devote one complete volume to the Soviet Union in all its aspects. Though successive editions have been notable for the obvious political factors that have been responsible for the inclusion and exclusion of entries for famous nationals according to the current state of their acceptance or condemnation by the existing regime, many critics have felt that the newest edition, the first volume of which was issued in 1970, is maturer than any of the others in this regard.

Opposition to encyclopaedias

Diderot, the editor, and André-François Le Breton, the publisher, faced such opposition from both church and state in their publication of the *Encyclopédie* (1751–65) that many of the volumes were secretly printed, and the last 10 were issued with a false imprint. In the early part of the 19th century, *Brockhaus* was condemned by the Austrian censor, and in 1950 its 11th edition was branded as reactionary by the East German government. Nor was political censorship the only form of oppression in the world of encyclopaedias. Antoine Furetière, on issuing his prospectus (1675) for his *Dictionnaire universel,* found his privilege to publish cancelled by the French government at the request of the Académie Française, which accused him of plagiarizing its own dictionary. The Leipzig book trade, fearing that publication of Johann Heinrich Zedler's huge *Universal-Lexikon* (1732–50) might put them out of business, made such difficulties that Zedler thought it best to issue his work in Halle.

The reader's needs. People look to encyclopaedias to give them an adequate introduction to a topic that interests them. Many expect the encyclopaedia to omit nothing and to include consideration of all controversial aspects of a subject. Encyclopaedia makers of the past assumed that there was a large public willing to read through an entire encyclopaedia if it was not too large. In the 18th century, for example, there was a good market for pocket-size compendia for the traveller, or for the courtier to browse in as he waited for an audience. Thus, although most encyclopaedias are multivolume works, there are many small works ranging from the *Didascalion* of the scholastic

philosopher and mystic theologian Hugh of Saint-Victor (*c.* 1128), through Gregor Reisch's *Margarita philosophica* (1496) and the French writer Pons-Augustin Alletz' *Petite Encyclopédie* (1766), to C.T. Watkins' *Portable Cyclopaedia* (1817). The last was issued by a remarkable publisher, Sir Richard Phillips, who realized the great demand for pocket-size compendia and drove a thriving trade in issuing a number of these; he is thought to have written large sections of these himself.

Royalty and encyclopaedias. Most of the classic Chinese encyclopaedias owe their existence to the patronage of emperors. In the West, the Roman scholar Pliny dedicated his *Historia naturalis* ("Natural History") to the emperor Titus; Julius Pollux dedicated his *Onomastikon* to his former pupil, the Roman emperor Commodus, while the Byzantine philosopher and politician Michael Psellus dedicated his *De omnifaria doctrina* ("On All Sorts of Teaching") to his former pupil the emperor Michael VII Ducas, ruler of the Eastern Roman Empire. Gervase of Tilbury, an English ecclesiastic, compiled his *Otia imperialia* ("Imperial Pastimes") for the Holy Roman emperor Otto IV, and Alfonso de la Torre prepared his *Visiõ delectable* for Prince Carlos of Viana. St. Isidore dedicated his encyclopaedia to the Visigothic king Sisebut, and the French king Louis IX patronized Vincent of Beauvais's *Speculum majus.* Nor did kings eschew the work of compiling encyclopaedias. The emperor Constantine VII of the Eastern Roman Empire was responsible for a series of encyclopaedias, and Alfonso X of Spain organized the making of the *Grande e general estoria* ("Great and General History").

Editorial censorship

Contents and authority. The extent to which readers have been dependent on editorial decisions concerning not only what to include but also what to exclude has yet to be explored in detail. For example, Vincent of Beauvais rarely mentioned the pagan and Christian legends that were so popular in his day. The anonymous compiler of the scholarly *Compendium philosophiae* ("Compendium of Philosophy"; *c.* 1316) was careful to omit the credulous tales that appeared in contemporary bestiaries. For many centuries it was not considered right to include biographies of men and women who were still alive. And the early Romans, such as Cato the Censor, rejected much of Greek theoretical knowledge, regarding it as a dangerous foreign influence and believing with the Stoics that wisdom consisted in living according to nature's precepts.

Whatever the compiler did decide to include had a far-reaching influence. Pliny's vast *Historia naturalis* has survived intact because for so many centuries it symbolized human knowledge, and even the "old wives' tales" it injudiciously included were unquestioningly copied into many later encyclopaedias. The influence of St. Isidore's work can be traced in writings as late as Sir John Mandeville's travels (published in French between 1357 and 1371) and the English poet John Gower's 14th-century *Confessio amantis* ("A Lover's Confession"). Honorius' *Imago mundi* is known to have influenced some of the German medieval chronicles and the Norse saga of Olaf Tryggvason. The main source of classics such as the *Roman de la rose,* the Alexander romances, Archbishop Giovanni da Colonna's *Liber de viris illustribus* ("Book Concerning Illustrious Men"), and the recorded lives of the saints can be traced to the *Speculum majus.* The direct and indirect influence of the critical encyclopaedias of Pierre Bayle and Denis Diderot is, of course, incalculable.

EDITING AND PUBLISHING

The length of encyclopaedias and encyclopaedic articles. There always have been and there still are a number of successful one-volume encyclopaedias. Current outstanding examples include *The Columbia Encyclopedia,* the *Petit Larousse, Hutchinson's New Twentieth Century Encyclopedia,* and the *Random House Encyclopedia.* In the Random House set the contents were divided into two sections, a *Colorpedia,* composed of relatively lengthy articles dealing with broad topics, and an *Alphapedia,* composed of concise entries on very specific subjects. Some booksellers and publishers confirm that there is, however unreasonably, a certain amount of public prejudice against the single-volume form, and that most people prefer a multivolume work. Throughout the entire history of encyclopaedias there has been much variation in the number of volumes. Many of the Chinese encyclopaedias have been very much larger than any Western work. Pliny's *Historia naturalis* comprised about 2,500 chapters, Zedler's *Universal-Lexicon* was planned for 12 volumes and eventually filled 64; the publishers of the *Encyclopédie* were faced with a lawsuit (1768–78) for producing a 26-volume encyclopaedia instead of the 10 volumes they had promised; and Johann Samuel Ersch and Johann Gottfried Gruber's German *Allgemeine Encyclopädie* ("General Encyclopaedia") had already reached 167 volumes at the time of its discontinuance. Today, although the major Soviet encyclopaedia consists of more than 50 volumes, most encyclopaedias range between 20 and 30 volumes, occupying between three and four feet of shelf space. Thus the modern encyclopaedia appears smaller than its 19th-century counterpart, but, in fact, the content may be greater because the thick mat paper of Victorian times has been replaced by a thinner paper capable of reproducing coloured and black-and-white halftone illustrations with sharp definition.

Even more noticeable than variations in the number of volumes in encyclopaedias has been an even greater variation in the average lengths of articles within those volumes. The 11th edition of the *Encyclopædia Britannica* contained almost twice as many articles as the last significant edition before it, but it contained only 15 or 16 percent more words. The difference had to do with editorial considerations regarding the matter of fragmentation. Although most of the major encyclopaedias of the past had devoted considerable space to any topic of major importance, there was increasing recognition in the 19th century that an alternative method of treatment would be to break large subjects into their constituent subtopics for alphabetical distribution throughout the set. Those who favoured this more fragmented approach argued that by focussing on the smaller part of the whole, the editors could facilitate the user's search for specific information and that the liberal provision of cross-references would facilitate a recombination of the fragments by those interested in the bigger picture. Against this practice, it was argued that most cross-references are not followed up by most readers, that the shorter fragmented pieces work against a correct understanding of the larger subject, and that fragmentation inevitably involved a great amount of repetition of basic information throughout all of the related articles. Nevertheless, *Brockhaus, Meyer, Larousse,* and other encyclopaedias of the shorter entry type have had and continue to have a strong following.

Authorship by one individual

Authorship. The first encyclopaedia makers had no doubts concerning their ability to compile their works single-handedly. Cassiodorus, Honorius Inclusus (or Solitarius), and Vincent of Beauvais fully justified this attitude, though their task was largely that of the anthologist. Vincent and many other encyclopaedists employed both scribes and scholars to help them in their work, but once the encyclopaedia reached the stage of independent writing it was clear that the editorial task was going to become more complex. Even so, some of the later pocket encyclopaedias—such as the English bookseller John Dunton's mediocre *Ladies' Dictionary* (1694), *An Universal History of Arts and Sciences* (1745) by the French-born Englishman Chevalier Denis de Coëtlogon, and the popular *Allgemeines Lexicon* (1721) by the Prussian scholar Johann Theodor Jablonski—were substantially or almost wholly the work of a single author; such items are, however, negligible.

John Harris, an English theologian and scientist, may have been one of the first to enlist the aid of experts, such as the naturalist John Ray and Sir Isaac Newton, in compiling his *Lexicon Technicum* ("Technical Lexicon"; 1704). Johann Heinrich Zedler, in his *Universal-Lexicon* (1732–50), went further by enlisting the help of two general editors, supported by nine specialist editors, the result being a gigantic work of great accuracy. The French *Encyclopédie,* the largest encyclopaedia issued at that time, inevitably had many contributors, although the French writer Voltaire said that Diderot's collaborator, the

Chevalier Louis de Jaucourt (aided by secretaries), contributed about three-quarters of the articles in that work. The pattern for future encyclopaedias was established: for any substantial work it would be necessary not only to have contributions from the experts of the day, but it would also be essential to have subject editors who could supervise the coverage and content in each area of knowledge. With little alteration, this system prevails today.

Encyclopaedia adjuncts. The readers of modern encyclopaedias are rarely aware of the numerous aids that have been provided to make their search for information so easy and efficient. Only when recourse is had to one of the older encyclopaedias does the reader become conscious of the advances that have been made. In former days it was often difficult to distinguish between one article and the next, because distinctive headings or inset titles or the use of boldface was rare. Nor was the necessity for running titles or alphabetical notations at the head of the pages fully appreciated. Even more troublesome was the problem of the arrangement of entries for several persons of the same name; reference to the older encyclopaedias under such headings as "Henry," "Charles," "John," or "Louis"—names held by both princes and religious potentates—will show how little the art of acceptable arrangement was understood.

Arrangement of articles

Cross-references and bibliographies. Cross-references are an essential feature of the modern encyclopaedia; they date back at least as far as Bandini's *Fons memorabilium universi,* but it was Brockhaus who introduced an ingenious system of using arrows instead of the words "see also." *The Columbia Encyclopedia* achieves the same effect by printing in small capital letters the words under which additional information can be found. Other features of interest in the modern encyclopaedia include the devotion of each volume to a letter of the alphabet (*Compton's Encyclopedia* formerly followed this system), or the indication of the division between letters by thumb-indexing or by the insertion of a thicker sheet of distinctively coloured paper. In established encyclopaedias the bibliographies for individual articles are usually the result of careful editorial consultation with the writer and with librarians.

Indexes. Undoubtedly the major adjunct of the modern encyclopaedia is its index. As early as 1614 the bishop of Petina, Antonio Zara, included an index of a kind in his *Anatomia ingeniorum et scientiarum* ("Anatomy of Talents and Sciences"). A Greek professor at Basel, Johann Jacob Hoffman, added an index to his *Lexicon universale* of 1677; the *Encyclopédie* was completed by a two-volume "Table analytique et raisonnée" for the entire 33 volumes of text, supplements, and plates; and the *Britannica* included individual indexes to the lengthier articles in its 2nd edition (1778–84) and provided its first separate index volume for the 7th edition (1830–42). The nature of good indexing was still far from being fully understood, however, and it was only later in the 19th century that really good encyclopaedia indexes were prepared. In the 20th-century encyclopaedias that provide indexes—and there are many that do not—the reader is invariably advised to read the guides to their use because the index is a sophisticated tool that, by the aid of a few simple typographical devices and editorial conventions, is able to offer a wealth of information in one alphabetical sequence.

Illustrative material. The use of illustrations in encyclopaedias goes back almost certainly to St. Isidore's time. One of the most beautiful examples of an illustrated encyclopaedia was the abbess Herrad's 12th-century *Hortus deliciarum.* In many earlier encyclopaedias the illustrations were often more decorative than useful, but from the end of the 17th century the better encyclopaedias began to include engraved plates of great accuracy and some of great beauty. The *Encyclopédie* is particularly distinguished for its superb volume of plates—they have even been reprinted in the 20th century. In modern times the trend has been toward more lavish illustration of encyclopaedias, including elaborate coloured anatomical plates with superimposed layers, and specially inset small coloured halftones, as well as marginal line drawings. Since 1950 a form of encyclopaedia has begun to appear that comprises large numbers of coloured illustrations with a somewhat subordinated text.

Early illustrated encyclopaedias

The level of writing. The American editor Franklin H. Hooper, undaunted by his own lack of scholarship, took a notable part in ensuring that the articles of the 11th edition of *Encyclopædia Britannica* were kept within the mental range of the average man. The problem of the encyclopaedist has always been to strike the right mean between too learned and too simplified an approach. The Roman Cassiodorus wrote his encyclopaedia to provide a bridge between his unlettered monks and the scholarly books he had preserved for their use. Hugh of Saint-Victor, the theologian and philosopher, achieved one of the best approaches in his charming *Didascalion* (*c.* 1128), in which he used an elegant and simple style that everyone could appreciate. The abbess Herrad, knowing her audience, described in didactic fashion the history of the world (with emphasis on biblical stories) and its content, with commentaries and beautifully coloured miniatures designed to help and edify the simple nuns in her charge. The master of Dante, Brunetto Latini, wanted to reach the Italian cultured and mercantile classes with his *Li livres dou trêsor* ("Treasure Books"; *c.* 1264) and therefore used a concise and accurate style that evoked an immediate and general welcome. Gregor Reisch managed to cover the whole university course of the day in his very pleasing and brief *Margarita philosophica,* which correctly interpreted the taste of the younger generation at the end of the 15th century.

Until the 17th century there had been a great many encyclopaedias written by clerics for clerics, and further examples continued to be published. After that time, more popular works began to be published as well, particularly in France, where such palatable compilations as the Sieur Saunier's *Encyclopédie des beaux esprits* ("Encyclopaedia of Great Minds"; 1657) had an immediate success. The philosopher Pierre Bayle in his *Dictionnaire historique et critique* (1697) first introduced the lay reader to the necessity of reading more critically; in this his work constituted a forerunner of the *Encyclopédie,* with its challenges to so many undiscriminating assumptions about religion and politics, history and government. On the other hand, the contemporary *Dictionnaire universel* of the Jesuit fathers of Trévoux had a popularity among the orthodox that caused it to run through six editions and gradually to increase its size from three to eight volumes between 1704 and 1771.

Encyclopaedias for clerics and lay readers

Supplementary material. The idea of keeping encyclopaedias up-to-date by means of supplements, yearbooks, and so on, is well over 200 years old. In 1753 a two-volume supplement to the 7th edition of Ephraim Chambers' *Cyclopaedia* was compiled by George Lewis Scott, a tutor to the English royal family. Charles-Joseph Panckoucke, a publisher, issued a four-volume supplement to the *Encyclopédie* (1776–77), in spite of Diderot's refusal to edit it. The *Britannica* included a 200-page appendix in the last volume of the 2nd edition (1784) and issued a two-volume supplement to the 3rd edition (1801; reprinted 1803). *Brockhaus* broke new ground by issuing in monthly parts (1857–64) a yearbook to the 10th edition (1851–55), which, on the commencement of the issue of the 11th edition, changed its name to *Unsere Zeit* ("Our Times") and doubled its frequency (1865–74). In 1907 Larousse began publication of the *Larousse mensuel illustré* ("Monthly Illustrated Larousse"). *The New International Encyclopaedia* issued a yearbook from 1908 (retrospective to 1903), and the *Britannica* issued one yearbook in 1913 and recommenced with the *Britannica Book of the Year* in 1938. The publication of supplements has a much longer history in China, but the system on which the Chinese operated was very different from that of the West (see below). Nowadays yearbooks are a common feature of encyclopaedias of standing in the United States and other countries. In the main, they are more effective in recording the events and discoveries of each year than they are in keeping the main articles up-to-date, but they perform an essential duty in informing their readers of much that is not reported or that is only inadequately reported in the press; at the same time, they provide a more

reasoned assessment and perspective than the daily newspapers and the weekly commentaries can usually achieve.

Some of the leading encyclopaedias offer additional services that are not too widely known. The modern encyclopaedia is a complex work of reference, and the reader needs expert guidance if he is to get the best from its contents. To this end, small subject guides are sometimes issued, which, in narrative form, outline the whole field and bring each topic into perspective, drawing attention to the appropriate articles that will throw further light on the matter. As a means of self-education, some of these outlines maintain a high standard and are an invaluable adjunct to the encyclopaedia. Another supplementary feature offered by some established encyclopaedias is a research service through which purchasers are permitted to submit a limited number of questions about topics either not dealt with in the set or dealt with inadequately. Such services have been provided in a variety of ways. In some cases, frequently asked questions may be answered with previously prepared reports listed in the publisher's catalog; in others, questions are referred to a special office staff for answers culled from the publisher's own data bases; and in still others they may be referred to researchers stationed at selected specialized libraries. Though increasingly expensive to maintain, such services have been thought to be advantageous to the reader, who secures from them a research support not otherwise available, and advantageous to the editorial staff, who may derive from them useful information about the kinds of problems being experienced by those who use their encyclopaedia.

Other supplementary material sometimes issued by encyclopaedias ranges from 10-year illustrated surveys of events to sets of books that have had a major impact on mankind. Although few publishers include dictionaries as an integral part of their encyclopaedia, they frequently supply a well-known, independently compiled work as part of their service. It is an increasingly common custom, however, for a modern encyclopaedia to incorporate an atlas and a gazetteer, often in the last volume.

Problems of encyclopaedias. *Authorship.* In using a reputable encyclopaedia the reader is inclined to accept the authenticity of any article he happens to read. Subconsciously he is aware that the highly organized body of scholars listed at the beginning of the work must inevitably have ensured the severe scrutiny of all material. Nevertheless, in recent years editors of encyclopaedias have tended more and more to commission signed articles by well-known experts. One of the most famous examples of this was the *Britannica's* commissioning of articles for its 1922 supplement from some of the most famous men and women of the day: "Belgium" by the Belgian historian Henri Pirenne; "Anton Ivanovich Denikin" by the Russian-born jurist and historian Sir Paul Vinogradoff; "Drama" by St. John Ervine, the Irish playwright and novelist; "Czechoslovakia" by the Czech statesman Tomáš Masaryk; and "Russian Army" by Gen. Yuri Danilov. This created a new dimension in encyclopaedias, for it introduced a personal element on a scale previously seen only in the columns of the *Encyclopédie.*

Famous contributors

There is, in fact, a difference in the treatment of a subject written by a politician such as Masaryk and by an academic historian of distinction. Each writer has something important to offer, and the results will be very different.

Length restrictions. The restrictions imposed by the space available for any particular article are of great consequence. If an expert is asked to contribute an article on his own field, his first reaction is often one of dismay at the comparatively small amount of space that can be allotted to it. Writing articles for encyclopaedias is an art of its own; within a limited space so much must be compressed—nothing important can be omitted, nothing trivial should be included. Most experts would agree that it is easier to write a book than an encyclopaedia article. They would also consider it simpler to write an article for a periodical, because encyclopaedia writing is teamwork in which each article is edited in relation to others closely connected by subject. If a writer makes a statement that is partly qualified or totally contradicted in another article, the contributions of both writers must be scrutinized by the editorial staff, whose job it is to effect some kind of eventual agreement. Truth can be viewed from many standpoints, and references to any controversy may produce problems demanding all the skill and tact of the editors to resolve, particularly when the reputation of the writer is at stake in a signed article.

Revision and updating. The revision and updating of an encyclopaedia is one of the greatest challenges to its makers, and one to which many ingenious, if admittedly partial, solutions have been found. Louis Moréri set the example in his rapid incorporation of new information in each succeeding issue of his widely used *Grand Dictionnaire historique* ("The Great Historical Dictionary"; 1674). When the German publisher Friedrich Arnold Brockhaus first issued his great encyclopaedia he was forced by an unexpectedly large public demand to issue edition after edition in quick succession (some of them even overlapped). In all of these he took great pride in providing the latest information, personally supervising much of the revision of individual articles. Moreover, he provided special supplements incorporating these revisions for purchasers of each edition, so that they did not have to buy the next in order to keep up-to-date.

In the 18th and 19th centuries, most encyclopaedias that lasted long enough to require revision met the problem by preparing a new edition or by issuing supplements. In the case of *Encyclopædia Britannica,* the first edition (1768–71) was replaced by an essentially new and enlarged second edition in 1777–84; the ninth edition (1875–89), however, remained in print until the preparation of the 11th edition (1910–11), with a 10th edition nominally created by the addition of 11 supplementary volumes in the interim. Among the most serious shortcomings of the new-edition method was the tendency of publishers to dismiss editorial staff after the preparation of a new edition, a practice which meant that skilled editors were dispersed and had to be replaced once the decision to create a new edition had been taken.

Early in the 20th century it became the practice to fill the gaps between new editions with annual summaries called yearbooks (considered above). A turning point came when, soon after the publication of its 14th edition in 1929, *Encyclopædia Britannica* announced the introduction of a system of continuous revision that in one form or another is now the practice of most major encyclopaedias in many countries. Under continuous revision programs, some percentage of the articles in a set are updated or improved in other ways on a flexible schedule. Several publishers were able to take advantage of 20th-century printing technologies to reprint their sets on an annual basis and to introduce into each new printing as many revised entries as possible. The system implies the existence of a permanent editorial department able, with the assistance of academic advisers and article authors, to monitor the condition of entries on a constant basis.

Continuous revision

Although some publishers have reported annual revisions of 10 percent or more of the entries in their set, actual practice has varied so widely that averages have little meaning.

Nor is continuous revision without drawbacks. The most serious disadvantage may relate to the rapidity with which articles in a set become noticeably unbalanced in relation to one another. Changes and events requiring revision of articles are more readily apparent in the scientific, technological, biographical, and historical areas, with the result that articles in such fields are revised much more frequently than articles in such fields as the humanities, where important changes do occur though more subtly.

An equally important disadvantage in continuous revision has to do with the inherent difficulty of revising, on an article-by-article basis, a set of reference books containing many thousands of articles. In the first place, editors are usually unable to revise all the articles that might be affected by a new development. In the case of the assassination of a president, for instance, the editors of the next printing might add the event to his biography and even to the history of his country but be unable to acknowledge the event in all the other articles in which the president's name appears. In the second place, it is a fact that updating a single article is not always as simple as it might at first appear to be. In a biography, for instance, critical events can occur so often that it soon becomes no longer possible simply to add an additional sentence to the end of the piece: the death of the subject of the biography might

be the occasion for a reassessment of his significance or for the disclosure of long unknown or unpublicized information about him; in archaeology, a new discovery may be at serious variance with several previously held theories on which a whole article might well be based. In such instances, revision must go beyond the simple addition of a sentence or the insertion of a word or date and may involve partial or complete rewriting. With the pace of modern research what it is, this can quickly become an ever-present editorial problem of great complexity.

It will be seen that the problem of keeping an encyclopaedia up-to-date has two facets: the first, that of finding ways to assure that any one printing or edition is as up-to-date as possible at the time of its preparation, and, the second, that of finding ways to make it possible for purchasers to maintain the set in an up-to-date condition. Continuous revision is one example of an effort to come to grips with the first aspect of the problem; yearbooks represent another type of effort. One apparent answer to both aspects, the loose-leaf format, has never been a publishing success. Nelson's *Perpetual Loose Leaf Encyclopaedia* (second edition, 1920) was discontinued; the prestigious *Encyclopédie française* (1935–66), however, continues to be available in both loose-leaf and bound volumes.

Given the rapidity of change in the contemporary world, it was to be expected that encyclopaedia publishers would quickly seek ways of exploiting new technologies in the field of information storage, retrieval, and distribution in solving their revision problems. Though most early studies centred on the computer and related word-processing equipment, other technologies, including the so-called videodisk, have also been examined for possible applications. The immense storage capacity and ease of access to, and manipulation of, stored data have already made the computer an invaluable adjunct in the editorial departments of many encyclopaedia publishers. Several encyclopaedias are known to have been totally captured on tape for computer processing; in a few instances, the computer has become a major agent of editorial production by which article text is generated, changed as needed, and recaptured in its new forms.

Computer applications

In studying the applications of computer technologies, at least two U.S. publishers have been involved in experimental programs that make the entire texts of their sets available as an on-line computer service. Grolier, Inc., which in 1982 acquired *Academic American Encyclopedia* from Arete Publishing Co., has proposed to make its complete computerized text available to anyone subscribing to certain data-transmission services, such as *The New York Times'* Information Bank. In a separate development, Encyclopædia Britannica, Inc., made tapes of its 30-volume 15th edition and related yearbooks available for on-line use by subscribers to the services of Mead Data Central, a division of the Mead Corporation of New York. Early results of the experiments have not been announced. Should they succeed, the way will be opened to the development of an electronic encyclopaedia independent of alphabetical arrangement, accessible through methods other than the use of an index, and capable of being updated on an almost daily basis as new data are substituted for old.

Controversy and bias. Throughout the years most major encyclopaedias have been accused of reflecting bias in one or more of their articles. In the *Encyclopédie,* the lack of neutrality was intentional and apparent. Various editions of *Encyclopædia Britannica,* almost from the beginning, were accused of bias as well. The practice of relying on outside specialists for articles, a practice now followed by most serious encyclopaedias, has increased the likelihood that bias will be worked into an article. Many critics have felt that the reader is protected in such cases by the fact that the identity of the contributor is not hidden. It has also been argued that the presence of slanted opinions in an article gave to older encyclopaedias a colour and sense of conviction that is lacking in most modern works. Modern editors of major encyclopaedias, nevertheless, make every effort to eliminate any hint of bias in their sets, but the task is a difficult one. For example, an account of the Korean War would vary according to whether it was written by a North or South Korean, a Chinese, or an American writer. Similarly, the inclusion of a map showing the frontiers between two or more nations may give rise to vigorous controversy if the nations involved were to dispute any part of the boundaries as shown. The illustration of a painting with an attribution to one artist may draw strong protests from art critics who do not agree with the writer. Controversy today has grown rapidly on many subjects that were not in dispute a few years ago.

The kinds of encyclopaedias

GENERAL ENCYCLOPAEDIAS

It is now possible to see, in the last 2,000 years of encyclopaedia production, the existence of a pattern closely related to the changing social needs of each age. The outstanding circumstances that governed the policy and production of encyclopaedias for the first 15 centuries were that comparatively few people were able to read and, stemming partly from this and partly from the cost of materials and workmanship, that copies of any lengthy work were very expensive. Only when printing was introduced into Europe did the cost of production drop by any large amount; this development in turn helped to stimulate the growth of readership. A notable feature at the time of the early printing press was the sudden growth in the popularity of some of the older encyclopaedias as a result of the tendency to ensure a ready market by printing works of which many manuscript copies were in circulation.

Influence of printing

During the first 16 centuries of their publication the great majority of encyclopaedias comprised great anthologies of the most significant writings on as many subjects as possible. These excerpts were arranged in an order that was constantly varying according to the individual compiler's concept of the hierarchies of human knowledge; some of these classification systems were more suitable than others, but none was completely successful in meeting the tastes of the reading public because there was no general agreement on the essential order of ideas. Although the compiler exercised considerable latitude in his choice of items to include in his encyclopaedia, he often restricted comment to a minimum, so that the reader was free to form his own opinion of what was offered. In addition, because the compiler selected his material from what had already been written, the gaze of the reader was being turned to the past, and, although he could enjoy the heritage of the preceding cultures, he was not being put in touch with as much of the contemporary world as he might have desired.

Around the 10th or 11th century, a new type of encyclopaedia began to emerge, probably stimulated by the growing number of language dictionaries that, starting well before printing was used, grew ever more numerous once they could be produced by this method. Many early dictionaries were little more than enlarged glossaries, but from the time of *Suidas* onward, there began to appear a type of dictionary—now called encyclopaedic—that added to the definition and etymology of a word a description of the functions of the thing or idea it named. In some dictionaries, such as those of the Estiennes, a French family of bookdealers and printers, this description might in some cases be of considerable length. Thus the compilers of the new form of encyclopaedia that emerged in the 16th and 17th centuries inevitably thought in terms of arranging their entries in alphabetical order, because the dictionaries had already familiarized the reading public with this system. It needed only the success of a single encyclopaedia, such as Moréri's *Grand Dictionnaire historique,* to prove to publishers in general that this was a formula with considerable promise.

The last half of the 18th century brought such an upheaval in man's concept of the world that the time was ripe for further experiments in the form of the encyclopaedia. The French encyclopaedists Diderot and d'Alembert and their band of contributors broke no new ground in the physical format and arrangement of the encyclopaedia, but their work inspired the intelligentsia of other nations to produce really good encyclopaedias of their own. It is no coincidence that both the German *Brockhaus* and the Scottish *Britannica* appeared with policies so different from all that had gone before that no pub-

Formulas of *Brockhaus* and *Britannica*

lisher of any new encyclopaedia could afford to ignore their new patterns. Their formulas were so good that the modern encyclopaedia is simply a vastly improved elaboration of their method of arrangement and organization. The compilers of both encyclopaedias had taken the best ideas from the anthologies and miscellanies of the early period of encyclopaedia making and from the later stage of encyclopaedic dictionaries. Realizing that the reading public would not tolerate the omission of some subjects and the unequal treatment of others, they prepared works in which at least a few lines were devoted to almost every conceivable topic, and for more important subjects a full account was provided, written by an expert, if possible.

The three periods of the history of encyclopaedias—(1) to 1600, (2) 1601–1799, and (3) 1800 onward—are very unequal. They are, moreover, to a certain extent misleading, for the different forms of the encyclopaedia overlapped at each turning point for some years, and even today there are still some important survivals from the two earlier periods. One can study and compare what each of the three main types of encyclopaedia has had to offer by opening the *Encyclopédie française, Webster's Third New International Dictionary,* and the *Encyclopædia Britannica* at the places in which each describes the same subject. The *Encyclopédie française* will provide one or more well-written treatises on the subject by writers of note. This is exactly what the encyclopaedias of the earliest period offered; and in both the old and the contemporary encyclopaedia the reader is left free to form his own opinion after reading what the experts have to say. *Webster's,* a one-volume work, of course provides much less, but it also gives much more, because it adds definitions and, often, explanatory drawings or diagrams to an admirably concise text that tells the reader much in a very few lines. This is exactly what the encyclopaedic dictionaries of Louis Moréri, Antoine Furetière, and others were offering in the 17th and 18th centuries. The *Britannica*'s contribution is distinct from those of the other two in that it provides a synthesis of what is known on the subject to date, and attempts to assess its current position. The comparison of these three examples gives only an approximate idea of the nature of the encyclopaedia in each of its three main stages, but it also helps to remind the reader of today that ideas concerning the form of an encyclopaedia have evolved considerably throughout the centuries.

Background of readers before 1600

The encyclopaedias of the period before 1600 apparently were designed for a small group of people, who had much the same educational background as well as similar interests and opportunities to pursue them. In general, they had a common outlook on both religious and secular matters. Moreover, although they were citizens of many different countries, they were united by their knowledge and use of Latin, the international language.

The Eastern Roman emperor Constantine VII Porphyrogenitus (905–959) tried to plant firmly in the hearts of the most worthy of his contemporaries both knowledge and experience of the past. His were troubled times, and he felt justified in using much of his enforced leisure (he came to the throne in 911 but was not allowed to rule until 945) to provide for the administrators and emissaries of his court the most useful extracts from the writings of a very catholic selection of authors, including the patriarch of Constantinople John of Antioch (Johannes Scholasticus), the Roman historian Appian, the Greek historian Polybius, the Greek philosopher Socrates, the 5th-century Byzantine historian Zosimus, and many others. One of the unexpected by-products of this industry was the preservation of a large number of writings, a service that some of the other medieval encyclopaedias also performed.

An advantage of the encyclopaedists of the first period (*i.e.,* before 1600) was that each of them either knew or could visualize his reading public, a point that encouraged a minimum of commentary and moralizing. In a way, they were performing the duties of a personal librarian in that they drew their readers' attention to innumerable passages that they believed might be useful to them in their work or their private lives. The possibility of achieving even more was fully appreciated: the English scholar Alexander Neckham, in his early 13th-century *De naturis rerum* ("On the Natures of Things") hoped that by the imparting of knowledge he might help to lift or lighten man's spirit, and to this end he tried to maintain a simple and admirably clear text. Neckham's near-contemporary Bartholomaeus Anglicus similarly set himself in his *De proprietatibus rerum* ("On the Characteristics of Things") to bring to his readers' attention the nature and properties of the things and ideas on which the early Christian Fathers and the philosophers had expatiated, but he forbore to comment on their writings, leaving his readers to form their own judgments. The anonymous compiler of the *Compendium philosophiae* ("Compendium of Philosophy"; *c.* 1316) believed the knowledge of truth to be the supreme and final perfection of mankind; thus he never moralized on the contents of his encyclopaedia, its cumulative effect thereby being the more impressive.

Within the early period of the history of encyclopaedias a number of stages can be distinguished that make each group of works of great importance in any study of the development of scholarship and the spread of learning throughout the West. Encyclopaedias of classical times reached their culmination in Pliny's *Historia naturalis,* which was issued in the time of the Roman emperor Titus (AD 39–81). Not one of the encyclopaedias of Pliny or his predecessors paid much attention to religion; if it was discussed the approach was antiquarian, the gods of the different nations ruled by Rome being named and described in a dispassionate spirit that reflected both the tolerance and the noninvolvement of the Romans in these matters. The emphasis instead was on government, geography, zoology, medicine, history, and practical matters. The theories of the various philosophers were outlined impartially, no indication being given of any personal preference. This objective approach adopted by the Romans in their encyclopaedias was not achieved again until the 19th century.

Encyclopaedias of classical times

By the time of the Roman philosopher Boethius and the statesman Cassiodorus (*i.e.,* the 5th and 6th centuries AD), the position concerning objectivity had changed. Like Pliny and the Roman statesman Cato, Cassiodorus had been an administrator; and, while his predecessors had been engaged in interpreting and epitomizing the knowledge of the ancient world for the benefit of their own people, Cassiodorus realized the necessity for providing a new interpretation of this knowledge for the Goths, the new masters of Italy. In the next 700 years the impact of Christianity brought a new phase in Western encyclopaedia making, just as the impact of Islām is clearly visible in the Arabic encyclopaedias of the same period. Although religion is not always given pride of place in the encyclopaedias of those times, it pervades the whole of their contents. Thus Cassiodorus' division of his encyclopaedia into two main sections—divine and human—is made even more interesting by his inclusion of cosmography, the liberal arts, and medicine in the first section. Although the compilers of the encyclopaedias of this period could envisage in theory a perfectly logical arrangement for their encyclopaedias by starting with the creation and working downward to the smallest and least significant of God's creations, in practice they found this very difficult to apply, and the result was often only superficially scientific. Moreover, the inclusion of such topics as astrology and magic was surprisingly prevalent and only began to disappear after the publication of *Liber floridus* ("The Flowering Book"; *c.* 1120), by Lambert, a canon of Saint-Omer, a work that discarded practical matters in favour of metaphysical discussion.

Use of the vernacular

The third stage in the development of encyclopaedias came with the introduction of vernacular editions, such as the *Mappemonde* and *Li livres dou trésor,* and the reflection of the impact of Greek philosophical works (in translation) in the middle of the 13th century. In this era there was an increasing number of lay encyclopaedists—*e.g.,* Latini, Bandini, de la Torre—and the subject coverage changed to give more space and importance to the practical matters that interested the rising mercantile class. At the same time, theology no longer dominated the classification schemes. Humanism reached its full expression in the Spanish philosopher Juan Luis Vives' *De*

disciplinis (1531), in which all the compiler's arguments were grounded on nature and made no appeal to religious authority. The printing press had eliminated one of the most vexatious problems: the introduction or perpetuation of textual errors by the manuscript copyists. At the same time, the wider circulation of encyclopaedias through the unrestricted sales of printed copies brought about a situation in which the compilers could no longer envisage their reading public and accordingly adjusted their approach to their largely unknown audience.

ENCYCLOPAEDIC DICTIONARIES

The period spanning the 17th and 18th centuries is characterized by the flourishing of the encyclopaedic dictionaries that were pioneered by the Estienne family in France in the 16th century. During these two centuries this form of encyclopaedia reflected two different policies. On the one hand there was the encyclopaedia, such as those of the Germans Johann Theodor Jablonski and Johann Heinrich Zedler, that paid particular attention to the fields of history and biography. On the other, there was a new form of encyclopaedia—if the exception of the 12th-century *De diversis artibus* be set aside—that devoted itself to the arts and sciences. The first type can therefore be said to be retrospective in approach, while the arts and sciences encyclopaedia was clearly identifiable with contemporary matters.

None of these divisions is actually clear-cut, for many traditional encyclopaedias continued to be compiled throughout the period, and not all the historical-biographical encyclopaedias ignored the arts and sciences or contemporary people and events. Nevertheless, the issue of Antoine Furetière's encyclopaedia and the immediate follow-up by *Le Dictionnaire des arts et des sciences* (1694) by the writer Thomas Corneille (the younger brother of the playwright Pierre Corneille) were sufficient to indicate the growing public interest in a more modern form of encyclopaedia. This indication was confirmed by the successful publication of John Harris' *Lexicon Technicum* (1704), which the author described as "an universal English dictionary of arts and sciences: explaining not only the terms of art, but the arts themselves." It is significant that Harris omitted such subjects as theology, biography, and geography. The Englishman Ephraim Chambers went even further in describing his internationally influential *Cyclopaedia* (1728) as

> an universal dictionary of arts and sciences; containing an explication of the terms, and an account of the things signified thereby, in the several arts, both liberal and mechanical, and the several sciences, human and divine, compiled from the best authors.

Ideal contents as viewed in the 18th century

No century has seen more public discussion of the nature of the encyclopaedia than the 18th; at the same time, there was much uncertainty concerning its ideal contents. The fine Italian encyclopaedia of Gianfrancesco Pivati (the secretary of the Academy of Sciences at Venice), the *Nuovo dizionario scientifico e curioso, sacroprofano* ("New Scientific and Curious, Sacred-Profane Dictionary"; 1746–51), avoided the subject of history, whereas the German writer Philipp Balthasar Sinold von Schütz's *Reales Staats- und Zeitungs-Lexicon* ("Lexicon of Government and News"; 1704) concentrated on geography, theology, politics, and contemporary history and had to be supplemented by the German economist Paul Jacob Marperger's *Curieuses Natur-, Kunst-, Berg-, Gewerk- und Handlungslexikon* (1712; "Curious Natural, Artistic, Mining, Craft, and Commercial Encyclopaedia"), which covered the sciences, art, and commerce.

The introduction of the arts and sciences type of encyclopaedia inevitably hastened the use of specialist contributors, for it widened the total subject field considerably. "Hübner" (as Sinold von Schütz's encyclopaedia was known from the writer of the preface) employed many contributors, and it is known from the draft prospectus of the British writer Oliver Goldsmith that an encyclopaedia he projected was to have included comprehensive specialist articles by the lexicographer Samuel Johnson, the statesman Edmund Burke, the portrait painter Sir Joshua Reynolds, the historian Edward Gibbon, the economist Adam Smith, and others. The remarkable progress made in this period can easily be judged when one compares the encyclopaedia *Lucubrationes* (1541), in which the author, Joachim Sterck van Ringelbergh, found it necessary to include a "miscellaneous" section (which he amusingly dubbed "Chaos"), with the approach of Johann Georg Krünitz, a German physician and philosopher, in his highly organized, modern *Oekonomisch-technologische Encyklopädie* ("Economic-Technological Encyclopaedia"; 1773–1858) with its 242 volumes.

THE MODERN ENCYCLOPAEDIA

The period of the encyclopaedic dictionary was brilliant, but it gradually became apparent that, in abandoning the systematic encyclopaedia of the earlier period in favour of the quick reference dictionary form, quite as much had been lost as had been gained. The comparatively brief entries in the encyclopaedic dictionary had, by accident of the alphabet, fragmented knowledge to such an extent that users received only a disjointed knowledge of the things in which they were interested. Nor had the willful and extremely individualistic effort of the French encyclopaedists Diderot and d'Alembert done more than confuse the issue, for they had bent the principles of encyclopaedia making to their own purposes. An initial solution to the problem was found by Andrew Bell (1726–1809), Colin Macfarquhar (*c.* 1745–93), and William Smellie (1740–95), three Scotsmen who were responsible for the first edition (1768–71) of *Encyclopædia Britannica.* Aware of the shortcomings of the *Encyclopédie,* they devised a new plan. Their encyclopaedia was to include about 45 principal subjects (distinguished by titles printed across the whole page), supported by another 30 lengthy articles, the whole being contained within one alphabetical sequence interspersed with numerous brief entries enhanced by references, where appropriate, to the principal subjects. Some of the principal articles, notably those on medical subjects, extended to well over 100 pages each. The three collaborators had thus incorporated the comprehensive treatment of important subjects accorded by the earliest form of encyclopaedias and had supplemented this with the attraction of the brief informative notices of minor topics that had been the chief feature of the encyclopaedic dictionary. The key to their success was, however, their retention of the single alphabetical sequence.

Plan of the first *Encyclopædia Britannica*

Meanwhile, Renatus Gotthelf Löbel was planning to compile an encyclopaedia that could supersede "Hübner." It was Sinold von Schütz who, in the fourth edition

of "Hübner," had introduced the word *Conversations-Lexikon* into the title, and it was Löbel who decided to give it pride of place in his new encyclopaedia. The *Konversationslexikon* was designed to provide the rapidly growing German bourgeoisie with the background knowledge considered essential for entry into the polite society of the day. When Brockhaus took over Löbel's bankrupt and incomplete encyclopaedia, he saw the value and appeal of this evocative word and retained it (in various spellings) for many years afterward. Löbel's and Brockhaus' solution to the problem of the form of the modern encyclopaedia was not the same as the *Britannica*'s; it is interesting to note that whereas the *Britannica* model has widely prevailed throughout the English-speaking world, *Brockhaus* has been the model for most of the encyclopaedias prepared in countries in which English is not widely spoken.

Format of the *Konversationslexikon*

Brockhaus, throughout its existence, has faithfully followed a system in which the whole of knowledge has been analyzed into very specific topics. These topics are arranged alphabetically and, under each heading, condensed entries convey the essential information. By ingenious cross-references, entries are linked with other entries under which further information can be found, thus avoiding the inclusion of an index. There is no difficulty in distinguishing encyclopaedias of the *Konversationslexikon* form from encyclopaedic dictionaries. The former are usually of considerable size (*Der grosse Brockhaus,* 1928–35, included 200,000 articles by over 1,000 authors) and possess elaborate cross-reference schemes. Moreover, whenever a really important subject occurs, considerable space is allowed, though the same principle of concentrated text is followed.

Although the *Britannica* and *Brockhaus* examples eventually became the models for 19th- and 20th-century encyclopaedias, there have been many survivals from the previous periods. Ersch and Gruber's enormous *Allgemeine Encyclopädie* ("General Encyclopaedia"; 1818–89) has been cited as a true example of the medieval "summa"—it is famed for including the longest article in any encyclopaedia, that on Greece, which fills 3,668 pages in volumes 80–87. The *Encyclopédie française* is an even later example of this form and, as Samuel Taylor Coleridge planned it, the *Encyclopaedia Metropolitana* could have proved the supreme example of this type of treatment. Meanwhile, the encyclopaedic dictionary has never died, and at the very time when *Brockhaus* and the *Britannica* were building their markets, Noah Webster was developing his dictionary's reputation for reliability into a household expression in the United States.

ENCYCLOPAEDIAS FOR SPECIAL INTERESTS

Most encyclopaedias have been compiled from a purely scholarly point of view and have had no particular ax to grind, though nearly all have been inhibited to a certain extent by the interests and policies of the milieu in which they made their appearance. There are, however, several encyclopaedias that have deliberately been planned for a special purpose. One that is unique and continues to be of the greatest value to historians is the work of the 16th-century Spanish Franciscan Fray Bernardino de Sahagún, who spent much of his life in missionary work in Mexico. Sahagún was ordered to write in Nahuatl the information needed by his colleagues for the conversion of the Indians. The result, the *Historia general de las cosas de Nueva España* ("General History of the Matters of New Spain") is a magnificent record of the Aztec culture as recounted by the Indians of south central Mexico. The arrangement of this work, written in pictorial language as well as in Spanish, follows the familiar medieval pattern and resembles most closely that of Bartholomaeus Anglicus (Sahagún may have been familiar with a recent translation of Bartholomaeus' encyclopaedia). *Historia* is one of the most remarkable encyclopaedias ever compiled, and it has also a special importance for students of language.

Older Arabic and Chinese encyclopaedias

Many of both the Arabic and Chinese classical encyclopaedias were compiled with the object of helping civil service candidates in their studies and of providing administrators with the cultural background needed for their work. Their interest to historians of the two cultures can well be understood, for their arrangement and contents throw useful light on the concepts of administration and justice (to name only two aspects) in the Chinese and Islāmic worlds during the 7th to 15th centuries.

Of the Western medieval encyclopaedias, the most interesting in this respect is the *De naturis rerum* (*c.* 1228–44) of the Dominican friar Thomas de Cantimpré. His aim was that of St. Augustine: to unite in a single volume the whole of human knowledge concerning the nature of things, particularly the nature of animals, with a view toward utilizing it as an introduction to theology. To achieve this he devoted the first part of his work to mankind, zoology, botany, and geology. He then compiled a much smaller section on cosmology. An additional section on astronomy followed later. Although it was a comparatively unorganized and ill-balanced work, the popular nature of this encyclopaedia, with its stories of magic and allegorical creatures, ensured its widespread success over two centuries.

Religion and politics were the main motives for writing encyclopaedias with a special purpose. Louis Moréri made no secret of his intention to produce an encyclopaedia that would defend the teaching and policies of the Roman Catholic Church. Antoine Furetière and Pierre Bayle, on the other hand, represented the philosophers, and their anticlerical bias was more in tune with the skeptical minds of the age. Nevertheless, there was still a strong orthodox following in France, as the long-continuing demand for the *Dictionnaire universel* of the Jesuit fathers of Trévoux demonstrated, and this encyclopaedia was as firmly in defense of Catholicism as the *Encyclopédie* was critical of it.

Diderot and d'Alembert's encyclopaedia had originally been intended by its publisher to be no more than an adaptation of Ephraim Chambers' *Cyclopaedia.* The outcome was a giant reference work that criticized the government, satirized the Calvinist clergy of Geneva, championed the Age of Reason, and supported an atheistic materialism. To the more rigid members of the French Establishment, the encyclopaedia was a monster. But the more worldly had no objection to a work whose succeeding volumes were each an audacious source of scandal.

Objectivity in encyclopaedias

Even Pierre-Athanase Larousse, the French encyclopaedist, was not impartial. His finest encyclopaedia, the *Grand Dictionnaire universel du XIX^e siècle* ("Great Universal Dictionary of the 19th Century"; 1865–90), one of the most influential of the century, was deliberately anticlerical in policy. And Herder, in the heart of Catholic Germany, produced a counterweight to the Protestant *Brockhaus* in his *Konversations-Lexikon* (1853–57), which adopted a distinctive Catholic viewpoint. This excellent encyclopaedia was early recognized for its general impartiality, scholarship, and accuracy. In the long run, both "Herder" and *Brockhaus* gradually eliminated their sectarian inclinations, and the current editions are both of high standard.

CHILDREN'S ENCYCLOPAEDIAS

Before the 19th century, only Johann Wagenseil (1633–1705) had produced an encyclopaedia for children—the *Pera Librorum Juvenilium* ("Collection of Juvenile Books"; 1695). Larousse issued an interesting *Petite Encyclopédie du jeune âge* ("Small Children's Encyclopaedia") in 1853, but the next, *Encyclopédie Larousse des enfants* ("Larousse Encyclopaedia for Children"), did not appear until 1957. The first of the modern children's encyclopaedias was, however, a long-standing favourite. Prepared by the English writer and editor Arthur Mee (1875–1943), it was called *The Children's Encyclopaedia* (1910) in Great Britain and *The Book of Knowledge* (1912) in the U.S. The contents comprised a series of vividly written and profusely illustrated articles; because the system of article arrangement was obscure, much of the success of the work as a reference tool resulted from its splendidly contrived index, which even now remains a model of its kind. Arthur Mee later produced a completely pictorial encyclopaedia, *I See All* (1928–30), that comprised thousands of small illustrations, each accompanied by only a few words of text. Librarians still treasure it for its reference value, even if it is no longer used by children. In 1917–18 a completely new children's encyclopaedia was published,

The World Book Encyclopedia, which the title page described as "organized knowledge in story and picture." A success from the start, it issued enlarged editions in quick succession. In 1925 a volume devoted to reading courses and study units was added, and the index was abandoned in favour of innumerable cross-references in the text. Annual supplements were also provided from 1922 onward. In 1961 a Braille edition in 145 volumes was issued; most of the illustrations were eliminated in this, but many of the diagrams and graphs were retained and in many cases the captions for the pictures were incorporated in the text. In 1964 a separate 30-volume set in a special large type was published for the use of the partially blind.

World War I put a halt to the idea of issuing a *Britannica Junior,* and the first edition of such a work was not published until 1934. It was based on *Weedon's Modern Encyclopedia,* whose copyright had been bought by Britannica. Renamed *Britannica Junior Encyclopædia* in 1963, it was specifically designed for children in elementary-school grades. One of its features is its ready-reference index volume, which combines short fact entries with indexing to longer general articles. In 1960 a British *Children's Britannica* was issued in London. Prepared under the direction of John Armitage, London editor of *Encyclopædia Britannica,* its contents were determined largely by material covered in the so-called 11-plus standardized tests given in Britain. A yearbook supplement was added later, and the set has undergone periodic continuous revision since its first release.

In 1971 a new encyclopaedia, called *Young Children's Encyclopaedia,* was issued by Encyclopædia Britannica, Inc. Prepared specifically for children just learning to read and not yet into elementary school, it consists of 16 volumes, in which all the illustrations are in colour and the accompanying informative text is brief. Since its original appearance, the set has been translated into Japanese and Korean.

Compton's Encyclopedia

In 1894 Frank E. Compton sold a U.S. school encyclopaedia, the *Students Cyclopedia,* from door to door to pay his way through college. This later became the *New Students Reference Work,* which Compton finally bought. While continuing to publish this, Compton designed a completely new and, for those times, revolutionary work, which first appeared in 1922 as *Compton's Pictured Encyclopedia.* In due course, the system of continuous revision was introduced, close cooperation with educational and library advisers was fostered, and contributions from well-known authors were encouraged. In 1971 *Compton's,* by then published by Encyclopædia Britannica, Inc., introduced *Compton's Young Children's Precyclopedia,* based on the *Young Children's Encyclopaedia* described above.

Unlike *World Book, Compton's,* and the *Britannica Junior Encyclopædia,* the *Oxford Junior Encyclopaedia* (intended for children of 11 upward) is systematically arranged. Each of the 12 text volumes is devoted to a broad subject field: mankind, natural history, the universe, communications, great lives, farming and fisheries, industry and commerce, engineering, recreations, law and order, the home, and the arts. The 13th volume is an index, which includes a special section of ready-reference material. The contents of each volume are arranged alphabetically (with cross-references), and there are many illustrations.

SPECIALIZED ENCYCLOPAEDIAS

The alternative title of the 12th-century *Speculum universale* ("Universal Mirror") of a French preacher, Raoul Ardent (a follower of Gilbert de La Porrée, a French theologian), was the *Summa de vitiis et virtutibus* ("Summa [Exposition] of Faults and Virtues"). The title gives the clue of Raoul's intent, which was to provide a modern authoritative account of the Christian attitude to the world. His plan was different from that of other encyclopaedists, for he limited his work to the discussion (in this order) of theology, Christ and the redemption, the practical and ascetic life, thought, prayer, ethics, the four cardinal virtues, human conduct, and the four senses. This work could, in fact, be termed the first of the specialized encyclopaedias.

Apart from isolated examples such as this, and the technical encyclopaedia of Roger of Helmarshausen, the specialized encyclopaedia did not really make an appearance until the 18th century. The stimulus was probably provided by the increasing number of encyclopaedias that included the arts and sciences to such a point that some of them included little else. In any classified encyclopaedia the individual classes do, of course, constitute a kind of specialized encyclopaedia, but such a work falls far short of the real thing in that it is not sufficiently self-contained to stand on its own. It was inevitable, as the boundaries of knowledge contained in encyclopaedias grew greater, that there would be at least some attempts to produce specialized works of this kind; the French publishers Panckoucke and Agasse did something of this nature in their rearrangement of the contents of Diderot's *Encyclopédie* as a series of 196 volumes of separate dictionaries covering 41 subjects. The idea might have taken hold had it not been for insuperable difficulties caused by the French Revolution.

First specialized encyclopaedia on biography

The first real effort toward a specialized encyclopaedia had come some years earlier, and the subject field that it treated was biography. The *Allgemeines Gelehrten-Lexicon* ("General Scholarly Lexicon"; 1750–51) was compiled by Christian Gottlieb Jöcher, a German biographer, and issued by Gleditsch, the publisher of both "Hübner" and Marperger and the opponent of Zedler's encyclopaedia. Jöcher's work was continued by the German philologist Johann Cristoph Adelung and others and is still of value today. The field of international biography is not a simple one to tackle, and there were only two further efforts of note: J.C.F. Hoefer (1811–78) compiled the *Nouvelle Biographie générale* ("New General Biography"; 1852–66) and J.F. Michaud (1767–1839) was responsible for the *Biographie universelle.* These two great works were to a certain extent competitive; this helped to improve their coverage and content; they are still heavily used in all research libraries. After their publication, the task of recording biographical information on a universal scale reverted to the general encyclopaedias.

Specialized encyclopaedias of chemistry

Developments in the field of specialized encyclopaedias correspond closely to other developments in the world of scholarship. It is, for example, no accident that so much attention should be paid to the subject of chemistry at a time when L.F.F. von Crell was issuing his series of abstract journals on chemistry. The English scientist and inventor William Nicholson (1753–1815) was first in the field with his *Dictionary of Chemistry* (1795), published by Sir Richard Phillips (who later issued C.T. Watkin's *Portable Cyclopaedia*). On this was based Andrew Ure's *Dictionary of Chemistry,* which was for a long time the standard reference work on the subject in Great Britain. In 1807 the German chemist Martin Heinrich Klaproth issued his *Chemisches Wörterbuch* ("Chemical Dictionary"), but a more important event was the publication of the *Handbuch der theoretischen Chemie* ("Handbook of Theoretical Chemistry"; 1817–19) by the German scientist Leopold Gmelin, a work of such excellence that it still appears in new editions from the Gmelin-Institut. Heinrich Rose, a German chemist, issued his *Ausführliches Handbuch der analytischen Chemie* ("Complete Handbook of Analytic Chemistry") in 1851, and the first edition of the famous Liebig, Poggendorff, and Wöhler's *Handwörterbuch der reinen und angewandten Chemie* ("Handbook of Pure and Applied Chemistry") was issued in 1837; its second edition (1856–65) was expanded to nine volumes. This work was continued by Hermann Fehling's *Neues Handwörterbuch der Chemie* ("New Pocket Dictionary of Chemistry"; 1871–1930). The French counterpart, C.A. Wurtz's *Dictionnaire de chimie pure et appliquée* ("Dictionary of Pure and Applied Chemistry"; 1869–1908), became the standard work of its day. The Russian-born chemist Friedrich Konrad Beilstein first issued his *Handbuch der organischen Chemie* ("Handbook of Organic Chemistry") in Hamburg, Germany, in 1880–83; it is the most extensive work of its kind today. The French chemist Edmond Frémy's *Encyclopédie chimique* ("Chemical Encyclopaedia") appeared in 1882–99, and *A Dictionary of Applied Chemistry,* edited by Sir Thomas Edward Thorpe, the English chemist, was first issued in 1890–93. Twentieth-century standard works include Fritz Ullmann's *Enzyklopädie der technischen Chemie* ("Encyclopaedia of Applied

Specialized encyclopaedias of chemistry

Chemistry"; 1914–23), Victor Grignard's *Traité de chimie organique* ("Treatise on Organic Chemistry"; 1935), *Elsevier's Encyclopaedia of Organic Chemistry* (1940), the *Encyclopedia of Chemical Technology* (1947–56; known by the names of its principal editors as "Kirk-Othmer"), Waldemar Koglin's *Kurzes Handbuch der Chemie* ("Short Handbook of Chemistry"; 1951), and the indispensable *Handbook of Chemistry and Physics.*

The impressive run of encyclopaedias and handbooks of chemistry over so long a period is paralleled only in the field of music, in which the *Musikalisches Lexikon* ("Musical Lexicon"; 1732) of the German composer and music lexicographer Johann Gottfried Walther began the trend and was supplemented by the very successful *Historisch-biographisches Lexicon der Tonkünstler* ("Historical and Biographical Lexicon of Musicians"; 1790–92) of the German organist and music historian Ernst Ludwig Gerber. The *Biographie universelle des musiciens et bibliographie générale de la musique* ("Universal Biography of Musicians and General Bibliography of Music"; 1835–44) was compiled by the director of the Brussels Conservatoire, the Belgian composer François-Joseph Fétis, almost coinciding with the equally voluminous *Encyklopädie der gesammten musikalischen Wissenschaften* ("Encyclopaedia of Collected Musical Knowledge") of Gustav Schilling, a German lexicographer and historian of music. A pupil of Mendelssohn, Hermann Mendel, founded the *Musikalisches Conversations-Lexikon* (1870), which was completed by August Reissmann, who also edited the musicologist and composer Auguste Gathy's *Musikalisches Conversationslexikon* (1871). The great *Encyclopédie de la musique et dictionnaire du Conservatoire* (1913–31) was begun by the French writer on music Albert Lavignac and continued by Lionel de La Laurencie, but the third part, a dictionary of names and subjects covered in the preceding parts, was never issued. Walter Willson Cobbett compiled the *Cyclopedic Survey of Chamber Music* (1929–30), and the English writer on music Sir George Grove first issued his *Dictionary of Music and Musicians* in 1879–89; it went through five editions until a new work, *The New Grove Dictionary of Music and Musicians,* appeared in 1980. The German music historian Hugo Riemann compiled his standard *Musik-lexikon* in 1882, and the comprehensive *Musik in Geschichte und Gegenwart* ("Music of the Past and Present") began publication in 1949.

Encyclopaedias of philosophy

The publication of the German philosopher G.W.F. Hegel's *Encyklopädie der philosophischen Wissenschaften* ("Encyclopaedia of Philosophical Knowledge"; 1817) was of more than subject importance in that it was a compendium of the author's philosophical system in three parts; Logic, Nature, Mind. It influenced many editors of general encyclopaedias during the rest of the century. The standard work in this field has for many years been the *Dictionary of Philosophy and Psychology* edited by the American psychologist James Mark Baldwin, though the publication of *The Encyclopedia of Philosophy* (1967) provided a substantial work more in line with modern tastes. Other works in this area include the Centro di Studi Filosofici di Gallarate's *Enciclopedia filosofica* (1957), the French philosopher André Lalande's *Vocabulaire technique et critique de la philosophie* ("Technical and Critical Vocabulary of Philosophy", first issued 1902–12), and the Austrian writer Rudolph Eisler's *Wörterbuch der philosophischen Begriffe* ("Dictionary of Philosophical Concepts").

The Architectural Publication Society began issuing its *Dictionary of Architecture* as early as 1852, but it took 40 years to complete. A more modern work is *Wasmuths Lexikon der Baukunst* ("Wasmuth's Lexicon of Architecture"; 1929–37). Further material is included in the *Encyclopedia of World Art* (1959–68), the *Reallexikon für Antike und Christentum* ("Encyclopaedia for Antiquity and Christianity"; 1950–), and the *Enciclopedia dell'arte antica, classica e orientale* ("Encyclopaedia of Ancient, Classical, and Oriental Art"; 1958–66).

The words "Pauly-Wissowa" are very familiar to a great number of people. August von Pauly (1796–1845), the German classical philologist, began issuing his *Real-Encyclopädie der classischen Altertumswissenschaft* ("Encyclopaedia of Classical Antiquities") in 1837. The new edition was begun by another German classical philologist, Georg Wissowa, in 1893. This enormous work on classical studies has no equal in any part of the world, though it can be supplemented in some areas by the encyclopaedic series *Handbuch der Altertumswissenschaft* ("Handbook of Antiquities") begun in 1887.

The Swiss theologian J.J. Herzog (1805–82) gave religion its first great encyclopaedia with his *Real-Encyklopädie für protestantische Theologie und Kirche* ("Encyclopaedia of the Protestant Church and Theology"; 1854–68). Philip Schaff (1819–93), a Swiss-born U.S. church historian, prepared the abridged English edition (1882–84) from which *The New Schaff-Herzog Encyclopedia of Religious Knowledge* stems. James Hastings, a Scottish clergyman, was responsible for no fewer than four encyclopaedic works in this field: *A Dictionary of the Bible* (1898–1904); *A Dictionary of Christ and the Gospels* (1906–08); *Encyclopaedia of Religion and Ethics* (1908–26), still of great importance; and *Dictionary of the Apostolic Church* (1915–18). An even more significant series is the *Encyclopédie des sciences ecclésiastiques* ("Encyclopaedia of the Ecclesiastical Sciences"), which will take many decades to complete. It comprises: *Dictionnaire de la Bible* (1907–); *Dictionnaire de théologie catholique* (1909–); *Dictionnaire d'archéologie chrétienne et de liturgie* (1928–53); *Dictionnaire d'histoire et de géographie ecclésiastiques* (1929–); and *Dictionnaire de droit canonique* ("Dictionary of Canon Law"; 1935–). Other important works are *The Catholic Encyclopedia* (1907–18), which has not been completely superseded by the *New Catholic Encyclopedia* (1967); the finely illustrated *Enciclopedia cattolica* (1948–54); *Die Religion in Geschichte und Gegenwart* ("Religion in the Past and Present"; 1909–13); and the *Lexikon für Theologie und Kirche* ("Lexicon of Theology and the Church"; 1930–38). Two recently published encyclopaedias of religion include *The Encyclopaedia of Islam* (1960–) and the *Encyclopaedia Judaica* (1971–72).

Almanacs and handbooks of social and political science

It was not until the 1860s that three of the most useful handbooks now in daily use began to appear. *The Statesman's Year-Book,* important for its statistical and political information, began publication in 1864. In 1868 the English publisher Joseph Whitaker first issued his *Whitaker's Almanack,* and the *World Almanack* started in the same year. The *Chicago Daily News Almanac* appeared from 1885 to 1946, and the *Information Please Almanac* began in 1947. Herder's *Staatslexikon* ("Lexicon of Political Science") was first published in 1889–97; this compendium was soon followed by the *Dictionary of Political Economy* (1894) by the English banker and economist Sir Robert Palgrave. In 1930–35 the *Encyclopaedia of the Social Sciences* was published; an immediate success, it is often referred to as "Seligman" after the name of its chief editor. The new *International Encyclopedia of the Social Sciences* (1968) did not supersede it in every respect. In a similar fashion, the *Handwörterbuch der Sozialwissenschaften* ("Pocket Dictionary of the Social Sciences"; 1952–) supplemented rather than superseded the standard *Handwörterbuch der Staatswissenschaften* ("Pocket Dictionary of Political Science," 4th ed.; 1923–39).

In the field of literature, if Isaac Disraeli's *Curiosities of Literature* (1791) is ruled out, the first important handbook is the *Dictionary of Phrase and Fable* (1870) by the English clergyman and schoolmaster Ebenezer Cobham Brewer (1810–97), supplemented with Brewer's *Reader's Handbook* (1879). Other important works include the *Dizionario letterario Bompiani degli autori* ("Bompiani's Literary Dictionary of Authors"; 1956–57), the *Dizionario letterario Bompiani delle opere* ("Bompiani's Literary Dictionary of Works"; 1947–50), *Cassell's Encyclopaedia of Literature* (1953), and the Oxford "companions" to American, English, and French literature. In the last quarter of the 19th century, three major specialized encyclopaedias were issued: *Dictionnaire de botanique* ("Dictionary of Botany"; 1876–92) of the French naturalist and physician Henri Baillon, the *Lexikon der gesamten Technik* ("Lexicon of Collected Technology"; 1894–99) of the German engineer Otto Lueger, and the Berlin Academy's *Enzyklopädie der mathematische Wissenschaften* ("Encyclo-

paedia of Mathematical Sciences"; 1898–1935). The last was shortly followed by the important but incomplete *Encyclopédie des sciences mathématiques pures et appliquées* ("Encyclopaedia of Theoretical and Applied Mathematical Sciences"; 1904–14).

Physics never received the degree of attention that the encyclopaedists accorded to chemistry and chemical engineering. The standard *Dictionary of Applied Physics* of the English physicist Sir Richard Glazebrook was first issued 1922–23. The *Handbuch der Physik* ("Handbook of Physics") was also issued during those years; the second edition (1955) is often referred to by the name of its editor, Siegfried Flügge. The most recent work is the *Encyclopaedic Dictionary of Physics* (1961–64), edited by James Thewlis.

In medicine the pioneer *British Encyclopaedia of Medical Practice* (1936–39) has been followed by *The Encyclopaedia of General Practice* (1963).

Other important encyclopaedias and handbooks issued in recent years include *The Encyclopedia of Photography* (1949), the superbly illustrated and well-documented *Enciclopedia dello spettacolo* ("Encyclopaedia of the Stage"; 1954–62), which includes all forms of staged entertainment; the *Dictionnaire du cinéma et de la télévision* ("Dictionary of the Cinema and Television"; 1965–); the *McGraw-Hill Encyclopedia of Science and Technology* (1960), and the *Encyclopedia of Library and Information Science* (1968–).

ENCYCLOPAEDIAS OF COUNTRIES AND REGIONS

A special kind of encyclopaedia dealing with a single country or region began to appear in the late 19th century. Sometimes it is possible to distinguish, by a subtle form of titling, those national encyclopaedias that deal with the world scene from those that concentrate chiefly on their own country. Thus the "Ruritanian Encyclopaedia" can usually be taken to be a work produced in Ruritania that takes a world view, while the "Encyclopaedia of Ruritania" probably deals mainly with Ruritania and the surrounding areas. There are no rules in this matter, and this method of differentiating between the two kinds can only be regarded as an imprecise way of identifying the kind of encyclopaedia in the first instance.

The encyclopaedias of geography are of particular use in this field because they cover in detail many islands, small cities, and other features that are only dealt with in the briefest fashion elsewhere. Of the modern geographical encyclopaedias the following are of especial importance: *Westermanns Lexikon der Geographie* (1968–); *Meyers Kontinente und Meere* ("Meyer's Continents and Seas"; 1968–); the Russian *Kratkaya geograficheskaya entsiklopedya* ("Short Geographical Encyclopaedia"; 1960–66); and the *Länderlexikon* ("Geographical Dictionary"; 1953–60), of which a new edition began to be issued in the early 1970s. These encyclopaedias have an additional value as sources of maps and illustrations that would be difficult to find elsewhere. The main modern encyclopaedias dealing with continents, regions, and countries are:

Encyclopaedias of continents, regions, and countries

Africa: *Encyclopaedia of Southern Africa* (1961); *Deutsches Kolonial-Lexikon* (1920); *Encyclopédie coloniale et maritime* (1941–); *Grande encyclopédie de la Belgique et du Congo* (1938–52).

Australasia: *The Australian Encyclopaedia* (1958); *Encyclopaedia of Australia* (1968); *The Modern Encyclopaedia of Australia and New Zealand* (1964); *An Encyclopaedia of New Zealand* (1966).

The Americas: *Diccionario enciclopédico de las Américas* (1947); *Verbo: enciclopédia luso-brasileira de cultura* (1963–); *Diccionario enciclopédico del Peru* (1967); *Enciclopedia Yucatanense* (1944–47); *Enciclopedia de México* (1966–); *Diccionario histórico-enciclopédico de la Republica de El Salvador* (1927–); *Diccionario geográfico, estadístico, histórico, de la isla de Cuba* (1863–66); *Gran enciclopédia argentina* (1956–64); *Encyclopedie van de Nederlandse Antillen* (1969); *Encyclopaedie van Nederlandsch West-Indië* (1914–17); *Enciclopédia larense* (1941); *Encyclopedia Canadiana* (1957–58).

Europe: *Flandria nostra* (1957–60); *Magyar életrajzi lexikon* (1967–69); *Encyclopaedia of Ireland* (1968); *Latvijas PSR mazā enciklopēdija* (1967–); *Latvju enciklopēdija* (1950–55); *Mažoji lietuviškoji tarybinė enciklopedija* (1966); *Norge* (1963); *Enciclopedia românîei* (1938–43); *Encyclopédie polonaise* (1916–20); *Sverige: land och folk* (1966); *Ukraine: A Concise Encyclopaedia* (1963–); *Narodna enciklopedija srpsko-hrvatsko-slovenačka* (1925–29).

Middle East: *Eretz-Yisra'el: Entziqlopedia Ṭopografit-Hiṣṭorit* (1946–55).

History of encyclopaedias

ENCYCLOPAEDIAS IN THE WEST

Early development. The first fragments of an encyclopaedia to have survived are the work of Speusippus (died 339/338 BC), a nephew of Plato's. Speusippus conveyed his uncle's ideas in a series of writings on natural history, mathematics, philosophy, and so forth. Aristotle's wide-ranging lectures at the Lyceum were equally influential, and he and Plato appear to have been the originators of the encyclopaedia as a means of providing a comprehensive cultural background.

The Greek approach was to record the spoken word. The Romans, on the other hand, aimed to epitomize existing knowledge in readable form. Their first known effort is the *Praecepta ad filium* ("Advice to His Son"; *c.* 183 BC), a series of letters (now lost) written by the Roman consul Cato the Censor to his son. Cato's intention was to provide a summary of useful information that could help in the process of living and in guiding and helping one's fellowmen. A more substantial attempt was made by the learned Latin writer Marcus Terentius Varro in his *Disciplinarum libri IX* ("Nine Books of Disciplines"), his *Rerum divinarum et humanarum antiquitates* ("The Antiquities of Things Divine and Human"), and his *Imagines,* which together covered the liberal arts, human efforts, the gods, and biographies of the Greeks and Romans.

The most important Roman contribution was the *Historia naturalis* of Pliny the Elder, a vast work constituting a kind of classified anthology of information. Although undiscriminating in its record of fact and fancy, it was nevertheless very influential; the Latin grammarian and writer Gaius Julius Solinus drew nearly 90 percent of his 3rd-century *Collectanea rerum memorabilium* ("Collection of Memorabilia") from Pliny, and the *Historia naturalis* served as a major source for other encyclopaedias for at least the next 1,500 years. Even today it is still an important record for details of Roman sculpture and painting.

Pliny's *Historia naturalis*

The statesman Cassiodorus, when he withdrew to the Vivarium in 551, dedicated this monastery to sacred and classical learning. His *Institutiones divinarum et saecularium*

Illustration from the entry on the winds in St. Isidore of Seville's *Etymologiae,* an edition published in Strasbourg *c.* 1473.

litterarum ("Institutes of Divine and Secular Literature") seems to have been designed to preserve knowledge in times that were largely inimical to it. In his encyclopaedia, Cassiodorus drew a clear distinction between the sacred and the profane, but the first Christian encyclopaedia to be compiled for the benefit of the newly converted Spanish population followed a different scheme. St. Isidore (*c.* 560–636) considered the liberal arts and secular learning to be the true basis of a Christian's education. His *Etymologiae* therefore paid much attention to practical matters and even included an etymological dictionary. This was in line with the thought of St. Jerome—on whose encyclopaedic *Chronicon* and *De viris illustribus* St. Isidore had drawn—who, in common with the early Christian Fathers, was eager to provide a basis for a Christian interpretation and organization of knowledge. This concept was much later to be renewed by the Catalan ecclesiastic Ramon Llull.

The development of the encyclopaedia during the next 500 years, though of social interest, was undistinguished from the point of view of scholarship. Rabanus Maurus (*c.* 776–856), one of the English scholar Alcuin's favourite pupils, compiled *De universo* ("On the Universe"), which, in spite of its being an unintelligent plagiarism of St. Isidore's work, had a lasting popularity and influence throughout the medieval period. A series of encyclopaedias of special subjects—undistinguished anthologies of classical and Christian writings on history, jurisprudence, agriculture, medicine, veterinary surgery, and zoology—was organized by the Byzantine emperor Constantine VII Porphyrogenitus (905–959). Michael Psellus (1018–96), a tutor of a later emperor, contributed a more interesting work, *De omnifaria doctrina,* in the form of questions and answers on both the humanities and science. At this time there was a growing influence on metropolitan and secular learning. In an attempt to counterbalance it, the brief but charming *Didascalion* of Hugh of Saint-Victor (*c.* 1096–1141), which paid much attention to practical matters as well as to the liberal arts, was soundly based on a profound classification of knowledge that influenced many later encyclopaedias. About this time an encyclopaedic dictionary known as *Suda,* or *Suidas,* broke with tradition by adopting alphabetical order for its contents. This had no effect on the plan of later encyclopaedias, but its contents included so much useful information that it has retained its importance as a source throughout the succeeding centuries.

Adoption of the alphabetical order in *Suda*

The *Liber floridus* (*c.* 1120) of Lambert of Saint-Omer is an unoriginal miscellany, but it has an interest of its own in that it discards practical matters in favour of metaphysical discussion and pays special attention to such subjects as magic and astrology. The greatest achievement of the 12th century was the *Imago mundi* of Honorius Inclusus. Honorius produced his "mirror of the world" for Christian, later abbot of St. Jacob, and drew on a far wider range of authorities than any of his predecessors. The arrangement of the first section on geography, astrology, and astronomy was sound; it started with the creation and worked down to individual countries and cities. This was followed by a "chronicle," and a third section provided a brief list of important events since the fall of Satan. Honorius accurately foresaw his book's fate: innumerable copies, unauthorized plagiarisms, incessant criticism, and incompetent additions for at least 200 years.

Probably the first encyclopaedia to be compiled by a woman, the *Hortus deliciarum* of the abbess Herrad (died 1195), comprised a magnificent illuminated manuscript with 636 miniatures, intended to help and edify the nuns in her charge. Bartholomaeus Anglicus based his *De proprietatibus rerum* (1220–40) on the works of St. Isidore and Pliny. It was designed for ordinary people and became Europe's most popular encyclopaedia for the next three centuries. But the outstanding achievement of the Middle Ages was the *Speculum majus* of Vincent of Beauvais. Vincent was not an original writer but he was industrious, and his work comprised nearly 10,000 chapters in 80 books; no encyclopaedia rivalled it in size until the middle of the 18th century. The work was very well balanced, almost equal space being allotted to the three sections. The "Naturale" dealt with God and man, the creation, and natural history. For this Vincent drew not only on Latin writings but also on Greek, Arabic, and Hebrew, which were at that time (through translations) making a very considerable impact on the thinking of the West. The "Doctrinale" covered practical matters as well as the scholastic heritage of the age. The "Historiale" included a summary of the first two sections and a history of the world from the creation to the times of St. Louis. A fourth section, "Morale," based principally on St. Thomas Aquinas, was added after Vincent's death. The influence of the *Speculum majus* was immediate and lasting. Translations were made into several languages, and complete reprints appeared as late as 1863–79. One of its many values is that it is a source for extracts from many documents of which no other parts have survived. Another is its detailed history of the second quarter of the 13th century.

Vincent's was the last major work of its kind. Later encyclopaedists began to compile for a wider public than the very limited world of religious communities. The first breakaway from Latin came with *Li livres dou trésor* ("Treasure Books") of Brunetto Latini (*c.* 1220–95), the master of Dante, and the Florentine poet and philosopher Guido Cavalcanti. Latini wanted to reach the mercantile and cultured classes of Italy; he therefore used French, their common language. The arrangement of his work was similar to Vincent's but his approach was concise. The language, the brevity, and the accuracy of his encyclopaedia had an immediate and wide appeal. A friend of Petrarch's, Pierre Bersuire, based his *Reductorium, repertorium et dictionarium morale utriusque testamenti* ("Moral Abridgment, Catalogue and Dictionary of Each Testament"; *c.* 1340) on Bartholomaeus' *De proprietatibus rerum.* In contrast to Latini's work, this was a return to the traditional, with its moralizings on the Bible, Ovid's *Metamorphoses,* and natural history, but it had a considerable success when printing was introduced, being issued 12 times by 1526.

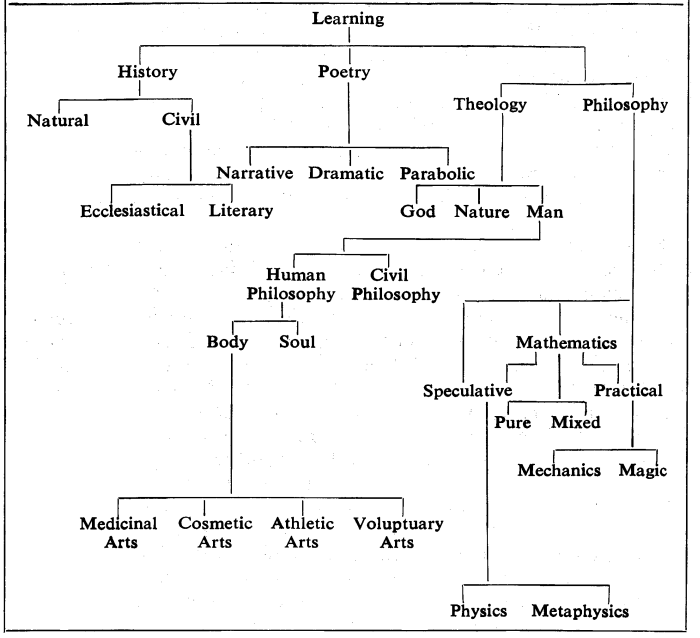
Brunetto Latini's breakaway from Latin

One of the most delightful of all encyclopaedias is the little *Margarita philosophica* that Gregor Reisch (died 1525) wrote for young people. In some 200 pages he contrived to cover in a very pleasing style the whole university course of the day, both the trivium and the quadrivium. The arrival of humanism is reflected in the *De disciplinis* of Juan Luis Vives, a pioneer in psychology and philosophical method; Vives grounded all his arguments on nature and made no appeal to religious authority. With the writing of the anonymous *Compendium philosophiae* (*c.* 1300) the concept of the modern scientific encyclopaedia was reached at last. It was the first encyclopaedia to adopt an inquiring and impartial attitude to the things described, and the old wives' tales that had filled so many pages of encyclopaedias from the time of Pliny onward were replaced by the latest scientific discoveries.

The first indigenous French encyclopaedia, the popular *Dictionarium historicum, geographicum et poeticum* ("Historical, Geographical, and Poetic Dictionary") of Charles Estienne (1504–64) was not published until 1553. For encyclopaedias in their own language, the French still had to rely on translations of the encyclopaedias of other nations, such as *Les diverses leçons* ("The Various Lessons"; 1552) of Pedro Mexia, a mediocre Spanish historian whose haphazard compilation was enormously popular in the 16th and 17th centuries.

The development of the modern encyclopaedia (17th–18th centuries). Francis Bacon's purpose in writing the *Instauratio magna* was "to commence a total reconstruction of sciences, arts, and all human knowledge, raised upon the proper foundations" in order to restore or cultivate a just and legitimate familiarity between things and the mind. Only a small part of this enormous work was ever completed, but the author had planned 130 sections divided into three main sections: external nature, man, and man's action on nature. From its proposed contents Bacon's intention was clearly to compile an encyclopaedia thoroughly scientific in character—"a thing infinite and beyond the powers of man"—that he himself recognized to be revolutionary in character. His most important contribution was, however, the devising of a new and thoroughly

Table 1: Francis Bacon's Classification of Knowledge



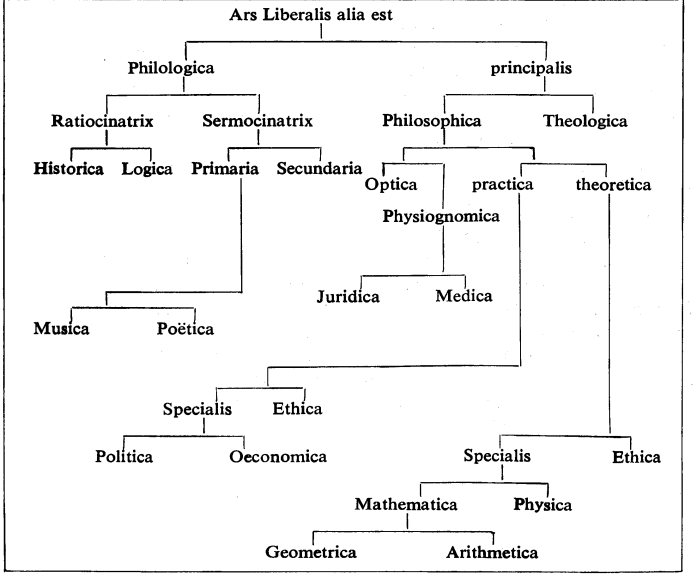
sound classification of knowledge that bears a remarkable resemblance to the classification put forward by Matthias Martini in his *Idea Methodica* (1606). Although Bacon was apparently unaware of this work, both philosophers were probably working from the same basic Platonic precepts. The results were profound: Diderot made a point of acknowledging the assistance Bacon's analysis of the structure of human knowledge had afforded him in planning the contents of the *Encyclopédie,* and Samuel Taylor Coleridge hailed "the coinciding precepts of the Athenian Verulam and the British Plato."

Bacon's influential classification

Only two more Latin encyclopaedias of any importance followed. Antonio Zara, bishop of Petina, compiled the *Anatomia Ingeniorum et Scientiarum* ("Anatomy of Arts and Sciences"; 1614), which was chiefly remarkable for the inclusion of an index. And Johann Heinrich Alsted, who, like Martini, came from Herborn, compiled an *Encyclopaedia* (1630) whose arrangement corresponds broadly to Matthias' classification of human knowledge.

Zara's and Alsted's encyclopaedias were organized systematically by classification. The turning point came with

Table 2: Matthias Martini's Classification of Human Knowledge



Louis Moréri's alphabetically arranged *Grand Dictionnaire historique* (1674), which was especially strong in geographical and biographical material. Its success was immediate; six editions were issued by 1691, each incorporating much new contemporary information. English editions followed in 1694, 1701, and (a supplement) 1705. Other encyclopaedias in England, Germany, Switzerland, and The Netherlands acknowledged its inspiration. The alphabetically arranged encyclopaedia in the vernacular had almost won the day, in spite of the German scholar Daniel George Morhof's modest success with his ill-balanced *Polyhistor Literarius, Philosophicus, et Practicus* ("Literary, Philosophical, and Practical History"; 1688–1708).

If there was any doubt concerning the more popular form of the encyclopaedia, the issue of Antoine Furetière's *Dictionnaire universel des arts et sciences* (1690) confirmed the true nature of public taste. Furetière not only compiled a fine encyclopaedic dictionary, but he emphasized the arts and the sciences, thus reflecting the rapidly growing public interest in modern culture, science, and technology. If confirmation were still needed, the Académie Française's commissioning of Thomas Corneille to compile *Le Dictionnaire des arts et des sciences* (1694), with its thorough and authoritative treatment of these new encyclopaedic features, demonstrated that even the more conservative scholars were by now keenly aware that a new spirit had arisen. The period of the clerical encyclopaedia had ended, as the Franciscan friar Vincenzo Maria Coronelli found when his *Biblioteca Universale Sacro-Profano* (1701–06) ceased publication at volume 7 of a projected 45.

Furetière's modern *Dictionnaire universel*

Pierre Bayle, in his *Dictionnaire historique et critique* (1697), achieved a most remarkable tour de force. Although his encyclopaedia purported to be an updating of the information in Moréri, the entries were largely unexceptionable. The real originality of his work lies in the profuse and scholarly footnotes and the commentaries that at times were an amazing mixture of skepticism, blasphemy, and ribaldry. Bayle challenged orthodox ideas; his brilliant mind spared nothing. This approach heralded that of Diderot, and the distinguished writers who revised later editions—Prosper Marchand and Pierre Desmaizeaux—continued in the same style.

The *Lexicon Technicum* (1704) of John Harris represented the powerful impact of the work of the Royal Society (founded 1660). Here was all the equipment of the modern encyclopaedia: excellent engraved plates, clear practical text, bibliographies appended to the more important articles. So far, England had had to make do with translations of French encyclopaedias. Harris' emphasis on the need to include scientific and technical subjects helped to reverse the trend. This process was completed by the issue of Ephraim Chambers' *Cyclopaedia* (1728). Like Harris, Chambers omitted people in favour of more information on the arts and sciences, and he paid more attention to clear expositions of ancient and modern philosophical systems. His admirably cross-referenced work is universally recognized as the father of the modern encyclopaedia.

The French were well aware of these developments. By 1744 five editions of Chambers' *Cyclopaedia* had been issued. The Paris publisher André Le Breton saw a ready market for a translation. The first proposals were a failure, however, and Diderot was enlisted to plan what at that time was still essentially a translation on a much broader basis. Under the hands of Diderot and d'Alembert the concept changed. The *Encyclopédie* (1751–65) was a philosophical undertaking carried out on a gigantic scale, and much of the writing was of a high standard. To the orthodox, it appeared that the project had got out of hand, but there were 2,000 subscribers to the first volume, and the subsequent scandals over the irreverent, authority-challenging articles only added to the number of purchasers. The equivocal attitude of high dignitaries in both church and court and the growing public dislike of the encyclopaedia's chief critics—the Jesuits—led to a complex situation in which official disapproval and substantial private encouragement caused the production and fortunes of the *Encyclopédie* and its producers to lurch dangerously from one crisis to another. Curiously, Diderot

Diderot's monumental *Encyclopédie*

did nothing to further the physical development of the encyclopaedia; his contribution was to fire men's minds with a willful guidance that conformed to the country's increasingly revolutionary spirit. As Voltaire said: "this vast and immortal work seems to reproach mankind's brief life span."

The shortcomings of the *Encyclopédie* were obvious. The essential ingredients of an encyclopaedia, the entries on every conceivable subject, had been sacrificed to make place for lengthy polemics on the controversial topics of the day. The *Encyclopædia Britannica* was intended to improve on this, and, with all its shortcomings, the first edition (1768–71) did exactly that. The achievement of its editors was the more remarkable in that there were already several English encyclopaedias on the market. The Scottish encyclopaedia, however, reflected the taste of the day better than any of its competitors, for it was a completely new work and not just a remaking of Chambers and Harris. There was much to criticize in the first edition, but the second (1777–84; dated 1778–83) was greatly improved, and succeeding issues of the *Britannica* made steady progress.

Meanwhile, Germany, at first largely dependent on translations of foreign encyclopaedias, had produced the scholarly "Hübner" (1704), as it was known from the name of the author of the preface in this first of the *Konversationslexikon* type. The form appealed to the rapidly growing middle class of the country, who welcomed encyclopaedias designed to provide them with an adequate cultural background for polite society. Johann Theodor Jablonski's illustrated *Allgemeines Lexicon* (1721) continued in this same style, and there were similar works compiled by the Swiss theologian and philologist Jakob Christoph Iselin and Antonius Moratori (1727). Johann Heinrich Zedler's huge *Grosses vollständiges Universal-Lexicon* ("The Great Comprehensive Universal Lexicon"; 1732–50) was in the older tradition but is important for its accuracy and its biographical and bibliographical material. An attempt to produce a German type of the *Encyclopédie* in 1778–1807 was, however, a failure. Friedrich Arnold Brockhaus recognized the real need of the German people. Reworking Renatus Gotthelf Löbel's bankrupt encyclopaedia, he produced his first *Konversations-Lexikon* (1796–1811), thereby setting the pattern for at least half of all succeeding encyclopaedias throughout the western world. Brief, well-designed articles tightly packed with facts, comprehensive coverage, and a reputation for accuracy and up-to-dateness were the ingredients for one of the most successful of encyclopaedias.

Brockhaus' Konversations-Lexikon

The 19th century. Having served a long apprenticeship as a reviser of Chambers' *Cyclopaedia,* Abraham Rees at last produced a completely original and finely illustrated work, *The New Cyclopaedia* (1802–20), the only serious rival to the *Britannica* in a generation that saw some dozen "new" encyclopaedias rise and fall. What might have been the greatest encyclopaedia of the century, the *Encyclopaedia Metropolitana* (1817–45), failed miserably because of the early withdrawal of its designer, Samuel Taylor Coleridge, and subsequent financial troubles; but from it came the most notable contribution to the philosophy of encyclopaedia making since Bacon—Coleridge's profound treatise "On Method" (1818).

To the principal influences on the compilation of encyclopaedias—Bacon, Diderot, the *Britannica,* and Brockhaus—must be added that of the Frenchman Pierre Larousse. His completely original approach to encyclopaedia making has given the series of encyclopaedias that bear his name a unique reputation. Emphasis throughout has been on readability; style has never been sacrificed to conciseness, and the successive editors of *Larousse* have paid very close attention to the changing public taste among French readers concerning the presentation of information.

The advent of Noah Webster was fully as epoch-making as that of Brockhaus and Larousse. Webster's informative *American Dictionary of the English Language* (1828) was encyclopaedic in character, but he avoided the long entries for the more important subjects that were such a feature of *Larousse.* Webster's approach appealed to the American taste and captured a huge market that has only increased with the years.

Brockhaus soon faced opposition, for his encyclopaedia was stronger on the humanities than on scientific and technical subjects. Joseph Meyer's *Der grosse Conversations-Lexikon* (1840–52) rectified this imbalance and was the first of a highly successful series that competed vigorously with *Brockhaus* for 100 years. In addition, Herder's *Conversations-Lexikon* (1853–57) and its subsequent editions provided the Catholic counterbalance in a country where Protestants and Catholics were almost equal in numbers.

The market for encyclopaedias in 19th-century Great Britain seemed inexhaustible, but many publishers lost money by putting out works that failed to capture the public's fancy. An exception was *Chambers's Encyclopaedia* (1860–68), which was unconnected with Ephraim Chambers' classic. Influenced by childhood access to a copy of the *Britannica,* Robert Chambers and his brother William compiled an original work, *Chambers's Encyclopaedia,* that took the *Konversationslexikon* form and thus found a new market that has continued to the present day.

Chambers's Encyclopaedia in England

In the first half of the 19th century there was increasing activity in other countries. Poland produced the *Encyklopedia Powszechna* (1858–68), known as "Orgelbrand" after its publisher. The Hungarians had followed the Bohemian *Slovník naučný* ("Scientific Dictionary"; 1860–90) with the *Egyetemes magyar encyclopaedia* ("Universal Hungarian Encyclopaedia"; 1861–76). The Russians had produced half an encyclopaedia, V.N. Tatishchev's *Leksikon rossyskoy* ("Russian lexicon"), in 1793, and then issued A. Starchevsky's *Spravochny entsiklopedichesky slovar* ("Encyclopaedic Reference Dictionary"; 1847–55) on the *Brockhaus* model. More important was the famous *Entsiklopedichesky slovar* ("Encyclopaedic Dictionary"; 1895), which became known as "Granat" after the Granat Russian Bibliographical Institute that produced it. A later edition (1910–48) of "Granat," in 58 volumes, is not exported from the Soviet Union. Modelled on the *Britannica,* this edition contained many important articles, such as Lenin's contribution on "Marx" and on "The Russian 19th-Century Agrarian Problem." Successive ideological changes in Russian society caused many changes in the text of "Granat," and it remains one of the most inaccessible of all Russian encyclopaedias outside the Soviet Union.

Larousse did not go unchallenged. Inspired by the French politician Ferdinand-Camille Dreyfus, *La Grande Encyclopédie* (1886–1902) provided France with a superb, authoritative, and comprehensive work, well documented, and of excellent scholarship throughout; it is still in use today. In Denmark the century ended with the issue of no fewer than three new good multivolume encyclopaedias: *Allers* (1892–99), *Hagerups* (1892–1900), and *Salmonsens* (1893–1911), a situation without parallel in the history of encyclopaedias. During the course of the century practically every feature of the modern encyclopaedia had been introduced, and editorial standards had at times risen to a height that modern editors can only envy.

The 20th century. In 1890–1906 a Russian edition of *Brockhaus,* which subsequently had considerable success, was issued from the St. Petersburg office of *Brockhaus.* In contrast, S.N. Yushakov designed his *Bolshaya entsiklopedya* ("Great Encyclopaedia"; 1900–09) on the "Meyer" model. After "Granat" the next important encyclopaedia was the 65-volume *Bolshaya sovetskaya entsiklopedya* ("Great Soviet Encyclopaedia"; 1926–47), which was eventually discredited; the second edition (1949–58) had a Marxist-Leninist approach but was less biassed on nonpolitical subjects. It represented almost the whole of the Soviet Union's cultural resources: 8,000 scholars contributed articles, and the appended bibliographies were truly international in scope. One complete volume was devoted to the Soviet Union. The yearbooks that supplemented this encyclopaedia were very well produced and maintained the high standards of the original work. From 1970 to 1978 a 30-volume third edition was issued. The reduction in size was accomplished by editing and the use of a smaller typeface. Early reviews indicated that the quality of the work was similar to that of the second edition.

Russian encyclopaedias

From 1973 to 1982 Macmillan released an English translation of the set.

There has also been a series of editions of the much smaller *Malaya sovetskaya entsiklopedya* ("The Little Soviet Encyclopaedia"), first issued in 1928–31.

In the U.S., the first edition of the *New International Encyclopaedia* was issued in 1902–04 and was subsequently supplemented by yearbooks. *The Encyclopedia Americana,* which traces its ancestry back to an English-language adaptation (1829–33) of the seventh edition of *Brockhaus,* took on new strength in 1902 when the editor of *Scientific American,* Frederick C. Beach, was appointed editor of the *Americana.* It has enjoyed growing success through its policy of following the continuous revision system, and yearbooks have supplemented it from 1923 onward. In 1950–51 a completely new American work, *Collier's Encyclopedia,* appeared in 20 volumes, and subsequent editions have been supplemented by yearbooks since 1960. *Collier's* is noted for its large number of illustrations and maps.

The "Espasa," the *Enciclopedia universal ilustrada europeo-americana* (1905–70), is a great encyclopaedia, which—like the *Enciclopedia italiana*—eschews revision in favour of a series of sizable supplements. Physically, it is the largest current encyclopaedia in the world. One complete volume is devoted to Spain and is separately revised and reissued from time to time. A smaller encyclopaedia, the *Diccionario Salvat* (first issued in 1907–13), is revised at frequent intervals. Another major Spanish encyclopaedia, the *Enciclopedia labor* (1955–60), is remarkable for devoting each volume to a major subject field, an index volume providing the key to the total contents. This encyclopaedia is valuable for the attention it pays to every part of the Spanish-speaking world.

Italian encyclopaedias

One of the most important of all encyclopaedias, the *Enciclopedia italiana* (1929–36), is famous for its lavish production, its superb illustrations, and its lengthy, scholarly, and well-documented articles. Even its defense of Fascist ideology is not allowed to impinge on the general impartiality of the text. Supplements have been issued since World War II. The postwar *Dizionario enciclopedico italiano* (1955–63), issued by the same publishers, is a much smaller but well-illustrated work. The *Enciclopedia Europe* was released in Milan between 1976 and 1981. Although consisting largely of brief articles, it has numerous signed long articles of good quality. In Germany, the three giants of the German encyclopaedia world—*Brockhaus,* "Meyer," "Herder"—continue to produce new editions, unchallenged by any new encyclopaedia of comparable scope.

In spite of the continuing popularity of *Larousse,* France has produced three other encyclopaedias of note in the 20th century. The *Encyclopédie française* (1935–66) is an outstanding collection of monographs by well-known scholars and specialists, arranged in classified form and available in loose-leaf binders, supplemented by a continuously revised index. Its 21 volumes, each under the direction of a different authority, deal with (1) man's mental tools (logical thought, language, and mathematics); (2) physics; (3) heaven and earth; (4) life; (5) living beings; (6) human beings (the normal man and the sick man); (7) the human species; (8) the study of the mind; (9) the economic and social universe; (10) the state; (11) international life; (12) chemical science and industry; (13) industry and agriculture; (14) man's daily life; (15) education and learning theory; (16, 17) arts and literatures, in two volumes; (18) the written word; (19) philosophy and religion; and (20) the world in its development (history, evolution, prospective); the 21st volume contains an index. The articles are notable for their almost total concentration on contemporary issues in the fields considered.

The *Encyclopédie de la Pléiade* (1955–) is an encyclopaedic series, each work (some in more than one volume) being a self-contained treatment of a broad subject field written in narrative form.

One of the most interesting new encyclopaedias is the *Encyclopaedia universalis* (1968–75), edited by Claude Grégory and owned by the French Book Club and Encyclopædia Britannica, Inc. This work, inspired by *L'Encyclopédie,* eschews the inclusion of minor items in favour of extensive and very well-illustrated articles on important subjects, and it pays special attention to modern science and technology. Of the 20 volumes (30,000,000 words), volumes 17–19 constitute a "thesaurus" of fact entries and index, and volume 20 is devoted to an exposition of the classifications used in constructing the encyclopaedia and to further elaborations. *Encyclopaedia universalis* is doubly notable as the product of a contemporary publishing phenomenon known in the industry as "coproduction." The term is applied in general to the collaborative efforts of publishers in two or more countries who have united to produce an encyclopaedia for sale in one of the countries or, with modifications in two or several. Successful examples of coproduction include the *Buritanika Kokusai Dai Hyakka Jiten* (or "Britannica International Encyclopædia") in Japan and the new Chinese encyclopaedia (both discussed elsewhere in this article). Encyclopædia Britannica, Inc., has, in addition, been similarly involved in the development of the Spanish-language *Enciclopedia Barsa* and the Portuguese-language *Enciclopédia Barsa,* each in 16 volumes; *Enciclopédia Mirador Internacional,* a scholarly 20-volume set first published in Brazil in 1975; and *Il Modulo,* a 24-volume set published in Italy. Other major instances of coproduction involve the interesting *The New Caxton Encyclopedia,* which originated in Italy with Instituto Geografico de Agostini and subsequently appeared in Great Britain, first in serial parts as *Purnell's New English Encyclopedia* (1965) and then in a bound set of 18 volumes (1966); in France there appeared a version called *Alpha: La Grande Encyclopédie Universelle en Couleurs,* and in Spain a version called *Monitor.* The American-made *The Random House Encyclopedia* has been adapted in various languages and under various names for distribution in several countries.

Co-production

Most countries have issued at least one good encyclopaedia, among which should be mentioned:

Bulgaria: *Kratka bŭlgarska entsiklopediia* (1963–).

Czechoslovakia: *Ottův slovník naučný* (1888–1909); *Masarykův slovník naučný* (1925–33); *Nový velký ilustrovaný slovník naučný* (1929–34); *Komenského slovník naučný* (1937–38); *Příruční slovník naučný* (1962–67).

Denmark: *Gyldendals Nye leksikon* (first issued 1931–32); *Raunkjaers konversations leksikon* (1948–57); *Gyldendals store opslagsbog* (1967–70).

Estonian S.S.R.: *Eesti nõukogude entsüklopeedia* (1968–).

Finland: *Otavan iso tietosanakirja/Encyclopaedia fennica* (1960–65); *Nuorten tieto* (1963–); *Fokus: Otavan kertovasti kuvitettu tietosanakirja* (1963–).

Greece: *Megalē hellenikē enkyklopaideia* (1926–34); *Eleutheroudakē enkyklopaidikon leksikon* (1927–31).

Hungary: *Révai nagy lexikona* (1911–35); *Új magyar lexikon* (1959–62); *Új idők lexikona* (1936–42).

The Netherlands: *Eerste nederlandse systematisch ingerichte encyclopaedie* ("ENSIE"; 1946–52); *Grote Winkler Prins encyclopedie* (1966– ; the latest in an outstanding series of "Winkler Prins" encyclopaedias starting in 1870–82); *Algemene nederlandse systematisch ingerichte encyclopedie* ("ANSIE"; 1955–); *Oosthoeks encyclopedie* (1968–); the latest edition of a series starting in 1916–23).

Norway: *Aschehougs Konversasjons leksikon* (1970– ; the latest in a series started in 1907–13); *Norsk konversasjonsleksikon* (first published 1931–34); *Norsk allkunnebok* (1948–61).

Poland: *Wielka Encyklopedia Powszechna PWN* (1962–).

Romania: the Romanian Academy's *Dictionar enciclopedic român* (1962–66).

Sweden: *Bonniers konversations lexikon* (first published 1922–32); *Focus uppslagsbok* (1958–60).

Turkey: *Türk ansiklopedisi* (1946– ; first called *Inönü ansiklopedisi*).

Yugoslavia: *Enciklopedija Jugoslavije* (1955–); *Enciklopedija leksikografskog zavoda* (first published 1955); *Pomorska Enciklopedija* (1954–64); *Hrvatska enciklopedija* (1941–45; unfinished, A–El only).

Lithuania (published in Boston): *Lietuviu enciklopedija* (1953–69).

ENCYCLOPAEDIAS IN THE EAST

China. The contribution from the East to the history of encyclopaedias is distinctive and covers a longer period than that of the West. The Chinese have produced encyclopaedias for approximately 2,000 years, but traditionally they differ from the modern Western encyclopaedia in that they are mainly anthologies of significant literature with some elements of the dictionary. Compiled by scholars of eminence, they have been revised rather than replaced over hundreds of years. In the main, they followed a classified form of arrangement; very often their chief use was to aid candidates for the civil service. The first known Chinese encyclopaedia, the *Huang-lan* ("Emperor's Mirror"), was prepared by order of the emperor in about AD 220. No part of this work has survived. Part of the *Pien-chu* ("Stringed Pearls of Literature"), prepared around 600, is still extant. About 620 the *I-wen lei-chü* ("Anthology of Art and Literature") was prepared by Ou-yang Hsün (557–641) in 100 chapters divided into 47 sections. The *Pei-t'ang shu-ch'ao* ("Extracts for Books") of Yü Shih-nan (558–638) was more substantial and paid particular attention to details of the organization of public administration. An annotated edition, edited by K'ung Kuang-t'ao, was published in 1880.

The earliest Chinese encyclopaedia

The *Ch'u-hsüeh chi* ("Entry into Learning") was a modest work compiled about 700 by Hsü Chien (659–729) and his colleagues. A more important book was the *T'ung-tien* ("Comprehensive Statutes") compiled by Tu Yu (735–812), a writer on government and economics. Completed in about 801, it contained nine sections: economics, examinations and degrees, government, rites and ceremonies, music, the army, law, political geography, national defense. In 1273 it was supplemented by Ma Tuan-lin's enormous and highly regarded *Wen hsien t'ung k'ao* ("General Study of the Literary Remains"), which included a good bibliography. Supplements to this work were published in the 17th, 18th, and 20th centuries. Under the order of the second Sung emperor, Sung T'ai Tsung, the statesman Li Fang organized the compilation of the vast *T'ai-p'ing yü-lan* ("Emperor's Mirror"), which included extracts from many works of literary and scientific standing that are no longer extant. In 1568–72 the *T'ai-p'ing yü-lan* was revised and reprinted from movable type; a new edition revised by Yüan Yüan appeared in 1812. The *Ts'e-fu yüan-kuei* (*c.* 1013), particularly strong in historical and biographical subjects, was almost as large as the *T'ai-p'ing yü-lan.*

The historian Cheng Ch'iao (1108–66) compiled the *T'ung chih* ("General Treatises"), an original work with a strong personal contribution; the printed edition (1747) was in 118 volumes. One of the richest and most important of all Chinese encyclopaedias, the *Yü-hai* ("Sea of Jade"), was compiled about 1267 by the renowned Sung scholar Wang Ying-lin (1223–92) and was reprinted in 240 volumes in 1738.

World's largest encyclopaedia

What was probably the largest encyclopaedia ever compiled, the *Yung-lo ta-tien* ("Great Handbook"), was issued at the beginning of the 15th century. Unfortunately, only a very small part of its 22,937 chapters has survived; these were published in 1963. A number of small encyclopaedias were issued in the 16th century, but the next important event was the publication of the small but profusely illustrated *San ts'ai t'u-hui* (1607–09), compiled by Wang Ch'i and his son Wang Ssu-i. In 1704–11 the Chinese literary encyclopaedia *P'ei-wen yün-fu* was compiled by order of the emperor K'ang-hsi; this was supplemented by the *Yün fu shi I* (1720). Other works ordered by the emperor include the *Pien-tzu lei-pien* (1726) and the *Tzu shih ching hua* (1727). In 1726 the huge *Ku-chin t'u-shu chi-ch'eng* ("Collection of Pictures and Writings") was published by order of the emperor. Edited by the scholar Ch'en Meng-lei, it filled over 750,000 pages and attempted to embody the whole of the Chinese cultural heritage.

At the turn of the century, a number of encyclopaedias were issued. Wang Chi's *Shih wu yüan hui,* which covered well over 2,000 topics, was compiled in 1796. Lu Feng-tso's *Hsiao chih lu* (1804) is particularly valuable for its attention to technical terms, which previous works had ignored. Ch'en Wei's *Ching Chuan II* (1804) concentrated on history and the great Chinese classics, whereas Wang Ch'eng-lieh's *Ch'i ming chi shu* (1806) is stronger in biographical material. Tai Chao-ch'un compiled the *Ssu shu wu ching lei tien chi ch'eng* (1887), a historical work for the use of civil-service candidates. Wei Sung's *I shih chi shih* (1888) had actually been compiled 65 years previously, but it paid far more attention to practical matters. The *Chiu T'ung T'ung* (1902) of Liu K'o-i was in large measure a reassembly of material in the older encyclopaedias in a more efficient classification. A more important work of the period is the largely historical and biographical *Erh shih ssu shih chiu t'ung cheng tien lei yao ho pien* (1902). The *Ch'ing ch'ao hsü wen hsien t'ung k'ao* (1905), compiled by Liu Chin Tsao, was revised and enlarged in 400 volumes in 1921. It includes contemporary material on fiscal, administrative, and industrial affairs and gives some attention to technical matters. Lu Erh-k'uei's *Tz'u-yüan* (1915), with a supplement issued in 1931, was the first really modern Chinese encyclopaedia and set the style for nearly all later works of this nature.

In 1980, officials of the Greater Encyclopedia of China Publishing House and Encyclopædia Britannica, Inc., announced an agreement under which the *Micropædia* of the 15th edition of *Encyclopædia Britannica* would be translated into Chinese for distribution in China. The eight-volume set for this project, named *The Concise Encyclopædia Britannica,* was published serially in 1984–85. It was also announced that an 80-volume set to be known as the *Greater Encyclopedia of China* would be released a volume at a time between 1980 and 1989.

Japan. In the Edo, or Tokugawa, era (1603–1867) there appeared a kind of encyclopaedia that consisted of extracts of major works in Japanese and Chinese. *Kojiruien* (51 volumes, 1879–1914) and *Nihon-hyakka-daijiten,* or the "Great Japanese Encyclopaedia" (10 volumes, 1908–19) were somewhat more akin to modern encyclopaedias but were mostly compilations of scientific works. More complete general encyclopaedias appeared in the Showa period (1926–); *Dai-hyakka* (28 volumes, 1931–35), *Koku-min-hyakka* (15 volumes, 1934–37), *Sekai-daihyakka* (24 volumes, 1955–68), and *Japonica* (19 volumes, 1967–72) are examples of well-compiled works. The *Buritanika Kokusai Dai Hyakka Jiten,* or "*Britannica International Encyclopædia*" (28 volumes), which began publication in 1972 and was completed in 1975, was the joint creation of Encyclopædia Britannica, Inc., and the Tokyo Broadcasting System acting together as TBS/Britannica Company, Tokyo. Unlike most Japanese-language encyclopaedias, which consist largely of simple short entries, its main body consists of 20 volumes of lengthy systematic entries. Other sections of the four-part set include a six-volume reference guide, consisting of many thousands of short factual entries; a reader's guide; and an index. There are also supplemental yearbooks.

The Arab world. The early encyclopaedias written in Arabic can be roughly divided into two classes: those designed for people who wished to be well informed and to make full use of their cultural heritage, and those for the rapidly growing number of official administrators. The latter type of encyclopaedia originated when the Arabs established their rule through so many parts of the Mediterranean region. The first true encyclopaedia was the work of Ibn Qutayba (828–889), a teacher and philologist, who dealt with his topics by quoting traditional aphorisms, historical examples, and old Arabic poems. The arrangement and contents of his *Kitāb ʿUyūn al-Akhbār* ("The Best Traditions") set the pattern for many later encyclopaedias. The 10 books were arranged in the following order: power, war, nobility, character, learning and eloquence, asceticism, friendship, prayers, food, women. Ibn ʿAbd Rabbih of Córdoba improved on Ibn Qutayba's work in his *ʿIqd* ("The Jewelled Necklace") by including more contemporary items of note.

Work of Ibn Qutayba

What has often mistakenly been referred to as the first encyclopaedia, the *Mafātīḥ al-ʿUlūm* ("Key to the Sciences"), was compiled in 975–997 by the Persian scholar and statesman al-Khwārizmī, who was well aware

of the content of the more important Greek writings. He divided his work into two sections: indigenous knowledge (jurisprudence, scholastic philosophy, grammar, secretarial duties, prosody and poetic art, history) and foreign knowledge (philosophy, logic, medicine, arithmetic, geometry, astronomy, music, mechanics, alchemy). The Ikhwān aṣ-Ṣafāʾ ("Sincere Brethren"), a religious or political party founded at Basra in the 10th century, published the *Rasāʾil Ikhwān aṣ-Ṣafāʾ*, a remarkable work that consisted of 52 pamphlets written by five authors, comprising all the knowledge available in their milieu. The work included (1) mathematics, geography, music, logic, and ethics; (2) the natural sciences and philosophy; (3) metaphysics; and (4) religion, astrology, and magic. A complete edition was published in 1887–89.

The Egyptian historian and civil servant an-Nuwairi (1272–1332) compiled one of the best known encyclopaedias of the Mamlūk period, the *Nihāyat al-ʿarab fī funūn al-adab* ("The Aim of the Intelligent in the Art of Letters"), a work of almost 9,000 pages. It comprised: (1) geography, astronomy, meteorology, chronology, geology; (2) man (anatomy, folklore, conduct, politics); (3) zoology; (4) botany; (5) history. A complete edition was issued in 1923. The *Masālik al-abṣār* ("Sight-Seeing Journeys") of al-ʿUmarī (1301–48) was chiefly strong on history, geography, and poetry. A third Egyptian, al-Kalka-shandī (died 1418), compiled a more important and well-organized encyclopaedia, *Ṣubḥ al-aʿshā*, that covered geography, political history, natural history, zoology, mineralogy, cosmography, and time measurement. Ibshīhī (flourished 1440) compiled a very individual encyclopaedia, the *Mustatraf* ("Spiritual Discoveries"), that covered the Islāmic religion, conduct, law, spiritual qualities, work, natural history, music, food, and medicine. At the turn of the Arab fortunes, Ibshīhī had recapitulated all that was best in their culture.

15th- and 16th-century Arabic encyclopaedias

The Persian lawyer ad-Dauwānī (1427–1501) published a kind of encyclopaedia, entitled *Unmūdag al-ʿūlūm*, that consisted of documented questions and answers and technical inventions on a very wide range of subjects. As-Sīrazī (died 1542) soon issued a refutation to it, the *Maqālatar radd ʿalā unmūdag al-ʿulum al-Galā līja*. The *Magmaʾ multaqat az-zuhūr birauḍa min al-manẓūm wal mantur* (1524) of al-Ḥanafī comprised an encyclopaedic survey and description of the various branches of knowledge, with an appendix containing an alphabetical list of the names of God. In Lebanon, Buṭrus al-Bustānī and his sons compiled the *Dāʾirat al-maʿārif* (1876–1900). A second edition (1923–25) was prepared by Muḥammad Farid Wajdi, and a third edition was begun by Fuʾād Afrām al-Bustānī in 1956. In 1955 Albert Rihani issued the one-volume *al-Mawsūʿat al-ʾarabīyah*.

Other areas. Other important encyclopaedias from the East include:

Burmese: the Burma Translation Society's *Myanma swezon kyan/Encyclopaedia Burmanica* (1954–).

Hebrew: *ha-Entziqlopedia ha-ʿIvrit* (*Encyclopaedia Hebraica* 1949–); *Entziqlopedia tevel u-melo'a* (1962–); *Entziqlopedia kelalit Massadah* (1958–60).

Indonesian: *Ensiklopedia Indonesia* (1954).

Sinhalese: *Sinhalese Encyclopedia* (1963–).

(R.L.C./W.E.P.)

DICTIONARIES

The distinction between a dictionary and an encyclopaedia is easy to state but difficult to carry out in a practical way: a dictionary explains words, whereas an encyclopaedia explains things. Because words achieve their usefulness by reference to things, however, it is difficult to construct a dictionary without considerable attention to the objects and abstractions designated. Nonetheless, while a modern encyclopaedia may still be called a dictionary, no good dictionary has ever been called an encyclopaedia.

Historical background

FROM CLASSICAL TIMES TO 1604

In the long perspective of human evolutionary development, dictionaries have been known through only a slight fraction of language history. People at first simply talked without having any authoritative backing from reference books. A short Akkadian word list, from central Mesopotamia, has survived from the 7th century BC. The Western tradition of dictionary making began among the Greeks, although not until the language had changed so much that explanations and commentaries were needed. After a 1st-century-AD lexicon by Pamphilus of Alexandria, many lexicons were compiled in Greek, the most important being those of the Atticists in the 2nd century, that of Hesychius of Alexandria in the 5th century, and that of Photius and the *Suda* in the Middle Ages. (The Atticists were compilers of lists of words and phrases thought to be in accord with the usage of the Athenians.)

Because Latin was a much-used language of great prestige well into modern times, its monumental dictionaries were important and later influenced English lexicography. In the 1st century BC, Marcus Terentius Varro wrote a treatise *De lingua Latina;* the extant books of its section of etymology are valuable for their citations from Latin poets. At least five medieval scholastics—Papias the Lombard, Alexander Neckam, Johannes de Garlandia (John Garland), Hugo of Pisa, and Giovanni Balbi of Genoa—turned their attention to dictionaries. The mammoth work of Ambrogio Calepino, published at Reggio (now Reggio nell'Emilia), in 1502, incorporating several other languages besides Latin, was so popular that "calepin" came to be an ordinary word for a dictionary. A Lancashire will of 1568 contained the provision: "I wyll that Henry Marrecrofte shall have my calapyne and my parafrasies." This is an early instance of the tendency that, several centuries later, caused people to say, "Look in Johnson" or "Look in Webster."

Interlingual dictionaries

Because language problems within a single language do not loom so large to ordinary people as those that arise in the learning of a different language, the interlingual dictionaries developed early and had great importance. The corporation records of Boston, Lincolnshire, have the following entry for the year 1578:

> That a dictionarye shall be bought for the scollers of the Free Scoole, and the same boke to be tyed in a cheyne, and set upon a deske in the scoole, whereunto any scoller may have accesse, as occasion shall serve.

The origin of the bilingual lists can be traced to a practice of the early Middle Ages, that of writing interlinear glosses—explanations of difficult words—in manuscripts. It is but a step for these glosses to be collected together at the back of a manuscript and then for the various lists—glossaries—to be assembled in another manuscript. Some of these have survived from the 7th and 8th centuries—and in some cases they preserve the earliest recorded forms in English.

The first bilingual glossary to find its way into print was a French–English vocabulary for the use of travellers, printed in England by William Caxton without a title page, in 1480. The words and expressions appeared in parallel columns on 26 leaves. Next came a Latin–English vocabulary by a noted grammarian, John Stanbridge, published by Richard Pynson in 1496 and reprinted frequently. But far more substantial in character was an English–Latin vocabulary called the *Promptorius puerorum* ("Storehouse [of words] for Children") brought out by Pynson in 1499. It is better known under its later title of *Promptorium parvulorum sive clericorum* ("Storehouse for Children or Clerics") commonly attributed to Geoffrey the Grammarian (Galfridus Grammaticus), a Dominican friar of Norfolk, who is thought to have composed it about 1440.

The next important dictionary to be published was an English–French one by John (or Jehan) Palsgrave in 1530, *Lesclaircissement de la langue francoise* ("Elucidation of the French Tongue"). Palsgrave was a tutor of French

in London, and a letter has survived showing that he arranged with his printer that no copy should be sold without his permission,

> lest his proffit by teaching the Frenche tonge myght be mynished by the sale of the same to suche persons as, besids hym, wern disposed to studye the sayd tongue.

A Welsh–English dictionary by William Salesbury in 1547 brought another language into requisition: *A Dictionary in Englyshe and Welshe moche necessary to all suche Welshemen as wil spedly learne the Englyshe tôgue.* The encouragement of Henry VIII was responsible for an important Latin–English dictionary that appeared in 1538 from the hand of Sir Thomas Elyot. Thomas Cooper enlarged it in subsequent editions and in 1565 brought out a new work based upon it—*Thesaurus Linguae Romanae et Britannicae* ("Thesaurus of the Roman Tongue and the British"). A hundred years later John Aubrey, in *Brief Lives,* recorded Cooper's misfortune while compiling it:

Thomas Cooper and his *Thesaurus*

> His wife . . . was irreconcileably angrie with him for sitting-up late at night so, compileing his Dictionary. . . . When he had halfe-donne it, she had the opportunity to gett into his studie, tooke all his paines out in her lap, and threw it into the fire, and burnt it. Well, for all that, that good man had so great a zeale for the advancement of learning, that he began it again, and went through with it to that perfection that he hath left it to us, a most usefull worke.

More important still was Richard Huloet's work of 1552, *Abecedarium Anglo-Latinum,* for it contained a greater number of English words than had before appeared in any similar dictionary. In 1556 appeared the first edition by John Withals of *A shorte Dictionarie for Yonge Beginners,* which gained greater circulation (to judge by the frequency of editions) than any other book of its kind. Many other lexicographers contributed to the development of dictionaries. Certain dictionaries were more ambitious and included a number of languages, such as John Baret's work of 1573, *An Alvearie: or triple Dictionarie, in Englishe, Latin, and French.* In his preface Baret acknowledged that the work was brought together by his students in the course of their exercises, and the title *Alvearie* was to commemorate their "beehive" of industry.

The first rhyming dictionary

The first rhyming dictionary, by Peter Levens, was produced in 1570—*Manipulus Vocabulorum. A Dictionarie of English and Latine wordes, set forthe in suche order, as none heretofore hath ben.*

The interlingual dictionaries had a far greater stock of English words than were to be found in the earliest all-English dictionaries, and the compilers of the English dictionaries, strangely enough, never took full advantage of these sources. It may be surmised, however, that people in general sometimes consulted the interlingual dictionaries for the English vocabulary. The anonymous author of *The Arte of English Poesie,* thought to be George Puttenham, wrote, in 1589, concerning the adoption of southern speech as the standard:

> herein we are already ruled by th' English Dictionaries and other bookes written by learned men, and therefore is needeth none other direction in that behalfe.

The mainstream of English lexicography is the word list explained in English. The first known English–English glossary grew out of the desire of the supporters of the Reformation that even the most humble Englishman should be able to understand the Scriptures. William Tyndale, when he printed the Pentateuch on the Continent in 1530, included "A table expoundinge certeyne wordes." The following entries are typical:

> Albe, a longe garment of white lynen.
> Boothe, an housse made of bowes.
> Brestlappe or brestflappe, is soche a flappe as thou seist in the brest or a cope.
> Consecrate, to apoynte a thinge to holy uses.
> Dedicate, purifie or sanctifie.
> Firmament: the skyes.
> Slyme was . . . a fattenesse that osed out of the erth lyke unto tarre/And thou mayst call it cement/if thou wilt.
> Tabernacle, an house made tentwise, or as a pauelion.
> Vapor/a dewymiste/as the smoke of a sethynge pott.

Spelling reformers long had a deep interest in producing English dictionaries. In 1569 one such reformer, John Hart, lamented that the "disorders and confusions" of spelling were so great that "there can be made no perfite Dictionarie nor Grammer." But a few years later the phonetician William Bullokar promised to produce such a work and stated, "A dictionary and grammar may stay our speech in a perfect use for euer."

The schoolmasters also had a strong interest in the development of dictionaries. In 1582 Richard Mulcaster, of the Merchant Taylors' school and later of St. Paul's, expressed the wish that some learned and laborious man "wold gather all the words which we vse in our English tung," and in his book commonly referred to as *The Elementarie* he listed about 8,000 words, without definitions, in a section called "The Generall Table." Another schoolmaster, Edmund Coote, of Bury St. Edmund's, in 1596 brought out *The Englishe Scholemaister, teachinge all his schollars of what age soever the most easie short & perfect order of distinct readinge & true writinge our Englishe tonge,* with a table that consisted of about 1,400 words, sorted out by different typefaces on the basis of etymology. This is important, because what is known as the "first" English dictionary, eight years later, was merely an adaptation and enlargement of Coote's table.

FROM 1604 TO 1828

First purely English dictionary

In 1604 at London appeared the first purely English dictionary to be issued as a separate work, entitled *A Table Alphabeticall, conteyning and teaching the true writing and understanding of hard usuall English wordes, borrowed from the Hebrew, Greeke, Latine,* or *French &c.,* by Robert Cawdrey, who had been a schoolmaster at Oakham, Rutland, about 1580, and in 1604 was living at Coventry. He had the collaboration of his son Thomas, a schoolmaster in London. This work contained about 3,000 words but was so dependent upon three sources that it can rightly be called a plagiarism. The basic outline was taken over from Coote's work of 1596, with 87 percent of his word list adopted. Further material was taken from the Latin–English dictionary by Thomas Thomas, *Dictionarium linguae Latinae et Anglicanae* (1588). But the third source is most remarkable. In 1599 a Dutchman known only as A.M. translated from Latin into English a famous medical work by Oswald Gabelkhouer, *The Boock of Physicke,* published at Dort, in the Netherlands. As he had been away from England for many years and had forgotten much of his English, A.M. sometimes merely put English endings on Latin words. When friends told him that Englishmen would not understand them, he compiled a list of them, explained by a simpler synonym, and put it at the end of the book. Samples are: "Puluerisated, reade beaten; Frigifye, reade coole; Madefye, reade dipp; Calefye, reade heat; Circumligate, reade binde; Ebulliated, read boyled." Thus, the fumblings of a Dutchman who knew little English (in fact, his errata) were poured into Cawdrey's word list. But other editions of Cawdrey were called for—a second in 1609, a third in 1613, and a fourth in 1617.

The next dictionary, by John Bullokar, *An English Expositor,* is first heard of on May 25, 1610, when it was entered in the Stationers' Register (which established the printer's right to it), but it was not printed until six years later. Bullokar introduced many archaisms, marked with a star ("onely used of some ancient writers, and now growne out of use"), such as "aye," "eld," "enewed," "fremd," "gab," and "glee." The work had 14 editions, the last as late as 1731.

Still in the tradition of hard words was the next work, in 1623, by Henry Cockeram, the first to have the word dictionary in its title: *The English Dictionarie: or, an Interpreter of hard English Words.* It added many words that have never appeared anywhere else—adpugne, adstupiate, bulbitate, catillate, fraxate, nixious, prodigity, vitulate, and so on. Much fuller than its predecessors was Thomas Blount's work of 1656, *Glossographia: or, a dictionary Interpreting all such hard words . . . as are now used in our refined English tongue.* He made an important forward step in lexicographical method by collecting words from his own reading that had given him trouble; and he often cited the source. Much of Blount's material was appropriated two years later by Edward Phillips, a nephew of the

poet Milton, for a work called *The New World of English Words,* and Blount castigated him bitterly.

Kersey's *New English Dictionary*

Thus far, the English lexicographers had all been men who made dictionaries in their leisure time or as an avocation, but in 1702 appeared a work by the first professional lexicographer, John Kersey the Younger. This work, *A New English Dictionary,* incorporated much from the tradition of spelling books and discarded most of the fantastic words that had beguiled earlier lexicographers. As a result, it served the reasonable needs of ordinary users of the language. Kersey later produced some bigger works, but all of these were superseded in the 1720s, when Nathan Bailey, a schoolmaster in Stepney, issued several innovative works. In 1721 he produced *An universal etymological English Dictionary,* which for the rest of the century was more popular even than Dr. Johnson's. A supplement in 1727 was the first dictionary to mark accents for pronunciation. Bailey's imposing *Dictionarium Britannicum* of 1730 was used by Samuel Johnson as a repository during the compilation of the monumental dictionary of 1755.

Many literary men felt the inadequacy of English dictionaries, particularly in view of the continental examples. The Accademia della Crusca, of Florence, founded in 1582, brought out its *Vocabolario* at Venice in 1612, filled with copious quotations from Italian literature. The Académie Française produced its dictionary in 1694, but two other French dictionaries were actually more scholarly—that of César-Pierre Richelet in 1680 and that of Antoine Furetière in 1690. In Spain the Royal Spanish Academy (Real Academia Española), founded in 1713, produced its *Diccionario de la lengua Castellana,* 1726–39, in six thick volumes. The foundation work of German lexicography, by Johann Leonhard Frisch, *Teutsch-Lateinisches Wörterbuch,* in 1741, freely incorporated quotations in German. The Russian Academy of Arts (St. Petersburg) published the first edition of its dictionary somewhat later, from 1789 to 1794. Both the French and the Russian academies arranged the first editions of their dictionaries in etymological order but changed to alphabetical order in the second editions.

Samuel Johnson's *Plan*

In England, in 1707, the antiquary Humphrey Wanley set down in a list of "good books wanted," which he hoped the Society of Antiquaries would undertake: "A dictionary for fixing the English language, as the French and Italian." A number of noted authors made plans to fulfill this aim (Joseph Addison, Ambrose Philips, Alexander Pope, and others), but it remained for a promising poet and critic, Samuel Johnson, to bring such a project to fulfillment. Five leading booksellers of London banded together to support his undertaking, and a contract was signed on June 18, 1746. Next year Johnson's *Plan* was printed, a prospectus of 34 pages, consisting of a discussion of language that can still be read as a masterpiece in its judicious consideration of linguistic problems.

With the aid of six amanuenses to copy quotations, Johnson read widely in the literature up to his time and gathered the central word-stock of the English language. He included about 43,500 words (a few more than the number in Bailey), but they were much better selected and represented the keen judgment of a man of letters. He was sympathetic to the desire of that age to "fix" the language, but he realized as he went ahead that "language is the work of man, of a being from whom permanence and stability cannot be derived." At most, he felt that he could curb "the lust for innovation."

The chief glory of Johnson's dictionary was its 118,000 illustrative quotations. No doubt some of these were included for their beauty, but mostly they served as the basis for his sense discriminations. No previous lexicographer had the temerity to divide the verb "take," transitive, into 113 senses and the intransitive into 21 more. The definitions often have a quaint ring to modern readers because the science of the age was either not well developed or was not available to him. But mostly the definitions show a sturdy common sense, except when Johnson used long words sportively. His etymologies reflect the state of philology in his age. Usually they were an improvement on those of his predecessors, because he had as a guide the *Etymologicum Anglicanum* of Franciscus Junius, as edited by Edward Lye, which became available in 1743 and which provided guidance for the important Germanic element of the language.

OA'TMEAL. *n. ſ.* [*oat* and *meal.*] Flower made by grinding oats.

Oatmeal and butter, outwardly applied, dry the ſcab on the head. *Arbuthnot on Aliment.*

Our neighbours tell me oft, in joking talk,
Of aſhes, leather, *oatmeal,* bran, and chalk. *Gay.*

OA'TMEAL. *n. ſ.* An herb. *Ainſworth.*

OATS. *n. ſ.* [æten, Saxon.] A grain, which in England is generally given to horſes, but in Scotland ſupports the people.

It is of the graſs leaved tribe; the flowers have no petals, and are diſpoſed in a looſe panicle: the grain is eatable. The meal makes tolerable good bread. *Miller.*

The *oats* have eaten the horſes. *Shakeſpeare.*

It is bare mechaniſm, no otherwiſe produced than the turning of a wild *oatbeard,* by the inſinuation of the particles of moiſture. *Locke.*

For your lean cattle, fodder them with barley ſtraw firſt, and the *oat* ſtraw laſt. *Mortimer's Huſbandry.*

His horſe's allowance of *oats* and beans, was greater than the journey required. *Swift.*

OA'TTHISTLE. *n. ſ.* [*oat* and *thiſtle.*] An herb. *Ainſ.*

The definition of "Oats" (top) by Samuel Johnson in his *Dictionary* of 1755 exemplifies his prejudice against the Scots and shows his divergence from his source, Nathan Bailey (bottom), who interspersed idiomatic examples throughout his entries (1736).

By courtesy of the Newberry Library, Chicago

OARS, [oran. *Sax.* aora *Su.*] a boat for carrying paſſengers, with two men to row it; alſo inſtruments wherewith boats are row'd.

To have an OAR in every Man's Boat.

That is, to meddle with every man's concerns,

OATS [of æten or etan. *Sax.* to eat] a grain, food for horſes.

To ſow one's wild OATS.

That is to play one's youthful pranks.

OAT *Thiſtle,* an herb.

OA'TEN, of or pertaining to oats

OATH [aŏ, *Sax.* Eeð, *Dan* and *Su.* Eedt, *Da.* Eyd, G.] a ſwearing, or confirming a thing by ſwearing.

OATH [in a legal ſenſe] a ſolemn action, whereby God is called to witneſs the truth of an affirmation, given before one or more perſons impowered to receive the ſame.

OAT-MEAL [of æten and mealepe, *Sax.*] meal or flour made of oats.

Four editions of the *Dictionary* were issued during Dr. Johnson's lifetime; in particular the fourth, in 1773, received much personal care in revision. The *Dictionary* retained its supremacy for many decades and received lavish, although not universal, praise; some would-be rivals were bitter in criticism. A widely heralded work of the 1780s and 1790s was the projected dictionary of Herbert Croft, in a manuscript of 200 quarto volumes, that was to be called the *Oxford English Dictionary.* Croft was, however, unable to get it into print.

Pronouncing dictionaries

The practice of marking word stress was taken over from the spelling books by Bailey in his *Dictionary* of 1727, but a full-fledged pronouncing dictionary was not produced until 1757, by James Buchanan; his was followed by those of William Kenrick (1773), William Perry (1775), Thomas Sheridan (1780), and John Walker (1791), whose decisions were regarded as authoritative, especially in the United States.

The attention to dictionaries was thoroughly established in U.S. schools in the 18th century. Benjamin Franklin, in 1751, in his pamphlet "Idea of the English School," said, "Each boy should have an English dictionary to help him over difficulties." The master of an English grammar school in New York in 1771, Hugh Hughes, announced: "Every one of this Class will have Johnson's Dictionary

in Octavo." These were imported from England, because the earliest dictionary printed in the U.S. was in 1788, when Isaiah Thomas of Worcester, Massachusetts, issued an edition of Perry's *Royal Standard English Dictionary.* The first dictionary compiled in America was *A School Dictionary* by Samuel Johnson, Jr. (not a pen name), printed in New Haven, Connecticut, in 1798. Another, by Caleb Alexander, was called *The Columbian Dictionary of the English Language* (1800) and on the title page claimed that "many new words, peculiar to the United States," were inserted. It received abuse from critics who were not yet ready for the inclusion of American words.

In spite of such attitudes, Noah Webster, already well known for his spelling books and political essays, embarked on a program of compiling three dictionaries of different sizes that included Americanisms. In his announcement on June 4, 1800, he entitled the largest one *A Dictionary of the American Language.* He brought out his small dictionary for schools, the *Compendious,* in 1806 but then engaged in a long course of research into the relation of languages, in order to strengthen his etymologies. At last, in 1828, at the age of 70, he published his master work, in two thick volumes, with the title *An American Dictionary of the English Language.* His change of title reflects his growing conservatism and his recognition of the fundamental unity of the English language. His selection of the word list and his well-phrased definitions made his work superior to previous works, although he did not give illustrative quotations but merely cited the names of authors. The dictionary's worth was recognized, although Webster himself was always at the centre of a whirlpool of controversy.

SINCE 1828

New trends in dictionary making

It was Noah Webster's misfortune to be superseded in his philology in the very decade that his masterpiece came out. He had spent many years in compiling a laborious "Synopsis" of 20 languages, but he lacked an awareness of the systematic relationships in the Indo-European family of languages. Germanic scholars such as Jacob Grimm, Franz Bopp, and Rasmus Rask had developed a rigorous science of "comparative philology," and a new era of dictionary making was called for. Even as early as 1812 Franz Passow had published an essay in which he set forth the canons of a new lexicography, stressing the importance of the use of quotations arranged chronologically in order to exhibit the history of each word. The brothers Jacob and Wilhelm Grimm developed these theories in their preparations for the *Deutsches Wörterbuch* in 1838. The first part of it was printed in 1852, but the end was not reached until more than a century later, in 1960. French scholarship was worthily represented by Maximilien-Paul-Émile Littré, who began working on his *Dictionnaire de la langue française* in 1844, but, with interruptions of the Revolution of 1848 and his philosophical studies, he did not complete it until 1873.

Among scholars in England the historical outlook took an important step forward in 1808 in the work of John Jamieson on the language of Scotland. Because he did not need to consider the "classical purity" of the language, he included quotations of humble origin; in his *Etymological Dictionary of the Scottish Language,* his use of "mean" sources marked a turning point in the history of lexicography. Even as late as 1835 the critic Richard Garnett said that "the only good English dictionary we possess is Dr. Jamieson's Scottish one." Another collector, James Jermyn, showed by his publications between 1815 and 1848 that he had the largest body of quotations assembled before that of *The Oxford English Dictionary.* Charles Richardson was also an industrious collector, presenting his dictionary, from 1818 on, distributed alphabetically throughout the *Encyclopaedia Metropolitana* (vol. 14 to 25) and then reissued as a separate work in 1835–37. Richardson was a disciple of the benighted John Horne Tooke, whose 18th-century theories long held back the development of philology in England. Richardson excoriated Noah Webster for ignoring "the learned elders of lexicography" such as John Minsheu (whose *Guide into the Tongues* appeared in 1617), Gerhard Johannes Vossius (who published his *Etymologicum linguae Latinae* in 1662), and Franciscus Junius (*Etymologicum Anglicanum,* written before 1677). Richardson did collect a rich body of illustrative quotations, sometimes letting them show the meaning without a definition, but his work was largely a monument of misguided industry that met with the neglect it deserved.

The beginnings of the *OED*

Scholars more and more felt the need for a full historical dictionary that would display the English language in accordance with the most rigorous scientific principles of lexicography. The Philological Society, founded in 1842, established an Unregistered Words Committee," but, upon hearing two papers by Richard Chenevix Trench in 1857—"On Some Deficiencies in Our English Dictionaries"—the society changed its plan to the making of *A New English Dictionary on Historical Principles.* Forward steps were taken under two editors, Herbert Coleridge and Frederick James Furnivall, until, in 1879, James Augustus Henry Murray, a Scot known for his brilliance in philology, was engaged as editor. A small army of voluntary readers were inspirited to contribute quotation slips, which reached the number of 5,000,000 in 1898, and no doubt 1,000,000 were added after that. Only 1,827,306 of them were used in print. The copy started going to the printer in 1882; Part I was finished in 1884. Later, three other editors were added, each editing independently with his own staff—Henry Bradley, from the north of England, in 1888, William Alexander Craigie, another Scot, in 1901, and Charles Talbut Onions, the only "Southerner," in 1914. So painstaking was the work that it was not finished until 1928, in over 15,500 pages with three long columns each. An extraordinary high standard was maintained throughout. The work was reprinted, with a supplement, in 12 volumes in 1933 with the title *The Oxford English Dictionary,* and as the *OED* it has been known ever since.

In the United States, lexicographical activity has been unceasing since 1828. In the middle years of the 19th century, a "war of the dictionaries" was carried on between the supporters of Noah Webster and those of his rival, Joseph Emerson Worcester. To a large extent, this was a competition between publishers who wished to preempt the market in the lower schools, but literary people took sides on the basis of other issues. In particular, the contentious Noah Webster had gained a reputation as a reformer of spelling and a champion of American innovations, while the quiet Worcester followed traditions.

In 1846 Worcester brought out an important new work, *A Universal and Critical Dictionary of the English Language,* which included many neologisms of the time, and in the next year Webster's son-in-law, Chauncey Allen Goodrich, edited an improved *American Dictionary* of the deceased Webster. In this edition the Webster interests were taken over by an aggressive publishing firm, the G. & C. Merriam Company. Their agents were very active in the "war of the dictionaries" and sometimes secured an order, by decree of a state legislature, for their book to be placed in every schoolhouse of the state. Worcester's climactic edition of 1860, *A Dictionary of the English Language,* gave him the edge in the "war," and James Russell Lowell declared: "From this long conflict Dr. Worcester has unquestionably come off victorious." The Merriams, however, brought out their answer in 1864, popularly called "the unabridged," with etymologies supplied by a famous German scholar, Karl August Friedrich Mahn. Thereafter, the Worcester series received no major re-editing, and its faltering publishers allowed it to pass into history.

The Century Dictionary

One of the best English dictionaries ever compiled was issued in 24 parts from 1889 to 1891 as *The Century Dictionary,* edited by William Dwight Whitney. It contained much encyclopaedic material but bears comparison even with the *OED.* Isaac Kauffman Funk, in 1893, brought out *A Standard Dictionary of the English Language,* its chief innovation being the giving of definitions in the order of their importance, not the historical order. Thus, at the turn of the new century, the U.S. had four reputable dictionaries—Webster's, Worcester's (already becoming moribund), the *Century,* and Funk's *Standard.* England was also well served by many (the original dates given here)—John Ogilvie (1850), P. Austin Nuttall (1855), Robert Gor-

don Latham (1866, re-editing Todd's Johnson of 1818), Robert Hunter (1879), and Charles Annandale (1882).

Kinds of dictionaries

GENERAL-PURPOSE DICTIONARIES

Although one may speak of a "general-purpose" dictionary, it must be realized that every dictionary is compiled with a particular set of users in mind. In turn, the public has come to expect certain conventional features (see below *Features and problems*), and a publisher departs from the conventions at his peril. One of the chief demands is that a dictionary should be "authoritative," but the word authoritative is ambiguous. It can refer to the quality of scholarship, the employment of the soundest information available, or it can describe a prescriptive demand for compliance to particular standards. Many people ask for arbitrary decisions in usage choices, but most linguists feel that, when a dictionary goes beyond its function of recording accurate information on the state of the language, it becomes a bad dictionary.

Most people encounter dictionaries in the abridged sizes, commonly called "desk" or "college-size" dictionaries. Such handy abridgments go back to the 18th century; Dr. Johnson issued an octavo size in 1756. Their form had become stultified until, in the 1930s, Edward Lee Thorndike, drawing upon the principles of the psychology of learning, produced a series for schools (*Beginning, Junior,* and *Senior*). His dictionaries were not "museums" but tools that encouraged schoolchildren to learn about language. He drew upon his word counts and his "semantic counts" to determine inclusions. The new mode was carried on to the college level by Clarence L. Barnhart in *The American College Dictionary (ACD),* in 1947, and in the later college-size works that were revised to meet that competition—the Merriam-Webster *Seventh New Collegiate* (1963), the *Standard College Dictionary* (1963), and *Webster's New World Dictionary* (1953, and second edition 1970). An especially valuable addition was *The Random House Dictionary* (1966), edited by Jess Stein in a middle size called "the unabridged" and by Laurence Urdang in a smaller size (1968). The Merriam-Webster *Collegiate* series was subsequently extended to eighth (1973) and ninth (1983) editions.

The *Third New International*

The Merriam-Webster *New International* of 1909 had a serene, uncluttered air that suited a simpler age. The second edition, completely reedited, appeared in 1934, and it, in turn, was superseded in 1961 by the *Third New International,* edited by Philip Babcock Gove. Because its competitors of similar size have not been kept up to date, it stands alone among American dictionaries in giving a full report on the lexicon of present-day English. Unfortunately, the advance publicity, before publication, emphasized the quotations from ephemeral writers such as Polly Adler, Ethel Merman, and Mickey Spillane and the statement about "ain't" as "used orally in most parts of the U.S. by many cultivated speakers." Such reports aroused a storm of denunciation in newspapers and magazines by writers who, others asserted, revealed a shocking ignorance of the nature of language. The comments were collected in a "casebook" entitled *Dictionaries and That Dictionary,* edited by James H. Sledd and Wilma R. Ebbitt (1962).

In 1969 came *The American Heritage Dictionary,* edited by William Morris, who was known for his valuable small dictionary *Words* (1947). The *American Heritage* was designed to take advantage of the reaction against the Merriam-Webster *Third.* A "usage panel" of 104 members, chosen mostly from the conservative "literary establishment," provided material for a set of "usage notes." Their pronouncements, found by scholars to be inconsistent, were supposed to provide "the essential dimension of guidance," as the editor put it, "in these permissive times." The etymological material was superior to that in comparable dictionaries.

In England, Henry Cecil Wyld produced his *Universal Dictionary of the English Language* (1932), admirable in every way except for its social class elitism. The smaller sized dictionaries of the Oxford University Press deserve their wide circulation.

SCHOLARLY DICTIONARIES

Thesaurus Linguae Latinae

Beyond the dictionaries intended for practical use are the scholarly dictionaries, with the scientific goal of completeness and rigour in their chosen area. Probably the most scholarly dictionary in the world is the *Thesaurus Linguae Latinae,* being edited in Germany. Its main collections were made from 1883 to 1900, but by 1969 its publication had reached only the letter *O.* A number of countries have "national dictionaries" under way—projects that often take many decades. Two have already been mentioned—the Grimm dictionary for German (a new edition begun in 1965) and the Littré for French (reedited 1956–58); but, in addition, there are the *Woordenboek der Nederlandsche taal* for Dutch, begun in 1882 and now very close to completion; the *Ordbok öfver svenska språket,* for Swedish, begun in 1882, reaching *S* in 1965; the *Slovar sovremennogo russkogo literaturnogo yazika* ("Dictionary of Modern Literary Russian," begun in 1950); the *Nynorsk ordbok* projected for Norwegian; and *Det Norske litteraere ordboksverk* projected for Danish. Of outstanding scholarship are the *Dictionary of Sanskrit on Historical Principles* being prepared at Pune (Poona), India, and *The Historical Dictionary of the Hebrew Language,* now getting under way in Jerusalem. The most ambitious project of all is located at the Centre National in Nancy, France, directed by Paul Imbs, preparing for a *Trésor de la langue française.* In the decade following 1960, over 250,000,000 word examples were collected, the latest techniques of computerization being used. It remains to be seen how much of this can be printed. A laboratory at Besançon, under the direction of B. Quemada, for contemporary French, has extensive collections.

The *Oxford English Dictionary* remains as the supreme completed achievement in all lexicography. Its size makes its revision impractical and the decision was therefore made for supplementation rather than revision. In 1919 plans were pushed forward for a set of "period dictionaries." After the completion of the *OED* in 1928, the remaining quotations, both used and unused, were divided up for use in each project. The prime mover of this plan, Sir William Craigie, undertook *A Dictionary of the Older Scottish Tongue* himself, covering the period from the 14th to the 17th century in Scottish speech. Enough material was amassed under his direction so that editing could begin in 1925, and before his death in 1957 he arranged that it should be carried on at the University of Edinburgh. By 1971 it had reached the word "natural." The work on the older period spurred the establishment of a project on modern Scots, which got under way in 1925, called *The Scottish National Dictionary,* giving historical quotations after the year 1700. By 1971 the project had passed the word "stane."

Period dictionaries for English

For the mainstream of English, a period dictionary for Old English (before 1100) was planned for many decades by a dictionary committee of the Modern Language Association of America (Old English section), but only in the late 1960s did it get under way at the Pontifical Institute of Mediaeval Studies at the University of Toronto. Plans are for the dictionary to be based on a combining of computerized concordances of bodies of Old English literature. A *Middle English Dictionary* has fared much better, convering the period 1100 to 1475. Started in 1925, it had reached the middle *L*'s by 1971, with an overwhelming fullness of detail. For the period 1475 to 1700, an *Early Modern English Dictionary* has not fared as well. It got under way in 1928 at the University of Michigan, and over 3,000,000 quotation slips were amassed, but the work could not be continued in the decade of the Great Depression, and only in the middle 1960s was it revived again. The *OED* supplement of 1933 is again being supplemented—this time in three large volumes, the first of which was published in 1972.

Craigie, in 1925, proposed a dictionary of American English. Support was found for the project, and he transferred from Oxford University to the University of Chicago in order to become its editor. The aim of the work, he wrote, was that of "exhibiting clearly those features by which the English of the American colonies and the United States is distinguished from that of England and the rest of the

English-speaking world." Thus, not only specific Americanisms were dealt with but words that were important in the natural history and cultural history of the New World. After a 10-year period of collecting, publication began in 1936 under the title *A Dictionary of American English on Historical Principles,* and the 20 parts (four volumes) were completed in 1944. This was followed in 1951 by a work that limited itself to Americanisms only—*A Dictionary of Americanisms,* edited by Mitford M. Mathews.

The English language, as it has spread widely over the world, has come to consist of a group of coordinate branches, each expressing the needs of its speakers in communication; further scholarly dictionaries are needed to record the particular characteristics of each branch. Both Canada and Jamaica were treated in 1967—*A Dictionary of Canadianisms on Historical Principles,* Walter Spencer Avis, editor in chief, and *Dictionary of Jamaican English,* edited by Frederic G. Cassidy and R.B. LePage. A historical dictionary of South African English is under way at Rhodes University, Grahamstown, South Africa, edited by William Branford, and some day full dictionaries must be compiled for Australian English, New Zealand English, and so on. Such dictionaries are valuable in displaying the intimate interrelations of the language to the culture of which it is a part.

SPECIALIZED DICTIONARIES

Earliest English etymological dictionary

Specialized dictionaries are overwhelming in their variety and their diversity. Each area of lexical study, such as etymology, pronunciation, and usage, can have a dictionary of its own. The earliest important dictionary of etymology for English was Stephen Skinner's *Etymologicon Linguae Anglicanae* of 1671, in Latin, with a strong bias for finding a classical origin for every English word. In the 18th century, a number of dictionaries were published that traced most English words to Celtic sources, because the authors did not realize that the words had been borrowed into Celtic rather than the other way around. With the rise of a soundly based philology by the middle of the 19th century, a scientific etymological dictionary could be compiled, and this was provided in 1879 by Walter William Skeat. It has been kept in print in re-editions ever since but was superseded in 1966 by *The Oxford Dictionary of English Etymology,* by Charles Talbut Onions, who had worked many decades on it until his death. Valuable in its particular restricted area is J.F. Bense's *Dictionary of the Low-Dutch Element in the English Vocabulary* (1926–39).

Two works are especially useful in showing the relation between languages descended from the ancestral Indo-European language—Carl Darling Buck's *Dictionary of Selected Synonyms in the Principal Indo-European Languages* (1949) and Julius Pokorny's *Indogermanisches etymologisches Wörterbuch* (1959). The Indo-European roots are well displayed in the summary by Calvert Watkins, published as an appendix to *The American Heritage Dictionary* mentioned earlier. Interrelations are also dealt with by Eric Partridge in his *Origins* (1958).

The pronouncing dictionary, a type handed down from the 18th century, is best known in the present day by two examples, one in England and one in America. That of Daniel Jones, *An English Pronouncing Dictionary,* represents what is "most usually heard in everyday speech in the families of Southern English persons whose men-folk have been educated at the great public boarding-schools." Although he called this the Received Pronunciation (RP), he had no intention of imposing it on the English-speaking world. It originally appeared in 1917 and was repeatedly revised during the author's long life. Also strictly descriptive was a similar U.S. work by John S. Kenyon and Thomas A. Knott, *A Pronouncing Dictionary of American English,* published in 1944 and never revised but still valuable for its record of the practices of its time.

The "conceptual dictionary," in which words are arranged in groups by their meaning, had its first important exponent in Bishop John Wilkins, whose *Essay towards a Real Character and a Philosophical Language* was published in 1668. A plan of this sort was carried out by Peter Marc Roget with his *Thesaurus,* published in 1852 and many times reprinted and re-edited. Although philosophically oriented, Roget's work has served the practical purpose of another genre, the dictionary of synonyms.

Dictionaries of usage

The dictionaries of usage record information about the choices that a speaker must make among rival forms. In origin, they developed from the lists of errors that were popular in the 18th century. Many of them are still strongly puristic in tendency, supporting the urge for "standardizing" the language. The work with the most loyal following is Henry Watson Fowler's *Dictionary of Modern English Usage* (1926), ably re-edited in 1965 by Sir Ernest Gowers. It represents the good taste of a sensitive, urbane litterateur. It has many devotees in the U.S. and also a number of competitors. Among the latter, the most competently done is *A Dictionary of Contemporary American Usage* (1957), by Bergen Evans and Cornelia Evans. Usually the dictionaries of usage have reflected the idiosyncrasies of the compilers; but, from the 1920s to the 1960s, a body of studies by scholars emphasized an objective survey of what is in actual use, and these were drawn upon by Margaret M. Bryant for her book *Current American Usage* (1962). A small corner of the field of usage is dealt with by Eric Partridge in *A Dictionary of Clichés* (1940).

The regional variation of language has yielded dialect dictionaries in all the major languages of the world. In England, after John Ray's issuance of his first glossary of dialect words in 1674, much collecting was done, especially in the 19th century under the auspices of the English Dialect Society. This collecting culminated in the splendid *English Dialect Dictionary* of Joseph Wright in six volumes (1898–1905). American regional speech was collected from 1774 onward; John Pickering first put a glossary of Americanisms into a separate book in 1816. The American Dialect Society, founded in 1889, made extensive collections, with plans for a dictionary, but this came to fruition only in 1965, when Frederic G. Cassidy embarked on *A Dictionary of American Regional English* (known as *DARE*).

The many "functional varieties" of English also have their dictionaries. Slang and cant in particular have been collected in England since 1565, but the first important work was published in 1785, by Capt. Francis Grose, *A Classical Dictionary of the Vulgar Tongue,* reflecting well the low life of the 18th century. In 1859 John Camden Hotten published the 19th-century material, but a full historical, scholarly survey was presented by John Stephen Farmer and W.E. Henley in their *Slang and Its Analogues,* in seven volumes, 1890–1904, with a revised first volume in 1909 (all reprinted in 1971). For the present century, the dictionaries of Eric Partridge are valuable. Slang in the United States is so rich and varied that collectors have as yet only scratched the surface, but the work by Harold Wentworth and Stuart B. Flexner, *Dictionary of American Slang* (1960), can be consulted. The argot of the underworld has been treated in many studies by David W. Maurer.

Bilingual dictionaries

Of all specialized dictionaries, the bilingual group are the most serviceable and frequently used. With the rise of the vernacular languages during the Renaissance, translating to and from Latin had great importance. The Welshman in England was provided with a bilingual dictionary as early as 1547, by William Salesbury. Scholars in their analyses of language, as well as practical people for everyday needs, are anxious to have bilingual dictionaries. Even the most exotic and remote languages have been tackled, often by religious missionaries with the motive of translating the Bible. The finding of exact equivalents is more difficult than is commonly realized, because every language slices up the world in its own particular way.

Dictionaries dealing with special areas of vocabulary are so overwhelming in number that they can merely be alluded to here. In English, the earliest was a glossary of law terms published in 1527 by John Rastell. His purpose, he said, was "to expown certeyn obscure & derke termys concernynge the lawes of thys realme." The dictionaries of technical terms in many fields often have the purpose of standardizing the terminology; this normative aim is especially important in newly developing countries where the language has not yet become accommodated to modern

technological needs. In some fields, such as philosophy, religion, or linguistics, the terminology is closely tied to a particular school of thought or the individual system of one writer, and, consequently, a lexicographer is obliged to say, "according to Kant," "in the usage of Christian Science," "as used by Bloomfield," and so on.

Features and problems

ESTABLISHMENT OF THE WORD LIST

Problems in selecting a word list

The goal of the big dictionaries is to make a complete inventory of a language, recording every word that can be found. The obsolete and archaic words must be included from the earlier stages of the language and even the words attested to only once (nonce words). In a language with a large literature, many "uncollected words" are likely to remain, lurking in out-of-the-way sources. The *OED* caught many personal coinages, but not "head-over-heelishness" (1882), "odditude" (1860), "pigstyosity" (1869), "whitechokerism" (1866), and other graceless jocularities. Also, the so-called latent words are a problem, when a lexicographer knows that a derivative word probably has been used, but he has no evidence for it. The *OED* had three quotations for "kindheartedness" but none for "kindheartedly," which any speaker of English would feel free to use. Some "ghost words" have arisen from the misreading of manuscripts and from misprints, and the lexicographer attempts to cast these out.

Various large blocks of words have a questionable status. Both geographic names and biographical entries are selectively included in some dictionaries but are really encyclopaedic. More than 2,000,000 insects have been identified and named by entomologists, while names of chemical compounds and drugs may be almost as numerous. Trade names and proprietary names may number in the hundreds of thousands. Vogue suffixes like "-ism," "-ology," "-scope," or "-wise" are used by some with the freedom of a grammatical construction. These millions are beyond what any dictionary can be expected to include.

For the smaller-sized dictionaries, the editors attempt to choose the words that are likely to be looked up. They comb the scholarly works carefully and supplement them from files that they may have collected. They may decide to put derivative words at the end of entries as "run-ons" or to have all words strictly as separate alphabetical entries. The size is ultimately decided by the commercial consideration of how much can be put into a work that can be sold for a reasonable price and held readily in the hand. (Bulk also influences the size of the word list for unabridged dictionaries.)

The establishment of a word list involves many difficult technical problems. Linguists tend to use the terms morpheme, free form, bound form, lexeme, and so on, inasmuch as "word" is a popular term not suited to technical use. A safe compromise is to use "lexical unit." This term allows the inclusion of set phrases (established groups) and idioms. Words having different etymological sources must be considered as different words. Thus "calf" in the sense of the young of a bovine animal came from Common Germanic, whereas "calf" for the fleshy back of the lower part of the leg came from Old Norse, perhaps from a Celtic source. A more difficult problem is found when a word entered the language at different points—such as "cookie," from the Dutch *koekje* "little cake," recorded in Scottish in 1701 in the form *cuckie,* then independently taken from the Dutch of the Hudson Valley in the form *cockie* in 1703, and perhaps independently taken into South African English from Afrikaans in the mid-19th century.

SPELLING

British and American spelling

Dictionaries have probably played an important role in establishing the conventions of English spelling. Dr. Johnson has received much credit for this, though he differed very little from his predecessors. He used the spelling "smoak" in the early part of his dictionary, but when he came to the entry itself, he changed it to "smoke," and this has prevailed. Noah Webster introduced some simplifications that have become accepted in American English. American dictionaries usually label the distinctive British spellings, such as "centre" and its class, "honour" and its class, "connexion," "gaol," "kerb," "tyre," "waggon," and a few others.

The desire for uniformity is so great that popular variants are not welcomed; the very common "alright" is not yet approved, nor is the widespread "miniscule" for "minuscule." The *OED* is exceptional in listing the early variant spellings, showing that a common word like "good" has been spelled in 13 different ways, with seven more from Scottish usage. When the spelling reform movement was at its height, from the 1880s to about 1910, the dictionaries included the new forms, but in recent years these have been expunged. The graphic dress of the language is now so sacrosanct that dictionaries are used as authoritarian "style manuals" in matters of spelling, hyphenation, and syllabification.

PRONUNCIATION

Dictionaries are more responsive to usage in the matter of pronunciation than they are in spelling. It is claimed that in the 19th century the Merriam-Webster dictionaries foisted a New England pronunciation on the United States, but in recent years many regional variations have been recorded. *Webster's Third New International* (1961) went to surprising lengths in its variants; perhaps its record is in giving 132 different ways of pronouncing "a fortiori."

The former practice of giving pronunciations as if the words were pronounced in isolation in a formal manner represented an artificiality that distorted language in use; recent dictionaries have marked pronunciation as it appears in continuous discourse. Furthermore, there has been a trend toward what has been called "democratization." In the word "government," for instance, it is recognized that many people do not pronounce an *n,* and some people actually say something like "gubb-munt." There is a constant battle between traditional spoken forms and spelling pronunciations.

Systems for indicating sounds

Since the alphabet is notoriously inadequate for recording the sounds of English, dictionaries are forced to adopt additional symbols. A system of using numerals over vowels was handed down from the 18th century, but that gave way to the diacritic markings of the Merriam-Webster series. The rise of the International Phonetic Alphabet (IPA) has offered another possibility, but the general public as yet finds it abstruse. Even more detailed symbols are needed in linguistic atlases and phonetic research. With considerable courage, Clarence L. Barnhart introduced the symbol schwa (ə) into *The American College Dictionary* (1947) for the neutral midcentral vowel, as at the beginning and end of "America," and the symbol has now become widely accepted. Although some systems are clumsier than others, the key does not matter much if it is applied consistently.

ETYMOLOGY

The supplying of etymologies involves such difficult decisions for a lexicographer as whether words should be carried back into prehistory by means of reconstructed forms or the degree to which speculation should be permitted. A U.S. Romance scholar, Yakov Malkiel, has presented the notion that words follow "trajectories"—by finding certain points in the history of a word, one can link up the developments in form and meaning. The austere treatment of some words consists in saying "derivation unknown," and yet this sometimes causes interesting possibilities to be ignored.

Native stock and loanwords

A fundamental distinction is made in word history between the "native stock" and the "loanwords." There have been so many borrowings into English that the language has been called "hypertrophied." The traditional view is to regard the borrowings as a source of "richness." A historical dictionary does its best to ascertain the date at which a word was adopted from another language, but the word may have to go through a period of probation. Murray, the editor of the *OED,* listed four stages of word "citizenship": the casual, the alien, the denizen, and the natural. The casuals may not be part of the language, as they appear only in travel writings and accounts of foreign

countries, but a lexicographer must collect citations for them in order to record the early history of a word that may later become naturalized. Some words may remain "denizens" for centuries, Murray pointed out, such as "phenomenon" treated as Greek, "genus" as Latin, and "aide-de-camp" as French. When a word is borrowed, its etymology may be traced through its descent in its original language.

Some early philosophies have assumed that there is a mystic relation between the present use of a word and its origin and that etymology is a search for the "true meaning." The recognition of continuous linguistic change establishes, however, that etymology is no more than early history, sometimes as reconstructed on the basis of relationships and known sound changes. Ingenuity in etymologizing is dangerous, and even plausibility can be misleading, but ascertained fact has overriding importance. It is curious that recent slang is often more uncertain in its origin than words of long history.

GRAMMATICAL INFORMATION

Dictionaries are obliged to contain the two basic kinds of words of a language—the "function words" (those that perform the grammatical functions in a language, such as the articles, pronouns, prepositions, and conjunctions) and the "referential words" (those that symbolize entities outside the language system). Each kind must be treated in a suitable way. Dictionaries have been much criticized for not including a sufficiency of grammatical information. It is usual to mark the part of speech, but not the categories of mass noun and count noun. (A mass noun, such as "milk" or "oxygen," cannot ordinarily be used in the plural, while a count noun is any noun that can be pluralized.) Such information is given in some dictionaries designed for teaching, and the technique could well be adopted more generally. The irregular inflections must be given, showing that one says "goose," "geese," but not "moose," "meese." Or in the verbs one says "walk," "walked," but "ride," "rode." It is usual to treat the different parts of speech as separate lexical entries, as in "to walk" and "to take a walk," requiring a parallel list of senses, but Edward Lee Thorndike, in his school dictionaries, experimented with grouping the parts of speech together when they had a similar sense.

Grammar and vocabulary

The relation of grammar to the vocabulary is the subject of considerable controversy among linguists. If one considers the analysis of language as one unified enterprise, then the grammar is central and the lexical units are inserted at some point in the analysis. Another view is that the division is into coordinate branches, such as phonology, syntax, and lexicon. Certainly lexicographers try to take advantage of all findings made by grammarians.

SENSE DIVISION AND DEFINITION

A language like English has so many complex developments in the senses—*i.e.*, the particular meanings—of its words that the task of the lexicographer is difficult. It is generally accepted that "meaning" is a suffusing characteristic of all language by definition, and the attempt to slice meaning into "senses" must be done arbitrarily by the person analyzing the language. This is where collected contexts form the basis of the lexicographer's judgment. He sorts the quotations into piles on the basis of similarities and differences and he may have to discard "transitional" examples. Figurative developments, such as the "mouth" of a river or the "foot" of a hill, make complications in the relationships.

For the order in which the senses of words are given, the order of historical development has been chiefly used. For an old word like "earth," the information may be insufficient. The editors of the *OED* had to give up, because, they said, "Men's notions of the shape and position of the earth have so greatly changed since Old Teutonic times"; they were obliged to compromise with a logical order. Sometimes, but not always, a word seems to have a "core," or central, meaning from which other meanings develop. If the historical order is followed, the obsolete and archaic meanings may have to appear first; and, therefore, some popular dictionaries give the most important meaning first and work down to the rare and occasional meanings at the end. The so-called "semantic count," giving senses in order of frequency, has also been used.

There seems to be no one method that is best for defining all words. The lexicographer must use artistry in selecting the ways that will convey a sense accurately and succinctly. He attempts to find what is "criterial" in a particular meaning, but he can also give further detail until he runs into the area of the encyclopaedic.

In logical theory it would be ideal to have a "metalanguage" in which definitions could be stated, but nothing of the sort is available for popular use. A "defining vocabulary" can be established, and in school dictionaries the definitions use simple words. In the last analysis all definitions have to fall back on undefined terms (to be accepted like axioms) that symbolize first-order experience of life. In this connection the logician Willard Quine has argued that lexicography is basically concerned with synonymy.

USAGE LABELS

Variations in language use

Part of the information that a dictionary should give concerns the restrictions and constraints on the use of words, commonly called usage labelling. There is great variation in language use in many dimensions—temporal, geographical, and cultural. The people who make a two-part division into "correct" and "incorrect" show that they do not understand how language works. The valuation does not lie in the word itself but in the appropriateness of the context. Therefore, it is preferable to be sparing in the use of labels and to allow the tone to become apparent from the illustrative examples. An important distinction was put forward in 1948 by an American philologist, John S. Kenyon, when he discriminated between "cultural levels," which refer to the degree of education and cultivation of a person, and "functional varieties," which refer to the styles of speech suitable to particular situations. Thus a cultivated person rightly uses informal or colloquial language when at ease with friends.

A lexicographer is faced with the difficult task of selecting a suitable set of labels. In the temporal categories, labels such as obsolete, obsolescent, archaic, and old-fashioned are dangerous, because some speakers have long memories and might use old words very naturally. The national labels are problematical, because words move easily from one branch of the language to another. The word "blizzard," for instance, is no doubt an Americanism in origin, but, since the 1880s, it has been so well known over the English-speaking world that a national label would be misleading. The label "dialect" or "regional," either for England or America, offers many problems, for alleged "boundaries" are permeable. The label "colloquial" was much misunderstood, and now "informal" is often used in its place. There may be a "poetic vocabulary" that needs labelling, and few people will agree on any definition of "slang."

It is revealing that in early printings of the Merriam-Webster *Third New International* under the word "cock-eyed," marked "slang," one of the quotations is by a careful stylist named Jacques Barzun; in order to use effective English, as he does, this cultivated writer is willing to draw upon slang. Some would argue that in marking the use as "slang," the Merriam-Webster staff was not sufficiently "permissive."

Some dictionaries wisely include special paragraphs on the constraints of usage, sometimes as a "synonymy" and sometimes as a "usage note."

ILLUSTRATIVE QUOTATIONS

Citation of sources

Dictionaries of the past have copied shamelessly from one to another, but the collecting of a file of illustrative quotations makes possible a fresh, original treatment. Scholarly works like the *OED* and its supplementations follow the canon of always using the earliest quotation and the latest for an obsolete word; in between, the quotations are selected for revealing facets of usage or for "forcing" a meaning. The criterion of use by only the best writers does not hold for a truly historical dictionary, because a "low" source may be especially revealing. The giving of exact source citations is not a matter of pedantry but es-

tablishes the scientific basis by which others can check the evidence. A different set of quotations, accurately attested, might have led to a different treatment. Thus the phrase "illustrative quotation" is something of a misnomer, for the quotations are more than "illustrative"; they form the basic evidence from which conclusions are drawn. It is the work of the editor to decide when the collections are sufficient—"ripe," as it were—to move from the collecting stage to the editing stage.

A small-sized dictionary may advantageously use made-up sentences, because an aptly framed "forcing" context can tell more than a definition. In fact, the habitual collocations of a word (the surrounding words with which it usually appears) may be revealing of the nature of a word. "Dictionaries of collocations" may be a step forward in future lexicography.

TECHNOLOGICAL AIDS

The development of machine aids, such as the computer, has been heralded by some as ushering in a new era in lexicography. Although the computer can do well in many tasks of great drudgery—mechanical excerpting of texts, alphabetizing, and classifying by designated descriptors—it is limited to what a human being tells it to do. It is difficult for a computer to sort out homographs—separate words that are spelled alike; and, at the editing stage, the delicate decisions must be humanly made.

Uses for computers

The computer can be used to good advantage in the compilation of concordances of individual authors or of limited texts, and then one type of dictionary could be made by a summation of concordances. Such a procedure, with a large body of literature like that of the Renaissance, would overwhelm an editor. More feasible, perhaps, is the establishment of a computerized archive that would never be published, but would serve as a storehouse from which, by advanced retrieval methods, the desired information could be called forth at will. The *Trésor de la langue française* of Nancy, already mentioned, is a step in this direction.

ATTITUDES OF SOCIETY

Without a doubt, dictionaries have been a conservative force for many hundreds of years, not only in countries that have had an official academy that has the national language as part of its province but also in the English-speaking countries, in which academies have been spurned. Well-entrenched popular attitudes account for this. A Neoplatonic outlook assumes that there exists an ideal form of language from which faltering human beings have departed and that dictionaries might bring people closer to the perfect language. Also, there is a widespread "yearning for certainty," a seeking for guidance amid the wilderness of possible forms. Thus, people welcome self-proclaimed "supreme authorities."

Americans have had additional reasons for their homage to the dictionary. In colonial times Americans felt themselves to be far from the centre of civilization and were willing to accept a book standard in order to learn what they thought prevailed in England. This linguistic colonialism lasted a long time and set the pattern of accepting the dictionary as a "lawgiver." In 1869, a cultural leader declared: "Upon the proper spelling, pronunciation, etymology, and definition of words, a dictionary might be made to which high and almost absolute authority might justly be awarded." In this vein teachers have taken pains to inculcate "the dictionary habit" in their pupils. Rather than observe the language around them, as Englishmen commonly do, Americans give up their autonomy and fly to a dictionary to settle questions on language. This call for dogmatic prescription has been a source of uneasiness to lexicographers, most of whom now argue that all they can do legitimately is to describe how the language has been used.

Observance of taboos

Social attitudes have affected the dictionaries also in the enforcement of certain taboos. Certain words commonly called obscene have been omitted, and, thus, irrational taboos have been strengthened. If the sex words were given in their alphabetical place, with suitable labels, the false attitudes in society would more readily be cleansed. A perennial problem in lexicography is the treatment of the terms of ethnic insult, such as "dago," "kike," and "wop." There is constant social pressure for leaving them out, and some dictionaries have succumbed to it, but it may be that an enlightened attitude shows that the open discussion of prejudices is the best way of getting rid of them.

The greatest value of a dictionary is in giving access to the full resources of a language and as a source of information that will enhance free enjoyment of the mother tongue.

Major dictionaries

For the English language the important dictionaries have already been cited in the appropriate sections; but the supreme achievement represented by the *OED* should be emphasized again. The major dictionaries in some other languages may be mentioned here.

Dictionaries of the Romance languages

For the French language, the Académie's dictionary is now in its eighth edition (1931–35) and manifests conservative views about the vocabulary, but three other works are actually more serviceable—the *Petit Larousse: dictionnaire encyclopédique pour tous* (1959); a new edition of the famous Littré, *Dictionnaire de la langue française* (1974), four volumes; and a splendid new work, Paul Robert, *Dictionnaire alphabétique et analogique de la langue française* (1960–64), six volumes. For French etymology alone, the standard work is Walther von Wartburg, *Französisches etymologisches Wörterbuch,* nearing completion in 1970 in volume 18, with a few gaps to be filled.

Among other Romance tongues, Italian has had many dictionaries. The Accademia della Crusca of Florence furnished its *Vocabolario* in a first edition in 1612, but the edition begun in 1863 bogged down at the letter *O* in 1923, and a successor work, begun in 1941, has not gone far. There is also the dictionary by G. Devoto and G.C. Oli, *Dizionario della lingua italiana* (1971). Following the model of the *OED* is the still uncompleted *Grande dizionario della lingua italiana* (1961), edited by Salvatore Battaglia. Very serviceable to English speakers is the *Italian Dictionary* of Alfred Hoare (1915; second edition, 1925) and that of Barbara Reynolds, begun in 1962, and still under way. For Spanish, the Real Academia Española in Madrid has done well since its first edition in 1726–39. At present the 18th edition, from 1956, is available. Contributions from New World Spanish need further scholarly treatment.

For the German language, the great dictionary begun by the brothers Grimm, completed in 1960, is to be re-edited in a project that will take many years; but, meanwhile, a standard work is that of Hermann Paul, *Deutsches Wörterbuch,* which first appeared in 1897 but is now available in a sixth edition (1968). The national dictionaries in the Scandinavian countries were mentioned above, but a work done with special scholarly skill is noteworthy: Einar Haugen, editor in chief, *Norwegian English Dictionary* (Madison, Wisconsin [Oslo printed], 1965), dealing with the two official languages of Norway, Bokmål and Nynorsk. Another form of a Germanic language, Afrikaans, which developed from the Dutch transplanted to South Africa in the 17th century, has a big dictionary under way. Publication of *Woordeboek van die Afrikaanse taal* began at Pretoria in 1950 as a collaboration of the best scholars in South Africa. A full dictionary of Yiddish requires profound scholarship, and this was provided by Uriel Weinreich in *Modern English-Yiddish, Yiddish-English Dictionary* (1968).

Special problems of Greek dictionaries

Greek lexicography offers special difficulties because of the long range of illustrious literature that must be covered and the split in recent centuries between Katharevusa, the literary language, and Demotic, the language of everyday life. For the English-speaking world, the standard work for Ancient Greek is by Henry George Liddell and Robert Scott, *A Greek-English Lexicon,* published in a first edition in 1843, but now available in a ninth edition, 1925–40. A full dictionary of Demotic, edited by Demetrius Georgacas at the University of North Dakota, is still in the project stage. For Russian the Soviet Academy of Arts has produced a useful work in four volumes (1957–61), but a more detailed one has been in progress since 1950, reach-

ing *F* in 1964. The Royal Irish Academy is at work on a definitive dictionary of Irish, but only "contributions" and certain parts are so far available. Many linguists have attempted to cover Arabic; probably the most useful work is that of Hans Wehr, as translated and edited by J. Milton Cowan, *A Dictionary of Modern Written Arabic* (1961). For Japanese, the standard source is the *Dai-jiten* ("Great Dictionary"), issued at Tokyo in 26 volumes (1934–36). The best known Chinese dictionary, *Tz'u hai,* was revised in 1969 and published in Taipei, Taiwan.

Titles of other works are to be found in the bibliographies listed below, especially in Constance Winchell's *Guide.*

(A.W.Re.)

BIBLIOGRAPHY

Encyclopaedias: There are two short and very readable introductions to the subject: LIBRARY OF CONGRESS, *The Circle of Knowledge* (1979), a well-illustrated guide issued in connection with a Library of Congress exhibition; and SIGFRID H. STEINBERG, "Encyclopaedias," *Signature,* New Series, no. 12, pp. 3–22 (1951), which is a brilliant conspectus of the whole field of encyclopaedia history. ROBERT L. COLLISON, *Encyclopaedias: Their History Throughout the Ages,* 2nd ed. (1966), lists and describes in one chronological sequence encyclopaedias from both East and West, and pays particular attention to *L'Encyclopédie, Brockhaus,* the *Britannica,* the *Metropolitana,* and *Larousse.* It also includes a reprint (pp. 238–295) of SAMUEL TAYLOR COLERIDGE's philosophical essay on the design of encyclopaedias, the "Treatise on Method." FRITZ SAXL, "Illustrated Mediaeval Encyclopaedias," in his *Lectures,* vol. 1, pp. 228–254, and vol. 2, plates 155–174 (1957, reprinted 1978), is an important and original contribution to the subject, the 20 illustrations being especially interesting. The *Journal of World History* devoted one complete issue (vol. 9, no. 3, 1966) to an international symposium on encyclopaedias, special attention being paid to St. Isidore, Hugh of Saint-Victor, Raoul Ardent, Vincent of Beauvais, Sahagún, *L'Encyclopédie,* the *Metropolitana,* the *Britannica, L'Encyclopédie française,* and Arabic and Chinese encyclopaedias of the classical period. ALBERT J. WALFORD (ed.), *Guide to Reference Material,* 4th ed. (1980–); and EUGENE P. SHEEHY *et al.* (comp.), *Guide to Reference Books,* 9th ed. (1976), and their supplements, both provide scholarly evaluations of the principal current English- and foreign-language encyclopaedias. GERT A. ZISCHKA, *Index Lexicorum: Bibliographie der Lexikalischen Nachschlagewerke* (1959), is important both for its excellent summary of the history of the encyclopaedia and for its extensive bibliography. FRANCES NEEL CHENEY and WILEY J. WILLIAMS, *Fundamental Reference Sources,* 2nd ed. (1980), includes discussions of good encyclopaedias and dictionaries. "The Uses of Encyclopaedias: Past, Present, and Future," in the *American Behavioral Scientist,* 6:3–40 (1962), is a stimulating symposium with contributions by Livio C. Stecchini, Jacques Barzun, Harry S. Ashmore, W.T. Couch, Charles Van Doren, Francis X. Sutton, David L. Sills, Carl F. Stover, and Alfred de Grazia. HERMAN KOGAN, *The Great EB* (1958), is a well-written and fascinating account of the *Britannica* and its history, but it is also valuable for the light it throws on the more practical problems and techniques of the encyclopaedia world in general. S. PADRAIG WALSH, *Anglo-American General Encyclopedias* (1968), is a dictionary of English-language encyclopaedias issued during the period 1703–1967, and has helpful evaluative notes. It has been continued by his *General Encyclopedias in Print, 1973–74: A Comparative Analysis* (1973). AMERICAN LIBRARY ASSOCIATION. REFERENCE AND SUBSCRIPTION BOOKS REVIEW COMMITTEE, *Purchasing a General Encyclopedia* (1969), is a pamphlet suggesting 12 criteria for evaluating the quality and usefulness of any encyclopaedia, and containing the committee's recommendations concerning a number of named encyclopaedias. The ALA's "Six Multivolume Adult Encyclopedias," *Booklist* 79(7):515–532 (December 1, 1982), and "Encyclopedia Yearbooks, Annuals, and Supplements", *Booklist* 77(14):1049–1054 (March 15, 1981), are analytical reviews based on these criteria. BOHDAN S. WYNAR (ed.), *American Reference Books Annual,* a reviewing service for reference books published in the United States, regularly includes overviews of encyclopaedias. KENNETH F. KISTER, *Encyclopedia Buying Guide,* 3rd ed. (1981), is a comprehensive consumer guide to general encyclopaedias in the English language. In each encyclopaedia the entry under the word "Encyclopaedia" or "Encyclopedia" will usually (but not invariably) provide information concerning its own history, and often gives very useful information on the history of encyclopaedias in general. Additional details may often be found in the encyclopaedia's general introduction, which is usually printed in the first volume.

Dictionaries: For the best list of dictionaries, see EUGENE P. SHEEHY *et al.* (comp.) *Guide to Reference Books,* 9th ed. (1976). See also ROBERT L. COLLISON, *Dictionaries of Foreign Languages* (1957); A.J. WALFORD (ed.), *A Guide to Foreign Language Grammars and Dictionaries,* 2nd ed. (1967); WOLFRAM ZAUNMULLER, *Bibliographisches Handbuch der Sprachwörterbücher* (1958); GERT A. ZISCHKA, *Index Lexicorum* (1959); and *Foreign Language-English Dictionaries,* 2 vol. (Library of Congress, Reference Department, 1955). For dictionaries published in Communist countries, see DANUTA RYMSZA-ZALEWSKA (ed.), *Bibliography of Dictionaries* (1965). Dictionaries of Americanisms and of slang are well covered by W.J. BURKE, *The Literature of Slang,* pp. 2–11 (1939). ANNIE M. BREWER, *Dictionaries, Encyclopedias, and Other Word-Related Books,* 3 vol., 3rd ed. (1982), is a classified catalog of more than 28,000 dictionaries and encyclopaedias.

History: For the history of classical dictionaries, see JOHN EDWIN SANDYS, *A History of Classical Scholarship,* 3rd ed., vol. 1, pp. 295–407 (1921). An old standard survey is JAMES A.H. MURRAY, *The Evolution of English Lexicography* (1900). See also MITFORD M. MATHEWS, *A Survey of English Dictionaries* (1933, reprinted 1966); and JAMES ROOT HULBERT, *Dictionaries: British and American,* rev. ed. (1968). For excellent scholarly details in their areas, see DE WITT T. STARNES, *Renaissance Dictionaries: English-Latin and Latin-English* (1954); DE WITT T. STARNES and GERTRUDE E. NOYES, *The English Dictionary from Cawdrey to Johnson, 1604–1755* (1946); and JAMES H. SLEDD and GWIN J. KOLB, *Dr. Johnson's Dictionary: Essays in the Biography of a Book* (1955). For the history of the *Oxford English Dictionary,* see WILLIAM A. CRAIGIE, "Historical Introduction," in the *Supplement* (1933), transferred to vol. 1 in the reissue of 1933; HANS AARSLEFF, "The Early History of the *Oxford English Dictionary," Bulletin of the New York Public Library,* 66:417–439 (1962), and *The Study of Language in England, 1780–1860* (1967), especially ch. 6. For American dictionaries, see JOSEPH HAROLD FRIEND, *The Development of American Lexicography, 1798–1864* (1967). The documents on the controversy over the Merriam-Webster *Third New International Dictionary* are collected by JAMES H. SLEDD and WILMA R. EBBITT in *Dictionaries and That Dictionary* (1962). For discussions of the technical problems arising in lexicography, see FRED W. HOUSEHOLDER and SOL SAPORTA (eds.), *Problems in Lexicography,* 2nd ed. (1967), papers of a conference held in 1960—especially practical is the paper by CLARENCE L. BARNHART, "Problems in Editing Commercial Monolingual Dictionaries," pp. 161–181; LADISLAV ZGUSTA, *Manual of Lexicography* (1971); and ALLEN WALKER READ, "Approaches to Lexicography and Semantics," in THOMAS A. SEBEOK (ed.), *Current Trends in Linguistics,* vol. 10, pp. 145–205 (1972). An "International Conference on Lexicography in English" was held in New York City, June 5–7, 1972; its proceedings are published in the *Ann. N.Y. Acad. Sci.* (1973). R.R.K. HARTMANN (ed.), *Lexicography: Principles and Practice* (1983), is a collection of papers concerned with the making of dictionaries.

Endocrine Systems

Endocrinology deals with the structure and function of glands that secrete materials internally. It is important to distinguish between an endocrine gland, which discharges substances called hormones directly into the bloodstream or lymph system, and an exocrine gland, which secretes substances through a duct opening in the gland onto an external or internal body surface. Salivary and sweat glands, examples of exocrine glands, secrete saliva and sweat, respectively, which act locally at the site of duct openings. In contrast, hormones that are secreted in minuscule quantities by endocrine glands, are transported by the circulation to exert powerful effects on tissues remote from the site of secretion.

As far back as 3000 BC, the ancient Chinese diagnosed some endocrinologic disorders and were able to provide effective treatments. For example, seaweed, which is rich in iodine, was prescribed for the treatment of goitre (enlargement of the thyroid gland). Perhaps the earliest demonstration in humans of direct endocrinologic intervention was the castration of men who could then be relied upon, more or less, to safeguard the chastity of women living in harems. During the Middle Ages and persisting well into the 19th century, it was a popular practice to castrate pubertal boys to preserve the purity of their treble voices. Castration established the testicle as the source of substances responsible for the development and maintenance of "maleness."

This knowledge led to an abiding interest in restoring or enhancing male sexual powers. John Hunter, an 18th-century Scottish surgeon, anatomist, and physiologist who practiced in London, transplanted successfully the testis (testicle) of a rooster into the abdomen of a hen. Charles-Édouard Brown-Séquard, a 19th-century French neurologist and physiologist, asserted that testes contained an invigorating, rejuvenating substance. His conclusions were based, in part, on observations obtained after he had injected himself with an extract of the testicle of a dog or of a guinea pig to which water had been added. These experiments were advances in that they resulted in the widespread use of organ extracts (organotherapy).

Modern endocrinology, however, is largely a creation of the 20th century. Its scientific origin is firmly rooted in the studies of Claude Bernard (1813–78), a brilliant French physiologist who made the key observation that complex organisms, such as humans, go to great lengths to preserve the constancy of what he called the "milieu intérieur" (internal environment). Later, an American physiologist, Walter Bradford Cannon (1871–1945), used the term homeostasis to describe this inner constancy.

The endocrine system, in association with the nervous system and the immune system, regulates the body's internal activities and external interactions to preserve the static internal environment. This control system permits the prime functions of living organisms—growth, development, and reproduction—to proceed in an orderly, stable fashion; it is exquisitely self-regulating so that any disruption of the normal internal environment by internal or external events is resisted by powerful countermeasures. When this resistance is overcome, sickness ensues.

For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* sections 421 and 423.

This article is divided into the following sections:

Traditional endocrinology

Because endocrinology involves an actively expanding body of knowledge, its borders remain difficult to define. The traditional core of an endocrine system, however, consists of (1) an endocrine gland, (2) its hormonal secretion, (3) a responding tissue containing a specific receptor to which the hormone will become bound, and (4) the action that results after the hormone becomes bound, termed the postreceptor response.

Embryonic origin of endocrine glands

Each endocrine gland consists of a group of specialized cells that have a common origin in the developing embryo. Many endocrine glands are derived from cells that arise in the embryonic digestive system (*e.g.*, the thyroid and pancreas) or from cells that migrate from the embryonic nervous system (*e.g.*, the parathyroid and adrenal medulla). Still others arise from a region of the embryo known as the urogenital ridge (ovary, testis, and adrenal cortex). The pituitary gland is derived from cells that originate in both the nervous system and the digestive tract. Each endocrine gland has a rich supply of blood, which is directly related to its role in synthesizing and secreting hormones. Many endocrine glands secrete more than one hormone. Some organs function both as exocrine glands and as endocrine glands. The pancreas is the best-known example.

In addition to the more traditional endocrine cells described above, specially modified nerve cells within the nervous system secrete important hormones into the blood. These special nerve cells are called neurosecretory cells, and their secretions are termed neurohormones to distinguish them from the hormones produced by traditional endocrine cells. The areas of the nervous system that produce neurohormones also have a rich vascular supply, and the neurohormones are either released into the blood or stored in adjacent blood-rich areas (called neurohemal organs) until needed.

Most hormones are one of two types: proteins (including peptides and modified amino acids) or steroids. The majority of hormones are the protein type. They are highly soluble in water and can be transported readily through the blood. The protein hormones, when initially synthesized within the cell, are contained within larger, biologically inert molecules called prohormones. The inactive portion of the prohormone is split away so that one or more active fragments that are released from the cell circulate through the blood. A smaller number of hormones are the water-soluble, fatty acid steroid hormones, all of which are synthesized from the precursor molecule cholesterol. These lipid hormones are transported through the blood by first being bound to proteins in the blood.

All body tissues that respond to a specific hormone contain specially shaped molecular configurations called receptors. These receptors are found on the surface of target cells, in the case of protein and peptide hormones, or within the cytoplasm, in the case of steroids and modified amino acid hormones. Each receptor has a strong, highly specific affinity (attraction) for a particular hormone.

This arrangement permits a specific hormone to have an effect only on those tissues for which it is "targeted," namely, those that are equipped with specific binding receptors. Usually, one segment of the hormone molecule exhibits a strong chemical affinity for the receptor while another area is responsible for initiating its specific action. Thus, hormonal actions are not general throughout the body but rather are aimed at specific target tissues.

The hormone-receptor complex

The hormone-receptor complex that is formed then activates a chain of specific chemical responses within the cells of the target tissue to complete the hormonal action. This action may be the result of the activation of enzymes within the target cell, of the interactions of the hormone-receptor complex with the nucleus of the cell, and consequent stimulation of new protein synthesis, or of a combination of both. It may even result in secretion of another hormone.

General features

THE NATURE OF ENDOCRINE REGULATION

Endocrine gland secretion is not a haphazard process; it is subject to precise, intricate control at several levels so that its effect may be integrated with those of the nervous system and the immune system. The simplest level of control resides at the endocrine gland itself. Characteristically, the signal for an endocrine gland to release more or

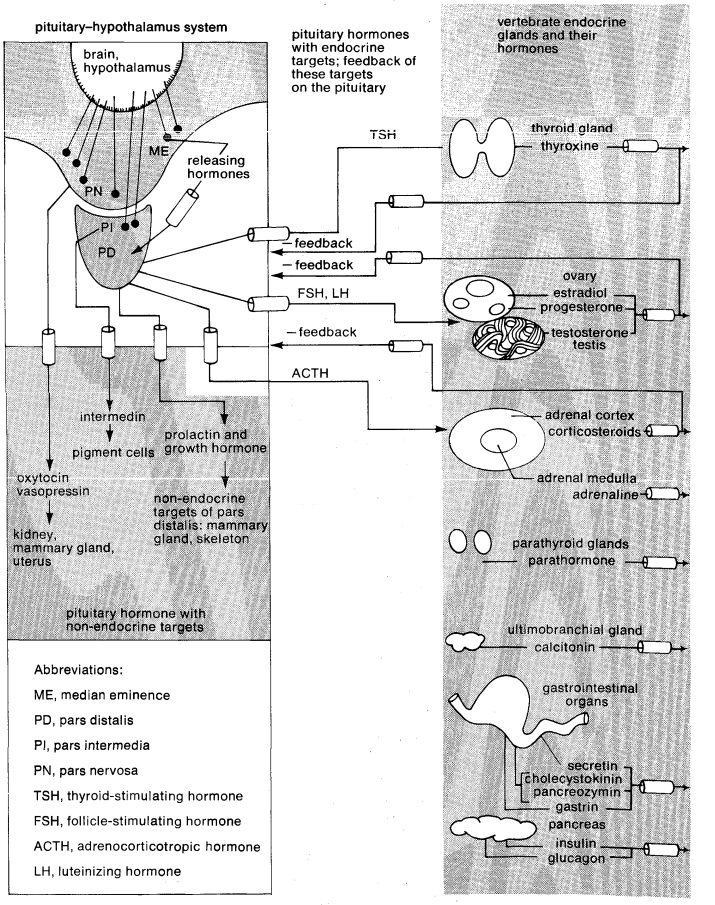


Figure 1: *Relationships of endocrine glands.* At the upper left is the pituitary-hypothalamus axis, and on the upper right are the endocrine target glands controlled through negative feedback by this axis. At the lower left are nonendocrine target organs of this axis. At the lower right are some endocrine glands that are not directly affected by the feedback mechanisms that regulate the endocrine and nonendocrine target organs.

less of its hormone is the level of some substance, either a hormone that influences the action of a gland (called a tropic hormone), a biochemical product such as glucose, or a biologically important element such as potassium or calcium. Because the endocrine gland has a rich supply of blood, it is able to detect changes in the level of this regulating substance.

Simple negative feedback

Some endocrine glands, for example the parathyroid glands located in the neck, are controlled largely by a simple negative feedback mechanism as demonstrated in Figure 2. Parathyroid hormone, known as parathormone (A), acts on its major target organ, bone (B), and other tissues to transport calcium into the blood, raising the serum calcium level (C). Elevated serum calcium levels inhibit the secretion of parathormone by the parathyroid glands (D). Thus, if for any reason serum calcium levels become elevated, parathormone secretion is blocked and calcium is not secreted into the serum from bone; the serum calcium level then falls back into the normal range. If, on the other hand, the serum calcium level should fall (E), the parathyroids are no longer inhibited from releasing parathormone and parathyroid gland activity is stimulated. (F) The increased circulating levels of parathormone stimulate increased dissolution of bone, releasing calcium. Thus, calcium enters into the serum from bone, and the serum calcium concentration rises until it reaches a normal level. In this fashion, in individuals with normal parathyroid glands, serum calcium levels are maintained within a narrow range even in the face of large changes in calcium intake or excessive losses of calcium from the body.

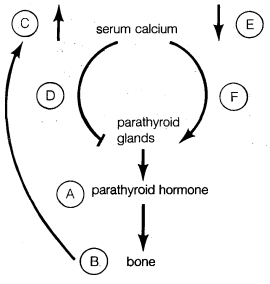

Figure 2: Control of parathyroid hormone secretion (see text).

Control of the hormonal secretions of a number of other endocrine glands is more complex because the glands are, themselves, target organs of a regulatory system called the hypothalamic-pituitary-target organ axis. Glands of this type include the thyroid, the adrenal cortex, and the gonads (testes and ovaries). The major mechanism involves interconnecting negative feedback loops, each similar to that described above, which involve the hypothalamus (a structure located at the base of the brain and above the pituitary), the anterior pituitary, and the target organ. The hypothalamus stimulates the pituitary, through neurohormones, to secrete pituitary hormones, which affect any of a number of target organs. The hypothalamic-pituitary-target organ axis is one of the more elegant devices to be found in nature. A generalized representation is illustrated in Figure 3 and discussed below.

The target gland secretes its hormone (target gland hormone), which (A) combines with the receptors of a secondary target tissue and is then inactivated. This continues until the concentration of target gland hormone in the blood exceeds the amount necessary to bind all of the tissue receptors. The effect of the target gland hormone on the secondary target tissue is quantitative; that is, within limits, the greater the amount of target gland hormone bound to receptors in the secondary target tissue, the greater the secondary target tissue cell response. The target gland hormone also binds to specific receptors in the anterior pituitary (B) to inhibit the secretion of pituitary-stimulating hormone (the hormone that stimulates the target gland to secrete more target gland hormone). As the concentration of the target gland hormone in the blood rises, there is an appropriate decrease in the production of pituitary-stimulating hormone. Thus, there will be less activation (C) of the target gland to produce its hormone. The end result of this feedback mechanism is that the high level of target hormone circulating in the bloodstream falls back to normal.

Conversely, as more target gland hormone is bound (A) to receptors in the secondary target tissue, the levels of target gland hormone circulating in the bloodstream falls. The overall inhibitory effects of target gland hormone on the pituitary gland then is reduced. Low levels of target gland hormone thus stimulate production of more pituitary-stimulating hormone (C), which in turn stimulates the secretion of target gland hormone by the target gland, until (B) the concentration of target gland hormone in the blood increases to a normal level.

A second, similar negative feedback loop is superimposed on the first. The target gland hormone binds to nerve cells in the hypothalamus (D), which inhibit the secretion of specific hypothalamic-releasing hormones (neurohormones) that stimulate the secretion of pituitary hormone (an important element in the previous negative feedback loop). The concentrations of hypothalamic-releasing hormones (E) within a set of veins that connects the hypothalamus and the pituitary gland (the hypophyseal-portal circulation) is reduced.

Nervous influences

The importance of this second loop (D and E) lies in the fact that the nerve cells of the hypothalamus communicate with nervous influences that extend down from the brain (G), including the cerebral cortex (the centre for higher mental functions, movement, perceptions, etc.), thus permitting the endocrine system to respond to physical and emotional stresses. The mechanism involves the interruption of the primary feedback loop (B and C) so that the concentrations of hormones in the blood can be increased or decreased appropriately in response to environmental stresses perceived by the nervous system (see below *The human endocrine system: The hypothalamus*). If this were not available, all blood hormones would be locked in at normal concentrations, even at times when it would be important to the body for these hormones to diverge from normal levels. Similarly, appropriate endocrinologic responses can be achieved from stimuli resulting from signals generated through the immune system to threats (such as bacterial invasion) from within the organism.

Finally, a third short loop (E and F) directly inhibits the release of a specific hypothalamic-releasing hormone by a pituitary hormone. In this fashion, concentrations of pituitary, thyroid, adrenal cortex, and gonadal hormones in the blood are maintained at normal, homeostatic levels, but, when necessary, the hormonal levels may be altered dramatically to meet changing circumstances of the internal or external environment.

This traditional view of the mechanisms that control endocrine secretion has been modified by evidence pointing to important supplemental control mechanisms. When, as is usually the case, more than one cell type is found within a single endocrine gland, the hormones secreted by one cell may exert a direct modulating effect upon the secretions of its immediate neighbour of a different cell type. This form of control is known as paracrine function. Similarly, the secretions of one endocrine cell may affect the activity of a neighbour cell of identical type, an activity known as autocrine function. Thus, endocrine cell activity may be modulated directly from within the endocrine gland itself without the need for hormones to enter the general circulation.

Paracrine and autocrine functions

Excluding from the definition of a hormone the requirement that it act at a site remote from the secreting endocrine cell allows additional classes of bioactive materials to be considered as hormones. Neurotransmitters, a group of chemical compounds of variable composition, are secreted at all synapses (junctions between nerve cells over which nervous impulses must pass). They facilitate or inhibit the transmission of neural impulses and have given rise to the hybrid science of neuroendocrinology (the branch of medicine that studies the interaction of the nervous system and the endocrine system). A second group of novel bioactive substances are called the prostaglandins, a complex group of fatty acids that are formed and secreted

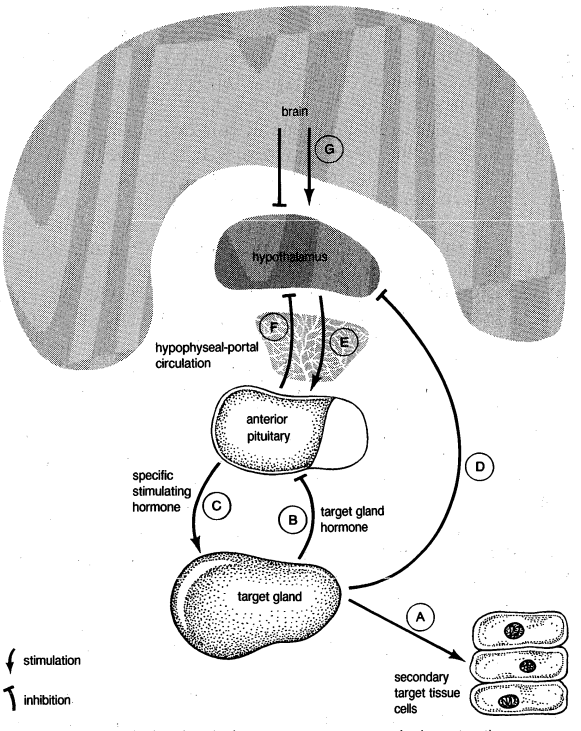

Figure 3: Hypothalamic-pituitary-target organ axis (see text).

by many tissues. They mediate important biological effects in almost every organ system of the body.

Growth factors

Another group of substances with hormonelike actions is called growth factors. These are substances that stimulate the growth of specific target tissue cells. They are distinct from the usual members of the endocrine family of growth hormones in that they were identified only after it was noted that target cells grown outside the organism in tissue culture could be stimulated to grow and reproduce by gland or tissue extracts chemically distinct from any known growth hormone.

Still another area of hormonal classification that has come under intensive investigation is the effect of endocrines on animal behaviour. While simple, direct hormonal effects on human behaviour are difficult to document because of the complexities of human motivation, there are many convincing demonstrations of hormone-mediated behaviour in other life forms. A special case is that of the pheromone, a substance generated by an organism that influences, by its odour, the behaviour of another organism of the same species. An often-quoted example is the musky scent of the females of many species, which provokes sexual excitation in the male. Such devices have obvious adaptive value for species survival.

FUNCTIONS OF THE ENDOCRINE SYSTEM

Maintenance of homeostasis. For an organism to function normally and effectively, it is necessary that the processes of its tissues operate smoothly and conjointly in a stable setting. The endocrine system provides an essential mechanism, called homeostasis, that integrates body activities and at the same time ensures that the composition of the body fluids bathing all of the constituent cells remains constant.

Scientists have postulated that the concentrations of the various salts present in the fluids of the body closely resemble the concentrations of salts in the primordial seas, which nourished the simple organisms from which increasingly complex species have evolved. Since any change in the salt composition in fluids that surround the cells (extracellular fluid), such as the fluid portion of the circulating blood (the intravascular plasma or serum), would necessitate large compensating changes in the salt concentrations within cells, the constancy of these salts (called electrolytes) is closely guarded. Even small changes in the circulating levels of these electrolytes (which include sodium, potassium, chloride, calcium, magnesium, and phosphate) elicit prompt, appropriate responses from the endocrine system, by employing negative feedback regulatory mechanisms similar to those described above, in order to restore normal concentrations.

Homeostasis

Not only is the level of each individual electrolyte maintained through homeostasis, but the total concentration of all of the electrolytes per unit of fluid (called the osmolality) is kept constant as well. If this were not the case, an increase in extracellular osmolality (or an increase in the concentration of electrolytes per unit of fluid) would result in the movement of intracellular fluid out of the cells, across the cell membrane, and into the extracellular compartment. Because the kidneys would excrete much of the fluid from the expanded extracellular volume, dehydration would be the result. Conversely, decreased plasma osmolality (or a decrease in the concentration of electrolytes per unit of fluid) would lead to a buildup of fluid within the cell.

Another homeostatic mechanism involves not an adjustment of the concentration of electrolytes in plasma but, rather, the maintenance of a normal total plasma volume. If the total volume of fluid within the circulation increases (a condition known as overhydration), the pressure against the walls of the blood vessels and the heart increase as well, stimulating sensitive areas in heart and vessel walls to release hormones that modulate the excretion of water and electrolytes by the kidney, thus reducing the total plasma volume to normal.

Growth and differentiation. Despite the many mechanisms designed to maintain a constant internal environment, the organism itself is subject to change; it is born (or hatches), it matures, and it ages. These changes are accompanied by supportive variations in body fluid composition. For example, the normal serum phosphate concentration in a child is about six milligrams per 100 millilitres, whereas about half that value is the normal concentration in an adult. These and other more striking changes are part of a second major function of the endocrine system, namely, the control of normal growth and development. The mammalian fetus develops in the uterus of the mother under the powerful influence not only of hormones from its own endocrine glands but from hormones generated in the mother's placenta as well, a system known as the

Control of growth

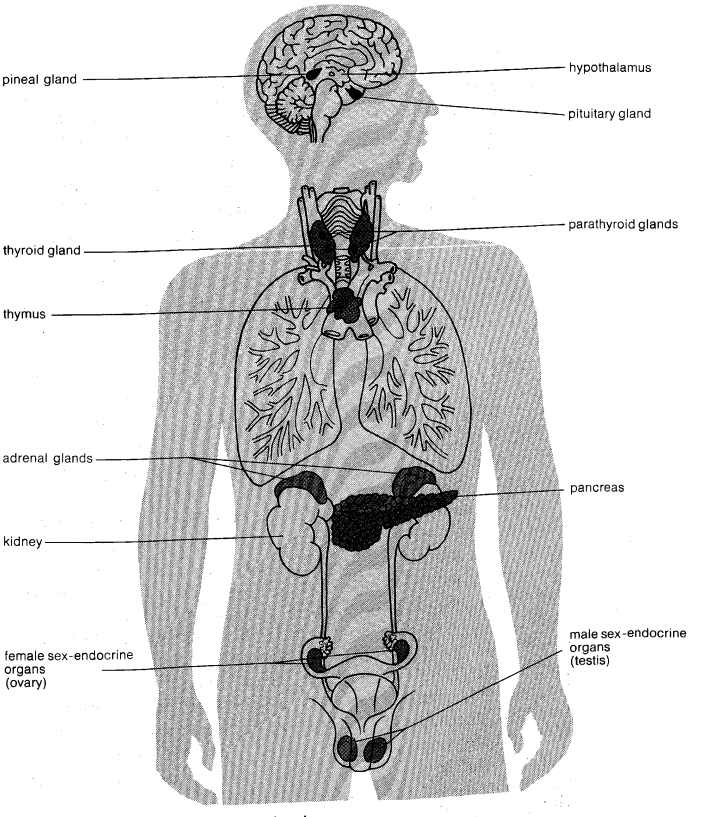

Figure 4: The human endocrine glands.

fetoplacental unit. Maternal endocrine glands assure that a proper mixture of nutrients is transmitted by way of the placenta to the growing fetus. Hormones also are present in the mother's milk and are transferred to the suckling young. There is evidence for the transmission of hormones into the eggs of nonmammals, which may influence the development of the embryo.

Sexual differentiation of the fetus into a male or a female is also controlled by delicately timed hormonal changes. After birth and a period of steady growth in infancy and childhood, the changes associated with puberty and adolescence take place. This dramatic transformation of an adolescent into a physically mature adult is also initiated and controlled by the endocrine system. Finally, as the endocrinology of aging has come under intensive investigation, changes associated with the process of normal aging and senescence have been discovered.

Adaptive responses to stress. Throughout the life of the organism endocrine influences are at play to enhance the ability of the body to respond to internal and external stressful stimuli. These changes allow not only the individual organism but also the species to survive. Early studies by Cannon led him to the thesis that acutely threatened animals respond with multiple physical changes, including endocrine changes, that prepare them to react or retreat, a process known as "the fight or flight reaction."

Adaptive responses for more prolonged stresses also occur. For example, in states of malnutrition typical of the self-induced semistarvation condition called anorexia nervosa, there is reduced secretion of thyroid hormones (hormones that generally stimulate metabolic processes of the body), leading to a lower metabolic rate. This change reduces the rate of the consumption of the body's fuel, and thus reduces the rate of consumption of the remaining energy stores. This change has obvious survival value; death from starvation is deferred.

Parenting behaviour. The endocrine system, particularly the hypothalamus, the anterior pituitary, and the gonads, is intimately involved in reproductive behaviour by providing physical, visual, and olfactory (pheromonal) signals that arouse the sexual interest of the male and the receptivity of the female. Furthermore, there are powerful endocrine influences on parental behaviour in all species, probably including humans.

Pheromones

ANATOMIC CONSIDERATIONS

Figure 4 illustrates those secretory organs that have traditionally made up the human endocrine system. While these obviously glandular structures synthesize and secrete specific hormones (Table 1), studies have revealed that most body tissues may also function as endocrine organs. The growing list includes the lungs, the heart, the skeletal muscles, the uterus, the kidneys, the salivary glands, and the lining of the gastrointestinal tract. Finally, as mentioned above, bundles of nerve cells, called nuclei, have evolved into classical endocrine organs; they secrete neurohormones into the bloodstream. (T.B.S.)

Comparative endocrinology

Comparative endocrinologists investigate the evolution of endocrine systems and the role of these systems in animals' adaptation to their environments and their production of offspring. Studies of nonmammalian animals have provided information that has furthered research in mammalian endocrinology, including that of humans. For example, the actions of a pituitary hormone, prolactin, on the control of body water and salt content were first discovered in fishes and later led to the demonstration of similar mechanisms in mammals. The mediating role of local ovarian secretions (paracrine function) in the maturation of oocytes (eggs) was discovered in starfishes and only later extended to vertebrates. The important role of thyroid hormones during embryonic development was first studied thoroughly in tadpoles during the early 1900s. In addition, the isolation and purification of many mammalian hormones was made possible in large part by using other vertebrates as bioassay systems; that is, primitive animals have served as relatively simple, sensitive indicators of the amount of hormone activity in extracts prepared from mammalian endocrine glands. Finally, some vertebrate and invertebrate animals have provided "model systems" for research that have yielded valuable information on the nature of hormone receptors and the mechanisms of hormone action. For example, one of the most intensively studied systems for understanding hormone actions on target tissues has been the receptors for progesterone and estrogens (hormones secreted by the gonads) from the oviducts of chickens.

Usefulness of comparative studies

Table 1: The Human Endocrine System

gland or tissue	hormone	chemical nature
Testis	testosterone	steroid
Ovary	estrogens (estradiol, estrone, estriol)	steroids
	inhibin (folliculostin)	polypeptide?
	progesterone	steroid
	relaxin	polypeptide
Thyroid gland	thyroxine (T_4)	amino acid
	triiodothyronine (T_3)	amino acid
Adrenal gland		
Medulla	epinephrine	amine
	norepinephrine	amine
	dopamine	steroid
Cortex	cortisol	steroid
	corticosterone	steroid
	aldosterone	steroid
	androgens	steroid
	estrogens	steroid
Pituitary gland		
Anterior lobe	corticotropin (adrenocorticotropin, ACTH)	polypeptide
	growth hormone (GH or somatotropin)	protein
	thyrotropin (thyroid-stimulating hormone, TSH)	glycoprotein
	follicle-stimulating hormone (FSH)	glycoprotein
	luteinizing hormone (LH, interstitial cell stimulating hormone, ICSH)	glycoprotein
	prolactin (PRL, luteotropic hormone, LTH, lactogenic hormone, mammotropin)	protein
Posterior lobe	oxytocin	polypeptide
	vasopressin (antidiuretic hormone, ADH)	polypeptide
Intermediate lobe tissue	α-melanocyte-stimulating* hormone (α-MSH)	polypeptide
	β-melanocyte-stimulating* hormone (β-MSH)	polypeptide
Hypothalamus	corticotropin-releasing hormone (CRH)	polypeptide?
	growth hormone-releasing hormone (GHRH)	polypeptide?
	thyrotropin-releasing hormone (TRH)	polypeptide
	follicle-stimulating hormone (FSH)	polypeptide?
	gonadotropin-releasing hormone (GnRH)	polypeptide
	prolactin-inhibiting factor (PIF)	polypeptide?
	somatostatin	polypeptide
	gastrointestinal neuropeptide	polypeptide
Pancreatic islets	glucagon	polypeptide
	insulin	polypeptide
	somatostatin	polypeptide
	pancreatic polypeptide	polypeptide
Parathyroid gland	parathyroid hormone (parathormone)	polypeptide
	calcitonin	polypeptide
Skin, liver, kidney	calciferols	steroids
Gastrointestinal mucosa		
Stomach	gastrin	polypeptide
Duodenum	cholecystokinin (CCK)	polypeptide
	secretin	polypeptide
	gastric-inhibitory polypeptide (GIP)	polypeptide
	vasoactive intestinal peptide (VIP)	polypeptide
	villikinin	—
	enterocrinin	—
Thymus	thymosin	polypeptide
Pineal	melatonin	amine (not secreted?)
Kidneys	renin	protein
	erythropoietin	protein?
Placenta	human chorionic gonadotropin (HCG)	glycoprotein
	human chorionic somatomammotropin (HCS)	protein
	renin	protein
	estrogens	steroids
	androgens	steroids
	progesterone	steroid
Multiple tissues	somatomedins (insulin-like growth factors)	polypeptides
	prostaglandins	steroids

*Intermediate lobe hormones referred to collectively as melanotropin or intermedin.

An understanding of how the endocrine system is regulated in nonmammals also provides essential information for regulating natural populations or captive animals. Artificial control of salmon reproduction has had important implications for the salmon industry as a whole. Some successful attempts at reducing pest insect species have been based on the knowledge of pheromones. Understanding the endocrinology of a rare species may permit it to be bred successfully in captivity and thus prevent it from becoming extinct. Future research may even lead to the reintroduction of some endangered species into natural habitats.

EVOLUTION OF ENDOCRINE SYSTEMS

Primitive endocrine glands

The most primitive endocrine systems seem to be those of the neurosecretory type, in which the nervous system either secretes neurohormones (hormones that act on, or are secreted by, nervous tissue) directly into the circulation or stores them in neurohemal organs (neurons whose endings directly contact blood vessels, allowing neurohormones to be secreted into the circulation), from which they are released in large amounts as needed. True endocrine glands probably evolved later in the evolutionary history of the animal kingdom as separate, hormone-secreting structures. Some of the cells of these endocrine glands are derived from nerve cells that migrated during the process of evolution from the nervous system to various locations in the body. These independent endocrine glands have been described only in arthropods (where neurohormones are still the dominant type of endocrine messenger) and in vertebrates (where they are best developed).

It has become obvious that many of the hormones previously ascribed only to vertebrates are secreted by invertebrates as well (for example, the pancreatic hormone insulin). Likewise, many invertebrate hormones have been discovered in the tissues of vertebrates, including those of humans. Some of these molecules are even synthesized and employed as chemical regulators, similar to hormones in higher animals, by unicellular animals and plants. Thus, the history of endocrinologic regulators has ancient beginnings, and the major changes that took place during evolution would seem to centre around the uses to which these molecules were put.

VERTEBRATE ENDOCRINE SYSTEMS

Evolutionary relationships

Vertebrates (phylum Vertebrata) are separable into at least seven discrete classes that represent evolutionary groupings of related animals with common features. The class Agnatha, or the jawless fishes, is the most primitive group. Class Chondrichthyes and class Osteichthyes are jawed fishes that had their origins, millions of years ago, with the Agnatha. The Chondrichthyes are the cartilaginous fishes, such as sharks and rays, while the Osteichthyes are the bony fishes. Familiar bony fishes such as goldfish, trout, and bass are members of the most advanced subgroup of bony fishes, the teleosts, which developed lungs and first invaded land. From the teleosts evolved the class Amphibia, which includes frogs and toads. The amphibians gave rise to the class Reptilia, which became more adapted to land and diverged along several evolutionary lines. Among the groups descending from the primitive reptiles were turtles, dinosaurs, crocodilians (alligators, crocodiles), snakes, and lizards. Birds (class Aves) and mammals (class Mammalia) later evolved from separate groups of reptiles. Amphibians, reptiles, birds, and mammals, collectively, are referred to as the tetrapod (four-footed) vertebrates.

The human endocrine system is the product of millions of years of evolution. and it should not be surprising that the endocrine glands and associated hormones of the human endocrine system have their counterparts in the endocrine systems of more primitive vertebrates. By examining these animals it is possible to document the emergence of the hypothalamic-pituitary-target organ axis, as well as many other endocrine glands, during the evolution of fishes that preceded the origin of terrestrial vertebrates.

The hypothalamic-pituitary-target organ axis. The hypothalamic-pituitary-target organ axes of all vertebrates are similar. The hypothalamic neurosecretory system is poorly developed in the most primitive of the living Agnatha vertebrates, the hagfishes, but all of the basic rudiments are present in the closely related lampreys. In most of the more advanced jawed fishes there are several well-developed neurosecretory centres (nuclei) in the hypothalamus that produce neurohormones. These centres become more clearly defined and increase in the number of distinct nuclei as amphibians and reptiles are examined, and they are as extensive in birds as they are in mammals. Some of the same neurohormones that are found in humans have been identified in nonmammals, and these neurohormones produce similar effects on cells of the pituitary as described above for mammals.

Neurosecretory centres

Two or more neurohormonal peptides with chemical and biologic properties similar to those of mammalian oxytocin and vasopressin are secreted by the vertebrate hypothalamus (except in Agnatha fishes, which produce only one). The oxytocin-like peptide is usually isotocin (most fishes) or mesotocin (amphibians, reptiles, and birds). The second peptide is arginine vasotocin, which is found in all nonmammalian vertebrates as well as in fetal mammals. Chemically, vasotocin is a hybrid of oxytocin and vasopressin, and it appears to have the biologic properties of both oxytocin (which stimulates contraction of muscles of the reproductive tract, thus playing a role in egg-laying or birth) and vasopressin (with either diuretic or antidiuretic properties). The functions of the oxytocin-like substances in nonmammals are unknown.

Tropic hormones

The pituitary glands of all vertebrates produce essentially the same tropic hormones: thyrotropin (TSH), corticotropin (ACTH), melanotropin (MSH), prolactin (PRL), growth hormone (GH), and one or two gonadotropins (usually FSH-like and LH-like hormones). The production and release of these tropic hormones are controlled by neurohormones from the hypothalamus. The cells of teleost fishes, however, are innervated directly. Thus, these fishes may rely on neurohormones as well as neurotransmitters for stimulating or inhibiting the release of tropic hormones.

Among the target organs that constitute the hypothalamic-pituitary-target organ axis are the thyroid, the adrenal glands, and the gonads. Their individual roles are discussed below.

The thyroid axis. Thyrotropin secreted by the pituitary stimulates the thyroid gland to release thyroid hormones, which help to regulate development, growth, metabolism, and reproduction. In humans, these thyroid hormones are known as triiodothyronine (T_3) and thyroxine (T_4). The evolution of the thyroid gland is traceable in the evolutionary development of invertebrates to vertebrates (Figure 5). The thyroid gland evolved from an iodide-trapping, glycoprotein-secreting gland of the protochordates (all nonvertebrate members of the phylum Chordata). The ability of many invertebrates to concentrate iodide, an important ingredient in thyroid hormones, occurs generally over the surface of the body. In protochordates, this capacity to bind iodide to a glycoprotein and produce thyroid hormones became specialized in the endostyle, a gland located in the pharyngeal region of the head.

The endostyle

From A. Gorbman and H.A. Bern, *Textbook of Comparative Endocrinology* (© 1963); by John Wiley & Sons, Inc.

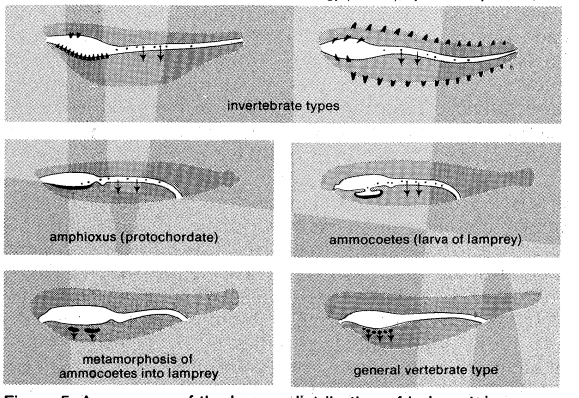

Figure 5: A summary of the known distribution of iodoproteins (shown as solid black) in the animal kingdom, suggesting a pattern of evolution of thyroid function.

When these iodinated proteins are swallowed and broken down by enzymes, the iodinated amino acids known as thyroid hormones are released. Larvae of primitive vertebrate lampreys also have an endostyle like that of the protochordates. When a lamprey larva undergoes metamorphosis into an adult lamprey, the endostyle breaks into fragments. The resulting clumps of endostyle cells differentiate into the separate follicles of the thyroid gland. Thyroid hormones actually direct metamorphosis in the larvae of lampreys, bony fishes, and amphibians. Thyroids of fishes consist of scattered follicles in the pharyngeal region. In tetrapods and a few fishes, the thyroid becomes encapsulated by a layer of connective tissue.

The adrenal axis. The adrenal axes in mammals and in nonmammals are not constructed along the same lines (Figure 6). In mammals the adrenal cortex is a separate structure that surrounds the internal adrenal medulla; the adrenal gland is located atop the kidneys. Because the cells of the adrenal cortex and adrenal medulla do not form separate structures in nonmammals as they do in mammals, they are often referred to in different terms; the cells that correspond to the adrenal cortex in mammals are called interrenal cells, and the cells that correspond to the adrenal medulla are called chromaffin cells. In primitive nonmammals the adrenal glands are sometimes called interrenal glands.

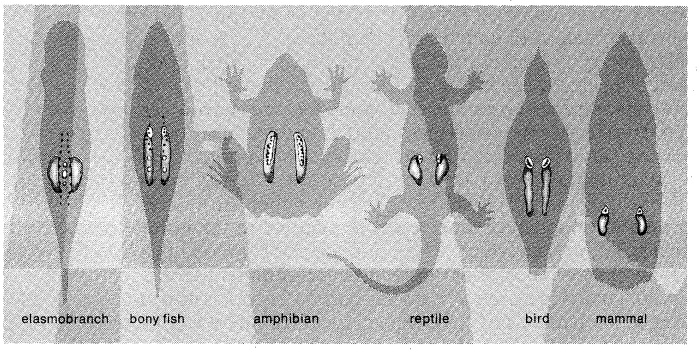

Figure 6: *Patterns of vertebrate adrenal glands.* White, interrenal or cortical tissue; black, chromaffin or medullary tissue; shaded area, kidney.

In fishes the interrenal and chromaffin cells often are embedded in the kidneys, whereas in amphibians they are distributed diffusely along the surface of the kidneys. Reptiles and birds have discrete adrenal glands, but the anatomical relationship is such that often the "cortex" and the "medulla" are not distinct units. Under the influence of pituitary adrenocorticotropin hormone, the interrenal cells produce steroids (usually corticosterone in tetrapods and cortisol in fishes) that influence sodium balance, water balance, and metabolism.

Gonadotropins

The gonadal axis. Gonadotropins secreted by the pituitary are basically LH-like and/or FSH-like in their actions on vertebrate gonads. In general, the FSH-like hormones promote development of eggs and sperm and the LH-like hormones cause ovulation and sperm release; both types of gonadotropins stimulate the secretion of the steroid hormones (androgens, estrogens, and, in some cases, progesterone) from the gonads. These steroids produce effects similar to those described for humans. For example, progesterone is essential for normal gestation in many fishes, amphibians, and reptiles in which the young develop in the reproductive tract of the mother and are delivered live. Androgens (sometimes testosterone, but often other steroids are more important) and estrogens (usually estradiol) influence male and female characteristics and behaviour.

Control of pigmentation. Melanotropin (melanocyte-stimulating hormone, or MSH) secreted by the pituitary regulates the star-shaped cells that contain large amounts of the dark pigment melanin (melanophores), especially in the skin of amphibians as well as in some fishes and reptiles. Apparently, light reflected from the surface stimulates photoreceptors, which send information to the brain and in turn to the hypothalamus. Pituitary melanotropin then causes the pigment in the melanophores to disperse and the skin to darken, sometimes quite dramatically. By releasing more or less melanotropin, an animal is able to adapt its colouring to its background.

Growth hormone and prolactin. The functions of growth hormone and prolactin secreted by the pituitary overlap considerably, although prolactin usually regulates water and salt balance, whereas growth hormone primarily influences protein metabolism and hence growth. Prolactin allows migratory fishes such as salmon to adapt from salt water to fresh water. In amphibians, prolactin has been described as a larval growth hormone, and it can also prevent metamorphosis of the larva into the adult. The water-seeking behaviour (so-called water drive) of adult amphibians often observed prior to breeding in ponds is also controlled by prolactin. The production of a protein-rich secretion by the skin of the discus fish (called "discus milk") that is used to nourish young offspring is caused by a prolactin-like hormone. Similarly, prolactin stimulates secretions from the crop sac of pigeons ("pigeon" or "crop" milk), which are fed to newly hatched young. This action is reminiscent of prolactin's actions on the mammary gland of nursing mammals. Prolactin also appears to be involved in the differentiation and function of many sex accessory structures in nonmammals, and in the stimulation of the mammalian prostate gland. For example, prolactin stimulates cloacal glands responsible for special reproductive secretions. Prolactin also influences external sexual characteristics such as nuptial pads (for clasping the female) and the height of the tail in male salamanders.

Functions of prolactin

Other vertebrate endocrine glands. *The pancreas.* The pancreas in nonmammals is an endocrine gland that secretes insulin, glucagon, and somatostatin. Pancreatic polypeptide has been identified in birds and may occur in other groups as well. Insulin lowers blood sugar (hypoglycemia) in most vertebrates, although mammalian insulin is rather ineffective in reptiles and birds. Glucagon is a hyperglycemic hormone (it increases the level of sugar in the blood).

In primitive fishes the cells responsible for secreting the pancreatic hormones are scattered within the wall of the intestine. There is a trend toward progressive clumping of cells in more evolutionarily advanced fishes, and in a few species the endocrine tissue forms only one or a few large islets. As a rule, most fishes lack a discrete pancreas, but all tetrapods have a fully formed exocrine and endocrine pancreas. The endocrine cells of all tetrapods are organized into distinct islets as described for humans, although the abundance of the different cell types often varies. For example, in reptiles and birds there is a predominance of glucagon-secreting cells and relatively few insulin-secreting cells.

Calcium-regulating hormones. Fishes have no parathyroid glands: these glands first appear in amphibians. Although the embryological origin of parathyroid glands of tetrapods is well known, their evolutionary origin is not. Parathyroid hormone raises blood calcium levels (hypercalcemia) in tetrapods. The absence in most fishes of cellular bone, which is the principal target for parathyroid hormone in tetrapods, is reflected by the absence of parathyroid glands.

Parathyroid glands

Fishes, amphibians, reptiles, and birds have paired pharyngeal ultimobranchial glands that secrete the hypocalcemic hormone calcitonin. The corpuscles of Stannius, unique glandular islets found only in the kidneys of bony fishes, secrete a peptide called hypocalcin. Fish calcitonins differ somewhat from the mammalian peptide hormone of the same name, and fish calcitonins have proved to be more potent and have a longer-lasting action in humans than human calcitonin itself. Consequently, synthetic fish calcitonin has been used to treat humans suffering from various disorders of bone, including Paget's disease (see below *The parathyroid glands: Metabolic bone disease*). The secretory cells of the ultimobranchial glands are derived from cells that migrated from the embryonic nervous system. During the development of a mammalian fetus, the ultimobranchial gland becomes incorporated into the developing thyroid gland as the "C cells" or "parafollicular cells."

Gastrointestinal hormones. Little research has been done on gastrointestinal hormones in nonmammals, but there is good evidence for a gastrinlike mechanism that controls the secretion of stomach acids. Peptides similar to cholecystokinin are also present and can stimulate contractions of the gall bladder. The gall bladders of primitive fishes contract when treated with mammalian cholecystokinin.

Other mammalian-like endocrine systems. *The renin-angiotensin system.* The renin-angiotensin system in mammals is represented in nonmammals by the juxtaglomerular cells that secrete renin associated with the kidney. The macula densa that functions as a detector of sodium levels within the kidney tubules of tetrapods, however, has not been found in fishes.

The pineal complex. In fishes, amphibians, and reptiles, the pineal complex is better developed than in mammals. The nonmammalian pineal functions as both a photoreceptor organ and an endocrine source for melatonin. Effects of light on reproduction in fishes and tetrapods are mediated at least in part through the pineal, and it has been implicated in a number of daily and seasonal biorhythmic phenomena.

Pineal functions

Prostaglandins. Many tissues of nonmammals produce prostaglandins that play important roles in reproduction similar to those discussed for humans and other mammals.

The liver. As in mammals, the liver of several nonmammalian species has been shown to produce somatomedin-like growth factors in response to stimulation by growth hormone. Similarly, there is evidence that prolactin stimulates the production of a related growth factor, which synergizes (cooperates) with prolactin on targets such as the pigeon crop sac.

Unique endocrine glands in fishes. In addition to the corpuscles of Stannius and the ultimobranchial glands, most fishes have a unique neurosecretory neurohemal organ, the urophysis, which is associated with the spinal cord at the base of the tail. Although the functions of this caudal (rear) neurosecretory system are not now understood, it is known to produce two peptides, urotensin I and urotensin II. Urotensin I is chemically related to a family of peptides that includes somatostatin; urotensin II is a member of the family of peptides that includes mammalian corticotropin-releasing hormone (CRH). There are no homologous structures to either the corpuscles of Stannius or the urophysis in amphibians, reptiles, or birds.

INVERTEBRATE ENDOCRINE SYSTEMS

Advances in the study of invertebrate endocrine systems have lagged behind those in vertebrate endocrinology, largely due to the problems associated with adapting investigative techniques that are appropriate for large vertebrate animals to small invertebrates. It also is difficult to maintain and study appropriately some invertebrates under laboratory conditions. Nevertheless, knowledge about these systems is accumulating rapidly.

Problems in invertebrate studies

All phyla in the animal kingdom that have a nervous system also possess neurosecretory neurons. The results of studies on the distribution of neurosecretory neurons and ordinary epithelial endocrine cells imply that the neurohormones were the first hormonal regulators in animals. Neurohemal organs appear first in the more advanced invertebrates (such as mollusks and annelid worms), and endocrine epithelial glands occur only in the most advanced phyla (primarily Arthropoda and Chordata). Similarly, the peptide and steroid hormones found in vertebrates are also present in the nervous and endocrine systems of many invertebrate phyla. These hormones may perform similar functions in diverse animal groups. With more emphasis being placed on research in invertebrate systems, new neuropeptides are being discovered initially in these animals, and subsequently in vertebrates.

The endocrine systems of some animal phyla have been studied in detail, but the endocrine systems of only a few species are well known. The following discussion summarizes the endocrine systems of five invertebrate phyla and the two invertebrate subphyla of the phylum Chordata, a phylum that also includes Vertebrata, a subphylum to which the backboned animals belong.

Phylum Nemertea. Nemertine worms are primitive marine animals that lack a coelom (body cavity) but differ from other acoelomates (animals that lack a coelom) by having a complete digestive tract. Three neurosecretory centres have been identified in the simple nemertine brain; one centre controls the maturation of the gonads, and all three appear to be involved in osmotic regulation.

Phylum Annelida. The cerebral ganglion (brain) of *Nereis,* a marine polychaete worm, produces a small peptide hormone called nereidine, which apparently inhibits precocious sexual development. There is a complex just beneath the brain that functions as a neurohemal organ. The epithelial cells found in this complex may be secretory as well, but this has not been proved. Neurohormones are released from the infracerebral complex into the coelomic fluid through which they travel to their targets. In the lugworm, *Arenicola,* there is evidence for a brain neuropeptide that stimulates oocyte maturation.

Phylum Mollusca. Within the phylum Mollusca, the class Gastropoda (snails, slugs) has been studied most extensively. The cerebral ganglion (brain) of several species (*e.g., Euhadra peliomorpha, Aplysia californica,* and *Lymnaea stagnalis*) secretes a neurohormone that stimulates the hermaphroditic gonad (the reproductive gland that contains both male and female characteristics); hermaphroditism is a common condition among mollusks. This gonadotropic peptide hormone (a hormone that has the gonads as its target organ) is stored in a typical neurohemal organ until its release is stimulated. For example, phototropic information detected by the so-called optic gland (located near the eye) can direct the release of the gonadotropic hormone. The gonadotropic hormones that cause egg laying in *Aplysia* and *Lymnaea* have been isolated, and they are very similar small peptides. The hermaphroditic gonad of *Euhadra* secretes testosterone (identical to the vertebrate testosterone), which stimulates formation of a gland that releases a pheromone for influencing mating behaviour. The optic gland of the octopus (of the class Cephalopoda) influences development of the reproductive organs on a seasonal basis. It is not known, however, whether any neurohormones are involved or whether this is purely a neurally controlled event.

The hermaphroditic gonad

Phylum Arthropoda. The arthropods are the largest and most advanced group of invertebrate animals, rivaling and often exceeding the evolutionary success of the vertebrates. Indeed, the arthropods are the most successful ecological competitors of humans. There are several major subdivisions, or classes, within the phylum Arthropoda, with the largest being Insecta (insects), Crustacea (crustaceans, including crabs, crayfishes, and shrimps), and Arachnida (arachnids, including the spiders, ticks, and mites). Even within these major classes, few species have been studied. Those that have been studied are large insects (*e.g.,* cockroaches, grasshoppers, and cecropia moths) and crustaceans.

The organizations of arthropod endocrine systems parallel those of the vertebrate endocrine system. That is, neurohormones are produced in the arthropod brain (analogous to the vertebrate hypothalamus) and are stored in a neurohemal organ (like the vertebrate neurohypophysis). The neurohemal organ of insects may have an endocrine portion (like the vertebrate adenohypophysis), and hormones or neurohormones released from these organs may stimulate other endocrine glands as well as nonendocrine targets. A general description of the endocrine systems of insects and crustaceans is given below.

Endocrine system organization

Class Insecta. Neurosecretory, neurohemal, and endocrine structures are all found in the insect endocrine system (Figure 7). There are several neurosecretory centres in the brain, the largest being the pars intercerebralis. The paired corpora cardiaca (singular, corpus cardiacum) and the paired corpora allata (singular, corpus allatum) are both neurohemal organs that store brain neurohormones, but each has some endocrine cells as well. The ventral nerve cord and associated ganglia also contain neurosecretory cells and have their own neurohemal organs; *i.e.,* the multiple perisympathetic organs located along the ventral nerve cord. The insect endocrine system produces neurohormones as well as hormones that control molting,

diapause, reproduction, osmoregulation, metabolism, and muscle contraction (Table 2).

Table 2: Processes in Insects Controlled by Neuropeptides of the Brain and/or Ventral Cord

Rhythms in activity levels
Colour changes

Molting. A peptide neurohormone that controls molting is secreted by the pars intercerebralis and is stored in the corpora cardiaca or corpora allata (depending on the group of insects). This brain neurohormone is known as the prothoracotropic hormone (PTTH), and it stimulates the prothoracic glands (also called ecdysial or molting glands). In turn, the prothoracic glands release the steroid ecdysone, which is the actual molting hormone. Ecdysone initiates shedding of the old, hardened cuticle (exoskeleton).

Prothoracotropic hormone

In the 1940s Sir Vincent (Brian) Wigglesworth discovered that distention of the abdomen of the blood-sucking hemipteran bug *Rhodnius prolixus* following consumption of a blood meal sends neural impulses to the brain and triggers the release of PTTH. A similar mechanism has been found in a herbivorous (plant-eating) hemipteran as well. Size seems to trigger molting in lepidopterans (moths, butterflies), although the mechanism is not understood. Each molt is aided by a small amount of juvenile hormone (JH) secreted by endocrine cells of the corpora allata. Without JH during a critical time of the intermolt period of the last larval stage, either a pupa stage (diapause, or a resting state) or an adult stage is achieved. Juvenile hormone also keeps the epidermis in a larval state and causes it to secrete larval cuticle. Without JH, the epidermis changes and secretes the adult cuticle type. Three different closely related forms of JH have been isolated from seven major insect orders.

Diapause. Some insects enter diapause during development. Diapause is characterized by cessation of development or reproduction, decrease in water content (dehydration), and reduction in metabolic activities. It usually is preceded by an accumulation of nutrients resulting in hypertrophy of the fat bodies. Environmental factors (such as temperature, photoperiod, and food availability) cause storage of neurohormones, and the corpora allata become inactive. Termination of diapause can be brought about by reversing the environmental conditions that induced the diapause. Although juvenile hormone can terminate diapause, it triggers diapause in some insects. The stage of the life history may be important in determining the role of JH. For example, in imaginal diapause (characterized by cessation of reproduction in the imago, or adult), the absence of JH initiates diapause. In lepidopterans, a peptide that initiates diapause has been isolated from the subesophageal ganglion.

Effect of environmental factors

Reproduction. In some insects the pars intercerebralis secretes a neurohormone that stimulates vitellogenesis by the fat body (vitellogenesis is the synthesis of vitellogenin, a protein from which the oocyte makes the egg proteins). This neurohormone is stored in either the corpora cardiaca or the corpora allata, depending on the species. Uptake of vitellogenin by the ovary is enhanced by JH. In most insects, JH also stimulates vitellogenin synthesis by the fat body. There is evidence that other neurohormones secreted by the pars intercerebralis also influence reproduction. Some induce other tissues to secrete pheromones that influence reproductive behaviour of other individuals. In the live-bearing tsetse fly, *Glossina,* a neurohormone released from the corpora allata stimulates milk glands that provide nourishment to the developing larvae.

Osmoregulation. All insects produce a diuretic hormone and many produce an antidiuretic hormone as well. Insects feeding exclusively on a liquid diet (such as plant sap or blood) have only the diuretic hormone that allows them to eliminate excess fluid and salts through the malpighian tubules (the insect kidney). These osmoregulatory neurohormones are produced both in the brain and in the ventral nerve cord.

Myotropic and metabolic factors. One or more small peptide neurohormones are produced in the brain and ventral nervous system and are stored in the corpora cardiaca and perisympathetic organs, respectively. These myotropic factors stimulate heart rate as well as contractions of the kidney tubules and digestive tract. The corpora cardiaca were named for the heart-stimulating action produced by extracts of these organs. The glandular portion of the corpora cardiaca is thought to secrete the hyperglycemic hormone that causes a rapid increase in blood levels of trehalose, the "blood sugar" of insects. It is sometimes called the hypertrehalosemic hormone. This hypoglycemic hormone apparently is identical to the myotropic factors in at least one species, the American cockroach. An adipokinetic neurohormone released from the orthopteran corpora cardiaca (locusts, grasshoppers) causes the release of diglycerides into the blood during, and immediately after, flight. It is a peptide similar to the myotropic factors.

Class Crustacea. Among the crustaceans, the major neuroendocrine system consists of the neurosecretory X-organ and its associated neurohemal organ, the sinus gland. Both an X-organ and a sinus gland are located in each eyestalk, and together they are termed the eyestalk complex. Two endocrine glands are well known: the Y-organ and the androgenic gland (see Figure 7). As in insects, hormones and neurohormones of the crustacean regulate molting, reproduction, osmoregulation, metabolism, and

heart rate. In addition, the regulation of colour changes is well developed in crustaceans, whereas only a few insects exhibit hormonally controlled colour changes.

Molting. The steroid ecdysone secreted from the Y-organ stimulates molting. After it is released into the blood, ecdysone is converted to a 20-hydroxyecdysone, which is the active molting hormone. Secretion of ecdysone is blocked by a neurohormone called molt-inhibiting hormone, produced by the eyestalk complex. The existence of several additional molting factors has been proposed from experimental studies, and the regulation of molting may be much more complicated than suggested here.

Reproduction. The eyestalk complex appears to produce a neurohormone that inhibits vitellogenesis by the fat body and blocks vitellogenin uptake by oocytes in the ovary. Older follicles in the ovary, however, may secrete a vitellogenin-stimulating hormone that overrides the effects of the eyestalk neurohormone. In shrimps and other crustaceans that exhibit sequential hermaphroditism, the androgenic gland produces a peptide hormone that is necessary to masculinize the gonad. These animals function first as males, and later with the degeneration of the androgenic gland they become females. Surgical removal of the androgenic gland causes a precocious change of a male to a female.

Osmoregulation. There are four known sources of factors that influence water and ionic balance (osmoregulation) in crustaceans. The brain factor is known to regulate function of the antennal glands (paired "kidneys" located at the base of each antenna), the intestine, and the gills. The thoracic ganglion factor affects the stomach, intestine, and gills. Both the antennal glands and the gills are affected by a factor from the eyestalk complex. Finally, the pericardial organs (neurohemal glands located in the pericardial cavity) influence salt and water metabolism by heart muscle and gills.

Myotropic factor. Heart rate is accelerated in crustaceans by a factor released from the pericardial organs. It is not known if this factor is the same one that has osmoregulatory actions mentioned above. There is evidence to suggest that the crustacean cardioacceleratory factor is identical to one of the insect cardioacceleratory factors.

Colour changes. Several neurohormones that regulate colour changes (chromatophorotropins) by pigment cells (chromatophores) have been found in extracts of the eyestalk complex. The best known are the light-adapting hormone and the red-pigment-concentrating hormone. This latter peptide is chemically similar to the insect adipokinetic and myotropic factors. Regulation of the chromatophores allows an animal to adapt to different backgrounds by changing colours or by becoming lighter or darker.

Phylum Echinodermata. Female sea stars (starfishes) are the only echinoderms that have been studied extensively. A neuropeptide called the gonad-stimulating substance (also called the gamete-shedding substance) is released from the radial nerves into the body cavity about one hour before spawning. Gonad-stimulating substance has been reported in more than 30 species of sea star. This neuropeptide contacts the ovaries directly and causes formation of 1-methyladenine, an inducer of oocyte maturation and spawning. This same hormone has been demonstrated in the ovaries of the closely related sea urchin, where it also promotes maturation of the oocyte.

Gonad-stimulating substance

Phylum Chordata. The phylum Chordata is separated into three subgroups (or subphyla). The invertebrate subphylum Tunicata consists of the marine tunicates, including the ascidians and salps. The invertebrate subphylum Cephalochordata includes the fishlike amphioxus (or lancelet). Amphioxus is a small marine animal that closely resembles the larva of the jawless fishes (class Agnatha). The subphylum Vertebrata is the largest chordate subgroup.

Subphylum Tunicata. The ascidians (also called sea squirts) have a tadpolelike larva that lives free for a short period. The larva eventually attaches itself to a solid substrate and undergoes a marked metamorphosis into the sessile adult sea squirt. The larva and adult have a mucus-secreting gland, the endostyle, that is believed to be the evolutionary ancestor of the vertebrate thyroid gland. Metamorphosis in ascidians can be induced by application of thyroid hormones.

Neurosecretory neurons in the cerebral ganglion (brain) contain the vertebrate peptide gonadotropin-releasing hormone (GnRH). Directly adjacent to the brain is the neural (or subneural) gland that may be the forerunner of the vertebrate pituitary gland. Extracts prepared from ascidian neural glands stimulate testicular growth in toads, demonstrating the presence of a gonadotropic factor in the neural gland. A protein similar to human prolactin has been found in the neural gland of *Styela plicata.*

Subphylum Cephalochordata. The cephalochordate brain contains neurosecretory neurons that possibly are related to a structure called Hatschek's pit, located near the brain. Hatschek's pit appears to be related to the neural gland and hence to the vertebrate pituitary gland. Treatment of amphioxus with GnRH or luteinizing hormone (LH) reportedly stimulates the onset of spermatogenesis in male gonads. Furthermore, extracts prepared from Hatschek's pit can stimulate the testis of a toad. Amphioxus has a mucus-secreting endostyle like that of the ascidians. and studies have shown that the cephalochordate endostyle can synthesize thyroid hormones, too. Thus, the basic organization of the vertebrate endocrine system appears to show its early beginnings in the simple organs of these invertebrate chordates. (D.O.N.)

Hatschek's pit

The human endocrine system

GENERAL ASPECTS

Integrative functions. The endocrine systems of humans and other animals serve an essential integrative function. Inevitably, humans are beset by a variety of insults, such as trauma, infection, tumour formation, genetic defects, and emotional damage. The endocrine glands play a key role in responding to these stressful stimuli. Less obvious are the effects of subtle changes in the concentrations of key elements of the body's fluids on the storage and expenditure of energy and the steady and timely growth and development of a normal human being. These more subtle changes largely result from the monitoring by and the response, sometimes minute by minute, of the endocrine system.

The menstrual cycle in the normal, mature female and the reproductive process in males and females are under endocrine control. Beyond this, lactation and probably some forms of parental behaviour are strongly influenced by endocrine secretions. The endocrine system works in concert with the nervous and the immune systems to permit the orderly progression of human life, and these systems provide the body's bulwark against threats to health and life.

Control of endocrine system

Anatomical considerations. There are some characteristics shared by all endocrine glands. Some glands, for example the thyroid gland, are discrete, readily recognized organs with defined borders that are easily separable from adjacent structures. Others are embedded in other structures (for example, the islets of Langerhans are found in the pancreas) and may be clearly seen only under the microscope. The boundaries of endocrinology, however, have yet to be sharply defined, and endocrine tissue has been identified in surprising locations, such as the heart. Under the microscope, endocrine cells appear to be rather homogeneous, usually cuboidal in shape, with a rich supply of small blood vessels. Sometimes, as is the case in the thyroid gland, endocrine cells are intermixed with other, distinctly different endocrine cells with a different embryological origin and an entirely different set of hormonal secretions. Finally, all nerve cells are capable of secreting neurotransmitters into the synapses between adjacent nerves, although some nerve cells, for example those of the neurohypophysis (posterior pituitary gland), also secrete neurohormones directly into the bloodstream.

Endocrine glands with mixed cell populations have not evolved by chance. The hormonal secretions of one set may modulate directly the activity of adjacent cells with different characteristics. This direct action on contiguous cells of different types, which diffuses the hormone to tar-

Paracrine function

get cells without moving it through the general circulation, is known as paracrine function. Even in homogeneous glandular tissues (*i.e.,* tissues comprising one cell type), the direct proximity of the cells in some way enhances the amount of hormonal secretions since isolated cells are less vigorous in their activity, under laboratory conditions, than are sheets of attached cells, a phenomenon known as autocrine function. On the other hand, hormonal secretions themselves inhibit further hormonal secretion if they remain in the vicinity of the parent cell.

When viewed under the ultramicroscope (a microscope of extraordinary magnifying power), the endocrine cell has the fine structure that is illustrated in Figure 8. Many of the various intracellular structures, called organelles, are involved in the sequence of events that occurs during the synthesis and secretion of hormones.

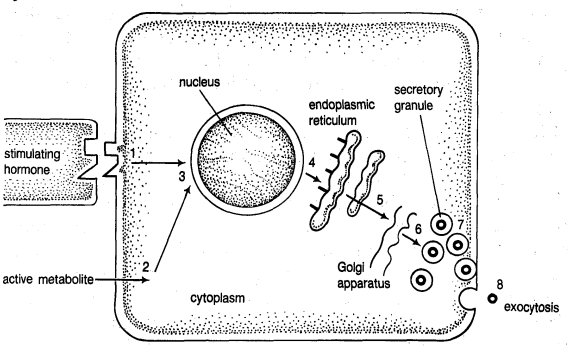

Figure 8: Intracellular structure of a typical endocrine cell.

Hormone synthesis. In the case of protein hormone synthesis, the target cell is stimulated at the cell surface (1 and 2) either by contact of a surface receptor with a stimulating hormone or by the entrance of a stimulating metabolite, such as glucose entering an insulin-producing beta cell. (It is important to note that there are also hormones and metabolites that lead to the inhibition of cell activity, but these are not discussed here.) Stimulation of the receptor at the cell surface is followed by a series of complex events within the cell membrane itself as well as within the cytoplasm of the cell. These events lead to the stimulation of DNA within the nucleus of the cell (3) to synthesize mRNA (messenger ribonucleic acid), which directs the synthesis of protein or steroid hormones.

Synthesis of mRNA

The mRNA unit contains the genetic code for the new protein. When mRNA leaves the nucleus and associates with the endoplasmic reticulum (4) in the cytoplasm, it directs the synthesis of a relatively inert precursor to the hormone, called a prohormone, from free amino acids available within the cytoplasm. The prohormone is sent to another cell organelle (5), the Golgi apparatus, where it is packaged into vesicles known as secretory granules (6). The granules migrate to the cell surface (7), and through a process known as exocytosis (8) the active hormone splits from the prohormone and is discharged through the cell wall.

In the case of steroid hormones, the precursor of all steroid hormones, cholesterol, is stored in vesicles within the cytoplasm. Through the actions of enzymes at various steps along the synthetic pathway, cholesterol is broken down and converted into steroid hormones.

Cholesterol is converted into pregnenolone in the first step of steroid biosynthesis. This action is the result of the cleaving enzyme that has been stimulated into action by corticotropin (ACTH) or angiotensin (which stimulate the adrenals), or the gonadotropins (hormones, such as LH and FSH, that stimulate the gonads). Pregnenolone is transported out of the mitochondria (where this initial step took place) to the endoplasmic reticulum (4), where it undergoes further enzymatic degradation to progesterone. At this point depending on the tissues in which the synthesis took place, progesterone is converted to the sex hormones (androgens and estrogens) or to the corticoids, mineralocorticoids, or adrenal androgens (steroid hormones of the adrenal cortex).

Regulatory mechanisms. Hormonal levels in the circulating body fluids vary in response to stimulatory or inhibitory influences acting on the hormone-producing cell. In the normal individual examined in a resting state, all circulating hormonal levels will be found to lie within a narrow normal range. Constant monitoring of hormonal supply to the tissues is essential to health, since sustained, inappropriate elevations or depressions of these levels will lead, in most instances, to disease states. Furthermore, since hormones are constantly being inactivated by tissue enzymes, the supply of hormones must be replenished regularly within the cell by synthesis and secretion.

Control of hormonal levels

The control of hormonal levels is maintained by a number of feedback devices. For target organs such as the thyroid, adrenal glands, and gonads, which also serve as endocrine glands, the hypothalamic-pituitary-target organ axis serves admirably. Other more direct feedback mechanisms, however, also operate (see Figure 2), for example, the stimulatory effect of low serum calcium levels on parathyroid glands and the stimulatory effect of elevated blood glucose levels on the beta cells of the islets of Langerhans. In another method of hormonal regulation, the metabolism of hormones after their secretion may either intensify or decrease hormonal action; for example, thyroxine may be converted in a number of tissues to triiodothyronine (T_3), a change that enhances hormonal potency by 2½ times. Alternatively, T_4 may be converted to an inactive isomer (a molecule with the same atoms but with small, biologically important differences in structure) of T_3 (reverse T_3). Finally, local effects may significantly modulate endocrine cell activity. For most endocrine cells, if the secreted hormone remains in the immediate vicinity of the cell, further synthesis of the hormone is strongly inhibited. This effect supplements the autocrine and paracrine effects on adjacent cells of a tissue.

Modes of transport. Most hormones are secreted into the general circulation to exert their effects on appropriate distant target tissues. There are important exceptions, however, in the case of self-contained portal circulations in which blood is directed to specific areas. A portal circulation begins in a capillary bed, forms into a set of veins, and then is dispersed into a second capillary bed. Thus, blood collected from the first capillary bed is directed solely into the tissues nourished by the second capillary bed.

Two portal systems

Two such portal circulations are present in the human body. One system, the hypothalamic-hypophyseal portal circulation, collects blood from capillaries originating in the hypothalamus and, through a plexus of veins surrounding the pituitary stalk, directs the blood into the substance of the anterior pituitary. In this instance, hormones secreted by the neuroendocrine cells of the hypothalamus are transported directly, via this circulatory system, to modulate the activity of the endocrine cells of the anterior pituitary. These hormones are largely, but not entirely, excluded from the general circulation. In a second system, the hepatic portal system, capillaries originating in the gastrointestinal tract and the spleen are transported through veins by way of the hepatic vein into the liver and again dispersed into hepatic capillaries. In this way hormones from the pancreatic islets of Langerhans, such as insulin and glucagon, are directed into the substance of the liver in high concentration before being distributed through the general circulation.

Carrier proteins

A further refinement in hormone transport is provided by circulating carrier proteins. These substances, manufactured and secreted by the liver, provide sites to which steroid and thyroid hormones are bound. Carrier proteins include the binding globulins that bind sex hormones from the gonads, and transcortin, to which hormones from the adrenal cortex are bound. In addition, there are two sets of proteins, the prealbumins and the thyroxine-binding globulins, which transport the thyroid hormones, T_4 and T_3. Furthermore, there is evidence that other protein hormones, such as growth hormone, also are bound to specific transport proteins. Indeed, it is the rule that important biologic substances are bound to specific carrier proteins as they course through the circulation.

Protein-bound hormones are in equilibrium with a much smaller concentration of free circulating hormones. As a free hormone leaves the circulation to exert its action on a tissue, an equal amount of hormone is immediately freed

from its binding protein. Thus, the carrier proteins serve as a depot within the bloodstream to maintain a normal concentration of the biologically important free hormone. A final refinement of this system is that the concentration of carrier proteins is similarly hormone-dependent. Estrogens are known to increase the secretion and concentration of essentially all carrier proteins, while androgens generally have an opposite effect.

The affinity of hormones for these binding proteins is not constant. The thyroid hormone T_4, for example, is far more tightly bound than is the hormone T_3, with the result that T_3 is more readily released as a free molecule and has easier access to tissues. Similarly, some drugs, such as phenytoin (Dilantin), have a molecular configuration that permits them to compete with thyroxine for binding to thyroxine-binding globulin. When present in high concentrations, such a drug may successfully displace the level of bound hormones in the blood.

Biorhythms. Some hormones, for example insulin, are secreted in brief spurts every few minutes. Presumably, the time between spurts is a reflection of the lag time necessary for the insulin-secreting cell to sense a change in blood sugar concentration. Other hormones, particularly those of the pituitary, are secreted in pulses that may occur at roughly hourly intervals. Apparently, pulsated secretion is a necessary requirement for pituitary gonadotropin secretion. When stimulated at about 80-minute intervals by the injection of a hypothalamic gonadotropin-releasing hormone (GnRH), pituitary gonadotropin secretion increases incrementally to high levels. If, however, gonadotrophs are subjected to a continuous, nonpulsatile injection of GnRH, gonadotropin secretion is completely inhibited.

Circadian rhythms

Superimposed on these pulsatile secretions are, for many hormones, changes in hormonal levels that occur at roughly 24-hour intervals. These periodic changes are called circadian rhythms. An example is shown in Figure 9, which illustrates the circadian changes in the blood concentration of cortisol, the major steroid hormone secreted by the adrenal cortex. Low levels occur during sleep, with a rapid rise in the early morning hours, followed by a graduated descent during the day, with intermediate elevations during meal times. This particular rhythm is dependent on night-day cycles and persists for some days after jet-plane travel into different time zones. The transitional period is reflected in the well-known phenomenon of jet lag. Other hormones follow other circadian rhythms. Pituitary growth hormone, prolactin, and the gonadotropins rise to their highest diurnal (daily) levels shortly after the onset of sleep and, in the case of gonadotropins, this sleep-related elevation is the first biochemical sign of the onset of puberty.

From E.D. Weitzman *et al.*, "Twenty-four-hour Patterns of the Episodic Secretion of Cortisol in Normal Subjects," *Journal of Clinical Endocrinology and Metabolism*, vol. 33, pp. 13–22, © by The Endocrine Society, 1971

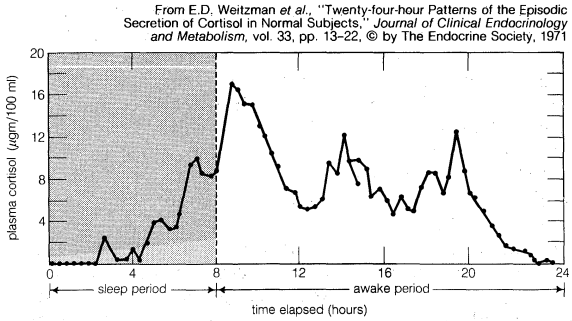

Figure 9: Circadian rhythm, a graphic depiction of cortisol values over a 24-hour period.

Monthly biorhythms are reflected in women in the menstrual cycle. Less obvious are seasonal cycles that occur in the secretion of thyroid hormones and testosterone. Finally, puberty itself is a complex, timed phenomenon that is thought to be associated with a reduction in secretion of melatonin, a hormone secreted by the pineal gland. This gland serves a regulatory function for many of the biorhythms, particularly those related to gonadal function.

ENDOCRINE DYSFUNCTION

Endocrine hypofunction and receptor defects. There are occasions when the body is best served by reducing the amount of hormone secreted by an endocrine gland (hypofunction). For example, the secretion of thyroid hormones decreases with protracted fasting. Because the thyroid hormones control energy expenditure, there is survival value in slowing the body's metabolism when there is no intake of food. Thus, there is a distinction between compensatory endocrine hypofunction and true endocrine dysfunction. Only those forms of hypofunction that reflect disease states are discussed in general terms below. Detailed descriptions of specific endocrine deficiency states are given in later sections devoted to each of the individual endocrine organs.

Destruction of endocrine cells

Endocrine glands may be destroyed in a variety of ways, but complete destruction is difficult. For most endocrine organs, at least 90 percent of the gland must be destroyed before a significant illness occurs. In the case of paired endocrine organs (parathyroids, adrenal glands, and the gonads) the removal of one of the pair is followed by a prompt compensatory increase in the activity of the remaining gland, so that an affected individual continues in good health.

Physical trauma (including surgical trauma and severe hemorrhage within the gland substance) may destroy any endocrine gland. Similarly, an invasion, known as infiltration, by cancer cells, inflammatory cells, large amounts of metal such as iron or copper, or by an abnormal protein, such as amyloid, may also seriously impair endocrine function. Bacterial infections (such as tuberculosis) and viral infections (such as mumps) also may lead to endocrine deficiencies. Although radiation damage from either X rays or radioactive elements is a well-recognized cause of hormonal deficiencies, both avenues have been adapted as forms of treatment when the problem is endocrine hyperfunction (excessive secretion by an endocrine gland).

Autoimmunity

Last, and perhaps most important, there is a growing understanding of an extraordinary phenomenon, known as autoimmunity, as a cause of endocrine deficiency. Certain antibodies generated by the body against its own tissues (see IMMUNITY), have been found to be active against certain endocrine tissues. Thus, not only are specific antibodies formed against specific endocrine glands, but there are also antibodies that affect specific aspects of endocrine function. For instance, in the case of the thyroid there are cytotoxic antibodies that eventually destroy the gland by attacking the cells; there are blocking antibodies that can, in effect, inactivate thyroid cell surface receptors and cause hypothyroidism; and there are stimulatory antibodies, which are a major cause of hyperthyroidism.

Constant exposure of an endocrine gland to blocking antibodies results in a reduction in its cell size and number, a condition known as atrophy. If long-lasting, atrophy may lead to irreversible destruction of the gland. Another cause of atrophy is a receptor defect that results when autoantibodies exert their actions against endocrine surface cell receptors. This kind of receptor damage has been found in females with premature ovarian failure associated with menopause, which can occur as early as the teenage years. It remains debatable whether a natural menopause is an example of hypofunction of the ovary, which should be viewed as pathological, or whether it represents another example of compensatory hypofunction with "survival value."

Endocrine atrophy is also associated with a number of forms of developmental failure, such as chromosomal abnormalities. For example, in Turner's syndrome, the Y chromosome of the two sex chromosomes, X and Y, is missing, resulting in the body configuration and orientation of a female despite the absence of functioning ovarian tissue. Another example is Klinefelter's syndrome, in which an extra X chromosome is added to the normal male complement of an X and a Y chromosome, leading to the development of an individual who appears as a feminized male and has some features of male hormone deficiency.

Secondary endocrine hypofunction

Secondary endocrine hypofunction is another distinct category of endocrine dysfunction, in which the gland is basically intact but lies dormant because it is either not stimulated or is directly inhibited. An important characteristic of this form of deficiency is that it is reversible, re-

turning to normal with the removal of the inhibiting agent. Secondary endocrine hypofunction results, for example, from the loss of a stimulating (tropic) hormone when the pituitary gland is completely destroyed. The loss of thyrotropin, corticotropin, and gonadotropins leads to hypofunction of the thyroid, adrenal, and gonads. Endocrine hypofunction may also occur as a result of exposure to excessive amounts of a hormone. In a patient taking large amounts of thyroid hormone the secretion of the thyroid-stimulating hormone thyrotropin by the anterior pituitary gland (see above *The nature of endocrine regulation*) will be inhibited, a change that puts the thyroid gland to rest.

Changes in the biochemical environment of the thyroid gland may also lead to a reduction in function. A well-known example is that of hypothyroidism due to iodine deficiency. Since iodine is an integral part of the thyroid hormone molecule, iodine deficiency leading to cretinism is common in those areas of the world in which salt contains little or no iodine. Drugs may also lead to a functional endocrine deficiency; such is the case in patients with manic-depressive psychosis treated with lithium, a drug that blocks thyroid gland activity. Finally, an excess of one hormone may lead to a deficiency of another. For example, overproduction of a pituitary hormone, prolactin, results in a secondary suppression of gonadal function, leading to amenorrhea in females and impotence in males. These changes are readily reversed when the level of prolactin in the bloodstream is returned to normal.

Iodine deficiency

Hormonal deficiency states can also occur from defective hormonal action on target organs. This concept was first proposed by an American clinical endocrinologist, Fuller Albright, and his associates in 1942. They studied a young woman who manifested all of the signs of deficiency of parathyroid hormone (PTH) but who, unlike the usual such patient, did not show any improvement after the injection of an extract of parathyroid gland. Albright termed this variant pseudohypoparathyroidism and postulated that "the disturbance is not a lack of PTH but an inability to respond to it." Direct evidence supporting this suggestion emerged only decades later, and other examples of unresponsiveness of target tissues to hormones have been documented. Thus, for example, an absence of receptors for male hormones makes individuals who are in genetic terms outwardly male appear to be female. Some diabetics do not respond to large quantities of insulin because they lack effective receptors in target cells for binding insulin. More common is resistance to insulin in diabetics due to the appearance of anti-insulin antibodies following insulin injections. Other antihormone antibodies may appear spontaneously and provoke endocrine deficiencies. Finally, there are rare instances in which hormone synthesis is abnormal so that the hormone secreted is chemically defective enough to impair its action on target tissues.

It should be noted that endocrine deficiencies may result from transmission of harmful materials from a mother to her fetus by way of the placenta. Toxic agents include autoantibodies and drugs, both of which cross the placenta readily and may damage the fetus even though, on occasion, the mother may remain unaffected.

The aging process

Because in many countries larger proportions of the populations are aging, an intensive search for the causes of aging processes has been instituted. An early popular theory was that aging resulted from multiple endocrine deficiencies. This idea has been discarded by most investigators. The only documented endocrine failure associated with age is the loss of ovarian hormones at the time of, and subsequent to, the menopause. Even here, however, the ovary continues to produce reduced amounts of estrogens. In general, endocrine function is highly variable in the aged. For most glands there is either no change or a modest reduction in endocrine secretions, but in the case of the pituitary gonadotropins, progressive gonad failure associated with aging results in pituitary hypersecretion (excessive secretion). Whether the changes observed have survival value is not known.

Endocrine hyperfunction. With excessive stimulation from any of a variety of causes, endocrine glands may become overactive, resulting in hypertrophy (increase in size of each cell) and hyperplasia (increase in cell numbers). The result is that the gland becomes enlarged. With continued stimulation, some undefined barrier is breached, and the hyperplastic glands undergo a transformation and begin uncontrolled multiplication of abnormal cells, termed neoplastic (tumorous). Because endocrine neoplasms are largely autonomous, they are far less sensitive to any inhibition of their hormonal secretions through negative feedback control. The result is that benign endocrine neoplasms (adenomas) persistently secrete excess hormone. Continued hyperstimulation causes some adenomas to undergo an additional change to a truly malignant neoplasm (a carcinoma), which is not only hyperfunctional but also is capable of invading adjacent structures and metastasizing (transferring) to distant organs, with the threat of causing death. Sometimes tumours of several endocrine glands occur simultaneously (see below *Ectopic hormone and polyglandular disorders*), which has been described as a syndrome (constellation of symptoms) called hereditary multiple endocrine neoplasia. It should also be noted, however, that many endocrine neoplasms produce no hormones whatsoever.

Neoplasms

Excess hormone secretion and the resultant symptoms may be produced by endocrine hyperplasia alone. One example of this occurs when a circulating autoantibody binds to receptors in the thyroid gland and causes the hypersecreting, hyperplastic thyroid typical of Graves' disease. Other syndromes of endocrine hyperfunction may result when a small endocrine tumour, innocuous in itself, secretes excessive amounts of a stimulatory hormone, which then provokes a secondary hyperplasia of a target gland. The classic instance is Cushing's disease, in which a small pituitary tumour produces excess quantities of adrenocorticotropin (ACTH) and leads to hyperplasia of both adrenal glands. The result is oversecretion of the hormones of the adrenal cortex, with striking consequences. A rare example of adenoma formation resulting from unremitting stimulation is found in patients with long-standing thyroid hormone deficiency. Through negative feedback mechanisms, the pituitary cells that secrete thyroid-stimulating hormone (TSH) become hyperplastic and eventually are transformed into TSH-producing adenomas of the pituitary.

Cushing's disease

Some endocrine tumours not only produce excess quantities of the expected hormone but also excess amounts of a hormone that is normally secreted by an entirely different endocrine gland. Thus, a medullary carcinoma of the thyroid originates from cells that normally produce calcitonin, a hormone which acts to lower the concentration of calcium in the blood. This tumour may hypersecrete not only calcitonin but also ACTH, normally a secretory product of cells of the pituitary gland. In addition, tumours arising from tissues that ordinarily have no endocrine function may secrete one or more hormones. A typical example is that of a cancer of the lung, which may produce one or more of an array of hormones, most commonly antidiuretic hormone. Such neoplasms are called ectopic (displaced) hormone-producing tumours.

The source of stimulation of hyperplastic glands is often known, as in the case of the parathyroid hyperplasia that follows persistently low levels of serum calcium in patients with severe kidney disease. In other instances, however, no cause has been identified; in these cases, the cause is said to be idiopathic. An example of idiopathic hyperplasia is the increase in the number of insulin-producing beta cells in the islets of Langerhans, which produces severe brain-damaging hypoglycemia (lowering of the blood sugar) in infants.

Some hormones exert their regulatory actions through an agonist/antagonist relationship to tropic hormones and receptor sites of the target cell. An agonist is a substance (for example, a hormone or a drug) that binds with specific receptors on target cells and elicits a response. An antagonist (also a hormone or drug) is a substance with a molecular structure similar enough to that of the agonist to compete with it and bind to the same specific receptors, although, once bound, it does not elicit a response. The actions of the antagonist hormone may modify the hypersecretion of the agonist hormone by binding with some of the available receptor sites, and the loss of an antagonist may

Agonists and antagonists

lead to effective hyperfunction of the agonist. An example is a person who has a deficiency of the adrenal cortex, which produces hormones that are sharply antagonistic to the action of insulin. When fasting or when injected with only a small amount of insulin, such individuals suffer the effects of severe hypoglycemia.

The general aspects of the human endocrine system discussed above may now be applied specifically in the more detailed discussion of individual endocrine glands.

THE HYPOTHALAMUS

Anatomy. The hypothalamus is an integral part of the substance of the brain. A small cone-shaped structure, it projects downward, ending in the pituitary (infundibular) stalk, a tubular connection to the pituitary gland. Figure 10 shows the relationship of these small structures in a lateral midline projection of the human head using the technique of magnetic resonance imaging. The round bony cavity containing the pituitary gland is called the sella turcica. The posterior portion of the hypothalamus, called the median eminence, contains many neurosecretory cells. Important adjacent structures include the mamillary bodies, the third ventricle, and the optic chiasm, the last being of particular concern to physicians because pressure from expanding tumours or inflammations in the hypothalamus or pituitary gland may result in severe visual defects or total blindness. Above the hypothalamus is the thalamus. (For discussion of the function of these surrounding structures, see NERVES AND NERVOUS SYSTEMS.)

Location

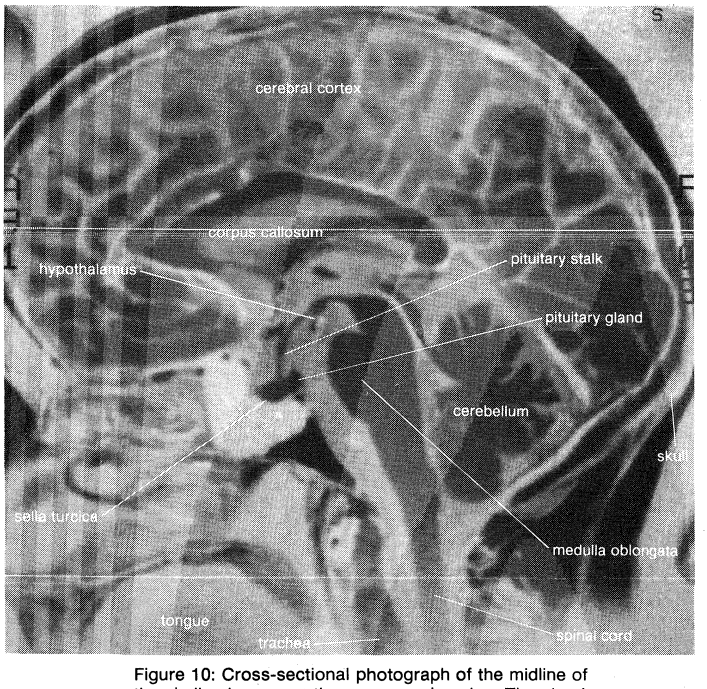

Figure 10: Cross-sectional photograph of the midline of the skull using magnetic resonance imaging. The glands within the brain and their physical interrelationships are illustrated (see text).

Regulation of hormone secretion. The hypothalamus, like the rest of the brain, consists of interconnecting nerve cells (neurons) with a rich blood supply. To understand hypothalamic function it is necessary to define the various forms of neurosecretion. First, there is neurotransmission, which occurs throughout the brain and is the process by which one nerve cell communicates with another at an intimate intermingling of projections from the two cells (a synapse). This transmission of an electrical impulse from one cell to another requires the secretion of a chemical substance from a long projection from one nerve cell body (the axon) into the synaptic space. The chemical substance that is secreted is called a neurotransmitter. The process of synthesis and secretion of neurotransmitters is similar to that shown in Figure 8 with the exception that neurosecretory granules migrate through lengths of the axon before being discharged into the synaptic space.

Classical neurotransmitters

Neurologists have long been aware of four classical neurotransmitters: epinephrine, norepinephrine, serotonin, and acetylcholine, but recently there have emerged a large number of additional neurotransmitters, of which an important group is the neuropeptides. While bioamines and neuropeptides function as neurotransmitters, some of them also perform the role of neuromodulators; they do not act directly as neurotransmitters but rather as inhibitors or stimulators of neurotransmission. Well-known examples are the opioids (for example, enkephalins), so named because they are the naturally occurring peptides with a strong affinity to the receptors that bind opiate drugs such as morphine and heroin. In effect, they are the body's opiates.

Thus the brain, and indeed the entire central nervous system, consists of an extraordinary network of neurons interconnected by neurotransmitters. The secretion of specific neurotransmitters, modified by neuromodulators, lends an organized, directed function to the overall system. These neural connections extend upward from the hypothalamus into other key areas, including the cerebral cortex. The result is that intellectual and functional activities as well as external influences, including stresses, can be funneled into the hypothalamus and thence to the endocrine system, from which they may exert effects on the body.

Neurohormones

In addition to secreting neurotransmitters and neuromodulators, the hypothalamus synthesizes and secretes a number of neurohormones. The neurons secreting neurohormones are true endocrine (neurohemal) cells in the classical sense since secretory granules containing neurohormones travel from the cell body through the axon to be extruded, where they enter directly a capillary network, thence to be transported through the hypophyseal-portal circulation to the anterior pituitary gland.

Finally, the neurohypophysis, or posterior lobe of the pituitary gland, provides the classical example of neurohormonal activity. The secretory products, mainly vasopressin and oxytocin, are extruded into a capillary network, which feeds directly into the general circulation.

The existence of hormones of the hypothalamus was predicted well before they were detected and chemically characterized, and they have been studied intensively by many investigators. Two groups of American investigators, led by Andrew Schally and Roger Guillemin, respectively, shared the Nobel Prize for Physiology or Medicine for 1977 for their research on pituitary hormones.

Releasing hormones

These neurohormones are known as releasing hormones because the major function generally is to stimulate the secretion of hormones originating in the anterior pituitary gland. They consist of simple peptides (chains of amino acids) ranging in size from only three amino acids (thyrotropin-releasing hormone) to 44 amino acids (growth hormone-releasing hormone).

Hormones. *Thyrotropin-releasing hormone.* Thyrotropin-releasing hormone (TRH), a neurohormone, is the simplest of the hypothalamic neuropeptides. It consists essentially of three amino acids in the sequence glutamic acid–histidine–proline. The simplicity of this structure is deceiving for TRH is involved in an extraordinary array of functions. Not only is it a neurohormone that stimulates the secretion of thyroid-stimulating hormone from the pituitary, and, quite independently, the secretion of another pituitary hormone called prolactin, but it also subserves other central nervous system activities because it is a widespread neurotransmitter or neuromodulator within the brain and spinal cord. There is evidence that TRH is involved in the control of body temperature and that it has psychological and behavioral effects, at least in animals. It may also have therapeutic value. There are studies suggesting that it mitigates the damage induced by spinal cord injury and that it leads to some improvement in the nervous disease known as amyotrophic lateral sclerosis (Lou Gehrig's disease).

These multiple effects are less surprising when it is considered that TRH appeared very early in the evolutionary scale of vertebrates and that, while the concentration of TRH is greatest in the hypothalamus, the total amount of TRH in the remainder of the brain far exceeds that of

the hypothalamus. The TRH-secreting cells are subject to stimulatory and inhibitory influences from higher centres in the brain and they also are inhibited by circulating thyroid hormone. In this way TRH forms the topmost segment of the hypothalamic-pituitary-thyroid axis.

Gonadotropin-releasing hormone. Gonadotropin-releasing hormone (GnRH), a neurohormone also known as luteinizing hormone-releasing hormone (LHRH), is a peptide chain of 10 amino acids. It stimulates the synthesis and release of the two pituitary gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH). While some investigators hold that there are two types of GnRH, most evidence supports the conclusion that only one type of neuropeptide stimulates the release of the two gonadotropins and that the variations in levels of both gonadotropins in the circulation are due to other modulating factors.

GnRH effects

Characteristic of all releasing hormones and most striking in the case of GnRH is the phenomenon of pulsatile secretion. In normal individuals, GnRH is released in spurts at intervals of about 80 minutes. The pulsatile administration of GnRH in large doses results in an ever-increasing concentration of gonadotropins in the blood. In striking contrast, the constant infusion of GnRH suppresses gonadotropin secretion. This phenomenon is advantageous for persons for whom suppression is important. Such persons include children with precocious puberty, and elderly men with cancer of the prostate. On the other hand, pulsatile administration of GnRH is efficacious in men or women in whom deficiency of gonadal function is due to impaired secretion of GnRH. A potential application of this phenomenon is the synthetic modifications of GnRH as a male as well as a female contraceptive.

Limbic system

Neurons that secrete GnRH have connections to an area of the brain known as the limbic system, which is heavily involved in the control of emotions and sexual activity. Studies in rats deprived of pituitary glands and ovaries but maintained on physiological amounts of female hormone (estrogen) have demonstrated that the injection of GnRH results in complex and striking changes in posture characteristic of the receptive female stance for sexual intercourse.

Some individuals have hypogonadism (in which the functional activity of the gonads is decreased and sexual development is inhibited) due to a congenital deficiency of GnRH, which responds to treatment with GnRH. Most of these people also suffer from hypothalamic disease and are deficient in other releasing hormones as well, but there are also individuals in whom GnRH deficiency is isolated and associated with a loss of the sense of smell (anosmia). Abnormalities in the pulses of GnRH secretion result in subnormal fertility, abnormal or absent menstruation, and possibly cystic disease of the ovary or even ovarian cancer.

Corticotropin-releasing hormone. Corticotropin-releasing hormone (CRH), a neurohormone, is a large peptide consisting of a single chain of 41 amino acids. It stimulates not only secretion of corticotropin in the pituitary gland but also the synthesis of corticotropin in the corticotropin-producing cells (corticotrophs) of the anterior lobe of the pituitary gland. Many factors, both neurogenic and hormonal, regulate the secretion of CRH, since CRH is the final common element directing the body's response to all forms of stress, whether physical or emotional, external or internal. (This key role of CRH in the hypothalamic-pituitary-adrenal axis is discussed below in connection with the adrenal gland.) Among the hormones that play an important role in modulating the influence of CRH is cortisol, the major hormone secreted by the adrenal cortex, which, as part of the negative feedback servomechanism (exerting control over another system through negative feedback), blocks the secretion of CRH. Vasopressin, the major regulator of the body's excretion of water, has an additional ancillary role in stimulating the secretion of CRH.

Cortisol

Excessive secretion of CRH leads to an increase in the size and number of corticotrophs in the pituitary gland, often resulting in a pituitary tumour. This, in turn, leads to excessive stimulation of the adrenal cortex, resulting in high circulating levels of adrenocortical hormones, the clinical manifestations of which are known as Cushing's syndrome. Conversely, a deficiency of CRH-producing cells can, by a lack of stimulation of the pituitary and adrenal cortical cells, result in adrenocortical deficiency. (These conditions are discussed below.)

Growth hormone-releasing hormone. Like CRH, growth hormone-releasing hormone (GHRH) is a large peptide. A number of forms have been described that differ from one another only in minor detail and in the number of amino acids (varying from 37 to 44). Unlike the other neurohormones, GHRH is not widely distributed in other parts of the brain. It is stimulated by stresses, including physical exercise, and secretion is blocked by a powerful inhibitor called somatostatin (see below *Somatostatin*). Negative feedback control of GHRH secretion is mediated largely through compounds called somatomedins, growth-promoting hormones that are generated when tissues are exposed to growth hormone itself.

Acromegaly

An excess of circulating growth hormone in adults leads to a condition called acromegaly. Rarely, a benign tumour, called a hamartoma, located in the hypothalamus may produce excessive amounts of GHRH, leading to acromegaly. Equally rare are tumours arising in the islets of Langerhans of the pancreas that may secrete excessive quantities of GHRH. Indeed, GHRH was first successfully isolated and analyzed from such an ectopic (abnormally positioned) hormone-producing tumour. Isolated deficiency of GHRH (in which there is normal functioning of the hypothalamus except for this deficiency) may be the cause of one form of dwarfism, a general term applied to all individuals with abnormally small stature.

Somatostatin. Somatostatin refers to a number of polypeptides consisting of chains of 14 to 28 amino acids. The name was coined when its discoverers found that an extract of the hypothalamus strongly inhibited the release of growth hormone from the pituitary gland. Somatostatin is also a powerful inhibitor of pituitary TSH secretion. Somatostatin, like TRH, is widely distributed in the central nervous system and in other tissues. It serves an important paracrine function in the islets of Langerhans, by blocking the secretion of both insulin and glucagon from adjacent cells. Somatostatin has emerged not only as a powerful blocker of the secretion of GH, insulin, glucagon, and other hormones but also as a potent inhibitor of many functions of the gastrointestinal tract, including the secretion of stomach acid, the secretion of pancreatic enzymes, and the process of intestinal absorption. Despite these multiple, widespread actions, the term somatostatin has persisted because of its major role as a regulator of GH secretion, and impaired somatostatin secretion may cause some forms of hypersecretion of growth hormone.

No examples of somatostatin deficiency have been found, but a tumour called a somatostatinoma has been well characterized in a number of patients. Persons with a somatostatinoma have cramping abdominal pain, persistent diarrhea, a mild elevation of blood glucose levels, and sudden flushing of the skin.

Prolactin-inhibiting and -releasing hormones. The hypothalamic regulation of prolactin secretion from the pituitary is different from the hypothalamic regulation of other pituitary hormones in two respects. First, the hypothalamus primarily inhibits rather than stimulates the release of prolactin from the pituitary (the hypothalamus stimulates the release of all other pituitary hormones). Thus, if pituitary cells are removed from the influence of the hypothalamus, few or none of the pituitary hormones are secreted, except for prolactin, which continues to be secreted by the prolactin-secreting cells (lactotrophs). Second, this major inhibiting factor is not a neuropeptide, but rather the neurotransmitter dopamine, a fact exploited in afflicted persons by physicians who are able to reduce abnormally high concentrations of prolactin by using drugs that mimic the prolactin-inhibiting effects of dopamine. Another prolactin-inhibiting factor (PRF) comes into play primarily during pregnancy and lactation. Prolactin-stimulating factors also exist, among them TRH.

Regulation of prolactin secretion

Prolactin deficiency is known to occur, but only rarely. Excessive prolactin production (hyperprolactinemia) is a common endocrine abnormality, and the prolactinoma is the most frequently encountered pituitary tumour.

Gastrointestinal neuropeptides. Although modern endocrinology began with the discovery that a substance, secretin, secreted into the blood from the cells lining the gastrointestinal tract stimulates the secretion of pancreatic juices, little attention was subsequently paid to gastrointestinal hormones. When investigators began to examine the distribution of neuropeptides within the body, however, there emerged a bewildering variety of these hormones, not only within the brain but also in the lining of the gastrointestinal tract and in other organs. The list includes glucagon, the enkephalins, secretin, cholecystokinin, gastrin, calcitonin, angiotensin, substance P, pancreatic polypeptide, neuropeptide Y (a human variant of a peptide called bombesin), delta-sleep-inducing peptide, and vasoactive intestinal peptide. The actions and interactions of these hormones both in the intestinal tract and in the brain are complex and are the subject of continuing investigations. Briefly, these peptides play important roles in the transmission and inhibition of pain stimuli, in eating and drinking behaviour, in memory and learning, in the regulation of body temperature, in the induction of sleep, and in sexual behaviour.

THE ANTERIOR PITUITARY

Anatomy. The pituitary gland lies at the base of the skull, nestled in a bony structure called the sella turcica. The gland is attached to the hypothalamus by the pituitary stalk, around and through which course the veins of the hypophyseal-portal plexus. In most species the gland is divided into three lobes: anterior, intermediate, and posterior. In humans the intermediate lobe does not exist as a distinct anatomic structure but rather remains only as dispersed cells. Despite its proximity to the anterior pituitary, the posterior lobe of the pituitary is functionally distinct and is an integral part of a separate neural structure called the neurohypophysis (see below *The posterior pituitary [neurohypophyses]: Neurohypophyseal unit*).

Pituitary lobes

The cells comprising the anterior lobe are derived embryologically from an extension of the roof of the pharynx, known as Rathke's pouch. While the cells appear to be relatively homogeneous (of the same type) under a light microscope, there are in fact five different types, each of which, except in pathological states, secretes the same hormone or hormones throughout its existence. The thyrotroph synthesizes and secretes thyrotropin (thyroid-stimulating hormone, or TSH); the gonadotroph, both LH and FSH; the corticotroph, corticotropin (also called adrenocorticotropic hormone, or ACTH); the somatotroph, somatotropin (also called growth hormone, GH); and the lactotroph, prolactin (PRL).

These hormones are proteins that consist of large polypeptide chains. Furthermore, the gonadotropins and TSH are glycoproteins in which there is linkage to carbohydrates known as polysaccharides. Each of these three hormones is composed of two glycopeptide chains; one of which, the alpha chain, is identical in all three hormones, while the other, the beta chain, differs in structure for each hormone, lending specificity for individual hormone action. As is the case in all protein hormones, hormones of the anterior pituitary are synthesized initially in the cytoplasm of the cell as larger, inactive molecules called prohormones, which are split into the active hormone molecules at the time of secretion into the circulation.

Alpha and beta chains

Hormones. *Thyrotropin.* Thyrotropin is also called thyroid-stimulating hormone (TSH). Thyrotropin-producing cells (thyrotrophs) make up about 10 percent of the anterior pituitary and are located mainly in the centre of the gland. Thyrotropin becomes attached firmly to receptors on the surface of the thyroid cells, forming thyroid follicles in the thyroid gland. Following binding, a complex train of events occurs so that preformed thyroid hormones are secreted and steps are set in motion for the synthesis of additional thyroid hormones. Thyrotropin exerts other pervasive effects. It stimulates the growth of thyroid cells and leads to increased blood flow through the gland. It also enhances the breakdown of thyroglobulin, a large thyroid-hormone-containing glycoprotein that is stored within the follicles of the thyroid gland.

The levels of thyrotropin in circulating fluids become elevated during thyroid hormone deficiency because there is no negative feedback inhibition of pituitary thyrotropin release by thyroid hormone. Elevated thyrotropin levels are found in other pathological states, including the presence of a thyrotropin-producing pituitary tumour. Low serum thyrotropin levels occur following damage to cells in the hypothalamus that produce thyrotropin-releasing hormone (TRH), following damage to the pituitary stalk, or, finally, following damage to the thyrotrophs themselves. Tests of increased sensitivity have made the measurement of thyrotropin in blood valuable in detecting subtle changes of both thyroid hyperfunction and hypofunction.

Levels of thyrotropin

Gonadotropins. Gonadotrophs, which amount to about 7 percent of all pituitary cells, secrete two hormones, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), but not in equal amount. The rate of secretion varies widely at different ages and at different times in the menstrual cycle of the female. Secretion of LH and FSH is low before puberty in both sexes. After puberty, about five times more LH than FSH is secreted. During menstrual cycles there is a dramatic rise in both hormones at the time of ovulation (see below *The ovary*), and secretion increases as much as 15-fold following menopause.

In men FSH stimulates the development of spermatozoa, in large part by acting on special cells in the testes called Sertoli cells. In women FSH stimulates the synthesis of estrogens as well as the maturation of cells lining the spherical, egg-containing structures known as the Graafian follicles. In menstruating women, there is a preovulatory surge in FSH levels in the blood. Inhibin, a hormone secreted by the Graafian follicles of the ovary and the Sertoli cells of the testis, inhibits the secretion of FSH from the pituitary gonadotroph.

In men androgens (male hormones) are secreted by specialized cells called Leydig cells, a process stimulated by LH. In women a preovulatory surge of LH is essential for rupture of the Graafian follicle so that the egg can be discharged on its journey to the uterus. The empty follicle becomes filled with other, progesterone-producing cells, transforming it into a corpus luteum.

Leydig cells

When a disease process leads to encroachment on the cells of the pituitary gland, usually the first evidence of cell failure is in the gonadotroph. Thus, disappearance of menstrual periods may be the first sign of a pituitary tumour in the female. In the male the most common symptom of gonadotropin deficiency is impotence. Isolated deficiencies of both LH and FSH do occur, but only rarely. In a male, LH deficiency alone leads to the appearance of what has been described as a "fertile eunuch"; there is sufficient FSH present to permit the maturation of spermatozoa, but because of the LH deficiency the man has, nonetheless, many of the characteristics of a castrate. Tumours also can produce an excess of LH or FSH, and pituitary tumours that secrete only the nonspecific, hormonally inactive alpha unit of glycoprotein hormones are not rare.

Corticotropin. Corticotropin, also called adrenocorticotropin hormone (ACTH), is a segment of a much larger prohormone glycoprotein molecule called pro-opiomelanocortin, which is synthesized by pituitary corticotrophs. This prohormone is split into a number of biologically active polypeptide fragments when the secretory granule is discharged from the cell. Among these hormones are corticotropin, whose major action is to stimulate growth and secretion of the cells of the adrenal cortex; alpha- and beta-melanotropin (melanocyte-stimulating hormone, MSH), which increases pigmentation of the skin; beta-lipotropin (LPH), which stimulates the release of fatty acids from adipose tissue; a small fragment of ACTH thought to improve memory; and beta-endorphin, a polypeptide that has excited a good deal of popular as well as scientific interest (see below *The adrenal cortex*).

Beta-endorphins (along with the enkephalins, which are neuromodulators) were discovered when investigators postulated that, since opiates such as morphine bind firmly to cell-surface receptors, there must exist natural substances that do likewise and have a narcotic action. The endorphins and enkephalins are known, therefore, as endogenous (self-generated) opiates or opioids. They have

Endorphins and enkephalins

powerful painkilling properties. Beta-endorphins instilled in the spinal fluid are capable of alleviating otherwise intractable pain in cancer patients. It has often been observed that severely traumatized individuals, those in battle, for example, appear to be free of pain. This phenomenon is due to the simultaneous release of beta-endorphin along with corticotropin in response to the stressful stimulus of the injury. There have also been reports of children with endorphin-producing pituitary tumours who are highly insensitive to pain. In addition, the release of endorphin or enkephalin may account for the euphoria ("high") experienced by long-distance runners. Finally, there is evidence, not fully accepted, that endogenous opioids stimulate appetite. This is seen in rats and obese persons who have a rare disease called Prader-Labhart-Willi syndrome. In these instances, the appetite is diminished after the administration of a narcotic antagonist, such as naloxone.

Hyperplasia or adenoma of corticotrophs gives rise to the constellation of symptoms called Cushing's syndrome. A deficiency of corticotropin also occurs both as part of the multiple deficiencies of panhypopituitarism and as an isolated defect. The diagnosis of corticotropin deficiency is important because afflicted persons who are also subjected to stress can succumb to severe shock. Once frequently administered in the treatment of disorders including allergic states, collagen disorders, and autoimmune diseases, corticotropin has been largely displaced by a number of synthetic variants of adrenal steroids.

Growth hormone. Somatotrophs are plentiful in the pituitary, constituting 40 percent of the gland. They are located predominantly in the lateral lobes and secrete between one and two milligrams of growth hormone (GH; also called somatotropin) per day. Growth hormone stimulates growth, not only of bone but of essentially all the tissues of the body. In biochemical terms, growth hormone simultaneously stimulates protein synthesis in tissues and enhances the breakdown of fat to provide the energy for the stimulated growth. Growth hormone is also an insulin antagonist and, in susceptible individuals, can lead to elevated sugar levels in the blood and diabetes mellitus.

Effects of GH

While GH may act on tissues directly, much of its effect is mediated by way of stimulating the liver and other tissues to manufacture and release secondary hormones, called somatomedins, which partly mimic the action of insulin. During childhood, somatomedin levels in the serum rise progressively with age, with an accelerated increase occurring at the time of the growth spurt of puberty, followed by a reduction to adult levels.

Growth hormone secretion is stimulated by growth hormone-releasing hormone (GHRH; also known as somatocrinin) and is inhibited by somatostatin. There are prominent daily fluctuations in growth hormone secretion in normal individuals, with the largest increase occurring shortly after the onset of sleep. Again, this increase is most pronounced at the time of puberty. Growth hormone levels in the serum are elevated in individuals with tumours that produce growth hormone, and its levels are unresponsive to stimulation in states of malnutrition.

There are many causes of short stature or dwarfism (see below *Growth and development*) other than deficient growth hormone secretion; for example, chromosomal abnormalities, malnutrition (including poorly controlled diabetes mellitus), thyroid deficiency, and disorders of bone formation are all examples of dwarfism with normal GH secretion. Nonetheless, growth hormone deficiency is a fairly common cause of short stature. Perhaps most frequent is GH deficiency resulting from damage to the hypothalamus and pituitary during fetal development or at birth because of trauma, lack of oxygen, or any of a number of other causes. When damage to the hypothalamus or pituitary is mild, growth hormone deficiency may be the only detectable manifestation of a disease state because the somatotrophs are the most sensitive of the pituitary cells to injury. When all of the cells of the pituitary are severely damaged or destroyed the patient is said to have panhypopituitarism (leading to diminished function of the gonads, the thyroid, and the adrenal glands).

Midgets usually suffer from one of two forms of hereditary (familial) isolated growth hormone deficiency. In some families the deficiency is the result of underproduction of GHRH, in which case growth hormone secretion may be stimulated by infusion of GHRH. In others, the problem lies in the somatotrophs themselves when they become incapable of manufacturing growth hormone. Growth hormone levels also tend to fall in some aged persons who otherwise appear to be normal.

In other forms of dwarfism, the hypothalamus and pituitary function adequately, and the abnormality lies rather in the lack of response of body tissues. A well-studied example is that of the Laron dwarf. These children suffer from a hereditary disorder characterized by the inability of growth hormone to bind to specific receptors in the body's tissues; circulating GH levels are elevated but somatomedin levels remain low because GH, unable to bind to receptors, cannot stimulate somatomedin secretion. Another example is the African Pygmy, in whom there is a resistance to the administration of GH. This is caused by an unresponsiveness to somatomedin, which suggests that there is a defect in the somatomedin receptors.

Growth hormone alone cannot generate growth without an adequate supply of food, so that in states of malnutrition dwarfism occurs in the face of a mild elevation in growth hormone concentrations in the blood.

Finally, an example of the effect of emotional and environmental factors on growth is found in the condition known as psychosocial dwarfism. Such children suffer emotional deprivation from uncaring or abusive parents. Growth hormone levels are low but return to normal along with an increased rate of growth when the children are removed to a more supportive environment, only to have the cycle repeated when the child is returned to the custody of the parents. These victims tend to be withdrawn and apathetic. They have disrupted sleep and bizarre eating and drinking habits. All of these symptoms are dramatically reversed when the child is removed to compassionate care in a hospital or foster home.

Psychosocial dwarfism

An adult GH-deficient dwarf has the body proportions of a young child. Radiographs (X-ray pictures) of growing ends of bone also show growth retardation in relation to the patient's chronological age. These changes are not apparent at birth but appear some time within the first two years of life. Puberty is often delayed, but untreated individuals may be fertile and give birth to normal children. When it appears in adults, GH deficiency produces only subtle changes, with minor decreases in strength and in the density of bones.

Growth hormone-deficient dwarfs respond dramatically to injections of human growth hormone. Supplies of GH were greatly limited in the past because the only source was GH extracted from human pituitary glands obtained at autopsies. With the availability of human GH manufactured by recombinant DNA technology using bacteria, the supply is potentially unlimited. Most treated patients achieve normal height, but in some, particularly those with the hereditary inability to synthesize growth hormone, antibodies to the injected growth hormone may block the therapeutic action. There is evidence that children with "constitutional short stature," that is, children from otherwise normal families in whom short stature is the rule in the absence of disease, may also respond to GH treatment.

Administration of human GH

Excess levels of growth hormone are most often caused by a benign tumour (adenoma) of somatotrophs of the pituitary gland. Rarely, a tumour of the lung or the pancreatic islets produces GHRH, which stimulates normal pituitary somatotrophs to excess secretion when released into the circulation. Even more rarely is there excessive, ectopic production of GH by tumour cells that do not ordinarily synthesize GH. If hypersecretion of growth hormone occurs during childhood, growth progresses at an inordinately rapid rate to extremes, 8 feet, 11 inches in the case of the "Alton Giant." Giantism is rare because such individuals usually have all of the infirmities described below for acromegaly.

The term acromegaly refers to the enlargement of the distal parts of the body; there is, in fact, progressive enlargement of the hands, feet, chin, and nose. Most other organs also become enlarged. The presence of a pituitary

tumour causes severe headaches, and the pressure of the tumour on the optic chiasm causes visual defects.

The acromegalic patient has overgrown supraorbital ridges, enlarged nasal sinuses that give a sonorous quality to the voice, an overgrown jaw, spaces between the teeth, and an enlarged tongue. The skin thickens, producing a permanently furrowed brow. The enlarged fingers are no longer tapered and become spatulated.

Because the metabolic actions of growth hormone are antagonistic to those of insulin, some acromegalic patients develop diabetes mellitus and are subject to all of its complications. Other problems include elevated blood pressure, heart disease, and progressive arthritis. Finally, because some of these tumours produce prolactin as well as growth hormone, males may have enlarged breasts, and both sexes may show abnormal lactation (milk secretion). Acromegaly can be treated with a considerable degree of success with surgery, with X-ray therapy, and with drugs such as bromocriptine or a synthetic, long-acting somatostatin.

Prolactin. On the evolutionary scale, prolactin is an ancient hormone serving multiple roles in mediating the care of progeny (it has been called the "parenting" hormone). Prolactin is a large protein molecule synthesized and secreted from cells, the lactotrophs, which compose 20 percent of the anterior pituitary gland and are located largely in the two lateral portions. Unlike other anterior pituitary cells whose activities are stimulated by hypothalamic-releasing hormones, the major modulating influence on lactotroph secretion is the inhibitory effect of the neurotransmitter dopamine, which, in the case of prolactin, functions as a hypothalamic neurohormone.

The "parenting" hormone

In the female, the major action of prolactin is to initiate and sustain lactation. In a breast-feeding mother, tactile stimulation of the nipples and breast by the suckling infant blocks the secretion of hypothalamic dopamine into the hypophyseal-portal circulation. This results in a sharp rise in serum prolactin levels followed by a prompt fall once feeding has stopped. Prolactin also inhibits secretion of GnRH from the hypothalamus and blocks the action of gonadotropins on the gonads. Thus, high prolactin levels reduce fertility in the female, protecting the lactating woman from a premature pregnancy. This protection is not absolute, however. Prolactin secretion is stimulated by estrogens and by TRH. This action of estrogens, much diminished in men, causes the level of prolactin to be relatively high in women. Finally, prolactin secretion is also stimulated by stress and exercise.

Actions of estrogens

Prolactin deficiency occurs along with the loss of other pituitary hormones in patients with panhypopituitarism from any cause. A striking example is that of Sheehan's syndrome, in which the anterior pituitary gland of the pregnant woman, for reasons poorly understood, is partly or totally destroyed during or shortly after the woman gives birth. Characteristically, in such a woman, breast milk is never produced.

Abnormally increased prolactin secretion may have many causes, including any of the many disease processes that damage the pituitary stalk (interrupting the flow of the prolactin inhibitor dopamine from passing through the hypophyseal-portal circulation to reach the lactotroph) and a number of drugs (particularly those used for the treatment of mental disease, high blood pressure, and the relief of pain). The most frequent cause of abnormally high prolactin levels is a tumour of the lactotrophs, termed a prolactinoma. In a large minority of hyperprolactinemic patients, however, no cause is discernible, and they are said to have "idiopathic hyperprolactinemia."

Prolactinomas were once thought to be quite rare. With the advent, in 1971, of a sensitive test for measuring serum prolactin, however, it became evident that hyperprolactinemia was common and that prolactinoma was the most frequently occurring pituitary tumour. It can be found usually in young adult females with abnormal lactation (galactorrhea) and disappearance of menstruation (amenorrhea), loss of sexual desire, and an inability to conceive. Prolactinomas are five times less common in men but are usually larger because the symptoms, particularly impotence, are gradual in onset.

Frequency of prolactinomas

In both sexes, symptoms attributable to the tumour mass alone, that is, headache and visual field defects, also occur. In women estrogen levels are decreased, resulting in osteoporosis. In men testosterone levels are lowered, contributing to a loss of physical strength as well as to impotence.

Initially, patients with prolactinomas were treated with X-ray therapy or neurosurgery; however, these forms of therapy largely have been replaced by the administration of potent drugs that mimic the neurotransmitter action of dopamine. These drugs promptly reduce elevated prolactin levels in all hyperprolactinemic patients, regardless of cause. In addition, individuals with prolactinoma usually demonstrate, sometimes quite strikingly, a decrease in the size of the tumour. This more conservative, pharmacological approach to treatment has been strengthened by the finding that patients with small prolactinomas may do well and exhibit no further tumour growth or increases in serum prolactin levels when left untreated.

THE POSTERIOR PITUITARY (NEUROHYPOPHYSIS)

Neurohypophyseal unit. The posterior pituitary lobe consists largely of extensions of processes (axons) from large clusters of cell bodies called nuclei (Figure 11). One pair, known as the superoptic nuclei, lies immediately above the optic tract, while the other pair, the paraventricular nuclei, lies on each side of the third ventricle of the brain. This anatomical complex forms the neurohypophyseal unit. There are neural connections upward to other centres of the brain, including a centre that modulates thirst. The two major neurohypophyseal hormones, vasopressin (also called antidiuretic hormone [ADH]) and oxytocin, synthesized in the cell body of the nuclei, descend through the long axons to be stored in secretory granules in the posterior lobe of the pituitary. Functionally, therefore, the posterior lobe is a storage and secretion site only.

Oxytocin and vasopressin. Oxytocin and vasopressin evolved from a single, primordial neurohypophyseal hormone, vasotocin, which is still present in lower vertebrates.

Evolutionary origins

After C.R. Kleeman in L.J. DeGroot *et al.* (eds.), *Endocrinology*, vol. 1, (1979); Grune and Stratton, Inc.

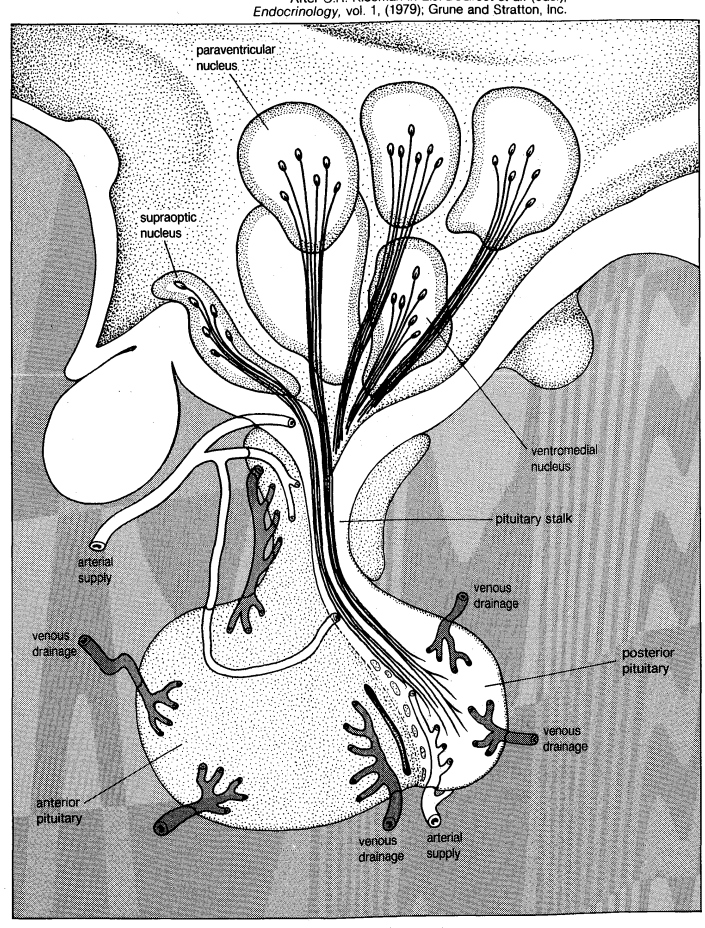

Figure 11: The neurohypophyseal unit.

Within the secretory granule, each hormone is attached to a large carrier protein, called neurophysin, from which it separates when the granule is discharged into the bloodstream. While vasopressin and oxytocin remain the major hormones synthesized by the neurohypophysis, it has become clear in recent years that other neuropeptides, including somatostatin, TRH, GnRH, CRF, and endogenous opiates are synthesized as well.

Vasopressin plays a key role in maintaining a constant total volume of water in the body and also in maintaining within narrow limits the concentration of dissolved substance (the osmolality) in those body fluids located outside body cells (extracellular water). In 1849, Claude Bernard noted that a small needle prick in the base of the brain led to a permanent, greatly increased urinary output. Following this, there ensued from the scientific community a confusing mixture of valid observations and false leads, until in the early 1930s Ernest Basil Verney showed unequivocally that the injection of a highly concentrated (hypertonic) salt solution into the carotid artery (the major artery carrying blood to the brain) resulted in a prompt increase in the excretion of urine from an animal's kidneys. This demonstrated (1) that there was a factor in the brain (vasopressin), which when let loose into the circulation enhanced water output, and (2) that this hormonal activity was stimulated by an increase in osmolality. It is now also known that vasopressin secretion increases in response to pain or stress.

Osmoreceptors

There is an osmoreceptor in the hypothalamus, which, when activated, leads to the release of vasopressin. Similarly, there exist two structures that are highly sensitive to distension and, in effect, serve as receptors for monitoring the total amount of fluid within the circulating blood: one is the carotid sinus, which is high in the neck and intimately associated with each carotid artery; and the other is a grouping of specialized cells in the left atrium of the heart. When the tissues of these structures are stretched by an expanding blood volume, nerves from these receptors carry impulses to the hypothalamus, thus inhibiting the cells of the neurohypophysis, shutting off the secretion of vasopressin, and resulting in increased urinary excretion of water.

The role of oxytocin is important, but more limited in scope. Oxytocin stimulates the contractions of the uterus, which are ongoing during the birth process; injections of oxytocin are used by obstetricians to stimulate uterine contractions in women whose labour is flagging. Oxytocin also prompts the milk glands of the mother's breast to release milk (milk let-down) within seconds after an infant begins to suckle by stimulating the contraction of muscular elements in the vicinity of the milk-containing glands.

There are no known diseases due to under- or overproduction of oxytocin. Emotional influences can affect oxytocin secretion; milk let-down may be premature, stimulated only by the cry of a hungry baby. While oxytocin is used to stimulate labour, delivery still may be normal in women in whom oxytocin deficiency is present.

Diabetes insipidus and inappropriate secretion of vasopressin. The clinical manifestations of diseases of the posterior pituitary may be considered in the context of two extremes in body water content: water intoxication (overhydration) and dehydration.

Water intoxication occurs when the body's ability to dispose of fluid is overcome by a large fluid intake or when the plasma volume percentage of water is increased because of defective mechanisms for the disposal of excess fluid, as is the case when more vasopressin is secreted than the body needs. Water intoxication from excessive fluid intake occurs rarely, having been reported in psychotic individuals, the winners of water-drinking contests, and individuals who have indulged in the overconsumption of beer (beer potomania).

A person becomes dehydrated when deprived of fluids or when there is excessive fluid loss from the body, such as occurs from excessive sweating, vomiting, or diarrhea. In these circumstances, the volume of fluid in the plasma is reduced and the concentration of solutes (the osmolality) is therefore proportionately increased. The decrease in body fluid and the proportional increase in solutes serve as potent stimuli for the secretion of vasopressin, which then acts on the kidneys to minimize urinary losses of water.

There are three disease states in which this regulatory mechanism fails. The first is termed adipsia (or hypodipsia), a rare disorder in which the brain's thirst centre is damaged. Individuals afflicted with adipsia become dehydrated, with little or no feeling of thirst. The problem can be alleviated by instructing them to drink adequate quantities of fluids at measured intervals.

Diabetes insipidus

The second disease, and by far the most common, is diabetes insipidus, so named because of the large volume of urine (which is tasteless rather than sweet as is the case in diabetes mellitus, where large quantities of the sugar glucose are present in the urine). Diabetes insipidus may be caused by trauma, including brain surgery, damage from brain tumours, or granulomatous infiltration, as in sarcoidosis, or, occasionally, for no discernible reason. Diabetes insipidus is rarely hereditary. Despite the frequency of head trauma, diabetes insipidus is an uncommon complication largely because it does not manifest itself until more than 85 percent of the neurohypophysis is destroyed.

The symptoms of diabetes insipidus include large urine volumes (usually from two to six litres each day, although up to 18 litres per day has been recorded) associated with frequent thirst and the ingestion of large quantities of water. If fluids are freely available the patient remains well except for the inconvenience of frequent drinking and of insomnia due to frequent urination. Occasionally, as a result of a patient's ongoing reluctance to urinate at frequent intervals, dilation of the kidney pelvis (hydronephrosis) and ureters (hydroureter) will occur, subsequently damaging kidney function. In the absence of a source of fluid, the patient becomes irritable and stuporous and will ultimately lapse into a coma and die. A highly satisfactory treatment is a long-acting, chemically modified form of vasopressin called desmopressin.

Nephrogenic diabetes insipidus

The third deficiency disease, a variant of diabetes insipidus, is called nephrogenic diabetes insipidus. It is a hereditary disorder linked to the X chromosome; males exhibit the disease whereas females are affected only slightly but are the sole carriers. The cause of the illness is not a deficiency of vasopressin (serum vasopressin levels may even be elevated); rather, the kidney tubules are defective and do not respond properly to the presence of vasopressin. Treatment with vasopressin or desmopressin is ineffective, but patients respond well to adequate fluid intake and a reduction in salt consumption.

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) may be acute and life-threatening, characterized by sleepiness that progresses to convulsions, coma, and death, or, more commonly, chronic, in which the onset is far slower and is associated with few or even no symptoms.

Tumours of the neurohypophysis that secrete excess amounts of vasopressin have not been observed; however, other tumours, particularly those of the lung, may secrete large amounts of vasopressin, producing SIADH. For reasons not understood, any tumour that occurs in the brain may be associated with SIADH, and the syndrome has been noted in patients who have a wide variety of lung diseases. Finally, certain drugs, particularly chlorpropamide (used in the treatment of diabetes mellitus), that augment the action of normal amounts of secreted vasopressin may produce symptoms of SIADH.

The syndrome involves a lower than normal concentration of salt in the circulating fluid. Treatment of the acute form of SIADH involves the administration of concentrated salt solutions along with a powerful diuretic, so that the concentration of solutes is increased while the total plasma volume is decreased. The chronic form is satisfactorily treated with a drug called demeclocycline.

THE THYROID GLAND

All animal life requires oxygen for sustenance, and the human species is no exception. Oxygen drives the basic metabolic processes that permit growth, development, reproduction, physical movement, and constant body temperature. The complex of chemical interactions necessary to sustain these processes is called metabolism, and the

prime, overall regulators of metabolism are the thyroid hormones.

Anatomy. The thyroid gland is located in the anterior part of the neck in the midline. It consists of two lateral lobes lying on each side of the thyroid cartilage (Adam's apple) and connected by a band of tissue called the isthmus. It is one of the larger endocrine glands, and its capacity to grow is phenomenal. Any enlargement of the thyroid, regardless of cause, is called a goitre. The thyroid arises in the embryo from a downward outpouching of the floor of the fetal pharynx, and a persisting remnant of this migration is known as a thyroglossal duct.

Goitre

If viewed under a three-dimensional microscope, the resting thyroid is seen as a collection of small, generally globular sacs, called follicles, filled with the prohormone thyroglobulin. The cells lining these globules are called follicular cells, and it is their function to synthesize thyroid hormones as part of the prohormone thyroglobulin and either to secrete them directly into the circulation or store them within the follicles. When the individual's requirement for thyroid hormone increases, thyroglobulin is split into its component parts, and the thyroid hormone thus released passes through the follicular cells to enter the circulation. Nestled in the spaces between the follicles are parafollicular cells. These, in essence, form a separate endocrine organ. They have an entirely distinct embryological origin, and they are not embedded in the substance of the thyroid gland, in many species other than man (see below *The parathyroid glands: Calcitonin*).

Biochemistry. The thyroid hormones are not proteins; rather, they are modifications, called thyronines, of an amino acid, tyrosine. Thyroid hormones are heavily laden with iodine. The major active thyroid hormones are thyroxine (T_4) and triiodothyronine (T_3). Even though the thyroid gland manufactures considerably more T_4 than T_3, T_3 is roughly $2\frac{1}{2}$ times more potent than T_4. Indeed, in many ways, T_4 serves as an additional, circulating depot for T_3 in that when T_4 leaves the circulation and travels through the cytoplasm to the nucleus of the target cell, its action at that site is preceded or accompanied by its conversion to T_3.

Thyroid hormones

Most of the T_4 and T_3 secreted by the thyroid is bound to special proteins (thyroxine-binding globulin [TBG] and prealbumins) in the serum, although small amounts of these hormones travel freely in the serum and are readily taken up by tissues to be replenished instantaneously from the T_4 that had been attached to the binding proteins.

Essentially all the cells in the body are target cells of thyroid hormones. The major function of the thyroid hormones is to stimulate the synthesis of protein once they have entered the cell nucleus. Another important function is to stimulate the activity of the cell's mitochondria. These intracellular organelles are the sites at which there is a controlled exchange of energy. Some energy is conserved for the body's functionings, while the remainder is dissipated as heat. The proportion of energy devoted to each of these processes is controlled by the thyroid hormones. There are other intracellular thyroid hormone functions that are not well understood, but it is clear that thyroid hormones modulate protein, carbohydrate, fat, and vitamin metabolism, as well as the generation of body heat. Thyroid hormones also modify the activity of the autonomic nervous system.

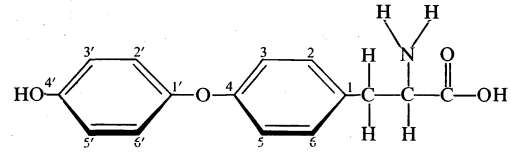
Regulation of hormone secretion. While multiple factors, including nerves supplying the thyroid gland, influence thyroid hormone secretion, by far the major influences are the negative feedback loops. The thyroid is a prime example of the negative feedback effects of the hypothalamic-pituitary-target organ axis. Briefly, thyroid hormones inhibit the release of thyrotropin-releasing hormone (TRH) from the hypothalamus and thyrotropin (thyroid-stimulating hormone [TSH]) from the anterior pituitary. Increased consumption of thyroid hormones decreases their concentration in the circulating fluids, resulting in enhanced thyrotropin secretion and thus an increased thyroid hormone secretion until a normal serum level is regained. Conversely, with the administration of the thyroid hormones, the resultant increased serum levels inhibit TRH and thyrotropin secretion and reduce the secretion of thyroid hormone from the thyroid gland until the elevated circulating thyroid level is returned to normal. If an amount of thyroid hormone equal to the normal daily thyroid output is administered to a patient, the thyroid gland is effectively suppressed; it produces no thyroid hormone because levels of circulating TSH are greatly reduced.

Major regulatory influences

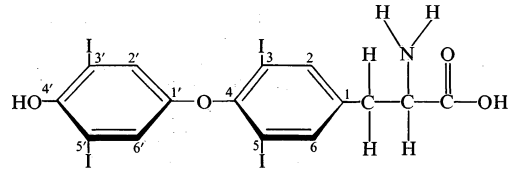
There is an important extrathyroidal mechanism for modulating thyroid hormonal activity, that is, the controlled conversion of T_4 into either the potent hormone T_3 or the inactive molecule rT_3 (Figure 12). Tissue enzymes, particularly abundant in the liver and kidney, control the conversion of T_4 to T_3 or reverse triiodothyronine (rT_3). Consequently, when T_4 is metabolized to T_3, thyroid hormone action is enhanced. Similarly, when the pathway for the conversion of T_4 to rT_3 is favoured, T_3 levels fall and thyroid hormone activity in that particular tissue is proportionally decreased.

Aside from the regulatory functions, other factors, external or internal, may also influence the circulating levels and utilization of thyroid hormones. In all forms of malnutrition, including anorexia nervosa, there is a significant reduction in the conversion of T_4 into T_3. The commensurate decrease in oxygen consumption and metabolic rate has survival value for a person deprived of adequate food to sustain health; in effect, death from starvation is postponed. Iodine intake is important because an inadequate dietary supply leads to reduced circulating thyroid levels and an ensuing increase in serum thyrotropin levels. This increase, while perhaps not adequate to produce sufficient thyroid hormone, nevertheless stimulates growth of the thyroid, with the resultant appearance of a goitre. In the short term, low environmental temperature leads to in-

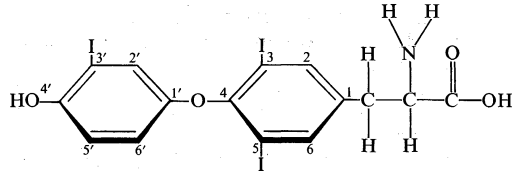
External and internal influences



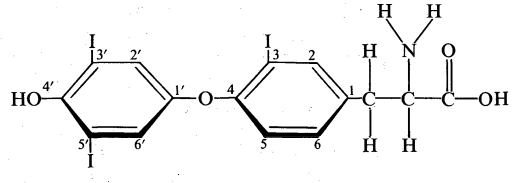
thyronine



3,5,3′,5′-tetraiodothyronine (T_4)
(thyroxine)



3,5,3′-triiodothyronine (T_3)



3,3′,5′-triiodothyronine
(reverse T_3; rT_3)

Figure 12: Structural diagrams of T_3, rT_3, and T_4, showing the synthesis of T_3 and rT_3 from T_4.

creased utilization of thyroid hormones, activation of the hypothalamic-pituitary-thyroid axis, and a consequent rise in T_4 and T_3 levels. As the environmental temperature rises, the converse results, and small, appropriate changes in normal persons have been noted with changes of season.

Finally, thyroid hormone levels may be affected by many illnesses that have nothing directly to do with the thyroid gland. For this reason, it is not easy to ascertain with certainty the influence of aging on thyroid hormone activity because it is difficult to accumulate large numbers of aged subjects who can be said to be free of any disease. It is generally agreed, however, that few important changes occur in thyroid activity during the normal aging process.

Diseases and disorders. *Hyperthyroidism.* When the human body is exposed to excessive amounts of thyroid hormone the result is a disease known as hyperthyroidism (or thyrotoxicosis). The most common cause of hyperthyroidism is Graves' disease, named after the Irish physician Robert J. Graves, who was among the first to describe it. It is noteworthy that hyperthyroidism is at least seven times more common in women than in men, although the reasons for this are poorly understood. Because there is a complex, hereditary tendency for the production of thyroid autoantibodies, it is not rare for Graves' disease to occur in many family members.

Graves' disease

Hyperthyroidism typically begins with a gradual onset of a constellation of symptoms, including increased nervousness and emotional instability associated with a fine tremor of the hands. The patient feels warm, perspires freely, and is intolerant of heat since a greater proportion of the body's energy is dissipated as heat. The pulse races, the heart thumps, and the systolic element of the blood pressure is elevated. In severe cases of hyperthyroidism, heart failure may occur. The drive to physical overactivity is dampened by increasing weakness and easy fatigue. Bowel movements may be normal, but they are often punctuated by bouts of diarrhea. Menstrual periods may become scant or may disappear entirely. Perhaps most striking is the apparent paradox of an increase in appetite associated with a loss of weight, the result of the fact that the excess of thyroid hormones leads to an increased metabolism. There is often, but not always, a swelling in the neck, and the physician's fingers may often detect the outline of an enlarged thyroid gland.

In patients with Graves' disease, an additional group of symptoms may appear. The eyes protrude (exophthalmos) and the distance between the opened eyelids increases so that in extreme cases the eyes may not close completely. The eyeball muscles and the entire orbit becomes inflamed and the patient may complain of double vision. Less often, there is a thickening of the skin over the shins (localized myxedema) and of the skin of the fingers (clubbing).

These changes, along with hyperthyroidism itself, stem from a pathological process called autoimmunity in which the body's immune system generates autoantibodies, called immunoglobulins, that are harmful to the body's own tissues. The first and most common cause of hyperthyroidism is the presence of antibodies producing Graves' disease. At least three sets of antibodies are involved. In the genesis of thyroid hypofunction, there is a fourth set of antibodies that competes with the hormones but does not induce the actions of the stimulating hormones once they are bound to the receptors.

The first set of antibodies is called the thyroid-stimulating immunoglobulins (TSI), which exert extraordinary effects unique throughout the endocrine system. They have a molecular configuration that mimics that of thyrotropin so that they are attracted to, and bind tightly with, the same receptors on the surface of thyroid cells that attract thyrotropin. The effects of thyrotropin are mimicked exactly. The result of TSI stimulation is the same as that of thyrotropin stimulation: thus, the number of follicular cells multiply and the thyroid enlarges, the follicles empty as the prohormone thyroglobulin is split, thyroid hormones are released, and the follicular cells are stimulated to synthesize and secrete excessive amounts of thyroid hormone. The end result is hyperthyroidism, or thyrotoxicosis.

TSI stimulation

The second set of autoantibodies attack orbital contents, including the eyeball muscles, producing Graves' ophthalmopathy and, less frequently, localized myxedema (dry, waxy swelling of the skin). The third set of antibodies is cytotoxic; that is, they damage and eventually destroy follicular cells. These cytotoxic immunoglobulins are an important cause of hypothyroidism, but when present early in the course of Graves' disease, they may only limit the effect of TSI. Thus a patient may manifest ophthalmopathy with normal or even reduced thyroid function. Furthermore, cytotoxic antibodies, even in the absence of TSI, may acutely damage thyroid follicles, leading to a leakage of large quantities of thyroid hormones so that a thyrotoxic state ensues.

The second most common cause of hyperthyroidism is toxic multinodular goitre. It begins early in life with iodine deficiency or other factors that block thyroid hormone secretion; the resulting low T_4 and T_3 levels lead to unremitting TSH secretion and to constant thyroid gland stimulation. This, in turn, produces glandular enlargements and the eventual formation of multiple nodules that produce excessive amounts of thyroid hormones autonomously. Less common is a benign tumour (toxic adenoma) of the thyroid, and rarely a malignant tumour may hypersecrete thyroid hormones. In such patients, hyperthyroidism may be due to overproduction of hormones from a metastatic deposit located in one or more parts of the skeleton, even though the thyroid gland itself has been removed surgically. Another rare form of hyperthyroidism results from inappropriate thyrotropin secretion. This may be caused by increased thyrotropin secretion resulting from a tumour of the pituitary thyrotrophs. Another cause of thyrotropin overproduction and secretion is the loss of cell receptors for thyroid hormones on the surface of thyrotrophs. As a consequence of this loss, the pituitary is not inhibited from releasing thyrotropin, resulting in persisting thyrotropin release.

Hyperthyroidism may also result from a hyperfunctioning ectopic tumour of thyroid tissue in the ovary (struma ovarii) or from the ingestion of excessive amounts of thyroid hormones. On occasion a person will, in order to lose weight or for some other reason, take large, toxic unprescribed amounts of thyroid hormone and may persist even to the point where surgical removal of the thyroid gland becomes necessary.

Effective treatments for hyperthyroidism include (1) surgical removal of all but a remnant of the thyroid gland, (2) the administration of drugs that specifically block the synthesis and release of thyroid hormones, and (3) the administration of radioactive iodine. This last form of treatment is effective because the thyroid gland, unable to distinguish between stable and radioactive forms of iodine, extracts both from the serum. Thus, follicular cells are damaged by the concentration of radioactivity within them to the point that the hyperthyroid state is relieved and the thyroid function returns to normal. In some instances, as is the case in excessive hormone release from inflammation of the thyroid or following ingestion of large amounts of thyroid hormone, drugs that block the manifestations of thyroid action on tissues, such as propranolol, are effective. Finally, for reasons not fully understood, using stable (nonradioactive) iodine also impairs release of thyroxine from the gland: improvement, however, may be short lived.

Treatments for hyperthyroidism

Hypothyroidism. Like hyperthyroidism, hypothyroidism can have many causes. It is, however, less common. In fact, overtreatment of hyperthyroidism with either radioiodine or surgery has emerged as the most frequent cause of hypothyroidism. In other instances, however, a child is born without a thyroid or an adult becomes hypothyroid without apparent cause. In some cases, autoantibodies appear and bind to thyrotropin receptors on the follicular cell, but unlike TSI, these autoantibodies are not agonists and do not accelerate the secretion of thyroid hormones. Instead, they are antagonists because they block access of thyrotropin to the receptor. As a result of their actions, the thyroid gland atrophies. Hypothyroidism may also occur as a result of disease of the cells of the hypothalamus that produce TRH or of the thyrotrophs of the anterior pituitary.

Hypothyroidism may also be associated with an enlarged

Hashimoto's thyroiditis

thyroid, a goitre. This is most commonly caused by inflammation of the thyroid (Hashimoto's thyroiditis) due to cytotoxic autoantibodies (see above *Thyroid gland: Hyperthyroidism*). The thyroid enlarges because of a heavy infiltration of white blood cells called lymphocytes. As discussed above, iodine deficiency results in goitre formation because of constant stimulation from elevated TSH levels in the serum. When iodine deficiency is severe, these compensatory efforts are inadequate and the patient becomes hypothyroid. In rare families there appears a hereditary absence of one of the enzymes essential for the synthesis of thyroid hormones. Although such individuals are hypothyroid from birth, they develop large goitres because of constant stimulation of the thyroid by TSH, a condition referred to as goitrous cretinism.

A number of drugs can block thyroid hormone synthesis and thus lead to goitrous hypothyroidism. Among them are the antithyroid drugs used in the treatment of hyperthyroidism, and lithium, prescribed for psychiatric disorders. There are a number of naturally occurring vegetable goitrogens, particularly cabbage. Finally hypothyroidism may be due to the absence of tissue receptors for the thyroid hormones. Persons with this very rare disorder have high but ineffectual serum levels of T_4 and T_3.

The onset of hypothyroidism may be gradual and subtle, so that it is often missed not only by the patient but also by a physician. It may be mild and difficult to diagnose, or all of its symptoms and conditions, called myxedema, may be present. The term myxedema stems from the fact that, for reasons not well understood, the hypothyroid patient produces an excess of a thick protein-containing (myxomatous) fluid that is deposited in the skin and other organs.

In many instances, the hypothyroid patient shows symptoms diametrically opposed to those of the patient with thyrotoxicosis. The patient is sluggish in movement and thought and has a thick, dry skin with coarse, dry, thinning hair. The patient does not eat excessively but gains weight. (Excessively obese persons, however, are rarely hypothyroid.) The tongue is large and impedes articulation of the guttural voice. The eyes are puffy and the lids lowered. Reflexes are slow, and there is continuing weakness. Females often have excessive menstrual bleeding and are relatively infertile. Patients prefer hot weather and are intolerant of cold. In fact, those with myxedema cannot generate additional body heat in response to a cold environment, so that when exposed to extreme cold, their body temperature may fall to levels as low as 74° F (23.3° C).

Myxedema is relatively common in the elderly, and the symptoms and signs are often mistaken for changes attributable to old age. While it is true that every endocrinologic disorder, whether hyperfunction or hypofunction, has been found to be sometimes associated with a mental aberration, most often depression, this may be striking in severe hypothyroidism; it has been called "myxedema madness." Treatment with T_4 may return the patient to a normal mental state, but the mental illness may remain unchanged or in some instances become even worse.

The same myxomatous fluid that infiltrates the skin often accumulates in body cavities as well. Thus what appears to be an enlarged heart in a chest X-ray film may be a benign collection of fluid in the pericardium, and similar changes may be found in the pleural and abdominal cavities.

Cretinism

Since the thyroid hormones pass only poorly from the maternal to the fetal circulation, iodine-deficient fetuses or those without thyroid glands become hypothyroid in utero and are born as cretins (infants whose growth and mental development are arrested) with a characteristic appearance somewhat similar to that present in myxedematous adults. Hypothyroidism also may be produced in the fetus when a pregnant woman is exposed to radioactive iodine or antithyroid drugs. Cretinism is associated with severe mental retardation, so that it is essential that hypothyroid infants be treated promptly with thyroid hormone. Indeed, it has become routine to check thyrotropin and T_4 levels in all infants at birth so that a child with any degree of hypothyroidism can be identified and promptly given the appropriate treatment.

Treatment of the adult with myxedema is relatively simple. The patient is given enough thyroxine to increase serum T_4 and decrease serum thyrotropin to normal levels. While the mental retardation of infantile cretinism cannot be reversed, both children and adults can be returned to a state of normal physical health.

Thyroid tumours. Thyroid tumours are remarkable in two respects. First, patients exposed to radiation from any source (nuclear blast, radioactive iodine, or X rays) have a much increased risk of developing thyroid tumours, including thyroid cancers. Second, unlike many other organ cancers, the most common thyroid tumour, a papillary carcinoma, pursues a slowly developing, painless course compatible with a long life span, and it is held in check when enough thyroxin is administered to suppress thyrotropin secretion. Other, less common thyroid tumours pursue a much more threatening course, and the most malignant of these may cause death within a few months to a few years.

Diagnostic techniques have improved to the point that it is relatively easy to ascertain the nature of a lump (mass) found on the thyroid gland. An image of the accumulation of administered radioactive iodine or technetium in the thyroid (thyroid scan) will demonstrate whether the mass is "hot" or "cold," that is, whether the mass is functionally active or not, functional activity being rare in thyroid cancers. Similarly, imaging with ultrasound will reveal whether the mass is fluid (cystic) or solid, cancers being solid. Finally, cells obtained by suction through a fine needle inserted through the skin into the mass may be examined under the microscope. These methods, particularly the last, may obviate the need for exploratory thyroid surgery.

The treatment of thyroid masses, also known as thyroid nodules, has long been controversial, but with increasing awareness of the slow course that many of these tumours pursue, surgeons now employ less radical procedures in dealing with them.

THE PARATHYROID GLANDS

Importance of calcium

The level of calcium in the blood is closely regulated, and wide fluctuations in either direction can be life-threatening. Calcium is a key element in the human body. Not only does it serve as the major constituent for bone, but it is also essential for the normal functioning of all body cells, as it is a mediator for many cell functions. For example, without calcium, blood will not clot. Many of these actions also require adequate supplies of magnesium and phosphorus. A healthy body needs a regular, continuous supply of these elements: about a gram each day for calcium and phosphorus and about one-third as much for magnesium.

Almost all the calcium contained in the body is deposited in bone (about 1.3 kilograms in the normal adult). While this mass provides skeletal support and serves as a reserve from which calcium may be mobilized, it is the remaining 1 percent, dissolved in body fluids, whose concentration is so carefully monitored. In the plasma, calcium exists largely as a dissociated ion (Ca^{2+}) loosely bound to plasma proteins with a small proportion bound more tightly to phosphate and citrate. To insure that calcium levels and distribution are maintained within narrow limits, parathyroid hormone (PTH), calcitonin, and the calciferols (the active metabolites of vitamin D) serve regulatory functions.

Anatomy. The parathyroid glands, usually four in number, are small structures adhering to or even imbedded in the substance of the thyroid gland. It is not surprising, therefore, that they were recognized as distinct endocrine organs rather late in the history of endocrinology, first described by a Swedish anatomist, Ivar Sandström, in 1880. At the beginning of the 20th century, symptoms due to parathyroid deficiency were attributed to the absence of the thyroid since the surgical removal of one was frequently accompanied by the inadvertent removal of the others. In 1909 an American pathologist, William G. MacCallum, recognized that parathyroid deficiency could be mitigated by the injection of calcium salts, and not until 1925 was an active parathyroid extract prepared by a Canadian biochemist, James B. Collip. In 1925 an Austrian surgeon, Felix Mandl, was the first to remove a

parathyroid tumour from a patient, and thereafter this and related subjects were extensively explored by the American clinical endocrinologist Fuller Albright.

Embryological development

The parathyroids arise in the embryo from the third and fourth pairs of branchial pouches, bilateral grooves resembling gill slits in the neck of the embryo and reminders of man's evolutionary debt to fishes.

Hormones. *Parathyroid hormone.* The parathyroids produce only one major hormone, parathyroid hormone (PTH), also called parathormone. Under the microscope the PTH-producing cells, the chief cells, occur in sheets interspersed with areas of fatty tissue. Occasionally the cells are arranged in follicles, similar to but smaller than those present in the thyroid gland. In common with other endocrine glands, the parathyroids synthesize a large prohormone, which is inactive. At the time of secretion the prohormone is split into an inactive fragment and PTH (a polypeptide containing 84 amino acids).

In contrast to the elaborate mechanisms controlling the secretion of other endocrine glands, the major determinant of PTH secretion is the level of ionized calcium in the serum (see above *The nature of endocrine regulation*). Should the serum calcium level rise, PTH secretion is inhibited. Conversely, should it fall, PTH levels rise. Magnesium controls PTH secretion in a similar fashion.

Actions of parathormone

The actions of PTH are multiple but they are all geared toward raising the level of ionized calcium in the plasma. Parathormone mobilizes calcium from bone by stimulating the activity of large, bone-dissolving cells called osteoclasts. It acts on the kidney to enhance the reabsorption of calcium by kidney tubules so that excretion of calcium in the urine is reduced. Parathyroid hormone acting in concert with vitamin D metabolites also enhances the absorption of ingested calcium from the bowel, and there is evidence that it provokes the transfer of some calcium from the milk in the breast of a lactating woman into her blood. On the other hand, PTH is a powerful inhibitor of renal tubular reabsorption of phosphate. Finally, an ancillary action of PTH is to assist in the regulation of body acidity by blocking tubular reabsorption of bicarbonate.

Calcitonin. Calcitonin was not recognized as a specific hormone until 1962. Calcitonin is a polypeptide containing 32 amino acids. It is synthesized and secreted from cells, termed parafollicular, or C, cells, which lie between the follicles of the thyroid gland. These cells do not have the same embryological origin as do the thyroid follicular cells; they migrate into the substance of the thyroid from a fetal structure called a branchial pouch. Human calcitonin differs considerably from the calcitonin of other species, and physicians take advantage of these differences when they administer salmon calcitonin, which provides a longer lasting, more potent action than does human calcitonin.

Major action

The major action of calcitonin is to lower the level of calcium in the blood by sharply inhibiting the ongoing dissolution of calcium from bone. Not unexpectedly, calcitonin secretion is stimulated whenever serum calcium levels rise above the normal range so that, between them, calcitonin and PTH effectively maintain steady calcemia in a normal individual.

Vitamin D and the calciferols. Unlike calcitonin, the awareness of vitamin D is relatively ancient. Vitamin D deficiency was first described more than 300 years ago as rickets, but it was not until 1971 that the chemical transformations that make vitamin D biologically active were described. The term vitamin D refers to a family of compounds that are derived from cholesterol. There are two major forms of vitamin D: vitamin D_3, found in animal tissues and often referred to as cholecalciferol, and vitamin D_2, found in plants and now better known as ergocalciferol. Both of these compounds are inactive precursors of potent metabolites; they fall, therefore, into the category of prohormones. This is true not only for the cholecalciferol found in animal tissues but also for that which is generated in human skin following exposure to ultraviolet light. These precursors are modified during their passage through the liver to a sterol called 25-hydroxycholecalciferol, and then further modifications, modulated by the serum PTH level, occur in the kidney. One of these products, 1,25-dihydroxycholecalciferol (calcitriol), is the most potent derivative of vitamin D. The other, 24,25-dihydroxycholecalciferol, has actions that are not clearly defined at present.

Vitamin D deficiency

Persons with a vitamin D deficiency suffer from rickets, characterized by soft, poorly calcified bone, along with poor absorption of calcium. Calcitriol or any of its precursors promotes a dramatic increase in the absorption of calcium by the intestine and a prompt repair of the diseased bone. It is generally agreed that the improvement in the bone results from the alleviation of the calcium deficiency; calcium is resorbed, but bone synthesis is not enhanced.

Diseases and disorders. *Hyperparathyroidism.* Overactivity of the parathyroid glands was originally thought to be a rare disorder because it was generally considered only in those patients who had definite symptoms. This view changed precipitously when the measurement of multiple plasma constituents, including calcium, became an integral part of a routine health examination. Hypercalcemia (excessive levels of calcium in the bloodstream) associated with few or no symptoms occurs in one in 1,000 adults, representing a large subpopulation in Western countries.

While there are many other disorders associated with elevated levels of calcium in the serum, including malignancy and the ingestion of too much vitamin D, primary hyperparathyroidism (primary in the sense that the parathyroid hyperfunction is not due to a known cause) is the preeminent cause of hypercalcemia. In hyperparathyroid patients, the hypercalcemia is often accompanied by a reduction in serum phosphorus levels and an increase in the levels of serum uric acid and serum acidity.

Almost all the symptoms of hyperparathyroidism result from hypercalcemia, but not all hypercalcemic patients become ill. (Thus, it is important for the physician to distinguish hyperparathyroidism from a chemical anomaly, called familial hypocalciuric hypercalcemia, in which elevated serum calcium levels are associated with a reduction in urinary calcium excretion. This condition is benign and usually no treatment is required.) Primary hyperparathyroidism results most often from an adenoma (a benign tumour), which secretes an excessive amount of PTH despite the elevation in serum calcium that it produces; because the adenoma is autonomous and not subject to negative feedback loops, elevated serum calcium levels are not followed by inhibition of PTH secretion. Primary hyperparathyroidism occasionally is associated with parathyroid hyperplasia, an increased number of hyperfunctioning cells that do not, however, cluster to form a typical adenoma. Rarely, a malignant tumour (a carcinoma of the parathyroid gland) may produce extraordinarily large amounts of PTH, which, in turn, produce dangerously high levels of serum calcium.

Asymptomatic hypercalcemia

With the advent of screening tests, large numbers of persons with mildly elevated serum calcium levels have been identified although the majority of these individuals are without symptoms. This form of asymptomatic hypercalcemia occurs most frequently in postmenopausal women. Symptoms include weakness, loss of appetite and weight loss, nausea, vomiting, and mental depression. There may be increased urinary output with an increased thirst and fluid intake. Constipation is a frequent problem. With severe, rapidly progressing hyperparathyroidism, there may be bone pain, stupor, and even coma. Weakened bones may form cysts (osteitis fibrosa cystica) and may break after little or no physical stress (pathological fractures). Since calcium does not dissolve readily in serum, elevated levels result in a precipitation of calcium deposits in susceptible tissues, most prominently the kidney, and the pain of kidney stones (renal colic) is often the first evidence of hyperparathyroidism. Kidney damage may progress to the point where the patient's life is threatened.

Although primary hyperparathyroidism may be hereditary or in some instances associated with multiple endocrine neoplasia (see below *Ectopic hormone and polyglandular disorders*), most often the cause of primary hyperparathyroidism is unknown. Known causes, referred to as secondary hyperparathyroidism, usually involve an unrelated kidney disease. When kidney failure occurs, serum calcium levels fall. The resulting increase in PTH

secretion often leads to severe bone disease along with intractable itching.

Causes of hypercalcemia

Hypercalcemia may result when malignant tumours (particularly of the lung) secrete substances, in most instances not PTH, that increase the rate of dissolution of bone. Another important cause of hypercalcemia is vitamin D intoxication (discussed below). The most common cause of hypercalcemia other than primary hyperparathyroidism results from invasion and destruction of bone by the spread of a cancer, most commonly cancer of the female breast. A number of drugs, most prominently diuretics such as hydrochlorothiazide or furosemide, may also increase serum calcium levels.

The treatment of symptomatic hyperparathyroidism is surgical removal of the tumour. The treatment of asymptomatic hyperparathyroidism is less clear-cut. Because some patients may remain symptom-free for years, one alternative is simply to observe the patient's course without treatment unless symptoms appear. If continued observation alone is psychologically distressing, however, surgical removal of the tumour is warranted. In the case of mild postmenopausal hyperparathyroidism, treatment with the estrogen hormone estradiol is effective for many patients.

If the serum calcium rises to dangerous levels, it can be lowered quickly by using intravenous fluids with a powerful diuretic, thus "washing out" the excess calcium. The drug plicamycin (mithramycin) is highly effective in lowering serum calcium, although it may have toxic side effects.

Hypoparathyroidism. If PTH secretion is greatly reduced or ceases entirely, mobilization of calcium from bone and other sources ceases, and a fall in serum calcium to abnormally low levels results. Hypoparathyroidism is a rare disorder; indeed, the most common cause is iatrogenic—*i.e.*, physician- or treatment-induced, such as the PTH deficiency that occurs following the inadvertent removal of parathyroid glands during thyroid surgery. Spontaneously occurring hypoparathyroidism is probably an autoimmune disease because serum autoantibodies are found in some afflicted individuals. This form of hypoparathyroidism may appear in the syndrome of multiple endocrine deficiencies (see below *Ectopic hormone and polyglandular disorders*). Impaired PTH secretion may occasionally occur in the presence of intact parathyroid glands. Such is the case when a person suffers from magnesium deficiency, usually associated with alcoholism. In such patients serum calcium levels remain persistently low until the magnesium deficiency is repaired. Finally, Albright described what he termed pseudohypoparathyroidism in which there is a defect in the binding of PTH to its cell surface receptor.

Symptoms of hypoparathyroidism

The symptoms of hypoparathyroidism are essentially those resulting from low levels of serum calcium. Most prominent is muscular cramping and twitching, exemplified dramatically by carpopedal (wrist and foot) spasms; during the spasms there are painful cramps of the toes and feet, along with severe, tetanic contractions of the muscles of the hands so that the four fingers are rigidly extended while the thumb presses against the palm. This neuromuscular excitability can progress to generalized convulsions. In addition, patients with long-standing hypocalcemia develop cataracts and calcification in the basal ganglia of the brain, which in turn can produce symptoms of parkinsonism. Occasionally, patients also have a spotty depigmentation of the skin (vitiligo) and hair loss. Patients suffering from pseudohypoparathyroidism also may have peculiar skeletal abnormalities: "short coupled," with a short neck and extremities, obese, with a rounded face, and sometimes shortened metacarpal bones.

When treatment is urgent, the patient is given calcium salts intravenously. Long-term therapy consists of treatment with vitamin D or one of its metabolites, along with calcium salts by mouth. Serum calcium levels must be monitored to be certain that, on the one hand, the patient is given enough medication to avoid hypocalcemia and, on the other hand, to prevent the hazards of hypercalcemia with its attendant complications, such as kidney stones.

It should be noted that there are causes for hypocalcemia other than hypoparathyroidism. In the past, vitamin D deficiency (rickets) was a common cause, but with the wide distribution of vitamin D supplements in milk and other foods this has become a rare event. There remain, however, patients who suffer from abnormalities in the metabolism of vitamin D (vitamin D-resistant rickets), which may be treated effectively either with very large doses of vitamin D or with 1,25-dihydroxycholecalciferol. Severe inflammation of the pancreas (pancreatitis) is associated with hypocalcemia, and low serum calcium levels may also occur in patients who suffer from intestinal malabsorption (sprue). In these individuals, ingested calcium binds to unabsorbed fat and is excreted. Treatment of the underlying condition relieves the symptoms.

Hypercalcitoninemia. It was not until 1968 that tumours of the parafollicular cells of the thyroid gland were discovered to secrete large amounts of calcitonin. These tumours sometimes occur among family members and sometimes as isolated cases. Such tumours, known as medullary carcinomas of the thyroid, also occur in one of the forms of multiple endocrine neoplasia (see below *Ectopic hormone and polyglandular disorders*). In most patients, serum calcium levels are not low, as might be expected, because any tendency to hypocalcemia is countered by increased PTH secretion. The threat of medullary carcinoma is the fact that it invades local areas in the neck and spreads to distant organs, resulting in death. Patients with these tumours have elevated serum calcitonin levels or are hyperresponsive to stimulation of the parafollicular cells by an infusion of calcium and a hormonal product called pentagastrin.

Medullary carcinomas of the thyroid

Early diagnosis is essential and asymptomatic family members should be checked regularly. If serum calcitonin levels are elevated or become abnormally elevated following stimulation, the patient's thyroid gland should be removed completely, followed by treatment with replacement doses of thyroxine.

Rickets, osteomalacia, and hypervitaminosis D. Vitamin D deficiency, known as rickets in children and osteomalacia in adults, was a worldwide problem, particularly in temperate zones, until the 1920s when it was found that it could be cured by exposure to light and by the administration of cod liver oil, a substance high in vitamin D. Affected individuals have soft bones, the literal meaning of the term osteomalacia. Their bones become distorted, resulting in bow legs, a bulging forehead, distortion of other bones of the head (craniotabes), and enlargement of the junctions of the ribs with the rib cartilage on the chest (rachitic rosary). These distortions are caused by the generation of excessive amounts of uncalcified bone in an attempt, in effect, to make up for the deficient calcium deposition. Healing takes place promptly with vitamin D supplements, and the disease has become rare with the irradiation of milk and other forms of preventive nutrition.

Vitamin D supplements

Osteomalacia also may be produced in patients suffering from intestinal malabsorption in which ingested vitamin D is not absorbed through the intestinal lining and then into the body. In rare instances families are afflicted with vitamin D-resistant rickets, in which enzymes for the production of the more potent vitamin D metabolites are missing, although this enzyme deficiency can be overcome by administering large doses of vitamin D. Finally, some drugs used to combat seizure disorders (phenytoin and barbiturates) may interfere with the formation of active vitamin D metabolites and thus cause osteomalacia. Because the conversion of 25-hydroxycholecalciferol to the potent derivative of vitamin D_3, 1,25-dihydroxycholecalciferol, takes place primarily in the kidney, this process is impaired in severe kidney disease. (The resulting bone disease, a form of osteomalacia, is known as renal osteodystrophy.)

Ingestion of megadoses of vitamin D produces bone disease associated with hypercalcemia. Treatment, of course, includes the discontinuance of the vitamin D supplements. Reversal of the process can be hastened by the administration of one of the cortisone family of drugs. Occasionally, as in the case of sarcoidosis, there is an abnormal sensitivity to vitamin D or an increased production of vitamin D metabolites, with the absorption of excessive amounts of calcium and the accompanying appearance of hypercalcemia. This disease, too, respond to corticosteroids.

Metabolic bone disease. While the skeleton is usually

thought of as that which is hard and unyielding in the human body, in reality living bone, like many other tissues of the body, undergoes a constant process of breakdown and renewal. This ongoing process of resorption and formation permits the skeleton to adjust to the changes required for healthy functioning, changes ranging from healing fractures to the subtle remodeling necessary to maximize bone strength following alterations in posture or gait. Normal bone provides rigid support, but at the same time it is not brittle. It consists of two major components: (1) a protein matrix consisting mostly of a fibrous protein called collagen; and (2) a mineral portion, mostly complex crystals of calcium and phosphate, which is embedded in the protein component. Bone contains nutritive cells called osteocytes, but the major metabolic activity is carried out by osteoblasts, which generate the protein matrix and osteoclasts (large, multinucleated cells that digest and dissolve bone).

Composition of bone

Only what is called metabolic bone disease, that is, disease which affects all the bones of the skeleton to a lesser or greater extent, is discussed below. These include osteoporosis, osteogenesis imperfecta, osteopetrosis, and Paget's disease of bone. For discussion of such metabolic diseases as rickets, osteomalacia, the bone disease of hyperparathyroidism, and vitamin D intoxication, see above.

The term osteoporosis, taken literally, refers to porous bone. There is simply less bone per unit volume (osteopenia) in osteoporosis. This is true despite the fact that the osteoporotic vertebral body may have collapsed on itself from pressures both from above and from below, forming what is known as a "codfish vertebra." In osteoporosis there is no difficulty with mineralization of bone; rather, the protein matrix is inadequate. There are many reasons for this change. Thinning of bones is part of the process of normal aging, but it can be much accentuated by numerous factors. Most prominent among these are the loss of estrogens in postmenopausal women; multiple forms of nutritional deficiency, including lack of dietary protein; vitamin C deficiency; alcoholism; and low calcium intake.

These deficiencies can occur not only because the required nutrients are not part of the diet but also because of any of a number of disorders associated with poor absorption of nutrients. Osteoporosis occurs rapidly in any person who becomes physically inactive, for example, paralyzed patients or those immobilized by arthritis. It can be produced by drugs such as the corticosteroids, heparin, and anticonvulsants. Estrogen deficiency is an important contributing factor, demonstrated by the fact that bone thinning occurs among those female ballet dancers and long-distance runners in whom menstruation disappears rather than in those in whom it does not. In most of these situations the rate of bone resorption exceeds that of bone formation so that, inevitably, osteopenia occurs.

Osteoporosis in postmenopausal women

Most patients with osteoporosis are women, although the disease does occur in men as well. Of the many causes of osteoporosis, by far the most common is that which occurs in the postmenopausal female. Those who are affected number in the millions, and it is estimated that approximately one-fourth of white women older than 60 years of age have some degree of osteoporosis. Many affected individuals, however, have no symptoms. Others suffer only mild back pain. As the anterior edges of the thoracic vertebra become compressed, the spine bends forward, producing the typical "dowager's hump," with an accompanying loss of height. A compression fracture of a vertebra may be signaled by a sudden, sharp pain in the affected area after minimal or no trauma. It is common, however, for the patient not to recall pain or trauma, and the vertebral fractures may be noted only as incidental X-ray findings. Fractures of the femur after little or no trauma (pathological fractures) are also quite common.

Since estrogens exert a preventive influence on the development of osteoporosis, it occurs most frequently in postmenopausal women. It is not clear why it occurs less frequently in black women than in caucasians. There is evidence that among blacks bone density at maturity is appreciably greater than among whites, so that when bone loss starts, usually several years before the onset of the menopause, those with the greatest bone density are least afflicted. Obesity also exerts a protective effect against osteoporosis, probably because adipose (fatty) tissue is capable of synthesizing estrogens.

Prevention and treatment of osteoporosis

With few exceptions the osteoporotic process (including the osteoporosis of immobilization of the young) is not reversible. The most effective measures are preventive. These include good nutrition and a liberal calcium intake throughout life, but particularly in the early postmenopausal years. Moderate, ongoing physical activity is also essential, but extraordinary long-term exercise (which may result in reduced estrogen secretion) is counterproductive. Estrogen treatment inhibits postmenopausal bone loss at least for the first several years, but whether this is advisable or necessary in all postmenopausal women is not known.

In patients already afflicted with osteoporosis, treatment with calcium, modest doses of vitamin D, or calcitriol may be helpful. Supplemental calcium fluoride also may be helpful, although occasionally at the cost of significant side effects. Again, exercise, even in the frail elderly, is considered an important component and may increase bone density.

Osteogenesis imperfecta, also known as brittle bones, is a rare inherited disease occurring in two forms. In one form, multiple fractures, particularly of the bones of the extremities, occur near the time of birth, and the death rate in afflicted infants is high. The second form is far less severe, with fractures of long bones occurring in adolescence and young adulthood. Associated abnormalities include a blue colour to the whites of the eyes (blue sclerae), along with abnormalities in heart valves. In this disorder there is an inherited defect in the formation of collagen, the protein most abundant in the organic matrix of bone and in heart valve tissue. There is no known treatment.

Osteopetrosis is another rare hereditary disease, characterized by abnormally dense bones that tend to crowd out the bone marrow. The severest form occurs in infants and was uniformly fatal until bone marrow transplantation emerged as a dramatically successful form of treatment.

Paget's disease

In a strict sense, Paget's disease is not a generalized metabolic bone disease; rather, it is a localized disease that may be disseminated to include a large portion of the skeleton. For this reason, it can be included with the metabolic disorders of bone.

The most graphic and detailed description of this disorder was provided by Sir James Paget, a prominent English surgeon. Paget believed the disease resulted from inflammation, and for this reason he called it osteitis deformans. This notion was soon discredited and many other possible causes were considered more seriously, but it now appears that Paget was correct. Under the ultramicroscope, structures that very closely resemble viruses have been seen in the osteoclasts of patients suffering from Paget's disease. The osteoclasts are extraordinarily active, digesting bone at a very rapid rate and at the same time activating a "coupling factor" that leads to a compensatory increase in bone synthesis by local osteoblasts. The result is a changed, "chaotic" bone structure leading to bone weakening and deformities.

The patient with classical, advanced Paget's disease has a large skull, a shortened spine, and bowed thighs and legs, producing a simian appearance. Pathological fractures are common, and the patient's course may be threatened by complications such as impingement of distorted vertebrae on the spinal cord, which threatens paralysis. Occasionally, the pathological stimulation of bone turnover leads to a transformation into bone cancer. There is no known cure, but the process can be suppressed effectively with a number of therapeutic agents, including salmon calcitonin, one of the diphosphonates, or plicomycin (mithramycin).

Fibrous dysplasia

Fibrous dysplasia also is a disseminated, rather than generalized, bone disease, and its cause is unknown. It may be monostotic (localized to one bone) or polyostotic. The disease leads to a gross distortion of bone structure that may result in a grotesque appearance of facial features. There are often accompanying patches of tan pigmentation (café au lait spots) and if the base of the skull is involved, particularly in females, puberty may occur at an inordinately young age (precocious puberty). (T.B.S.)

THE PANCREAS

The discovery of insulin in 1921 by a Canadian surgeon, Frederick Banting, with the assistance of a medical student, Charles Best, was one of the most dramatic events in modern medicine. It not only saved the lives of innumerable patients affected with childhood diabetes but it also ushered in present-day understanding of the complexities of the endocrine pancreas. The importance of the endocrine pancreas lies in the fact that its principal hormone, insulin, plays a central role in the regulation of energy metabolism and that a relative or absolute deficiency of insulin leads to diabetes mellitus, still a leading cause of disease and death throughout the world.

Anatomy. In humans the pancreas weighs approximately 80 grams, has roughly the configuration of an inverted smoker's pipe, and is situated in the upper abdomen. The head of the pancreas (equivalent to the bowl of the pipe) is immediately adjacent to the duodenum, while its body and tail extend across the midline nearly to the spleen. The bulk of pancreatic tissue is devoted to its exocrine function, the elaboration of digestive enzymes that are secreted via the pancreatic ducts into the duodenum.

The islets of Langerhans

The endocrine pancreas consists of the islets of Langerhans. Approximately 1,500,000 islets, weighing about one gram in total, are scattered throughout the gland. The embryonic origin of the cells that make up the islets is not clear; both endodermal and neuroectodermal precursors have been proposed. Approximately 75 percent of the cells in each islet are the insulin-secreting beta (B) cells, which tend to cluster centrally (Figure 13, top). Around the periphery lie the alpha (A), delta (D), and F (or PP) cells, which secrete glucagon, somatostatin, and pancreatic polypeptide, respectively. Each islet is supplied by one or two minute arteries that branch into numerous capillaries; from this network, capillaries emerge to coalesce into small veins outside the islet. The islets also are richly supplied with autonomic nerves. Thus, islet function may be modulated by neural control, by circulating metabolites and hormones, and by secretion of hormones locally (paracrine effects).

The principal function of the endocrine pancreas is the secretion of insulin and other polypeptide hormones necessary for the orderly cellular storage and retrieval of such dietary nutrients as glucose, amino acids, and triglycerides.

Hormones. *Insulin.* Insulin, produced by the beta cells of the islets of Langerhans, is a moderate-sized protein composed of two chains, the alpha chain (with 21 amino acids) and the beta chain (with 30), linked by sulfur atoms. Insulin is derived from a larger prohormone molecule

Proinsulin

called proinsulin. Proinsulin is relatively inactive, and normally little of it is secreted. It contains a connecting peptide, or C-peptide, composed of 31 amino acids with an additional amino acid at either end linked to the alpha and beta chains, respectively. As is the case with other prohormones, the connecting peptide of proinsulin is cleaved off before insulin is released into the circulation. Insulin leaves the pancreas through veins, which empty into the portal vein perfusing the liver. Typically the pancreas of a normal adult contains approximately 200 units (eight milligrams) of insulin; the average daily secretion of insulin into the circulation ranges between 35 and 50 units.

Although a number of physiological events influence insulin secretion, the most important is the concentration of glucose in the arterial (oxygenated) blood perfusing the pancreas. When the plasma glucose level rises, insulin release is stimulated; as plasma glucose falls, so does the rate of insulin secretion. Even during prolonged fasting, however, a baseline secretion of insulin continues. Insulin secretion also is influenced by neurotransmitters interacting with islet cell receptors, particularly those that bind norepinephrine.

The action of insulin can be appreciated by considering its effect on three tissues important in metabolism (adipose tissue, muscle, and liver) and by noting the consequences of its deficiency in diabetes mellitus (see below *Diabetes mellitus*). Insulin has profound effects on adipose tissue and lipid metabolism: it permits the entry of glucose into the fat cell (adipocyte) and then stimulates the metabolism

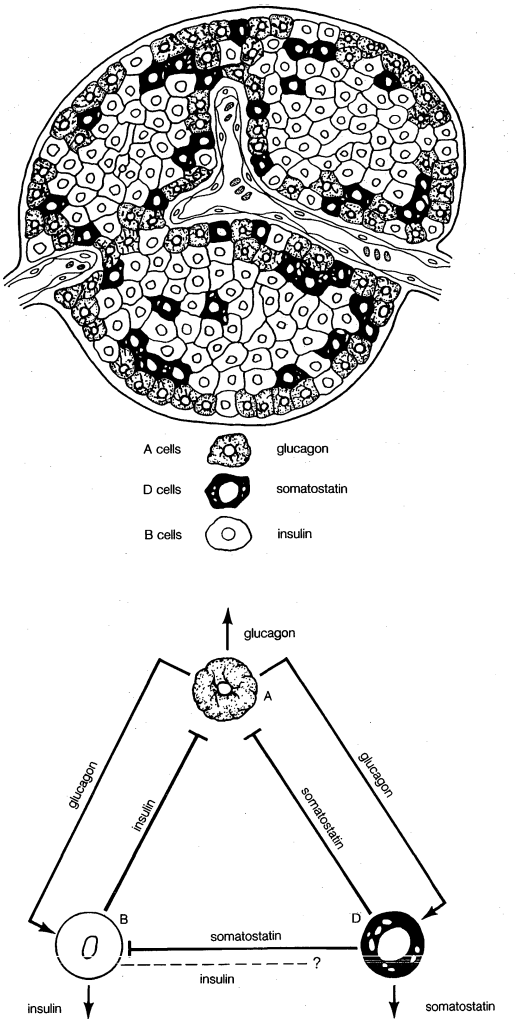


Figure 13: *Relationships of the cells of the islets of Langerhans.*
(Top) Cross-section of a normal islet. (Bottom) Possible paracrine cell–cell interactions within the islets. Stimulatory actions of the peptides on the neighbouring cells are represented by long arrows; inhibitory actions are represented by short bars. Endocrine secretion into the circulation is shown by short arrows.
From R.H. Unger and L. Orci, *New England Journal of Medicine*, vol. 304, p. 1518 (1981); reprinted by permission of the *New England Journal of Medicine*

of glucose once it is in the cell. The presence of glucose within the adipocyte, in turn, leads to increased formation of fatty acids and triglycerides. Insulin has a stimulatory effect on lipoprotein lipase, an enzyme located in the walls of the capillaries in adipose tissue and one that is required for splitting circulating triglycerides, a necessary step before the fatty acid contained in triglycerides can enter fat cells. Finally, insulin is the most potent inhibitor of the release of stored fatty acids. As the level of plasma insulin rises, the release of fatty acid, or lipolysis, is markedly suppressed; conversely, as insulin falls, the release of fatty acid accelerates.

Insulin stimulates the transport of glucose and amino acids into muscle cells and prompts the conversion of amino acids into protein. Thus, insulin is required to replete the glycogen, a stored form of glucose, that is oxidized during exercise and to replenish protein needed for muscle growth and repair. Insulin is not required for the transport of glucose into liver cells, but the hormone profoundly affects intracellular metabolism in the liver. It promotes glycogen formation, stimulates the utilization of glucose, and suppresses those enzymes necessary for new glucose formation (gluconeogenesis) and glycogen breakdown (glycogenolysis). The overall effect of insulin is to increase glucose utilization and storage and decrease its release by the liver.

Overall effect of insulin

Glucagon. Glucagon is produced by the alpha cells

of the pancreas and also is secreted by cells scattered throughout the gastrointestinal tract. A number of forms of glucagon have been found; the biologically active one appears to contain 29 amino acids. Radioimmunoassays can distinguish between pancreatic glucagon and similar peptides from the gut. Circulating glucagon levels are high in the fasting state. Secretion is stimulated by amino acids and gastrointestinal peptide hormones. Normally, ingested glucose is a potent suppressor of glucagon release, an effect that is probably mediated by an increase in circulating insulin. Secretion of glucagon also is inhibited by free fatty acids and by somatostatin and appears to be modulated by the autonomic nervous system. Circulating glucagon binds to specific receptors on the surface of liver cells (hepatocytes), leading to the breakdown of liver glycogen into glucose, which is then released into the blood. Glucagon is estimated to be responsible for most of the hepatic glucose production after an overnight fast.

Somatostatin. Somatostatin, a peptide that was discovered initially in the hypothalamus (see above *Hypothalamus: Growth hormone-releasing hormone*), contains 14 amino acids, is produced by the D cells of the islets, and has a number of effects on digestion. It inhibits gastrointestinal motility and blood flow, secretion of stomach acid, secretion of pancreatic exocrine, and the absorption of triglyceride from the bowel.

Effects of pancreatic hormones

In summary, it appears that the hormones insulin, glucagon, and somatostatin act in concert to control the flow of nutrients into and out of the circulation. The relative concentrations of these hormones regulate the rates of absorption and peripheral disposal of substances such as glucose, amino acids, and fatty acids. The anatomic proximity of the B, A, and D cells in the islets is significant. Somatostatin and glucagon appear to have a paracrine relationship whereby they influence the secretion of each other, and both affect the rate of insulin release (Figure 13, bottom).

Pancreatic polypeptide. Pancreatic polypeptide, secreted by the F (or PP) cells, contains 36 amino acids. Circulating levels rise following ingestion of a meal. An increase in the level of free fatty acids in the blood suppresses its secretion. Pancreatic polypeptide can inhibit gallbladder contraction and pancreatic exocrine secretion, but its biologic role is uncertain.

Hormonal control of energy metabolism. The functions of the pancreatic hormones, particularly insulin and glucagon, can best be appreciated by considering their roles in maintaining glucose homeostasis and in regulating nutrient storage. An adequate supply of glucose is required for optimal body growth and development and for the health of the central nervous system, for which glucose is the major (and usually the only) source of energy. It is not surprising, therefore, that elaborate mechanisms have evolved to ensure that a normal plasma glucose level is maintained regardless of whether a person is feasting or fasting. Another requirement for survival is the ability of the body to store excess nutrient fuel for recall and use during periods of scarcity. Adipose tissue serves this need. Compared to carbohydrate and protein, fat yields twice the calories per gram. Furthermore, adipose tissue contains less than 10 percent water. Thus, a kilogram of fat has 10 times the caloric value of a portion of muscle of the same weight. Following the ingestion of a meal, the carbohydrate content is assimilated as glucose, leading to an elevation in blood glucose and to an increase in plasma insulin from 10 microunits per millilitre to 50–100 microunits per millilitre. This high level of insulin promotes glucose uptake by the liver, adipose tissue, and muscle. Fatty acids and amino acids derived from the digestion of fat and protein are also deposited in the liver and peripheral tissues. Glucose production by the liver is inhibited, and brain metabolism is fueled by dietary glucose. Insulin also suppresses lipolysis so that the concentration of free fatty acids in the plasma falls. Thus, the "fed," or anabolic, state is characterized by nutrient storage dependent on an increase in circulating insulin.

The anabolic state

Within a few hours after a meal, when gastrointestinal absorption of nutrients is complete, the level of insulin falls and hepatic production of glucose resumes, sustaining the needs of the brain. Similarly, lipolysis increases, providing fuel for muscle. After a longer period of fasting, (*e.g.,* 12 to 14 hours or overnight), the insulin level falls still lower and plasma glucagon increases. Hepatic glycogen becomes depleted, and glucose production is achieved by gluconeogenesis, a process requiring precursor carbon molecules such as the amino acid alanine from muscle breakdown and glycerol from lipolysis. Thus, the "fasting," or catabolic, state is characterized by a low level of insulin, an increased concentration of glucagon, and a withdrawal of stored nutrients.

With further fasting, lipolysis continues to increase for a few days before it plateaus at a high rate. A large proportion of elevated fatty acids are converted to the "ketone bodies" in the liver, a process enhanced by the high level of glucagon. The brain, previously an avid and fastidious consumer of glucose, begins to use ketones as well as glucose. Eventually, more than one-half of the brain's daily metabolic energy needs are met by the ketone bodies, thus substantially diminishing the need for hepatic glucose production. The decrease in gluconeogenesis reduces the need for protein-derived amino acids, sparing muscle and making survival during prolonged fasting possible. Starvation is characterized by very low levels of insulin, elevated concentrations of glucagon, and very high concentration of circulating free fatty acids and ketones.

Insulin actions

In summary, in the fed state insulin mediates (1) the transport of glucose into body tissues (to be consumed as fuel or stored as glycogen), (2) the transport of amino acids into tissues (to build or replace protein), and (3) the transport of glucose and fatty acids into adipose tissue (to provide a fuel depot for future energy needs). During fasting, insulin levels are depressed and the opposite sequence of events occurs, modulated by glucagon and other "anti-insulin" hormones such as cortisol from the adrenal cortex.

Diseases and disorders. *Diabetes mellitus.* A relative or absolute deficiency of insulin results in the disease diabetes mellitus, by far the most common disorder of the endocrine system. The number of individuals with diabetes doubles every 15 years. While insulin, discovered by Banting and Best in 1921, can prevent early death from diabetic coma, insulin treatment does not prevent the chronic, disabling complications of the disease. Statisticians list diabetes mellitus among the top 10 causes of death in the United States, for example, and cite it as the leading cause of blindness and uremia.

Types of diabetes

In the United States, the National Institutes of Health has classified diabetes into a number of types. Type I, or insulin-dependent diabetes mellitus (IDDM), formerly termed juvenile-onset diabetes, can occur at any age of life. Affected individuals have insulin deficiency due to islet cell loss and may become comatose when exogenous insulin is withheld. Type II, or non-insulin-dependent diabetes mellitus (NIDDM), previously called maturity-onset diabetes, also can occur at any age but is most common in adults. Affected individuals are not prone to coma except in the presence of stress, although they often require insulin to control hyperglycemia. The majority are obese. Other types are a miscellaneous group, formerly called secondary diabetes, and include diseases attacking the pancreas (*e.g.,* hemochromatosis, pancreatitis), and syndromes characterized by insulin antagonism (*e.g.,* Cushing's disease, acromegaly). The term impaired glucose tolerance (IGT) is applied to those who have oral glucose tolerance tests (OGTT) that exceed normal levels but are not sufficiently abnormal to justify the diagnosis of diabetes mellitus. Most of these individuals do not progress to overt diabetes and do not develop the chronic complications of the disease. The term gestational diabetes mellitus (GDM) is reserved for diabetes or glucose intolerance that develops, or is first recognized, during pregnancy. Patients usually revert to normal glucose tolerance following pregnancy.

In order to diagnose diabetes mellitus in an apparently healthy adult, a physician must observe either two fasting plasma glucose values greater than 140 milligrams per decilitre or any two values greater than 200 milligrams per decilitre following a 75-gram oral glucose load. Criteria

for the diagnosis of glucose intolerance include a fasting plasma glucose value between 115 and 140 milligrams per decilitre, a two-hour postprandial value between 140 and 200 milligrams per decilitre, and at least one value greater than 200 milligrams per decilitre during a standard oral glucose tolerance test.

Causes of diabetes

It seems likely that there are two distinct causes for IDDM and NIDDM. A genetic factor appears to be more important in NIDDM, since analysis of a large series of identical twins has shown a concordance (the appearance of the trait) in both twins of more than 90 percent for NIDDM, while in IDDM the rate is about 50 percent. This relatively low incidence of the disease among the identical twins of insulin-dependent diabetics suggests that other factors are important. One such factor may be immune-related. Among insulin-dependent diabetics, there is a relatively high prevalence of certain patterns of the inherited tissue compatibility antigens (HLA), while in NIDDM the prevalence of these HLA types is normal. In addition, there is a high prevalence of autoantibodies to islet cells found in the sera of insulin-dependent diabetics, along with inflammation of the islets. There is evidence that in some cases of IDDM, viral infections may play a role. Coxsackie virus B_4 has been isolated from the pancreas of a child who died accidentally shortly after the onset of diabetes. This virus was cultured and found to cause beta cell damage when injected into mice. Further evidence for an infectious factor in the causation of type I diabetes mellitus is the seasonal appearance of new cases of the disease.

Viral and autoimmune factors

It may be that viral and autoimmune factors combine to cause diabetes, the viral infection of the pancreas leading to the release of proteins into the circulation that are recognized as foreign by the victim's immune system. In this theory, autoantibodies cause destruction of the beta cells of the pancreas. This thesis suggests the possibility of preventing the disease either by immunization against suspect viruses or early treatment with immunosuppressive drugs. Patients with NIDDM appear to suffer from resistance to insulin along with abnormal secretion of the hormone. In fact, these patients may initially have higher than normal concentrations of plasma insulin. The primary site of resistance is likely to be within the cell (*i.e.*, a postreceptor defect), although a receptor abnormality may also be implicated. In many, but not all type II patients, resistance to insulin is linked to obesity.

A relative or absolute deficiency of insulin results in hyperglycemia, the central biochemical feature of the disease. Hyperglycemia ensues because of impaired transport of glucose into muscle and adipose tissue and the increased release of glucose into the circulation by the liver. Above a glucose concentration of about 180 milligrams per decilitre the kidney tubules are unable to reabsorb all of the glucose filtered by the glomeruli. The excretion of glucose by the kidney requires a simultaneous movement of water out of the plasma and into the kidney, from which it is excreted. The subsequent increase in the relative concentration of solutes in the water-depleted plasma in turn stimulates the thirst centres of the hypothalamus in the brain. Three classic conditions thus result: polyuria (excretion of a large volume of urine in a specific amount of time); polydipsia (excessive, long-term thirst); and polyphagia (voracious eating). All can be explained in terms of the body's loss of large quantities of glucose and water, which results in a compensatory increase in hunger and thirst. With more severe insulin deficiency, hyperglycemia and glycosuria intensify, liquid intake falls behind urinary loss, and dehydration and shock ensue. The rate of fatty acid release from adipose tissue is greatly accelerated. Much of the fatty acid reaching the liver is converted to the ketone bodies acetoacetic acid and beta-hydroxybutyric acid. Both substances lower the pH of the blood, normally held at a pH of 7.4. As the acidic state progresses, there is depression of cerebral and myocardial function, culminating in coma and death. Appropriate fluid therapy and administration of insulin is life saving. The blood sugar is lowered, dehydration and shock are reversed, and the blood pH is restored to normal.

Prolonged survival of patients with diabetes mellitus has led to an increasing incidence of chronic complications, most of which can be explained by changes in the patient's blood vessels. Small blood vessel disease (microangiopathy) is unique to diabetes; the principal feature seen under the microscope is thickening of the walls of the capillaries. With time, affected capillaries become leaky, leading to changes in the retina (retinopathy) and kidney (nephropathy). Ultimately, there may be retinal hemorrhage leading to blindness and severe impairment of renal function causing uremia. Diabetic patients are also afflicted by an increased incidence of large vessel disease. Microscopically, hardening of the arteries (atherosclerosis) in the diabetic is not different from that seen in nondiabetic individuals; however, it occurs earlier and progresses faster in diabetic patients. Premature coronary artery disease is a common cause of death among diabetics. The large arteries of the lower extremities are often affected, contributing to the high incidence of foot ulceration and gangrene and resulting in amputation.

Complications of diabetes

Not all complications are directly related to vascular disease. Early cataract formation, impaired function of the autonomic nervous system, and peripheral nerve damage (neuropathy) cannot be fully explained by blood vessel changes. Autonomic nervous system dysfunction may be manifested by gastric retention, chronic diarrhea, incomplete emptying of the bladder, impotence, and low blood pressure when standing. Diabetic neuropathy often affects the lower extremities, causing either loss of feeling or disagreeable sensations of burning or itching. It is not known if these complications are due to long-standing hyperglycemia and insulin deficiency or are caused, at least in part, by an unidentified factor.

Treatment of diabetes

There are three basic components in the treatment of IDDM: insulin, diet, and exercise. Insulin is prepared in a number of forms, providing short, intermediate, and long actions to accommodate the specific needs of individual patients. Sources of insulin traditionally have been from pork and beef pancreases, but insulin with a structure identical to that produced by human islets is now widely available. It is either synthesized using recombinant DNA technology or prepared by the chemical alteration of porcine insulin. Insulin is given by one or more injections each day or by continuous infusion using an insulin pump, a computerized device the size of a deck of cards, which is worn by the patient and delivers a preset amount of hormone throughout the day. A typical diabetic diet contains sufficient total calories to maintain ideal body weight and consists of carbohydrate, fat, and protein and of ample fibre. Simple sugars and alcohol are prohibited. Compared to insulin and diet, exercise is more difficult to measure. Ideally, the diabetic exercises a fixed amount each day, and insulin and diet are tailored to accommodate that amount.

The goals of treatment include maintenance of the blood sugar near or within normal limits, freedom from hypoglycemia, and an acceptable life-style. The blood sugar usually can be monitored at home by the patient. Measurement of that portion of hemoglobin complexed to glucose provides another index of the adequacy of blood sugar control. Proteins exposed to glucose-containing solutions undergo glycosylation (*i.e.*, a certain number of glucose molecules become irreversibly fixed to the protein molecule). The higher the glucose concentration, the greater the degree of glycosylation. In normal humans approximately 6 percent of circulating hemoglobin is glycosylated; in poorly controlled diabetics, the figure may be 14 percent or more. Glycosylation of structural proteins, such as those in the basement membranes of capillaries, may play a role in the pathogenesis of the chronic complications of diabetes.

In the treatment of NIDDM, diet and exercise again are important. In the obese patient, evidence of diabetes mellitus may disappear if the patient can achieve and maintain ideal body weight. Insulin or a blood-sugar-lowering drug, however, may be required to control blood sugar.

Hypoglycemia. Although a wide array of human ills are attributed to low blood sugar (hypoglycemia), well-documented hypoglycemia is not common except among insulin-dependent diabetics. Regardless of the underlying

cause, the manifestations of hypoglycemia evolve in a characteristic pattern. Mild hypoglycemia causes hunger, fatigue, tremor, perspiration, weakness, and anxiety. These same symptoms often appear in a variety of conditions other than hypoglycemia, however. To implicate hypoglycemia properly, such symptoms should be associated with a blood glucose of less than 40 milligrams per decilitre and be promptly relieved by the administration of glucose. More severe hypoglycemia leads to blurred vision, impaired mentation, and bizarre behaviour. A staggering gait and irrational, hostile behaviour are frequently misinterpreted as drunkenness. Finally, the patient becomes comatose and may develop generalized seizures. If severe hypoglycemia remains untreated, permanent brain damage or death can result.

The principal causes of hypoglycemia can be grouped into two large categories: fasting and fed (or "reactive"). The time of day at which hypoglycemia occurs provides a clue to the underlying cause. Since liver production sustains the blood glucose level during periods of fasting, rare, inherited disorders that cause impairment in glycogen storage or gluconeogenesis lead to fasting hypoglycemia. This typically occurs in the early morning hours after eight or nine hours of fasting. Fasting hypoglycemia is also caused by insulin-secreting islet cell adenomas. In these cases, hypoglycemia is prevented during the waking hours by frequent eating, leading to weight gain.

Reactive hypoglycemias

Far more common are the reactive hypoglycemias, triggered by the assimilation of glucose following a meal. Normally, the secretion of insulin is commensurate with the degree of postprandial elevation of the blood sugar. After surgery that impairs the reservoir function of the stomach, ingested glucose is dumped into the duodenum and upper jejunum, where it is rapidly absorbed. The resulting excessive hyperglycemia stimulates a brisk release of insulin, leading to moderately severe hypoglycemia within two hours of the meal. There is another group of patients who assimilate glucose at an excessive rate even though they have not had gastrointestinal surgery. Such individuals typically have symptoms three to four hours after the ingestion of a large quantity of glucose. Manifestations of hypoglycemia usually can be avoided in reactive hypoglycemia by restricting the amount of glucose in the diet. The most frequent cause of clinically significant hypoglycemia is self-administration of insulin by the diabetic patient. This may result from an excessive dose of insulin, inadequate dietary amounts, or excessive physical activity. Rarely, hypoglycemia may be self-induced by emotionally disturbed patients with access to insulin.

Tumours of the pancreas. Inappropriate hypersecretion of pancreatic hormones may be due to diffuse hyperplasia (abnormal multiplication) of the secretory cells, adenomas (benign tumours), or carcinomas (malignant tumours). Hypersecretion of insulin is most frequently due to a single insulin-producing adenoma. Single or multiple insulinomas may occur as part of the syndrome of multiple endocrine neoplasia. Malignant insulinomas are less common. Diffuse hyperplasia of beta cells (nesidioblastosis) may cause hypoglycemia in infants. Glucagon-secreting tumours (glucagonomas) produce the "diabetes-dermatitis syndrome." Patients have mild diabetes, anemia, and a red, blistering rash that appears in one area of the body and then fades, only to reappear at a different site. Patients have elevated plasma glucagon levels, but marked hyperglycemia is prevented by an offsetting increase in insulin secretion.

Somatostatin-producing tumours are difficult to diagnose because findings are nonspecific and include diabetes mellitus, gallstones, excessive fat in the stool, indigestion, and diminished secretion of gastric acid. Plasma somatostatin levels are increased when measured by radioimmunoassay, and both insulin and glucagon concentrations are decreased. Pancreatic polypeptide-secreting islet cell tumours have been found in patients with the syndrome of multiple endocrine neoplasia. Pancreatic tumours may also be the source of "ectopic" hormone secretions (in which a hormone is secreted from a tissue type that normally does not secrete it; see below *Ectopic hormone and polyglandular disorders*). (T.W.B.)

THE ADRENAL CORTEX

Anatomy. The adrenal glands lie on the upper inner surface of each kidney. Each gland consists of two parts that are quite distinct anatomically, embryologically, and functionally. The inner core (adrenal medulla) is discussed separately below. The outer covering (adrenal cortex) is derived from the fetal mesodermal ridge, a structure that also gives rise to the kidneys so that the juxtaposition of the two organs is not surprising. Within the adrenal cortex are three zones known as the outer (zona glomerulosa), the middle (zona fasciculata), and the inner (zona reticularis). Under the microscope the cells are rather typical endocrine cells; the distinction between zones is made by differing staining characteristics.

The zones of the cortex

Hormones. Adrenocortical cells synthesize and secrete chemical derivatives (steroids) from cholesterol, the major animal sterol. While cholesterol can be synthesized in many body tissues, further differentiation into steroid hormones takes place only in the adrenal cortex and in its embryological cousins, the ovaries and the testes.

The adrenal cortex is capable of synthesizing all of the steroid hormones produced by the body, including the progestogens and estrogens (see below *The ovary*), androgens (see below *The testis*), mineralocorticoids (which are secreted from the zona glomerulosa), and glucocorticoids (which are synthesized and released from the zona fasciculata and zona reticularis of the adrenal cortex). Although upwards of 60 steroids are manufactured in the adrenal cortex, only a few members of these three major categories are important in body functioning.

Aldosterone. The biologic effect of aldosterone, the principal mineralocorticoid produced by the zona glomerulosa, is to set in motion a set of reactions at the cell surface of all body tissues in order to enhance the uptake and retention of sodium in all cells and the extrusion of potassium from them. Such fluxes of sodium and potassium following the administration of aldosterone are detectable even in glandular secretions, such as sweat. It also has a major impact on kidney function, acting on the renal tubules to retain sodium within the circulation while increasing the excretion of potassium into the urine. At the same time, by increasing the reabsorption of bicarbonate by the kidney, aldosterone tends to decrease the acidity of body fluids.

Cortisol. Cortisol (hydrocortisone) is the major human glucocorticoid. It exerts multiple and varied effects. It also serves as a mineralocorticoid but is considerably less effective than aldosterone. Cortisol plays a major role in the body's response to stress. In fasting, for example, it sustains the blood sugar concentration by blocking the egress of glucose into all tissues other than the critically important brain and spinal cord, while it simultaneously increases the breakdown of protein from muscle and other organs and hastens the conversion of newly generated amino acids to glucose to replenish the supply constantly being consumed by the brain.

"Permissive" actions

In addition, glucocorticoids have a "permissive" action for many chemical reactions in the body; that is, their presence is necessary for the action to occur, but they themselves do not initiate it. For example, the secretion of acid into the stomach does not occur in the total absence of glucocorticoids, but, in the presence of normal amounts of cortisol, acid can be excreted in small or large amounts as the body requires.

Cortisol, along with more potent and longer-acting synthetic derivatives like prednisone, methylprednisolone, and dexamethasone exerts powerful anti-inflammatory effects. Physicians take advantage of these properties in treating patients with serious inflammatory illnesses such as rheumatoid arthritis, disseminated lupus erythematosus, and multiple sclerosis. If, however, the inflammation has a bacterial or viral origin, the steroids may do more harm than good because the spread of the infection is facilitated while the signs of inflammation are masked (see IMMUNITY). Finally, corticosteroids in large doses impair the functioning of the immune system so that the production of harmful antibodies, such as those produced in allergic diseases, may be suppressed. It is important to note that these beneficial effects are offset by serious side effects

of large-dose, long-term corticosteroid therapy, effects that closely mimic many of the symptoms of Cushing's syndrome (see below).

Adrenal androgens. Ordinarily, adrenal estrogens do not play an important role in the body's economy, but adrenal androgens do make a significant contribution. These androgens are not as potent as testosterone, the major steroid secreted by the testis, but a number of them, including androstenedione, dehydroepiandrosterone (DHEA), and its sulfate (DHEAS) may be converted to stronger androgens such as testosterone. Although little androgen is secreted before puberty, the output increases dramatically at puberty so that the adrenal cortex makes a significant contribution, known as the adrenarche, to developmental changes in both sexes.

All steroid hormones, including those from the adrenal cortex, are bound to steroid-binding globulins (transcortin) in the circulation and are released at the surface of a target cell. The steroid passes into the cell cytoplasm and is bound to an intracellular binding protein and thence is transported into the cell nucleus. There the hormone exerts its effect by modulating gene activity so that the synthesis of some proteins is stimulated while that of others might be inhibited. The net effect is the biologic action noted at the physiological or pathological level. The steroid hormones undergo inactivation in a complex series of transformations principally in the liver but in other tissues as well, leading to a total loss of hormonal activity.

Regulation of hormone secretion. The three classes of corticosteroids (the mineralocorticoids, the glucocorticoids, and the adrenal androgens) are regulated largely by separate mechanisms. Glucocorticoids are regulated by way of the classical hypothalamic-hypophyseal feedback system shown in Figure 3. Within the family of glucocorticoids, the cortisol level is the one most closely guarded. Furthermore, the ongoing feedback control is modulated by hypothalamic biorhythmic activity illustrated in the case of cortisol in Figure 9. When the individual is exposed to physical or emotional stress, the self-regulating mechanism is interrupted and plasma cortisol is increased to deal with the stress. Adrenal androgen secretion is controlled primarily by ACTH, although there is evidence that prolactin stimulates the secretion of adrenal androgens as well.

Regulation of corticosteroids

Aldosterone secretion is modulated directly by serum electrolyte levels. Lowered serum sodium concentrations enhance aldosterone secretion, but a far more potent stimulus is a high serum potassium level.

A major regulator of aldosterone secretion is the renin-angiotensin system, although ACTH also stimulates mineralocorticoid secretion. Renin is an enzyme secreted into the blood plasma from specialized cells encircling the arteriole located at the entrance to the glomerulus (the renal capillary network that is the filtration unit of the kidney). Renin secretion is inhibited when these cells, contained in what is known as the juxtaglomerular apparatus, are compressed by dilatation of this entering (afferent) arteriole provoked by an increase in plasma volume. When plasma volume decreases, renin secretion is stimulated.

Renin catalyzes the conversion of a plasma protein, angiotensinogen, into an active decapeptide, angiotensin. Angiotensin is a potent stimulator of arteriole constriction and aldosterone secretion. Both actions result in higher blood pressure, the first by increasing resistance to the flow of blood ejected by the heart, and the second by increasing total plasma volume. These are key responses when blood pressure falls to a dangerously low level. On the other hand, excessive renin secretion can lead to ongoing high blood pressure with its dangerous consequences to the health of the patient.

For a number of years investigators have sought a factor secreted by the hypothalamus that would specifically modulate aldosterone secretion in the same negative feedback fashion that relates pituitary corticotropin to the adrenocortical glucocorticoid, cortisol. Several candidates, including melanotropin (MSH) and endorphins, have emerged. Whether either or both of these hormones completely fulfill this role remains uncertain.

More recently, a new group of factors, the atrial natriuretic (sodium-excreting) peptides (atriopeptin, atrin), have been characterized. These hormones are secreted into the blood when the upper chambers of the heart, the atria, are stretched by an expanded volume of blood. The major polypeptide isolated from human atria, atrin, contains 28 amino acids. In general, the actions of atrin oppose those of angiotensin; atrin blocks the contractions of muscles in the walls of arteries so that the arteries dilate, and atrin inhibits the synthesis and secretion of aldosterone. Furthermore, it inhibits the release of renin from the juxtaglomerular cells, and finally it acts directly on the kidney to increase the excretion not only of urine but also the sodium chloride, potassium, magnesium, and phosphorus contained in it. This powerful natriuretic action may have important therapeutic applications in patients with heart failure, high blood pressure, liver disease, or other illnesses associated with the retention of fluid. Finally, it should be noted that the adrenal glands are influenced not only by endocrine factors but also by neural influences. The neurotransmitter dopamine is a powerful suppressor of aldosterone secretion, while serotonin may have a stimulating effect.

Atrial natriuretic peptides

Diseases and disorders. *Adrenal insufficiency (Addison's disease).* Adrenal insufficiency is a rare disease. In the past it was caused most commonly by destruction of both adrenals in tuberculosis patients. More recently, it has been found that destructive autoantibodies are most often the cause, sometimes as part of the inherited syndrome of multiple endocrine deficiencies (see below *Ectopic hormones and polyglandular disorders*). Other infectious diseases such as histoplasmosis may also destroy both adrenals. The adrenal glands may be involved in many other pathological processes (for instance, invasion by cancer), but adrenal insufficiency does not supervene because more than 90 percent of the total of adrenal cortical tissue must be destroyed before it becomes incapable of providing for the body's needs. Adrenal insufficiency may be secondary to diseases of the pituitary or hypothalamus, resulting in deficiencies of corticotropin or CRH, respectively.

Addison's disease, if undiagnosed, leads to death. The onset of Addison's disease is often gradual and puzzling to both patient and physician. There is an increasingly generalized weakness along with an inordinate tiredness after physical activity. The patient loses appetite and weight and suffers occasional bouts of vomiting and diarrhea. There is increasing pigmentation, not only in exposed areas but also in the nails and in the skin creases. The patient's blood pressure falls, and there may be episodes of fainting upon arising from bed or from a chair. The patient must eat regularly because even minor delays result in hypoglycemic episodes. If the disease is caused by an infectious agent, there may be calcification in the area of the adrenals seen on X-ray examination of the abdomen.

Addison's disease

The symptoms intensify over a period of months until, either spontaneously or as the result of physical stress, such as trauma or an intercurrent illness, the patient suffers acute adrenal insufficiency, known as Addisonian crisis, and experiences a catastrophic change in status. With intensified vomiting, diarrhea, and fever and with a precipitous fall in blood pressure, the patient goes into shock and dies.

Addisonian crisis may occur also in individuals who have no previous adrenal disease. During or shortly after birth some infants suffer bilateral massive adrenal hemorrhage. A similarly destructive hemorrhage can occur in adults, especially those who are treated with anticoagulants like heparin and undergo an operation or other trauma. Cortisol given intravenously is life-saving.

In chronic adrenal deficiency the patient can be kept alive and well with modest doses of cortisol taken orally, often along with a synthetic mineralocorticoid. Occasionally, salt tablet supplements are useful. The dosage must be sharply increased during periods of acute illness or injury. Before the advent of these simple therapeutic measures patients with Addison's disease died within two to three years after diagnosis. Such patients can now look forward to a full life span as long as they are prepared to increase the dosage of cortisol in the event of serious physical stress.

Hypercorticism (Cushing's syndrome). Hypercorticism, the illness resulting from overactivity of the adrenal cortex, exemplifies nicely the medical term syndrome, a constellation of symptoms and signs that together makes up a specific, easily recognized clinical entity, but which has diverse causes. In 1932, the American Harvey Cushing, a pioneer in the field of neurosurgery, described the clinical picture of patients harbouring a specific type of pituitary tumour, an entity that became known as Cushing's disease.

Further studies over the years have revealed that, with minor variations, the clinical picture described by Cushing could also result from at least four other causes: a benign tumour or a cancer of the adrenal cortex; a corticotropin-releasing, hormone-producing hamartoma of the hypothalamus; a number of tumours, both benign and malignant, that ordinarily do not secrete hormones (ectopic hormones that then produce tumours); and finally, the therapeutic administration of large doses of adrenocortical hormones (iatrogenic, or physician-induced, Cushing's syndrome). Thus, ordinarily, the clinician first makes the diagnosis of Cushing's syndrome and then explores further to determine the specific cause so that appropriate, specific treatment can be administered.

Causes of Cushing's syndrome

Cushing's disease results from a hyperfunctioning, corticotropin-producing, benign (rarely malignant) tumour of pituitary corticotrophs. Secreted along with corticotropin is melanotropin (MSH) so that the patient becomes progressively pigmented in a fashion similar to what is seen in patients with Addison's disease. For reasons poorly understood, the patient gains weight in a peculiar distribution; the obesity is confined to the central body areas—the abdomen and back and buttocks—with rather thin extremities. Excess fat deposits occur at both temples, giving rise to a "moon face," and fat may be deposited in the anterior neck ("dewlap"), below the neck posteriorly ("buffalo hump"), around the heart, and even in the spinal canal. Most of the symptoms result from the powerful protein catabolic and gluconeogenetic effects of the glucocorticoids. All patients show progressive weakness and muscle wasting. The skin becomes thin and fragile so that hemorrhages beneath the skin occur frequently. The bone becomes osteoporotic. The increased glucose production may lead to diabetes mellitus as an additional complication. Finally, in women, ovulation is suppressed and there is often amenorrhea along with hirsutism (hairiness), the result of increased adrenal androgen secretion.

Treatment

Treatment is directed against the specific cause. Pituitary tumours are removed surgically, and recurrences may be treated with X-ray therapy. Adrenal tumours also are removed surgically. Adrenocortical carcinomas usually carry a grave prognosis; initially they are treated by surgical removal unless they have already metastasized, in which case a number of drugs are available that block the secretion of corticosteroids. In addition, drugs have been introduced that block the peripheral action of glucocorticoids by displacing them from the specific receptors. Ectopic corticotropin-producing tumours are treated either by surgery, X-ray therapy, or chemotherapy. Occasionally, if the Cushing's syndrome becomes life-threatening and the usual forms of therapy have been unsuccessful, both adrenal glands may have to be removed. The ensuing adrenal insufficiency is treated in a fashion similar to that in patients with Addison's disease. In those patients in whom the primary cause is a pituitary tumour, bilateral adrenalectomy is sometimes followed by a rapid progression in growth of the tumour along with intense skin pigmentation, a combination known as Nelson's syndrome.

Hypoaldosteronism. Total destruction of the adrenal glands by definition includes hypoaldosteronism as part of the disorder. There exists, however, a disease in which adrenocortical function is intact except for defective synthesis and secretion of aldosterone from the zona glomerulosa.

Isolated aldosterone deficiency results in a low level of sodium in the serum (hyponatremia) along with an elevated level of potassium (hyperkalemia). These biochemical changes produce weakness as well as an increased risk of dangerous abnormalities in heart rhythm, some of which are fatal. Hypoaldosteronism is frequently associated with kidney disease, especially in diabetics, and in these instances the cause stems from deficient production of renin with consequent low levels of angiotensin and a reduced stimulus for the secretion of aldosterone. Rarely, the deficiency lies in an inadequate production of the enzyme needed to synthesize angiotensin (angiotensin-converting enzyme). As a result, plasma renin levels are elevated. In other cases there is an enzymic defect in aldosterone production, which may be hereditary. Treatment requires the administration of fludrocortisone, a powerful synthetic mineralocorticoid. Aldosterone itself is poorly absorbed when taken orally.

Hyperaldosteronism (Conn's syndrome). In 1955, an American internist, Jerome Conn, described a form of high blood pressure associated with hypokalemia and reduced acidity of the blood (alkalosis) in patients who harboured a benign tumour of adrenal glomerulosa cells. These patients were found to have high levels of aldosterone in the circulation, and for most the hypertension and hypokalemia disappeared with the removal of the adrenal adenoma. Aside from the sometimes severe symptoms of high blood pressure, such as headache, patients often note weakness, increased urination, increased thirst, and peculiar skin sensations along with muscle cramping. Abnormalities in heart rhythm also may occur, and if potassium loss is severe there may be impaired glucose tolerance, although diabetes is not common.

Symptoms of Conn's disease

Hyperaldosteronism may occur as a secondary phenomenon in other diseases, particularly those accompanied by increases in extracellular fluid (edema). Examples include heart failure, severe liver disease, and a kidney ailment, nephrosis, characterized by excessive loss of plasma proteins. While the cause of increased aldosterone secretion in these illnesses is not clearly understood, successful treatment of the primary disease leads to a restoration of aldosterone levels to normal.

An American endocrinologist, Frederic Bartter, described individuals who exhibited hyperplasia of the juxtaglomerular apparatus, high serum renin and angiotensin levels with resultant elevations in plasma aldosterone associated with hypokalemic alkalosis. These individuals, however, had a consistently normal blood pressure. The onset is usually in late infancy or childhood, and patients often show evidence of dwarfism and mental retardation. The cause is not well understood, but the hypokalemia and some of the symptoms may be reversed by the use of drugs, such as indomethacin, that inhibit the formation of prostaglandins.

Congenital adrenal hyperplasia. Congenital adrenal hyperplasia is a disorder in which the hereditary absence of a single enzyme has far-reaching consequences. In the most common form of this deficiency, an adrenal enzyme called 21-hydroxylase is absent. As a result, the adrenals cannot synthesize aldosterone and cortisol. The low levels of circulating cortisol reduce inhibition of corticotropin secretion by the pituitary. The resulting high levels of corticotropin lead to excessive secretion of adrenal androgens. When this enzyme deficiency is absolute, the child may die at, or soon after, birth from adrenal insufficiency. When the enzyme deficiency is only partial, the child may survive. Because the excess of adrenal androgens begins in utero, however, children are born with striking signs of masculinization (virilization): newborn genetic females have an enlarged clitoris, often mistaken for a penis, and an enlarged vulva, which resembles a bilobed scrotum. These individuals, known as female pseudohermaphrodites, may reach maturity and live out their lives as short, stocky males. They are, of course, infertile since they have vestigial ovaries rather than testes. A variation on this disorder occurs late in adolescence and is diagnosed in women who appear normal except for the development of excessive hair on the face and extremities (hirsutism). In genetic males, the excessive androgens lead to striking muscle development and an enlarged penis, the "infant Hercules."

21-hydroxylase deficiency

Treatment of the juvenile form of this disorder depends upon the time of diagnosis. If the patient is near the age of puberty, it is generally considered wise to permit the genetic female to maintain the male gender role since it has become deeply embedded. When the diagnosis is

made at birth, however, treatment with replacement doses of cortisol permit a reversal of the entire process. Normal levels of cortisol reduce the excessive secretion of corticotropin, which in turn decreases the secretion of male sex hormones (adrenal androgens) to normal. The patient then develops normally, and the ambiguous genitalia can be corrected surgically. For the late-onset type, treatment with cortisol or one of the synthetic glucocorticoids arrests the process.

Other enzyme deficiencies in adrenal hyperplasia result in still other dramatic variations. The absence of 17α-hydroxylase leads to a stockpiling of steroid precursors, sometimes including a powerful mineralocorticoid called desoxycorticosterone. The result in a child is similar to that seen in primary aldosteronism (hyperaldosteronism) with hypertension and hypokalemic alkalosis. Another genetic defect, 18-hydroxylase deficiency, blocks the formation of aldosterone so that the child shows evidence of mineralocorticoid deficiency, excreting excessive amounts of salt. This is a hereditary form of hyperaldosteronism. These variants are also treated with replacement doses of the deficient hormone.

THE ADRENAL MEDULLA

Anatomy. The adrenal medulla is embedded in the centre of the adrenal cortex. It is quite small, making up only about 10 percent of the total adrenal weight. It is composed of chromaffin cells, so called because the granules within the cells darken after exposure to chromium salts. Chromaffin cells have migrated from the embryonic neural crest and represent specialized neural tissue. Indeed, the adrenal medulla forms an integral part of the sympathetic nervous system, a major subdivision of the autonomic nervous system (see NERVES AND NERVOUS SYSTEMS: *The autonomic nervous system*), and the combined activities have been referred to as the sympathoadrenal system.

Medullary hormones

Included among the medullary hormones, the catecholamines, are dopamine, norepinephrine, and epinephrine, all of which are synthesized in the brain and sympathetic nerve endings. The adrenal medulla differs from most other endocrine glands in that the major stimulus for the release of the catecholamines is by stimulating sympathetic nerve endings to release acetylcholine (ACh), an important neurotransmitter of the peripheral nervous system (nerves and ganglia located outside the central nervous system, or the brain and spinal cord). When stimulated, the medullary cell ejects the chromaffin granules from the cytoplasm into the bloodstream, a process known as exocytosis. Thus, the adrenal medulla is a neurohemal organ.

Catecholamines. The catecholamines are synthesized from the amino acid L-tyrosine. Serial changes in chemical structure are catalyzed by enzymes, leading to the following synthetic sequence: L-tyrosine → L-dopa (dihydroxyphenylalanine) → dopamine → L-norepinephrine (noradrenaline) → L-epinephrine (adrenaline). The close proximity of the adrenal cortex to the adrenal medulla is not accidental. The enzyme that mediates the transformation of L-norepinephrine to L-epinephrine is formed only in the presence of high local concentrations of glucocorticoids from the adjacent cortex; chromaffin cells in tissues outside the adrenal cortex are incapable of synthesizing epinephrine.

Synthesis of catecholamines

L-dopa is well known for its role in the treatment of parkinsonism, but its biological importance lies in the fact that it is a precursor of dopamine, a neurotransmitter widely distributed in the central nervous system, including the basal ganglia of the brain (groups of nuclei within the cerebral hemispheres that collectively control muscle tone, inhibit movement, and control tremor). It is a deficiency of dopamine in these ganglia that leads to parkinsonism, a deficiency that is at least partially repaired by the administration of L-dopa. Under ordinary circumstances, far more epinephrine than norepinephrine is released from the adrenal medulla; in the catecholamine neurotransmitting function throughout the body, norepinephrine is far more widespread. It is likely that the full complement of hormones secreted by the adrenal medulla is not yet completely known. There is strong evidence to indicate, for example, that enkephalins (neurotransmitters with opiate-like effects) are contained within chromaffin granules and are secreted into the general circulation.

In physiological terms, a major action of the hormones of the adrenal medulla conjoined with the sympathetic nervous system is to initiate a rapid, generalized bodily response described by Walter Cannon as "fight or flight." This response may be triggered by a fall in blood pressure, pain (including burns), or abrupt emotional upheavals. An injection of epinephrine, in fact, closely mimics the symptoms of an anxiety attack (sweating, tremor, greatly increased heart rate). Metabolic changes also stimulate catecholamine secretions as evidenced by the rapid rise in plasma epinephrine levels when an individual becomes hypoglycemic (has a greatly decreased glucose level). Thus, much of what is called a hypoglycemic reaction is the result of a large epinephrine discharge.

Action of catecholamines

The action of catecholamines on the body's organs and tissues is widespread and complex. There actions, however, are rarely isolated; they usually occur in concert with other neural or hormonal responses. Furthermore, tissue responses depend on the fact that there are two major types of adrenergic receptors on the surface of target organs and tissues: alpha-adrenergic and beta-adrenergic receptors, or alpha receptors and beta receptors, respectively (see NERVES AND NERVOUS SYSTEMS: *Biodynamics of the vertebrate nervous system*). Both contain a number of subtypes so that receptor responses to the catecholamines have some degree of specificity and coordination. In general, the alpha-adrenergic receptors constrict blood vessels and the uterus, relax the intestine, and dilate the pupils. Beta receptors stimulate the heart, dilate the bronchi and blood vessels, and relax the uterus and intestines. It should be noted that there also are specific receptors to dopamine.

The effects of catecholamines on the heart result mainly from their association with beta receptors. When catecholamines bind to these receptors in the surface membranes of heart cells, pulse rate and strength of heart muscle contraction are increased so that the amount of blood moved through the heart per minute (cardiac output) increases. This sequence of events increases the body's requirement for oxygen and raises blood pressure, a consequence of greater blood flow through the heart. Drugs, such as propranolol, that block the activation of these beta receptors (beta blockers) are often used for the treatment of high blood pressure and cardiac pain (angina pectoris). Conversely, since activation of beta receptors results in bronchial dilation (expansion of the air passages in the lung) because of the heightened need for oxygen, propranolol is contraindicated in the treatment of asthma; it would worsen the bronchial constriction that already exists in the condition.

Catecholamines also play key roles in the generation of body heat (thermogenesis). Oxygen is consumed in metabolic processes in the body that produce heat. When catecholamines stimulate beta receptors and increase the overall level of oxygen in the body, more oxygen is consumed, and more heat is produced. Catecholamines also increase available body fuels such as glucose and free fatty acids. They stimulate the breakdown of glycogen, which is stored in the liver and muscle, to glucose (glycogenolysis) and the breakdown of triglycerides, the stored form of fat, to free fatty acids (lipolysis). Finally, the catecholamines are regulatory agents in hormone secretion; they serve as neurotransmitters modulating the secretion of releasing hormones in the hypothalamus, and they stimulate the release of glucagon and somatostatin and inhibit the release of insulin from the islets of Langerhans of the pancreas.

Role as neurotransmitters

All catecholamine effects on hormonal secretion are stimulatory and affect the thyroid and parathyroid, the gonads (ovary and testis), and the placenta. There is evidence, however, that stimulation of dopaminergic receptors blocks the secretion of aldosterone from the adrenal cortex. Excessive secretion or ingestion of the thyroid hormones increases the number of beta receptors so that many of the clinical consequences of the hyperthyroid state can be suppressed by using beta blockers.

Adrenomedullary dysfunction. Isolated loss of the medulla of both adrenals does not occur; such destruction is always accompanied by impairment of the function of the

cortex of both adrenals. Any effects that can be attributed to the loss of the medulla are overshadowed by the predominating signs of Addison's disease.

Tumours of the adrenomedullary chromaffin cells, called pheochromocytomas, do occur and may produce striking, largely predictable signs and symptoms that are exaggerations of the physiological actions of the catecholamines. Pheochromocytomas are tumours of the chromaffin cell, usually benign but occasionally malignant. Commonly unilateral, these tumours may be present in both adrenals when they appear in the hereditary form of multiple endocrine neoplasia. Extra-adrenal tumours of these chromaffin cells have been found in multiple locations, extending from the patient's neck to the urinary bladder, most often in a collection of cells known as the organ of Zuckerkandl. While the normal adrenal medulla secretes mostly epinephrine, pheochromocytomas predominately secrete norepinephrine.

High blood pressure is an invariable finding in adrenomedullary hyperfunction. It may be constant, and it may be difficult to distinguish from the common forms of hypertension. In some instances, however, there is a sudden increase in norepinephrine secretion, provoking the sudden explosive onset of its vasopressor actions, such as a severe headache, excessive sweating, palpitation of the heart, ashen pallor, tremor, and anxiety. These attacks may end abruptly and the patient may appear to be normal following the attack. They may last from minutes to hours and may occur at intervals ranging from, for example, once a month to several per day. In persons in whom tumours secrete an appreciable amount of epinephrine, anxiety may be more marked and the patient may lose weight, be feverish, and show evidence of diabetes mellitus.

Treatment

Excess secretion of either norepinephrine or epinephrine by such tumours may be treated therapeutically or in preparation for surgery by using alpha- or beta-receptor antagonists (drugs that compete with epinephrine and norepinephrine for receptor sites on target organs but do not elicit a response once bound; in essence they tie up many of the potential binding sites of these overly secreted catecholamines). Surgical removal of the isolated tumour remains the favoured treatment. When malignant pheochromocytomas have spread to other organs, however, antagonist drugs may be continued indefinitely.

THE OVARY

Anatomy. The ovaries are multipurpose organs. They harbour, nurture, and guide the development of the egg so that when it is extruded from the ovary (ovulation) it has been prepared for its migration down the fallopian tube, its penetration by sperm, and its eventual implantation in the wall of the uterus. Additionally, the ovary is a sophisticated endocrine structure. It secretes hormones essential for the onset of menstruation (menarche) and its cyclical perpetuation. At the same time, the ovary produces profound alterations in body physique that transforms a prepubertal girl into a mature woman.

The mature ovary is a roughly bean-shaped structure weighing about 14 grams. It, like the adrenal gland, consists of an outer cortex and a central medulla with the addition of an inner hilus (depression or pit) that serves as the point of entry and exit of blood vessels and nerves. The ovaries are located in the pelvis, attached to a structure called the broad ligament (see REPRODUCTION AND REPRODUCTIVE SYSTEMS: *The human reproductive system*).

Follicle maturation

Immature follicles (primordial follicles) embedded in fibrous tissue (stroma) enlarge as the follicle matures and moves through the cortex toward the outer surface of the ovary. The cells lining the follicle multiply and become layered into a zona granulosa. Along with this change the stromal cells immediately surrounding the follicle arrange themselves concentrically to form a theca (an enclosing sheath). This egg-containing mature structure is known as a Graafian follicle. Both granuloma cells and thecal cells secrete steroid hormones known as estrogens. The follicular fluid bathing the ovum is an extraordinarily complex liquid containing not only high concentrations of estrogens but also other steroids (progestogens and androgens), pituitary hormones (FSH, LH, prolactin, oxytocin, and vasopressins), and numerous enzymes and bioactive proteins.

During the maturation (follicular) phase of the menstrual cycle, follicles continue to enlarge until one (or, rarely, two) follicles rupture at the ovarian surface. The egg is extruded and promptly enters the fallopian tube to begin its journey to the uterus. The supportive role of the follicle does not end with the discharge of the egg. Thecal cells penetrate the emptied follicle and, together with persisting but modified granulosa cells, fill the follicle, now called a corpus luteum, which is the source of serum progesterone during the postovulatory (progestational or luteal) phase of the menstrual cycle. With menstruation, the corpus luteum becomes scarred and contracted (atretic), remaining as a corpus albicans. In the event that the extruded egg is fertilized and pregnancy ensues, the corpus luteum persists and continues to secrete increasing amounts of progesterone during the first trimester. As might be expected, these changes are controlled by secretions from the hypothalamus and the anterior pituitary gland.

Regulation of hormone secretion. Before the onset of puberty the ovaries are quiescent, and the stroma of the cortex and medulla are studded with multiple primordial follicles. Puberty is heralded by subtle but far-reaching changes. Some undefined event stimulates the secretion of luteinizing hormone-releasing hormone (GnRH) from the hypothalamus, and GnRH secretion becomes pulsatile. Animal studies support the notion that puberty is precipitated by a reduction in the secretion of melatonin, a hormone of the pineal gland. There is, however, no evidence that melatonin has a role in the onset of puberty in humans.

The onset of puberty

Secretion of GnRH activates gonadotrophs from the anterior pituitary, resulting in enhanced secretion of both follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The secretion of these hormones, particularly LH, is much enhanced shortly after the onset of sleep; increased nocturnal secretion of LH is the earliest change detectable in the pubertal child. It appears that GnRH secretion is inhibited by neurons that secrete dopamine and is stimulated by noradrenergic neurons (involved with norepinephrine). Endogenous opiates, especially beta-endorphin and dynorphin, also play important roles in regulating the frequency and strength of GnRH secretion.

The increased secretion of estrogens from the ovaries, stimulated by LH secretion coupled with maturing Graafian follicles (resulting from the increased FSH secretion) leads to menarche. Before long, the cyclic activity characteristic of the normal female hypothalamus appears (Figure 14B). Immediately following the cessation of menstruation, the sequence begins with a gradual rise in the blood level of estradiol (the most potent of the estrogens), paralleled by a slow rise in serum LH. An inconspicuous rise in androgens also occurs while progesterone and its precursor, 17-hydroxyprogesterone, remain suppressed. Finally, the rising estradiol level trips off a mid-cycle surge of LH and FSH (an example of a positive feedback mechanism). The abrupt rise in gonadotropins precipitate ovulation, ending the follicular phase. With the formation of the corpus luteum, estrogen levels fall but not back to baseline, while the levels of 17-hydroxyprogesterone and progesterone are much elevated. At the end of the luteal phase all hormonal levels return to baseline, and the withdrawal of the estrogens precipitates the next menstrual period. The normal menstrual cycle is 28 days long although it varies considerably from one woman to another and occasionally in the same woman, with irregularities occurring most frequently shortly after puberty or before the menopause.

The premenstrual fall in levels of estrogen and progestins occurs because of a degeneration and loss of function of the corpus luteum (luteolysis) that results from a faltering of LH pulses from the pituitary. The endometrium, which had become increasingly thickened and vascular, undergoes a constriction of small arteries. Cutting off oxygen and nutrient supplies to the endometrial lining leads to cell death and the subsequent sloughing and bleeding characteristic of menstruation. It should be noted that the basal body temperature, which fluctuates only mildly during the follicular phase, shows a rather abrupt progressive rise

Luteolysis

after ovulation, paralleling the increase in progesterone (Figure 14A). This thermogenic action results from the effect of the elevated progesterone levels on temperature-regulating centres in the base of the brain. (The structural and functional changes that occur in the fallopian tubes [oviducts], lining of the uterus [endometrium], distal opening to the uterus [cervix], and vagina and that accompany the endocrinologic fluctuations are discussed in the article REPRODUCTION AND REPRODUCTIVE SYSTEMS: *The human reproductive system.* The extension and accentuation of these changes, which occur in the event of pregnancy, are also discussed there.)

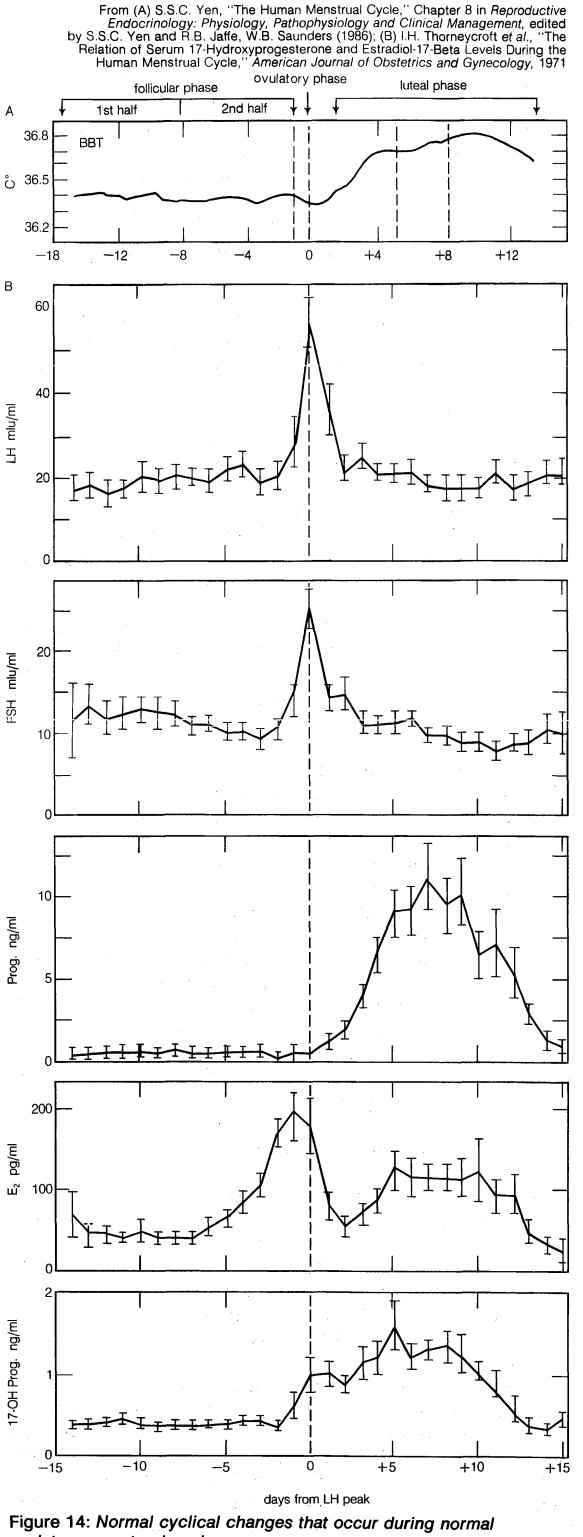

Figure 14: *Normal cyclical changes that occur during normal ovulatory menstrual cycle.*
(A) Changes in basal metabolic temperatures (BBT). (B) Normal levels of luteinizing hormone (LH), follicle-stimulating hormone (FSH), progesterone (Prog.), estradiol (E_2), and 17-OH progesterone (17-OH Prog.).

Hormones. As is the case in the adrenal cortex, the parent sterol from which all ovarian steroid hormones are formed is cholesterol. Both estrogens and progestogens are synthesized from a common precursor, pregnenolone, itself formed from cholesterol. These chemical sequences also include dehydroepiandrosterone, androstenedione, and testosterone, all of which are steroids that are primarily androgens (male sex hormones).

Synthesis of ovarian hormones

Once secreted into the blood, estrogens share with androgens, particularly testosterone, a binding globulin (testosterone-estradiol-binding globulin, TeBG), which transports them to target tissues. At this site, the estrogens easily penetrate the cell surface and are bound to an intracellular binding protein. It is in this form that they are transported to the cell nucleus, where they modulate protein synthesis by influencing the formation of DNA.

Estradiol, the most potent of the three major estrogens, is formed by both granulosa and thecal cells, perhaps acting together. Estrone can be formed from estradiol, but its major precursor is androstenedione. Estriol is formed from both estrone and estradiol and is the weakest of the estrogens. Indeed, in some circumstances estriol appears to have anti-estrogen effects; that is, it may bind to tissue estrogen receptors without setting in train estrogen effects and, while doing so, block the receptor from access to more potent estrogens such as estradiol. It has been suggested that it protects against the development of breast cancer in women. Catechol estrogens are metabolic products that also have anti-estrogen effects.

Formation of progesterones

The progesterones (progestins) are formed by the corpus luteum. Progesterone is also produced by the adrenal cortex, but the rise that occurs in its serum level during the luteal phase stems from ovarian secretion. The hormone 17-hydroxyprogesterone is secreted by thecal cells and accounts for most of the hormone found in the blood; again, the adrenal cortex may secrete a lesser amount at a constant rate.

Among the many nonsteroidal substances secreted into the follicular fluid is a substance called inhibin (folliculostatin), which is secreted by granulosa cells (and by Sertoli cells in the male). The primary action of inhibin is to inhibit the secretion of pituitary FSH. Since the major action of FSH is to stimulate the formation and function of granulosa cells, the relationship between inhibin and pituitary FSH represents a classical negative feedback servomechanism. Relaxin, a polypeptide hormone produced by the corpus luteum, induces a relaxation of the pubic ligaments connecting the two halves of the pelvis, an action that mitigates the discomfort of a woman in labour and eases the passage of the child. Finally, the ovary contains both oxytocin and vasopressin in high concentration, which serve a paracrine function. Oxytocin may assist in the expulsion of the egg from the ovary and may also mediate the process of luteolysis (break up of the corpus luteum). Vasopressin constricts local blood vessels after the egg is extruded.

Functions of ovarian hormones

Ovarian hormones have multiple functions. Pulsatile secretion of LH occurs well before the onset of the first menses (menarche) so that the rate of estrogen secretion also increases progressively. This results in the progressive development of breasts (thelarche) and the appearance of pubic hair and culminates in the menarche. Estrogens, including those contained in oral contraceptives, also exert ongoing generalized effects in the adult female. They mildly impair the body's ability to metabolize glucose, and they tend to increase the level of fats (triglycerides) in the blood. These effects are easily obviated by other endocrine adjustments in the normal woman, but they have an impact when these compensatory mechanisms are impaired. Estrogens increase the serum concentration of a large number of binding proteins that transport other materials; these include binding proteins for cortisol, thyroxine, iron, and copper, as well as those that bind estrogens and testosterone (TeBG). Finally, estrogens tend to increase the concentration of sodium, and therefore the degree of water retention, again particularly in susceptible women.

Diseases and disorders. *Precocious puberty.* In a setting such as the ovary, in which a complex train of interlocking hormonal activities must occur in proper sequence, it is not surprising that there are a number of abnormalities in function. Among them is precocious puberty, defined as the onset of menstruation before the age of nine years. In true precocious puberty, which may occur as early as the age of two years, ovulation takes place, and the child must be protected from the threat of pregnancy. The cause of this disorder is unknown, and affected girls are otherwise normal.

Nonetheless, treatment is important for proper psychological and social development. Synthetic steroids that inhibit the secretion of gonadotropins from the pituitary have been used successfully. They lead to the regression of breast size, the suppression of menstruation, and the prevention of aberrations of height (a pubertal growth spurt that takes place too early, followed ultimately by short stature in the adult). This form of treatment is being superseded by the use of synthetic derivatives of hypothalamic GnRH. These derivatives are long-acting and block pituitary receptors, both by occupying receptor sites and by preventing the pulsatile stimulation by the naturally occurring GnRH.

Pseudoprecocious puberty

Pseudoprecocious puberty occurs from tumours that secrete GnRH or from tumours that secrete the gonadotropins themselves. Although these patients show breast development, the appearance of pubic hair, and menstrual bleeding, they do not ovulate and they are infertile. Treatment is directed against the tumour that is secreting the hormones.

Menstrual disorders. In the adult female who has matured normally, any of a number of menstrual dysfunctions can appear, most of which lead to infertility. Indeed, a common disorder that occurs most often during adolescence or around the menopause is dysfunctional uterine bleeding. Menstrual bleeding occurs at irregular intervals and ovulation is absent. It results from a sluggish LH response to rising estrogen levels in girls and a suboptimal estrogen rise in aging women. Treatment may be with progestins or an estrogen-progestin combination. A second disorder that is being diagnosed with increasing frequency is hyperprolactinemia (see above *The anterior pituitary gland: Prolactin*), but not always associated with a disappearance of menses (amenorrhea) and the spontaneous secretion of breast milk (galactorrhea).

A rare, but intriguing, aberration is false pregnancy (pseudocyesis). A woman, wanting to be pregnant, generates impulses from the cerebral cortex that stimulate the hypothalamus, resulting in an increase in the secretion of LH and prolactin. Changes typical of a first trimester pregnancy then appear. These changes regress promptly when the patient is made aware that she is not pregnant. A mild form of this disorder occurs in patients in whom the corpus luteum persists for longer than the normal 14 days. This persistent corpus luteum syndrome may lead to a prolonged period of amenorrhea.

Anorexia nervosa

A more threatening form of amenorrhea occurs in patients with anorexia nervosa, in which voluntary food restriction is stringent, and in those with bulimia, in which periodic eating binges are followed by self-induced vomiting. The severely affected patient, by mechanisms not well understood, physically regresses to a prepubertal state; amenorrhea and suppression of gonadotropin secretion occur. This regression is associated with a reduction in total fat stores below a critical weight and is almost always reversed by weight gain. These changes may be related to the ability of fat tissue to metabolize estrogens from estrone through the most potent steroid, estradiol, to the least potent, estriol.

The treatment of patients with anorexia nervosa varies with the severity of the malnutrition. Intravenous infusion of nutrients (parenteral alimentation) is used in those whose illness has become life-threatening. In those affected less severely, the treatment is psychological, and the best results are obtained when the patient's family participates along with the patient. A less threatening variant is the amenorrhea of the ballet dancer or marathon runner whose single-minded pursuit of excellence through strenuous physical activity leads to a reduction of fat mass below the critical level. Again, if the individual is compliant, effective treatment consists simply of reducing the amount of strenuous physical activity.

The psychological influence on hypothalamic function is also manifest in a far less severe disorder, psychogenic amenorrhea. Individuals so afflicted respond to psychological stress by reducing gonadotropic secretion; normal menses return when the stress is relieved.

Some young adult women who are in otherwise good health, suffer at the time of menstruation from pelvic cramps (dysmenorrhea), headache, nausea, vomiting, weakness, and dizziness long thought to be psychological in origin. It has become clear that the symptoms are not psychogenic but, rather, are due to an increased secretion of prostaglandins from the uterus. Prostaglandins increase the strength of uterine contractions and cause widespread constriction of blood vessels. The patient's symptoms are completely or partially relieved by taking drugs that inhibit the synthesis of prostaglandins (*e.g.,* ibuprofen, or indomethacin).

Premenstrual syndrome

Another constellation of symptoms that has generated debate is premenstrual syndrome (PMS). Perhaps one in 10 women with normal cycles becomes aware of breast tenderness, weight gain with bloating of the abdomen and swelling of the feet, increased irritability with mental depression, and fatigue. The symptoms appear seven to 10 days before the onset of menstruation. In extreme instances, episodes of violence or other forms of psychotic behaviour follow. Evidence suggests that PMS is due to an increased secretion of endogenous opiates, followed by a rather abrupt withdrawal of these mood-altering hormones. A number of drugs, including GnRH analogues, narcotic antagonists, and clonidine, a drug that stimulates alpha-andrenergic receptors, have been used in treatment.

In addition to the functional (secondary) causes of amenorrhea described above, there are abnormalities in which menstruation is never initiated, the primary amenorrheas. These disorders may reflect serious problems in growth and development (see below *Growth and development: Disorders of growth*). Only a more benign aberration is considered here, that of delayed puberty and adolescence. It is not rare that an otherwise normal girl not have the onset of puberty until after age 13, with delays extending as long as age 18. This delay in adolescence is a benign variant of the normal pubertal process. It is important to reassure the patient and her family and to deal with the psychological problems that this lag in development may produce.

Physical effects of menopause

The menopause. The menopause occurs in women between the ages of 45 and 55 years, with the five-year interval between 45 and 50 being the most frequent time of onset. During the menopause the ovary's eggs and their nurturing Graafian follicles are depleted, and the ovary shrinks and becomes wrinkled; it contains many atretic follicles, and the stroma cells become much increased. Such ovaries cannot synthesize sufficient estrogen to sustain the premenopausal relationships of the hypothalamic-pituitary axis. Thus, as the serum estrogen levels fall, pituitary secretion is less inhibited, and there is a progressive increase in the levels of pituitary gonadotropins. The senescent (aging) ovary, however, is no longer capable of responding to pituitary hormones.

As a result of progressive estrogen deficiency, the uterus and breasts decrease in size, the vagina becomes dry, and sexual intercourse often becomes painful (dyspareunia). In about three-fourths of all females there occurs some degree of increased irritability along with "hot flashes," characterized by a flushing of the skin, profuse sweating, and a feeling of warmth. These episodes are a frequent source of embarrassment during the day and a cause of insomnia at night. While the mechanism is not clearly understood, it has been shown that there is an abrupt rise in pituitary LH secretion simultaneous with a rise in skin temperature. Probably both of these parallel changes are due to simultaneous stimulation of temperature-regulating centres and GnRH production at the base of the brain. There is a minority of women who suffer no menopausal symptoms. It is thought that they are able to convert

enough steroid precursors into estrogens, particularly in fat tissue, to avoid the abrupt fall in estrogen levels that are the rule. An important consequence of the menopause in caucasian women is osteoporosis (see above *The parathyroid glands: Metabolic bone disease*).

Premature ovarian failure

When menses ceases before age 40, the patient is said to have premature ovarian failure. Some of these patients may be afflicted with a genetic disorder. In others, premature failure may be generated by ovarian autoantibodies. Others suffer a loss of ovarian receptors (the resistant ovary syndrome) for unknown reasons.

Administration of estrogens suppresses menopausal symptoms in most women, but estrogen treatment increases the risk of carcinoma of the lining of the uterus and perhaps of the breast as well. Some physicians recommend a combination of estrogens and progestins to simulate a normal menstrual cycle. Some investigators have recommended that all menopausal women be given hormonal replacement indefinitely, but others are concerned that the prophylactic administration of these hormonal agents to the entire postmenopausal population may be costly in terms of benefits as compared to risks. They believe that the administration of hormones should be reserved only for those who have distressing symptoms or who are likely to develop osteoporosis.

Functional androgen excess. Androgens are integrated into the normal endocrinologic pattern of functioning in the adult woman. The two major androgens secreted by the ovaries are androstenedione and testosterone; dehydroepiandrosterone (DHEA) and DHEA-sulfate (DHEAS) are contributed by the adrenal cortex. Other tissues, including skin, fat, muscle, and brain, are capable of converting precursor steroids locally to active hormones, thus permitting the accumulation of high concentrations of steroids in key local areas without having a generalized effect throughout the body.

Local activation of steroid hormones

In view of the numerous sites of androgen production, it is not surprising that there are multiple causes for syndromes of androgen excess. Some, such as Cushing's syndrome, congenital adrenal hyperplasia, and androgen-producing adrenal tumours, have been discussed previously (see above *The adrenal cortex: Congenital adrenal hyperplasia*), where the important distinction between hirsutism and virilization is made. Tumours (including cancers) of granulosa and thecal cells of the ovary usually overproduce both estrogens and androgens and may result in all of the features of androgen excess.

While it is important to rule out these serious illnesses, they are relatively rare. Hirsutism is common, however, occurring most often as part of the syndrome of polycystic ovaries (PCO). Since any of a number of androgens may be secreted in excess in this syndrome, it probably has more than one cause; and the androgens arise either from the adrenals or the ovaries. The ovaries become enlarged with a thickened capsule and contain many atretic follicles. Typically, the patient has hirsutism, amenorrhea, infertility, acne, and obesity. The obesity leads to an excess of estrogens from conversion of androgens in peripheral tissues, resulting in impaired secretion of gonadotropins and a consequent suppression of ovulation, with or without amenorrhea.

Treatment involves suppressing excess adrenal androgen production by using synthetic glucocorticoids such as prednisone, by suppressing the actions of the ovary using oral contraceptives, or by blocking the androgenic receptors in tissues with antagonistic drugs such as spironolactone. Effective treatment restores normal menstrual activity and fertility, and although it does not reverse the hirsutism in most instances, further progression is arrested.

THE TESTIS

Anatomy. The testes, or testicles, are the male gonads. They contain germ cells that differentiate into mature spermatozoa, supporting cells called Sertoli cells, and testosterone-producing cells called the Leydig cells. The germ cells migrate to the fetal testes from the embryonic yolk sac. The Sertoli cells are analogous to the granulosa cells in the ovary, and the Leydig (interstitial) cells are analogous to the stromal cells of the ovary.

The embryonic differentiation of the primitive, indifferent gonad into either the testes or ovaries forms a fascinating chapter in fetal development (see below *Growth and development*). Testosterone and its potent derivative, dihydrotestosterone, play key roles in the formation of male genitalia in the fetus in the first trimester of pregnancy. During the first four weeks after birth, they sensitize the genitalia to respond appropriately to androgens when puberty begins. The testes are formed in the abdominal cavity and descend into the scrotum during the seventh month of pregnancy. Stimulation of testicular descent is provided by androgens, along with a protein hormone called Müllerian-inhibiting substance. It is not uncommon in normal males for the testes to be incompletely descended and easily retracted into the abdomen, but this condition usually corrects itself by the age of three months.

Masculinization of the fetus

The adult testis consists largely of a series of tubules with a central cavity. Sperm cells are continuously maturing as they move from the outer edge of the tubule into the central lumen; the most primitive forms, called spermatogonia, differentiate first into spermatocytes and then spermatids. They eventually mature into spermatozoa and are released into the lumen. Spermatozoa travel through the tubular network to be stored in seminal vesicles and, finally, to be ejaculated with the semen. Interspersed among the seminiferous tubules are Sertoli cells, and in the area between tubules (interstitium) are located the hormone-secreting Leydig cells.

Regulation of hormone secretion. Androgen levels in the circulation are regulated by the classical hypothalamic-pituitary-target gland axis (Figure 3). The secretion of pituitary LH (sometimes referred to in the male as interstitial cell stimulating hormone, or ICSH) is secreted following stimulation by gonadotropin-releasing hormone (GnRH) from the hypothalamus. Luteinizing hormone stimulates the Leydig cells to secrete testosterone. When testosterone levels rise above normal, GnRH and LH secretion are inhibited. In the normal course of events, therefore, testosterone levels remain within normal bounds.

The hypothalamic component of this axis comes into play when it is appropriate to override the usual constraints. It has been shown in primates, for example, that serum testosterone levels rise when males are placed in proximity to receptive females, but the level falls when these same males are caged with unreceptive, hostile males to whom they are strangers. It is thought by some that the reduction in serum testosterone levels in such an alien environment is accompanied by a decrease in aggressive behaviour, which, literally, may have survival value. A relation between androgen levels and aggressive behaviour in humans remains uncertain; complex social and interpersonal factors make interpretation difficult.

Transport of testosterone

Like other steroid hormones, testosterone is transported in the plasma bound to a testosterone-binding globulin (TeBG) and to albumin. Only about 2 percent of testosterone is transported unbound in the plasma. Free testosterone is in equilibrium with that which is bound so that when the free steroid enters the cell some bound testosterone is freed simultaneously.

Hormones. Testosterone serves as a circulating prohormone for an important steroidal metabolite, dihydrotestosterone, that performs most of the androgenic functions in the body. Testosterone may also be converted into the potent estrogen estradiol in tissues, particularly adipose tissue. Furthermore, testosterone is interconvertible with androstenedione, which, again in adipose tissue, may be converted to the estrogen estrone.

Testosterone has two major actions: it serves as the feedback inhibitor of GnRH secretion from the hypothalamus and LH secretion from the pituitary, and it directs the development of embryonic Wolffian ducts into the formation of seminiferous tubules. Dihydrotestosterone is responsible for ongoing sperm maturation (spermatogenesis), for the virilization of the embryonic genitalia, and for sexual maturation at puberty. In addition, androgens are powerful anabolic hormones; that is, they enhance the growth of body tissues, particularly muscle.

Normal spermatogenesis requires the secretion of LH and FSH. Luteinizing hormone stimulates testosterone se-

cretion from Leydig cells in the stroma of the testis; the testosterone is converted to dihydrotestosterone, and it must be present locally in high concentration for normal generation of sperm to proceed. Follicle-stimulating hormone acts directly on the seminiferous tubules to stimulate the normal maturation of sperm. Finally, as indicated previously, androgens stimulate Sertoli cells to secrete inhibin. When released into the blood, inhibin dampens pituitary FSH secretion, an additional component of the feedback control mechanism.

Diseases and disorders. *Precocious and delayed puberty.* Male children also can undergo true precocious puberty or the various forms of pseudoprecocious puberty. In addition, there is a poorly understood form of sexual precocity that is a familial (autosomal dominant) disorder in which precocious puberty appears in males in the absence of any increased pituitary gonadotropin secretion and in the absence of any hormone-secreting tumour. The reasons for this inherent premature overactivity of the testes are unknown. It has been suggested that it be called familial testotoxicosis.

Familial precocious puberty

The young child develops pubic hair, a pigmented scrotum, an enlarged penis, and increased muscle development. Since in the affected male child, unlike the female with true precocious puberty as described above, the hypothalamus and pituitary are not activated, treatment with GnRH analogues is not effective. Instead, these patients are treated with an inhibitor of testosterone synthesis called ketoconazole. Severe disease of the testes can prevent completely, or block partially, the onset of puberty.

Hypogonadism. In addition to the functional changes akin to those previously described in females and leading to delayed puberty and adolescence, there are organic diseases that lead to permanent gonadal deficiency. Aside from the various forms of disease and injury, including surgery, that lead to panhypopituitarism, the most common form of gonadotropin deficiency is due to a defect in the hypothalamus that results in an inability to synthesize and secrete GnRH. Persons with this defect (Kallmann's syndrome) may be born with other malformations, including a much undersized penis (microphallus), and there is often an associated loss of smell (anosmia). They do not undergo puberty unless treated. That the defect lies in the hypothalamus is shown by the fact that when these individuals are treated with GnRH, serum gonadotropin levels increase. Conventional treatment of this disorder has been with injections of testosterone, but nasal insufflation of GnRH has been successful.

There are a number of other causes for gonadotropin deficiency. Various tumours in the area of the hypothalamus and pituitary as well as a number of rare disorders, such as the Prader-Labhart-Willi syndrome, may produce hypogonadotropic hypogonadism, in the latter instance due to a chromosomal defect.

Factors causing hypogonadism

In the adult male hypogonadism can occur as a consequence of hypothalamic or pituitary deficiencies (see above *The hypothalamus: Gonadotropin-releasing hormone*). In addition, gonadotropin secretion may be suppressed when hyperprolactinemia occurs (see above *The anterior pituitary: Prolactin*). The testes are susceptible to acquired diseases as well, the most common being mumps orchitis, usually affecting only one testis (unilateral), but when both testes are infected full-blown hypogonadism and infertility may result. Physical trauma, X-ray therapy, and a number of drugs, including commonly used chemotherapeutic agents for the treatment of cancer, can temporarily or permanently impair testosterone synthesis. Alcoholics who sustain severe liver damage are often estrogenized, but alcoholism is associated with a direct inhibition of testosterone synthesis as well. Finally, gonadal failure is commonly associated with a number of chronic illnesses, particularly kidney disease and sickle-cell anemia.

Symptoms of testosterone deficiency

The symptoms of testosterone deficiency in the adult male include the cessation of hair loss. (Normal testosterone levels are necessary for the usual pattern baldness, which occurs frequently in mature men; the converse is not true, however, and most men who retain a full head of hair also maintain normal circulating androgen levels.) The skin of the hypogonadal male is smooth, with a rather fine wrinkling, particularly in front of the ears and around the mouth. Hair in the pubic area and in the beard becomes sparse. There may be some breast enlargement (gynecomastia), and the hips may become broad and assume a female configuration (gynecoid habitus). The testes become smaller than normal, and they may be insensitive to pain. Affected individuals complain of weakness, usually lose interest in sexual activity, and are unable to achieve an erection or to ejaculate.

Treatment of androgen deficiency caused either by a hypothalamic-pituitary axis defect or by a gonadal defect includes the administration of testosterone, usually by intramuscular injection. Many of the symptoms are entirely reversible. Testicular size, however, may decrease even further because of the inhibition of FSH secretion resulting from the administration of testosterone.

Testicular tumours

Hypergonadism. Testicular tumours occur both in children and in adults. Tumours may appear in both testes, and the risk is much increased in those who have undescended testes (cryptorchidism). By far the most common tumours are those of germ cells (seminomas). Previously almost uniformly fatal, testicular tumours are now treated through surgery and chemotherapy, and the survival rates of patients harbouring these tumours have risen dramatically. Tumours of the Leydig cells are quite rare and are almost always benign. Nonetheless, they secrete large quantities of testosterone, precipitating a pseudopuberty in the prepubertal boys and hypergonadism in adult males. The hypergonadal male may lose head hair while showing increased abnormal hairiness in other areas of the body. Acne often reappears, and there may be muscular enlargement due to overgrowth of cells. Because large amounts of the excess testosterone are metabolized to estrogens, patients may develop enlarged breasts.

GROWTH AND DEVELOPMENT

The processes of growth and development are usually accepted as facts of everyday life; however, when one considers the powerful forces at work and the many harmoniously intermingled regulators that harness them, the emergence of a mature adult human being is a source of wonder. The carefully monitored conversion of a crude mixture of nutrients, often ill-balanced, into growing body tissues is integral to the purview of the endocrine system, although the nervous and immune systems play important roles as well.

Patterns of growth

From the 10th to the 20th week of pregnancy, the fetus grows at a rate of 52 inches (132 centimetres) per year. This phenomenal growth rate tapers rapidly as birth approaches. Weight at birth is an important marker. Low birth weight is not surprising in infants coming from families whose histories include low birth weight, but it may also be an indication of premature birth or of poor intrauterine nourishment from a mother living in poverty or with poor hygiene. Growth during infancy remains rapid and then progresses at a slower but steady rate until the onset of puberty, when there is a striking acceleration. The pubertal growth spurt lasts about two years, and it is accompanied by the appearance of secondary sexual characteristics. With puberty, there ensues an increase in nocturnal secretion of growth hormone.

Endocrine influences. Accurate estimates of bone age are made by examining radiographs (a film record of a structure using X rays) of the hands and wrists of large numbers of normal children. In children with endocrine disorders, bone age may not correlate closely with chronological age; bone age is retarded in growth hormone-deficient children and increases in children with growth hormone-producing tumours. Hyperthyroidism, even when it occurs in the developing embryo, is associated with an advanced bone age, while the opposite is true with thyroid deficiency. Children with Cushing's syndrome not only have osteoporosis but retarded bone age as well. An excess both of androgens and of estrogens is associated with a relatively advanced bone age, while a partial androgen deficiency leads to an increase in prepubertal growth of the extremities, resulting in adults with long arms and long legs attached to a short trunk (eunuchoid habitus).

Insulin is a potent growth hormone, and childhood di-

abetics are notoriously small for their ages. Indeed, like hypothyroid children, some never advance to the pubertal state unless proper insulin replacement therapy is provided.

Growth factors. When investigators began studying the effects of biologic materials on cells and tissues developed for laboratory research outside of the body, they discovered a group of peptide hormones that were distinct from any previously known hormones and were active in stimulating the growth in size and number of these cells living outside the body. This group of peptides include somatomedins, epidermal growth factor, platelet-derived growth factor, nerve growth factor, erythropoietin, lymphokines, thymosin, and transforming growth factors, all of which are discussed below.

Somatomedins. The most intensively studied of these peptide growth factors are the somatomedins, also known as insulin-like growth factors. Of these, somatomedin-C (SmC), also called insulin-like growth factor I (IGF I), along with the related insulin-like growth factor II (IGF II) have emerged as the most important biologically. These two somatomedins are distinguishable in terms of specific actions on tissues and, more precisely, different specific tissue receptors. Somatomedin-C is a peptide with an amino acid structure strongly reminiscent of the prohormone of insulin, proinsulin. It is not surprising, therefore, that both somatomedins have effects that mimic those of insulin when incubated with adipose tissue in the laboratory, but they are far less potent than insulin.

Somatomedin-C

The major action of the somatomedins is on cell growth. Indeed, many of the effects of growth hormone are mediated by way of the somatomedins. Growth hormone stimulates many tissues, particularly those of the liver, to synthesize and secrete the somatomedins. The somatomedins, in turn, stimulate both hypertrophy and hyperplasia of most tissues, including bone. In normal children, blood levels of SmC rise progressively through puberty to adolescence. Abnormally low levels of SmC can be found in individuals with growth hormone deficiency, while abnormally high levels of SmC are found in patients with acromegaly. It is likely that the major actions of the somatomedins occur at the site of their formation, where local concentrations are quite high and cell growth can be stimulated without having the somatomedins pass through the general circulation; in effect, the somatomedins and other growth factors may exert their major actions by way of paracrine and autocrine effects.

Epidermal growth factor. Epidermal growth factor (EGF), a peptide containing 53 amino acids, has been found to be identical to urogastrone, a peptide isolated from the urine of pregnant women, which blocks the secretion of gastric juices. An unlikely, but nonetheless major, site of EGF formation is the salivary gland. Epidermal growth factor stimulates many epithelial tissues to proliferate, and it has been postulated that it plays a major role in the rapid proliferation of these tissues in the fetus. In the adult, EGF formation is dependent upon and stimulated by the presence of androgens. The full clinical implications of EGF are uncertain. A study in mice revealed that when the submandibular salivary glands were removed before an adult female became pregnant, subsequent litters had a high mortality rate within the first four weeks after birth and that maternal milk production was greatly decreased.

Platelet-derived growth factor. Platelet-derived growth factor (PDGF) is a polypeptide contained in blood platelets and released during the process of blood clotting. It stimulates the proliferation of fibroblasts (cells essential for healing) at the site of a wound. It may also play a key role in the pathological process called hardening of the arteries (atherosclerosis). Platelets are attracted to and aggregate around collections of fat in the walls of blood vessels (plaques), and the release of PDGF at these sites stimulates the proliferation of cells in the vessel walls, causing them to narrow. The aggregation of platelets has been inhibited by drugs such as aspirin (see below *Prostaglandins*) in the blood vessels of laboratory animals, thus preventing the development of atherosclerosis.

Blood clotting

Nerve growth factor. Nerve growth factor (NGF) plays an important physiological role in fetal life. It stimulates the growth of nerve cells that form the sympathetic nervous system and may play a similar supporting role in normal adults. It has been incriminated in the genesis of two unusual but disabling disorders. The first, called familial dysautonomia, is a serious affliction of the sympathetic nervous system manifested by an inability to sustain blood pressure in the erect posture, along with other defects (see above *The adrenal medulla*). Persons with the disease are unable to synthesize NGF normally. Another rare disorder, intestinal ganglioneuromatosis, which is part of a hereditary endocrine disease, multiple endocrine neoplasia type II (see below *Ectopic hormone and polyglandular disorders*), is characterized by an impressive overgrowth of nerve cells in the intestinal wall thought to be the result of hypersecretion of NGF in local supporting cells.

Erythropoietin. A number of growth factors specific for bone marrow cells have been identified. Chief among these is erythropoietin, which stimulates the bone marrow to increase the production of red blood cells (erythrocytes). Erythropoietin is a rather specialized protein, a sialoprotein, containing 70 percent protein, which is synthesized in the kidney of the adult and is released into the general circulation. In this respect it is a more orthodox hormone since its mode of action is endocrine rather than paracrine or autocrine.

The secretion of erythropoietin is stimulated both by androgens and by growth hormone, but the primary stimulus for erythropoietin secretion is a lack of oxygen in the tissues. The amount of circulating erythropoietin increases greatly in individuals living at high altitude, patients with disease of the heart and lungs, and in those with erythropoietin-producing tumours of the kidney. Erythropoietin deficiency occurs in patients with severe kidney disease and treatment with erythropoietin has been found to alleviate the anemia associated with renal insufficiency.

Mode of action

There are analogous hormonal proteins that are growth factors for two types of white blood cells, both granulocytes and monocytes. These proteins have been referred to as colony-stimulating factors and macrophage growth factors, respectively.

Lymphokines. Lymphocyte production is regulated by growth factors known as lymphokines. Among the lymphokines are a group known as the interleukins. Interleukin-1 stimulates the growth of monocytes and also stimulates the production of interleukin-2, which in turn stimulates the proliferation of T cells. Interleukin-3 acts on lymphocytes at an earlier stage of differentiation (see IMMUNITY).

Thymosin and thymopoietin. The thymus gland has important functions in the immune system, but it also produces a growth factor called thymopoietin, a single-chain peptide consisting of 49 amino acids that stimulates the differentiation of primitive thymus lymphoid cells (prothymocytes) into mature T cells. Thymosin, a 28-amino-acid peptide, stimulates the growth and differentiation of thymocytes and has been reported to be helpful in the treatment of persons with inherited immunodeficiency disease (see IMMUNITY).

The thymus gland

Transforming growth factors. An important area of research has been the exploration of roles played by certain growth factors in transforming normal cells into malignant cells. Unlike normal cells under similar conditions, transformed cells grown in the laboratory in cell cultures multiply at a rapid rate even in the absence of a growth-supporting serum, and, unlike normal cells, which have a limited capacity to replicate in the laboratory, transformed cells become immortal in that they can survive in cell culture indefinitely. Presumably, the transformation permits the cells to synthesize, and be stimulated by, their own growth factors in an autocrine fashion. Transformation can take place in laboratory cultures of cells that have been infected with any of a variety of viruses. While transforming growth factors (TGF) are present in malignant cell cultures, they are present in lower concentrations in normal cells; the synthesis of TGF may be directed by specialized genes, called oncogenes.

Disorders of growth. *Sexual differentiation.* The embryological and anatomic aspects of the gonads and genitalia are detailed in the article REPRODUCTION AND

REPRODUCTIVE SYSTEMS: *The human reproductive system;* and descriptions of chromosomes and the genes they bear is described in GENETICS AND HEREDITY, THE PRINCIPLES OF: *Human genetics,* so that only a brief review is presented here. In humans, each egg contains 23 chromosomes, of which 22 are autosomes and one is a female sex chromosome (the X chromosome). Each sperm also contains 23 chromosomes: 22 autosomes and either one female sex chromosome or one male sex chromosome (the Y chromosome). An egg that has been fertilized by the penetration of a sperm has a full complement of 46 chromosomes, of which two are sex chromosomes. The genetic sex of the individual, therefore, is determined at the time of fertilization; fertilized eggs containing an XY sex chromosome complement are ordained to be males, while those containing an XX array are destined to develop as females.

he sex
ıromo-
ɔmes

Regardless of this preordination, however, all developing embryos become feminized unless masculinizing influences come into play at key times during gestation. A testis-organizing factor assists the Y chromosome in initiating male sexual differentiation by directing the embryonic gonads, which initially are sexually undifferentiated (indeterminate), to develop as fetal testes. The X chromosome also participates in the differentiating process because two X chromosomes are necessary for the development of normal ovaries. In every embryonic life the fetus contains structures capable of developing into either male or female genitalia.

During the third fetal month, the fetal testis of the XY embryo secretes testosterone, an event that has striking consequences. The ducts that would have otherwise developed into oviducts (fallopian tubes) atrophy, while a separate set of ducts (Wolffian ducts) are stimulated to develop eventually into seminiferous tubules along with the ducts (vas deferens) connecting them to the urethra of the penis. If the fetal gonad does not secrete testosterone at the proper time, the genitalia develop in the female direction regardless of whether testes or ovaries are present. In the normal female fetus, no androgenic effects occur; the ovaries develop along with the Müllerian ducts while the Wolffian duct system deteriorates. Sexual differentiation is completed at puberty and a normal adult male or female develops.

In the adult there is a marker for the genetically normal female cell. The nucleus of such a cell contains a darkly staining mass at its edge. This mass, called the X chromatin or Barr body, is an inactive X chromosome. During normal cell activity the DNA of only one X chromosome participates; the other persists only as an inactive Barr body. Such chromatin masses are not found in normal genetic males because they have only one active X chromosome for the cell nucleus. Not the same X chromosome becomes inactive in every cell of a normal female, so that some cells express the X chromosomal activity of the father while others express that of the mother. In effect, every normal female is what is called a mosaic, an individual whose active chromosomal components vary from one cell to another. This state of affairs is known as the Lyon hypothesis.

ɜarr body

It should be mentioned that sexual differentiation occurs in the hypothalamus as well. During the newborn period, exposure to androgen leads to a pulsatile but otherwise unvarying secretion of hypothalamic gonadotropin-releasing hormone throughout adult life. In contrast, the lack of a neonatal androgen influence leads in the mature female to the characteristic monthly cycles of GnRH secretion, reflected in normal menstrual cycles.

In such a complex system there are many opportunities for some form of aberrant development. The causes of these disorders, while not fully understood, have been greatly elucidated by rapid advances in chromosomal analysis, the identification of isolated genetic defects in steroid hormone synthesis, and an expanded understanding of abnormalities in steroid hormone receptors. When techniques became available for microscopic examination of the full complement of individual chromosomes, soon followed by sophisticated fluorescent staining techniques, a good deal of confusion surrounding the clinical distinctions among abnormalities of sexual differentiation were resolved.

Klinefelter's syndrome. Klinefelter's syndrome (47,-XXY seminiferous tubule dysgenesis) is the most frequent chromosomal disorder (occurring in one in 1,000 males). Symptoms and features were first described in 1942 by the American physician Harry F. Klinefelter, a student of Fuller Albright. It later became known that affected individuals had an extra X chromosome in each cell so that the sex chromosome content was XXY and the total number of chromosomes in each cell was 47 rather than 46. Viewed under the microscope, the cells of these individuals contain Barr bodies because, as in normal females, one of the two X chromosomes is inactive.

Symptoms of Klinefelter's syndrome

These patients have the outward appearance of males with firm, small testes. They cannot generate sperm, and they often have enlarged breasts and buttocks and inordinately long legs. Testosterone production is deficient and there is a compensatory increase in the pituitary gonadotropin secretion. While normal in intelligence, some of these persons have difficulties in making social adjustments. Klinefelter's syndrome occurs more often in the children of mothers over the age of 35 years.

The mosaic form of Klinefelter's syndrome (46,XY/47,-XXY) is the second most common type of chromosomal disorder in males. Such persons generally have fewer symptoms than do patients with the complete syndrome. Far rarer variants occur, including 48,XXYY; 48,XXXY; 49,-XXXYY; and 49,XXXXY. These patients suffer from a variety of additional abnormalities and, unlike those with classical Klinefelter's syndrome, they are always mentally retarded. Another variant is the XX male syndrome. Such persons show changes typical of Klinefelter's syndrome. Apparently they have Y chromosome material transferred to one of the autosomes. Treatment with androgens serves to reduce the gynecomastia and evidence of male hypogonadism while increasing the strength and libido of all variants of Klinefelter's syndrome.

Turner's syndrome. Turner's syndrome (gonadal dysgenesis) occurs as a result of a deletion of a sex chromosome so that in the typical patient there is a 45,X chromosomal complement. In genetic terms, these individuals are neither male nor female since the second, sex-determining chromosome is absent. Without a Y chromosome to direct fetal gonads to the male configuration, they develop as females with no Barr bodies demonstrable in cell nuclei. Clinically, they tend to resemble one another—with a small chin and prominent folds of skin at the inner corners of the eyes (epicanthal folds), low-set ears, a short neck with redundant skin (webbed neck), a shieldlike or square chest, and short stature. Both the internal and external genitalia are infantile, and the gonads are present only as "streaks" of connective tissue.

If untreated these patients fail to develop secondary sex characteristics, and they are susceptible to a number of threatening congenital abnormalities of the heart and large blood vessels. Turner's syndrome, in genetic terms, is extremely common since one-tenth of all spontaneously aborted fetuses have a 45,X constitution; only 3 percent of afflicted fetuses survive to term.

Treatment of Turner's syndrome

It is possible to use growth hormone to increase ultimate height of patients with Turner's syndrome, but it is more important to treat them with estrogens at the time of puberty. This leads to the appearance of secondary sexual characteristics along with monthly vaginal bleeding simulating a menstrual cycle. Aside from the psychosocial benefits, estrogen treatment prevents the emergence of the severe osteoporosis found in untreated patients.

As with Klinefelter's syndrome, Turner's syndrome has multiple variants in its chromosomal constitution, which include mosaics and chromosomal translocations (in which a portion of one chromosome is transferred and attached to one of the arms of another chromosome). A frequent variant is the 45,X/46,XY mosaic, in which an individual may be reared as either a male or a female because the genitalia are "ambiguous," it being difficult to determine whether the phallus is an enlarged clitoris or a small penis. These patients also have streak gonads with an increased risk that they will undergo a malignant change.

Rarely, patients with 46,XY or 46,XX chromosome complements are found to have streak gonads, and they never develop secondary sexual characteristics, although they are spared the skeletal changes associated with Turner's syndrome.

True hermaphrodites

Hermaphroditism. Hermaphroditism is, in strict medical terms, quite rare. A true hermaphrodite is an individual who harbours ovarian and testicular tissue, both clearly defined when examined under a microscope. Separate ovarian and testicular tissue may be present, or the two tissues may be combined in an ovotestis. Most often, but not always, the chromosome composition is 46,XX, and in every such individual there also exists evidence of Y chromosomal material on one of the nonsex chromosomes (autosomes). These individuals usually have ambiguous external genitalia with a sizable phallus so that, generally, they are reared as males. They develop breasts during puberty and menstruate. In some instances even pregnancy and childbirth have occurred. Spermatogenesis is rare.

Treatment depends upon the age at which the diagnosis is made. If it is decided that a male identity is deeply embedded and therefore a male role is preferable, all female tissues, including the oviducts and ovaries, are removed. In those persons to be reared as females, the male sexual tissues are removed. In older patients, the accepted gender should be reinforced by the appropriate surgical procedures and hormonal therapy.

There exist rare sex chromosome abnormalities that are not associated with any gonadal defects. These include 47,XXX; 48,XXXX; and even 49,XXXXX. People with such abnormalities are usually mentally retarded, and the diagnosis is often made by the finding of multiple Barr bodies in the nuclei of cells of patients confined in mental hospitals. Males with a 47,XYY complement were long thought to be predestined to become tall men with severe acne who commit violent crimes (XYY syndrome). Later studies have documented that these predictions were greatly exaggerated. Although there appears to be a somewhat increased risk of aberrant behaviour, the majority of such men behave in an entirely normal fashion.

Hormonal causes

Female pseudohermaphroditism. Genetic females (46,XX) who often are assigned the male gender have in the past been produced by hormones used to sustain pregnancy. If, in the first trimester of pregnancy, a mother is administered androgens, progestogens, anabolic steroids such as Danazol, or even the synthetic estrogen stilbestrol, her female child may be masculinized during fetal development. Androgen-producing tumours of either adrenal or ovarian origin may also lead to masculinization of the female fetus. (For discussion of female pseudohermaphroditism due to an enzyme defect in the adrenal cortex, see above *The adrenal cortex.*)

Male pseudohermaphroditism. Male pseudohermaphrodites are genetic males (45,XY) who develop female configurations and identities. The gonads are testes, but the genital ducts and external genitalia are female. Secondary sex characteristics may never appear in some patients, while others may achieve a fully feminized physique. Male pseudohermaphroditism is rare and almost always results from genetic defects, usually autosomal recessive in type. Although a number of specific defects lead to feminization of a genetic male, they all share, by one mechanism or another, a loss of androgenic effects on body tissues. In a few rare instances Leydig cells are absent or greatly reduced in number, presumably because the receptors for LH are defective; without Leydig cells little testosterone is produced. In other patients there are enzymic deficiencies analogous to what occurs in female pseudohermaphrodites (see above *The adrenal cortex*), but in this instance resulting in fetal androgen deficiency.

Complete testicular feminization

In some patients, tissue receptors for androgens are absent or reduced, forming a spectrum of syndromes of partial to complete resistance to androgens. Perhaps the most striking example is complete testicular feminization. Affected patients are born with female genitalia and a vagina that ends blindly. They have well-defined testes located either in the labia or within the abdomen; nevertheless, they grow into well-proportioned, attractive females with normal breasts and scant or absent axillary and pubic hair. They have a strong female orientation, but they do not menstruate. The hormonal aberrations in these patients are dramatic and predictable. With a loss of hypothalamic and pituitary androgen receptors there is no inhibin of gonadotropin secretion, and plasma LH levels remain elevated and lead to enhanced stimulation of the Leydig cells. In consequence, serum testosterone levels are much elevated, and Leydig cells are greatly increased in number. The FSH levels are usually normal, probably due to increased inhibin production by Sertoli cells. The peripheral conversion in tissues of the increased amounts of testosterone to estrogens leads to an increase in estrogen levels above normal values for males.

In another extraordinary variant, the lesion lies not in the loss of androgen receptors but rather in a loss of the 5 α-reductase, an enzyme necessary for the conversion of testosterone to the more potent hormone dihydrotestosterone. In this syndrome, because of a lack of testosterone directing fetal development toward a normal male configuration, genetic males are born with what appears to be female genitalia with an enlarged clitoris. These persons are often raised as females, but at puberty an increase in testosterone secretion leads to clear-cut masculinization without enlarged breasts. There then ensues a transition from a prepubertal female to an adult male. This change in gender identity takes place apparently without undue emotional turmoil.

Vanishing testes syndrome

In some fetuses there occurs, for unknown reasons, a regression and disappearance of the testes of genetic males, the "vanishing testes syndrome." When this occurs early in pregnancy and before androgen-induced differentiation toward male genitalia, the child is born with female genitalia. If the testes disappear during the crucial period between eight and 10 weeks of gestation, the child is born with ambiguous genitalia, whereas if the disappearance occurs after this key period, the individual is a male, but without any testes (anorchia).

Treatment of such persons must be highly individualized. In most instances, the gender identity has been firmly implanted by the age of 18 months, and sexual changes are attempted only after careful consideration. Intra-abdominal testes should be removed because of an increased risk of tumour formation. The patient can be treated at the appropriate time with sex hormones.

Homosexuality and transsexualism. The genesis of homosexual and transsexual behaviour is complex and poorly understood. Undoubtedly, environmental and psychosocial influences play important roles, but only the rather meagre knowledge of endocrine influences is discussed here. While early studies suggested a number of abnormalities in homosexual males, including low serum testosterone levels and abnormal ratios of several steroid hormones, later, more stringent investigations generally have not confirmed these differences. It is clear that treatment of male homosexuals with androgens may increase the sexual drive but only in the direction that had been accepted previously.

Recent theories

There is more recent evidence from studies in animals and from inferential studies in humans that severe emotional stress in mothers early in pregnancy may lead to homosexuality in their male offspring. In some studies, elevated serum testosterone levels were found in female homosexuals, while in others no differences were found. Generally, endocrine function has been found to be normal in transsexual men; however, some studies have indicated that these individuals have mildly elevated serum LH levels along with a hyperresponsiveness to the stimulation of LH by GnRH.

It may well be that these confusing conclusions result from the study of heterogeneous populations. Some homosexual behaviour may be predetermined by aberrant hormonal influences during pregnancy while others may be a response to environmental influences. If so, divergent, indeterminate results of hormonal studies would not be surprising.

THE PINEAL GLAND

The pineal gland, the most enigmatic of endocrine organs, has long been of interest to anatomists. Several

millennia ago it was thought to be a valve that controlled the flow of memories into consciousness. René Descartes, the 17th-century French philosopher-mathematician, concluded that the pineal was the seat of the soul. A corollary notion was that calcification of the pineal caused psychiatric disease, a concept that provided support for those who considered psychotic behaviour to be rampant; modern examination techniques have revealed that all pineal glands become more or less calcified.

Anatomy. The pineal organ is small, weighing little more than 0.1 gram. It lies deep within the brain between the two cerebral hemispheres and above the third ventricle of the spinal column. It has a rich supply of adrenergic nerve fibres that greatly influence its secretions. Microscopically, the gland is composed of pinealocytes (rather typical endocrine cells except for extensions that mingle with those of adjacent cells). Supporting cells that are similar to astrocytes of the brain are interspersed.

Hormones. The pineal gland contains a number of peptides, including GnRH, TRH, and vasotocin, along with a number of important neurotransmitters such as somatostatin, norepinephrine, serotonin, and histamine. The major pineal hormone, however, is melatonin, a derivative of the amino acid tryptophan. Melatonin was first discovered because it lightens amphibian skin, an effect opposite to that of melanocyte-stimulating hormone of the anterior pituitary. Secretion of melatonin is enhanced whenever the sympathetic nervous system is stimulated. Of greater interest, however, is the fact that secretion increases soon after an animal is placed in the dark; the opposite effect takes place immediately upon exposure to light. Its major action, well documented in animals, is to block the secretion of GnRH by the hypothalamus and of gonadotropins by the pituitary. While it was long thought that a decrease in melatonin secretion heralded the onset of puberty, this hypothesis cannot be supported by studies in humans. It is possible that the pineal contains an as yet unidentified hormone that serves that function.

Melatonin

Pineal tumours. Pineal tumours are rare, occurring most often in children and young adults. The most common of these are germ cell tumours (germinomas and teratomas), which arise from embryonic remnants of germ cells. These tumours are malignant and invasive and may be life-threatening. Tumours of pinealocytes also occur and vary in their potential for malignant change.

Pineal tumours may cause headache, vomiting, and seizures due to the increase in pressure within the head that results from the enlarging tumour mass. Endocrinologic effects may also be observed. Some patients may become hypogonadal with regression of secondary sex characteristics, while others may undergo precocious puberty because of secretion of chorionic gonadotropin. Diabetes insipidus is frequently associated and is usually due to tumour invasion of the hypothalamus and posterior pituitary. Invasion of the pituitary stalk may interfere with the ongoing inhibition of prolactin secretion by dopamine from the hypothalamus, resulting in elevated serum prolactin levels, a finding that may lead to a mistaken diagnosis of prolactinoma. Treatment consists of surgical relief of the increased intracranial pressure and X-ray therapy.

HORMONES OF THE INTESTINAL MUCOSA

In 1902, two English physiologists, Sir William M. Bayliss and Ernest H. Starling, placed dilute hydrochloric acid into a segment of a dog's bowel from which the nerve supply had been severed. They then scraped off the bowel lining, boiled it, filtered it, and injected the filtrate into a dog's vein. The injection was followed shortly by a greatly increased secretion of pancreatic juices. They named the unidentified water-soluble material in the filtrate "secretin," and thus was modern endocrinology born. With this discovery emerged the pivotal concept of chemical messages acting at a distant site to regulate bodily functions. Interest in secretin soon waned, however, overshadowed by discoveries in what became the mainstream of endocrinology. It was not until the advent of modern techniques for isolating, characterizing, and measuring protein hormones that interest in the endocrinology of the gastrointestinal tract was revived. It has become clear that the intestinal tract is not only a complex system dedicated to the digestion and absorption of nutrients but also a large endocrine organ that secretes many hormones.

Secretin. Secretin, a polypeptide containing 27 amino acids, is concentrated in the lining of the upper intestine. When hydrochloric acid from the stomach passes into the duodenum, secretin is released into the blood and soon prompts the pancreatic acinar cells to release water and bicarbonate into the pancreatic ducts and from there into the duodenum. By this mechanism, hydrochloric acid, which can be damaging to intestinal lining, is promptly diluted and neutralized by the pancreatic water and bicarbonate. Secretin is used as a stimulator of the pancreas to evaluate exocrine pancreatic functions of patients.

Neutralizing hydrochloric acid

Gastrin. Gastrin is a 17-amino-acid polypeptide that is secreted into the circulation by cells lining the stomach. Gastrin stimulates the secretion of hydrochloric acid and a digestive enzyme, pepsin, into the stomach cavity, while simultaneously increasing the contractions of its distal part. The medical significance of gastrin lies in the fact that there are pancreatic islet cell tumours that secrete large quantities of gastrin or its prohormone, "big gastrin." The affected patient has severe peptic ulcer disease that is unresponsive to the usual forms of treatment. There is often associated diarrhea with bowel movements containing large amounts of fat. Gastrinomas often form part of the syndrome of multiple endocrine neoplasia (MEN I) discussed below. Treatment consists of removing the tumour surgically when feasible or, when not, of cutting the vagus nerve, followed by the administration of a gastric-acid-inhibiting drug such as cimetidine.

Gastric inhibitory polypeptide. Gastric inhibitory polypeptide (GIP) is a hormone secreted by cells of the intestinal mucosa that blocks the secretion of hydrochloric acid into the stomach. It also serves to enhance insulin secretion from the beta cells of the islets of Langerhans so that plasma insulin levels rise after a meal even before the ingested glucose or amino acids enter the blood, an example of an anticipatory hormonal action.

Cholecystokinin. The secretion of cholecystokinin (CCK) is stimulated by the introduction of hydrochloric or fatty acids into the stomach or duodenum. As its name implies, cholecystokinin stimulates the gall bladder to contract and release stored bile into the intestine. Similarly, it stimulates the flow of pancreatic juices. There is interest in the possibility that intestinal hormones, particularly CCK, may induce satiety. According to this hypothesis, after a person eats a meal, the secreted CCK stimulates the satiety centre of the hypothalamus so that the individual "feels full" and stops eating. Because CCK is also known to contract the muscles of the channel leading from the stomach into the duodenum, thus inhibiting gastric emptying, it is possible, however, that people have the feeling of being full simply because of gastric distension.

Vasoactive intestinal polypeptide. Vasoactive intestinal polypeptide (VIP), a 28-amino-acid polypeptide, is secreted by cells throughout the intestinal tract. It acts to change the activity of the intestinal mucosa so that water and electrolytes are secreted rather than absorbed as usual.

Effect on intestinal mucosa

Pancreatic islet cell tumours that secrete excessive amounts of VIP are called VIPomas (Verner-Morrison syndrome). Affected persons have a severe, intractable, debilitating watery diarrhea with an associated loss of large quantities of potassium. If the patient is unable to replace the lost fluids adequately, the resulting dehydration may become life-threatening, leading to use of the term pancreatic cholera. Removal of the tumour and postsurgical chemotherapy has improved the survival rate considerably, even though metastases occur in about one-third of these patients.

Other gastrointestinal hormones also serve as neurotransmitters in the brain, but they have not been found to produce disease. These hormones include katacalcin, caerulein, motilin, neuropeptide Y, and gastrin-releasing peptide (bombesin-like peptide). Glucagon (see above *The pancreas*) and somatostatin (see above *The hypothalamus* and *The pancreas*) also serve as gastrointestinal hormones and brain neurotransmitters, and they also produce rare hyperfunctioning pancreatic tumours.

PROSTAGLANDINS

The prostaglandins (PGs) are a common group of modified fatty acids that are astonishingly diverse in their actions; for the most part, they have a local (paracrine) function. The study of these powerful agents had modest beginnings when, in 1935, a Swedish physiologist and Nobel laureate, Ulf von Euler, and other investigators found that extracts of seminal vesicles or of human semen lowered blood pressure and caused contraction of strips of uterine tissue. Von Euler coined the term prostaglandin because he assumed that the active material came from the prostate gland.

The prostaglandins comprise a group of related cyclic, unsaturated fatty acids that are derived primarily from the 20-carbon, straight-chain, polyunsaturated fatty acid precursor, arachidonic acid. Each prostaglandin differs from the others in subtle changes in chemical structure or side-chain substitutions; these differences are responsible for the different biologic activities of the members of the prostaglandin group.

Arachidonic acid

Arachidonic acid is a key component of the phospholipids, which are themselves integral components of cell membranes. In response to a variety of stimuli, a chain of events is set in motion that results in prostaglandin release (Figure 15).

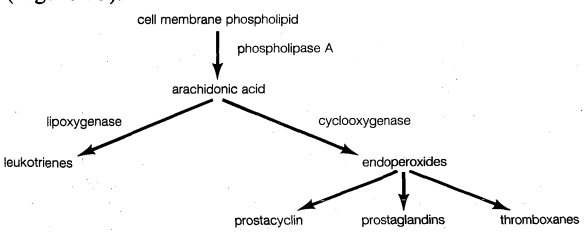

Figure 15: Synthetic pathways of arachidonic acid breakdown from phospholipids of the cell membrane.

The actions of an enzyme, phospholipase A, induce the phospholipids to release the precursor, arachidonic acid. One enzyme, lipoxygenase, catalyzes the synthesis of the leukotrienes. Another enzyme, cyclooxygenase, stimulates the conversion of arachidonic acid to several endoperoxides. The endoperoxides undergo further biosynthesis to the prostaglandins, prostacyclin, and the thromboxanes. (The thromboxanes and prostacyclin are important compounds that have functions in the process of blood coagulation. Leukotrienes, converted from endoperoxides in white blood cells, or leukocytes, are important mediators of the inflammatory process.)

The actions of the prostaglandins are multiple and variable; the same prostaglandin might stimulate a reaction in one tissue and inhibit it in another. Prostaglandin effects are usually manifested locally around the site of prostaglandin synthesis.

When the actions of prostaglandins are stimulatory, they act as intermediaries (necessary elements that elicit a subsequent step along a synthetic or biologic pathway) in the formation of cyclic 3′,5′-adenosine monophosphate (cyclic AMP, cAMP), and thus the final biologic actions of the target cells.

This synthetic pathway begins when tropic hormones (hormones of one endocrine gland that affect the actions of other endocrine structures) are bound to receptors on the surface of the cells of the target organ. These tropic hormones, called first messengers, initiate the prostaglandin-synthesis pathway discussed above, and the increased concentration of prostaglandins around the target organ stimulates the intracellular synthesis of cAMP from adenosine triphosphate (ATP), a process that brings about the biologic action of the target organ. Unaccountably, prostaglandins may inhibit the synthesis of cAMP in some tissues.

Vasodilator effect

Prostaglandins are powerful vasodilators; that is, they relax the muscles in the walls of blood vessels so that the diameters become larger and there is less resistance to the flow. Consequently, the blood pressure falls. Again, the effect can be local. An important example of the vasodilation effect of prostaglandins is found in the kidney, where widespread vasodilation leads to an increase in the flow of blood to the kidney and an increased excretion of salt in the urine. Thromboxanes, on the other hand, are powerful vasoconstrictors in the same setting.

Some diuretics, such as furosemide, probably act by releasing prostaglandins in the kidney. Prostaglandins inhibit the action of vasopressin on the kidney tubules, resulting in enhanced urinary excretion of water. The resultant tendency to dehydration from this enhanced excretion of water leads to local secretion of another kidney prostaglandin that stimulates the secretion of renin (see above *The adrenal cortex: Aldosterone*). Renin stimulates the production of aldosterone, which has the affect of conserving sodium and water, thus combating the dehydration and elevating the depressed blood pressure.

Although prostaglandins were first detected in semen, no biologic role for them has been defined in the male reproductive system. This is not true, however, for females. It has been shown that prostaglandins mediate the control of GnRH over LH secretion, modulate ovulation, and stimulate uterine muscle contraction. Discovery of this last property has led to the successful treatment of menstrual cramps (dysmenorrhea) through the use of inhibitors of prostaglandin synthesis, such as ibuprofen. Prostaglandins also play a role in inducing labour in pregnant women at term or in inducing therapeutic abortions.

The process of clot formation begins with an aggregation of blood platelets. This process is strongly stimulated by thromboxanes and inhibited by prostacyclin. Prostacyclin is synthesized in the walls of blood vessels and serves the physiological function of preventing needless clotting. Thromboxanes, on the other hand, are synthesized within the platelets themselves and are released. The platelets adhere to one another and to blood vessel walls. Through prostaglandin and thromboxane mechanisms, clotting is prevented when it is unnecessary and takes place when it is necessary. Platelets adhere in arteries that are affected by the process of atherosclerosis; they form plaques along the interior surface of the vessel wall. This type of platelet aggregation and clotting leads to blocking (occlusion) of the vessel wall, the most common cause of heart attack (coronary artery occlusion). This biologic insight has led to the widespread recommendation that those at risk for a coronary occlusion take aspirin, an inhibitor of the enzyme cyclooxygenase, daily as a preventive measure.

Role in inflammation

Prostaglandins also play a pivotal role in inflammation, a process characterized by the ancient Romans as consisting of redness (*rubor*), heat (*calor*), pain (*dolor*), and swelling (*tumor*). These changes are due to a local dilation of blood vessels that permits increased blood flow to the affected area. The blood vessels become more permeable, leading to the escape of infection-fighting fluid and white blood cells from the blood into the surrounding tissues. These changes are mediated by prostaglandins, particularly the subgroup called leukotrienes. Thus, effective treatment to suppress inflammation in inflammatory but noninfectious diseases, such as rheumatoid arthritis, is to treat the patient with inhibitors of prostaglandin synthesis, such as aspirin. Similarly, the pain and fever of other disseminated inflammations can be alleviated by these nonsteroidal anti-inflammatory drugs.

Another crucial mechanism of the body that protects it from invasion by bacteria, viruses, or other noxious agents is known as the immune response. It begins when a foreign substance is ingested by a mobile, scavenging, white blood cell, called a macrophage. The macrophage interacts with a special white blood cell called a T-lymphocyte (T cell), which in turn activates B-lymphocytes (B cells or plasma cells). The result is that the B cell elaborates and secretes specific proteins (antibodies) that are designed to make the ingested foreign invader more susceptible to attack and ingestion by other white blood cells.

In cellular immune response, T cells become activated at the site of damage and release proteins called lymphokines, which attract macrophages to the local area and stimulate them to ingest the offending agents. Prostaglandins generally attenuate the immune response by inhibiting both T cell and B cell activity, but some prostaglandins, particularly the leukotrienes, enhance inflammatory responses.

The understanding of the immune response marks a ma-

Anaphylactic reactions

jor advance in medicine since aberrations in this response cause hypersensitivity (anaphylactic) reactions, allergies, and autoimmune diseases. Examples include harmful reactions to drugs such as penicillin; hay fever; bronchial asthma; rheumatoid arthritis; Graves' disease; and autoimmune endocrine deficiency diseases. Prostaglandins play important roles in the genesis of these disorders, an awareness that has led to the development of a number of powerful inhibitors of prostaglandin synthesis for use in treatment.

The functioning of the digestive tract is also influenced by prostaglandins. Depending on the setting, various prostaglandins may either enhance or inhibit the contraction of the smooth muscles of the intestinal walls. They are also powerful inhibitors of stomach secretions, perhaps because they inhibit the secretion of the stomach hormone gastrin, which stimulates gastric secretion. It is not surprising, then, that drugs, like aspirin, which inhibit prostaglandin synthesis may lead to peptic ulcers. Prostaglandin action on the digestive tract may cause a severe watery diarrhea and may mediate the effects of vasoactive intestinal polypeptide (VIP) in the Verner-Morrison syndrome (see above *Hormones of the intestinal tract*), as well as the effects of cholera toxin.

Prostaglandins induce several effects on endocrine function. Perhaps of greatest importance is the ability of prostaglandins to stimulate the resorption of bone in diseases such as rheumatoid arthritis and to cause hypercalcemia, particularly in patients harbouring malignant tumours.

The therapeutic applications of the prostaglandins and of the drugs that inhibit prostaglandin synthesis are listed in Table 3. The drugs fall into two categories. In the first are agents like hydrocortisone and its synthetic derivatives, such as prednisone, which stabilize cell membranes and, in large doses, block the liberation of arachidonic acid. In the second are drugs that block the action of the enzyme cyclooxygenase. Among these are aspirin, acetaminophen, indomethacin, and ibuprofen.

Table 3: Therapeutic Applications of the Prostaglandins*

prostaglandins	PG synthesis inhibition
Current	
Midtrimester abortion	Rheumatoid arthritis
Peripheral vascular disease	Fever and headache
Hemodialysis	Bartter's syndrome
Induction of labour	Patent ductus arteriosus
Potential	
Hypertension	Hypercalcemia of malignant disease
Congestive heart failure	Periodontal inflammation
Infertility	Cholera and certain diarrheal states
Coronary and deep thrombosis	Burns
Peptic ulceration	Lupus erythematosus
Gastric hyperacidity	Glaucoma
Bronchial asthma (PGE)	Migraine headache
Nasal congestion	Bronchial asthma (leukotriene)

ECTOPIC HORMONE AND POLYGLANDULAR DISORDERS

Tumour development

In discussing general characteristics of endocrine hyperfunction above it was indicated that the cells of endocrine glands, following long-term stimulation, increase in size (hypertrophy) and number (hyperplasia). If the stimulation persists, these cells may be transformed into a tumour, which may be either benign or malignant.

For reasons that have aroused much speculation but remain poorly understood, these changes may occur in more than one endocrine gland, simultaneously or consecutively, even though the embryonic origin of the cells of the other endocrine glands that are involved may be different, and even though this propensity to tumour formation is confined to endocrine glands only (multiple endocrine neoplasia). Similarly, for equally obscure reasons, multiple endocrine glands may be attacked by autoantibodies with the result that the patient is afflicted with multiple hormonal deficiencies (multiple endocrine deficiency syndromes). Finally, there have emerged syndromes due to excessive amounts of hormones produced by tumours of tissues that do not ordinarily produce hormones at all (ectopic hormone production). This transformation initially was thought to occur when the tumours activated genes that generated these hormones, and that ordinarily were repressed in the cell of the nonendocrine tissue. Recent evidence has revealed that most tissues synthesize small amounts of most hormones and, indeed, other substances that have no hormonal activity, so that the change that occurs following tumour formation is a quantitative rather than a qualitative one.

Multiple endocrine neoplasia. Multiple endocrine neoplasias (MEN) are hereditary disorders usually occurring in an autosomal dominant genetic distribution (*i.e.*, the defect is not tied to the sex of the individual and statistically, one-half of the children of an affected person will also be affected) so that families are heavily sprinkled with affected individuals. There are several defined patterns of glandular involvement which usually, but not always, "breed true" in that the clusters of glandular involvement follow the same groupings from one family member to another. Studies of distribution in humans are necessarily incomplete because the endocrine tumours do not appear simultaneously. Thus, a patient who may appear to have an incomplete expression of one of these inherited syndromes when first examined may later develop the full clinical picture.

Principal glands involved

The first described and the most frequently occurring of these unusual disorders is multiple endocrine neoplasia type I (MEN I). The principal glands involved in this syndrome are the parathyroids, the pancreatic islets, and the anterior pituitary. All four parathyroid glands are involved either by hyperplasia alone or a mixture of hyperplasia and adenomas. The symptoms of hyperparathyroidism may be mild and are often overshadowed by the disabling problems engendered by the islet cell tumours. Two-thirds of patients with MEN I develop gastrinomas with severe, intractable peptic ulcers. Insulinomas with severe hypoglycemia also occur frequently, and in some patients both tumours arise. The pituitary manifestations are most frequently those of prolactinoma or acromegaly (see above *The anterior pituitary*). Involvement of the adrenal cortex and the thyroid glands may occur, but it is possible that these aberrations are coincidental rather than an integral part of the hereditary disease. Treatment consists of attacks on individual hyperfunctioning glands as they appear; however, in contrast to sporadic cases, it is important to counsel families to have all members screened for evidence of MEN I because early treatment is more effective and less risky.

Multiple endocrine neoplasia type II (MEN II) is composed of another distinct constellation of glandular involvements: a medullary carcinoma of the thyroid; pheochromocytoma, usually bilateral; and, again, hyperparathyroidism. Medullary carcinomas of the thyroid arise from the parafollicular C cells (see above *The thyroid gland*), which secrete calcitonin (see above *The parathyroid glands*). Medullary thyroid carcinoma occurs in all affected families except those who, by screening techniques, are detected at an early stage when C cell hyperplasia has not yet been transformed into a carcinoma. Medullary thyroid carcinoma is an example of ectopic hormone production in that these tumours may elaborate excessive quantities not only of the expected hormone, calcitonin, but also ectopically of other bioactive substances, including corticotropin, prostaglandins, serotonin, and the neurotransmitter substance P. While only a small minority of all patients harbouring pheochromocytoma have MEN II, when these tumours do occur in both adrenal glands, the likelihood is much greater that MEN II is present. As in the case of C cells, adrenal medullary hyperplasia precedes the development of true tumour formation. The high blood pressure and other symptoms characteristic of pheochromocytoma have been described previously (see above *The adrenal medulla*), and, again, parathyroid hyperplasia occurs more frequently than parathyroid tumours in this syndrome. Early screening of family members is strongly recommended, and treatment does not

differ from that applied to patients with a single hyperfunctioning endocrine gland.

MEN IIB

A variant of MEN II is termed MEN IIB, or MEN III. Patients with this disease also suffer from medullary thyroid carcinoma and pheochromocytoma, but they differ in that hyperparathyroidism rarely occurs, and affected family members uniformly develop mucosal neuromas. These are nerve tumours, usually benign, involving the lips and linings of the mouth, nose, and throat. They may be recognized at birth or in early childhood as "bumpy lips," and these neuromas may be scattered throughout the gastrointestinal tract, causing constipation and, less frequently, vomiting and difficulty in swallowing.

On rare occasions, some patients with multiple endocrine neoplasia do not fit established patterns. Some of these aberrations may be explained by coincidence, but others seem to represent true MEN of a mixed type, for example, pheochromocytoma associated with pancreatic islet cell tumours.

Multiple endocrine deficiency syndromes. In multiple endocrine deficiency syndromes, affected families have some or all of a bewildering array of ailments shown in Table 4. Investigators have found it convenient to divide these deficiency diseases into two types, although, from inspection of the Table, it can be seen that there is considerable overlap. Type II is inherited in an autosomal-dominant pattern, while type I is thought to be due to autosomal-recessive inheritance. What is inherited in both types is the propensity to develop circulating autoantibodies directed against, and destroying, one or more of the tissues listed in Table 4.

Table 4: Autoimmune Polyglandular Syndromes*

type II	type I
Hyperthyroidism	Hypoparathyroidism
Hypothyroidism	Yeast (*Candida*) infection of the skin and mucous membranes
Diabetes, type I	Adrenal insufficiency
Adrenal insufficiency	Hepatitis
Myasthenia gravis	Malabsorption
Celiac disease	Vitiligo
Hypogonadism	Pernicious anemia
Pernicious anemia	Alopecia
Vitiligo (skin depigmentation)	Hypothyroidism
Alopecia	

*Adapted from J.D. Wilson and D.W. Foster (eds.), *Williams Textbook of Endocrinology*, 7th ed., Philadelphia, W.B. Saunders Co., 1985. Reprinted by permission.

These autoantibodies (see above *The human endocrine system: Endocrine dysfunction*) may be detected in the blood many years before the discernible disease appears. The apparently paradoxical appearance of hyperthyroidism in type II results from the development of circulating thyroid-stimulating autoantibodies. Type II diseases are distinguishable from type I in that multiple generations are affected, the highest incidence occurring between the ages of 20 and 60, and that affected individuals are not afflicted with mucocutaneous candidiasis (a fungal infection of the mucous membranes and skin). Type I, in contrast, has its onset in infancy or childhood, it is commonly associated with candidiasis, and it is characterized by the appearance of the disease in siblings but without transmission from one generation to the next. Treatment is directed toward each individual abnormality.

Onset of MEN syndromes

Ectopic hormone production. Previous views that it is rare for excessive quantities of hormones to be secreted by tumours of nonendocrine origin have been supplanted by demonstrations that ectopic hormone production is indeed quite common (Table 5). Ectopic corticotropin production, the most common of these syndromes, is most frequently associated with carcinoma of the lung, carcinoma of the thymus, or islet cell tumour; however, it may also occur in association with a long list of other neoplasms, including pheochromocytoma, bronchial adenoma, medullary thyroid carcinoma, and carcinomas of the ovary, prostate, breasts, kidney, testes, gallbladder, and even of the appendix. Patients usually have the intense pigmentation and severe depletion of potassium that is characteristic of overproduction of ACTH and of mineralocorticoids. In addition the excessive tissue breakdown characteristic of Cushing's syndrome is added to the debilitating effects of the cancer itself. Treatment ordinarily involves removal or destruction of the cancer, but occasionally, when the tumour cannot be completely removed, an attack on the overactive adrenals, either with drugs or by surgical removal, is warranted.

Table 5: Hormones and Hormone Precursors Reported to be Produced by Neoplasms*

ACTH, lipotropin, and pro-opiomelanocortin
Corticotropin-releasing hormone
Chorionic gonadotropin and its subunits (α and β)
Vasopressin
Growth factors (*e.g.*, IGF)
Parathyroid hormonelike materials
Osteoclast-activating factor
Erythropoietin
Eosinophilopoietin
Growth hormone
Growth hormone-releasing hormone
Prolactin
Gastrin
Gastrin-releasing peptide (and bombesin)
Secretin
Glucagon
Calcitonin
Renin
Vasoactive intestinal peptide
Somatostatin
Hypophosphatemia-producing factor
Prostaglandins
Estrone and estradiol

Chorionic gonadotropin

The synthesis of chorionic gonadotropin (a hormone produced by the placenta that stimulates the gonads) originally was thought to be confined to one of the membranes covering the fetus. Recent, more sensitive testing, however, has revealed that at least one segment of this hormone is synthesized in almost all tissues. Chorionic gonadotropin is a glycoprotein similar to TSH, LH, and FSH in that it contains both alpha and beta chains. It is likely that it is a fragment of the beta chain that is found in tumour tissues. As much as 13 percent of all carcinomas are associated with increased circulating levels of chorionic gonadotropin-like material. Affected patients may have no symptoms or may have symptoms similar to those produced by excessive LH secretion.

There are numerous other manifestations of ectopic hormone production. They include the secretion of bioactive materials that result in hypoglycemia, hypercalcemia, hypocalcemia, and the inappropriate secretion of vasopressin (see above *The posterior pituitary*), growth hormone, and growth-hormone-releasing hormone. As discussed above, treatment is aimed at ablating or reducing the activity of the offending tumour or mitigating the effects of the hormone produced in excess.

ENDOCRINE CHANGES WITH AGING

Because the endocrine glands play pivotal roles both in reproduction and in development, it seems plausible to extend the role of the endocrine system to account for the progressive bodily changes that occur with aging (senescence). Indeed, for a time, an "endocrine theory of aging" enjoyed wide popularity among scientists. Early in the 20th century, the possibility that aging could be deferred and virility restored by the injection of crude extracts of monkey glands attracted a good deal of attention. Upon closer scrutiny, however, it has become clear that the endocrine glands weather the ravages of age quite well and, in a number of instances, tend to mitigate its effects. (For a discussion of the aging process, see GROWTH AND DEVELOPMENT, BIOLOGICAL.)

The menopause. The most striking change with age is that of the menopause (see above *The ovary*). Estrogens are produced by granulosa cells and cells of the stroma, which line the egg-containing ovarian follicles. Because the number of these follicles in the ovaries is limited, their depletion with age makes inevitable the reduction in estrogen

Reduced estrogen levels

secretion, which, in endocrinologic terms, defines the onset of the menopause. The low circulating estrogen levels reduce hypothalamic and pituitary inhibition of GnRH, LH, and FSH secretion so that circulating levels of these hormones undergo a striking and sustained elevation; a three- to fourfold increase above premenopausal values is found in women above the age of 60. Prolactin secretion also increases. Clearly, in normal postmenopausal women, while the ovaries have "failed" to a large degree, the hypothalamus and pituitary have not.

The testis. Reduction in the number of androgen-secreting Leydig cells leads to a tendency toward a decrease in serum testosterone levels, which are compensated for by an increase in gonadotropin secretion. The result is that the healthy, aging male maintains androgen synthesis and secretion at or near normal levels and may father children despite a greatly advanced age. (For further discussion of changes in the gonadal axis in males with age, see above *The testis.*)

Thyroid and adrenal function. Changes in thyroid function with age are subtle and have limited clinical significance. Circulating levels of the thyroid hormone T_4 remain normal while those of the thyroid hormone T_3 tend to decrease. There appears to be reduced responsiveness of TSH-secreting cells to stimulation with thyrotropin-releasing hormone. Some slowing of the metabolic rate may serve well the "weary bones" and tissues of the healthy aged. Similarly, the hypothalamic-pituitary-adrenocortical axis undergoes minor changes but remains intact with advancing years. Plasma cortisol levels remain essentially unchanged. Aldosterone secretion decreases as do plasma renin concentrations, but the healthy elderly are able to maintain normal balances of fluids and electrolytes (see above *The adrenal cortex*).

Growth hormone, parathyroid, and antidiuretic hormones. Growth hormone secretion decreases variably with age. In some healthy elderly persons it is moderately reduced as compared to young adults, and in some otherwise apparently healthy aged individuals there seem to

Growth hormone

be deficient responses in growth hormone secretion. It is possible, then, that a subpopulation of the aging population may benefit from growth hormone treatment. Serum parathyroid levels seem to rise with age, a change that may serve to maintain normal serum calcium levels. Similarly, the secretion of antidiuretic hormone (vasopressin) tends to be elevated and hyperresponsive. This may occur in response to an increasing difficulty of the aging kidneys to prevent inordinate excretion of water.

The pancreatic islets. It has been well documented that blood sugar levels, while normal in the fasting state, respond to the ingestion of glucose with increments proportional to the age of the subject; that is, the older the healthy subject, the higher the maximal increase in blood glucose after glucose ingestion. The accompanying increase in levels of serum insulin, although appreciable, is clearly not enough to maintain the glucose levels in the range found in healthy young adults. Whether these changes should be viewed as abnormal or whether they merely reflect modifications appropriate to the aging process remains a matter of debate.

In summary, endocrine changes in healthy aging individuals do not account for the aging process. There is evidence that, with aging, there is a progressive loss in the numbers of hormonal tissue receptors, and, more often than not, there is an appropriate increase in hormone secretion to maintain a healthy homeostatic balance. The case of the failing ovary excepted, the endocrine glands generally sustain their major function of supporting a state of health in the face of declining tissue and organ function until such time as the whole organism falters and decrepitude ensues. (T.B.S.)

Energy Conversion

Over the centuries a wide array of devices and systems has been developed for converting energy from forms provided by nature to those most useful to society. Some of these energy converters are quite simple. The early windmills, for example, transformed the kinetic energy of wind into mechanical energy for pumping water and grinding grain. Other energy-conversion systems are decidedly more complex, particularly those that take raw energy from fossil fuels and nuclear fuels to generate electrical power. Systems of this kind require multiple steps or processes in which energy undergoes a whole series of transformations through various intermediate forms.

Many of the energy converters widely used today involve the transformation of thermal energy into electrical energy. The efficiency of such systems is, however, subject to fundamental limitations, as dictated by the laws of thermodynamics and other scientific principles. In recent years, considerable attention has been devoted to certain direct energy-conversion devices, notably solar cells and fuel cells, that bypass the intermediate step of conversion to heat energy in electrical power generation.

This article traces the development of energy-conversion technology, highlighting not only conventional systems but also alternative and experimental converters with considerable potential. It delineates their distinctive features, basic principles of operation, major types, and key applications. For a discussion of the laws of thermodynamics and their impact on system design and performance, see THERMODYNAMICS, PRINCIPLES OF.

The article is divided into the following sections:

FUNDAMENTALS OF ENERGY CONVERSION

General considerations

Definition of energy

Energy is usually and most simply defined as the equivalent of or capacity for doing work. The word itself is derived from the Greek *energeia: en,* "in"; *ergon,* "work." Energy can either be associated with a material body, as in a coiled spring or a moving object, or it can be independent of matter, as light and other electromagnetic radiation traversing a vacuum. The energy in a system may be only partly available for use. The dimensions of energy are those of work, which, in classical mechanics, is defined formally as the product of mass (m) and the square of the ratio of length (l) to time (t): ml^2/t^2. This means that the greater the mass or the distance through which it is moved or the less the time taken to move the mass, the greater will be the work done, or the greater the energy expended.

DEVELOPMENT OF THE CONCEPT OF ENERGY

The term energy was not applied as a measure of the ability to do work until rather late in the development of the science of mechanics. Indeed, the development of classical mechanics may be carried out without recourse to the concept of energy. The idea of energy, however, goes back at least to Galileo in the 17th century. He recognized that, when a weight is lifted with a pulley system, the force applied multiplied by the distance through which that force must be applied (a product called, by definition, the work) remains constant even though either factor may vary. The concept of vis viva, or living force, a quantity directly proportional to the product of the mass and the square of the velocity, was introduced in the 17th century. In the 19th century the term energy was applied to the concept of the vis viva.

Isaac Newton's first law of motion recognizes force as being associated with the acceleration of a mass. It is almost inevitable that the integrated effect of the force acting on the mass would then be of interest. Of course, there are two kinds of integral of the effect of the force acting on the mass that can be defined. One is the integral of the force acting along the line of action of the force, or the spatial integral of the force; the other is the integral of the force over the time of its action on the mass, or the temporal integral.

Evaluation of the spatial integral leads to a quantity that is now taken to represent the change in kinetic energy of the mass resulting from the action of the force and is just one-half the vis viva. On the other hand, the temporal integration leads to the evaluation of the change in momentum of the mass resulting from the action of the force. For some time there was debate as to which integration led to the proper measure of force, the German philosopher-scientist Gottfried Wilhelm Leibniz arguing for the spatial integral as the only true measure, while earlier the French philosopher and mathematician René Descartes had defended the temporal integral. Eventually, in the 18th cen-

tury, the physicist Jean d'Alembert of France showed the legitimacy of both approaches to measuring the effect of a force acting on a mass and that the controversy was one of nomenclature only.

To recapitulate, force is associated with the acceleration of a mass; kinetic energy, or energy resulting from motion, is the result of the spatial integration of a force acting on a mass; momentum is the result of the temporal integration of the force acting on a mass; and energy is a measure of the capacity to do work. It might be added that power is defined as the time rate at which energy is transferred (to a mass as a force acts on it, or through transmission lines from the electrical generator to the consumer).

Conservation of energy (see below) was independently recognized by many scientists in the first half of the 19th century. The conservation of energy as kinetic, potential, and elastic energy in a closed system under the assumption of no friction has proved to be a valid and useful tool. Further, upon closer inspection, the friction, which serves as the limitation on classical mechanics, is found to express itself in the generation of heat, whether at the contact surfaces of a block sliding on a plane or in the bulk of a fluid in which a paddle is turning or any of the other expressions of "friction." Heat was identified as a form of energy by Hermann von Helmholtz of Germany and James Prescott Joule of England during the 1840s. Joule also proved experimentally the relationship between mechanical and heat energy at this time. As more detailed descriptions of the various processes in nature became necessary, the approach was to seek rational theories or models for the processes that allow a quantitative measure of the energy change in the process and then to include it and its attendant energy balance within the system of interest, subject to the overall need for the conservation of energy. This approach has worked for the chemical energy in the molecules of fuel and oxidizer liberated by their burning in an engine to produce heat energy that subsequently is converted to mechanical energy to run a machine; it has also worked for the conversion of nuclear mass into energy in the nuclear fusion and nuclear fission processes.

Heat as a form of energy

ENERGY CONSERVATION AND TRANSFORMATION

The concept of energy conservation. A fundamental law that has been observed to hold for all natural phenomena requires the conservation of energy—*i.e.*, that the total energy does not change in all the many changes that occur in nature. The conservation of energy is not a description of any process going on in nature, but rather it is a statement that the quantity called energy remains constant regardless of when it is evaluated or what processes—possibly including transformations of energy from one form into another—go on between successive evaluations.

The law of conservation of energy is applied not only to nature as a whole but to closed or isolated systems within nature as well. Thus, if the boundaries of a system can be defined in such a way that no energy is either added to or removed from the system, then energy must be conserved within that system regardless of the details of the processes going on inside the system boundaries. A corollary of this closed-system statement is that whenever the energy of a system as determined in two successive evaluations is not the same, the difference is a measure of the quantity of energy that has been either added to or removed from the system in the time interval elapsing between the two evaluations.

Possible forms of energy within a system

Energy can exist in many forms within a system and may be converted from one form to another within the constraint of the conservation law. These different forms include gravitational, kinetic, thermal, elastic, electrical, chemical, radiant, nuclear, and mass energy. It is the universal applicability of the concept of energy, as well as the completeness of the law of its conservation within different forms, that makes it so attractive and useful.

Transformation of energy. *An ideal system.* A simple example of a system in which energy is being converted from one form to another is provided in the tossing of a ball with mass m into the air. When the ball is thrown vertically from the ground, its speed and thus its kinetic energy decreases steadily until it comes to rest momentarily at its highest point. It then reverses itself, and its speed and kinetic energy increase steadily as it returns to the ground. The kinetic energy E_k of the ball at the instant it left the ground (point 1) was half the product of the mass and the square of the velocity, or $\frac{1}{2}mv_1^2$, and decreased steadily to zero at the highest point (point 2). As the ball rose in the air, it gained gravitational potential energy E_p. Potential in this sense does not mean that the energy is not real but rather that it is stored in some latent form and can be drawn upon to do work. Gravitational potential energy is energy that is stored in a body by virtue of its position in the gravitational field. Gravitational potential energy of a mass m is observed to be given by the product of the mass, the height h attained relative to some reference height, and the acceleration g of a body resulting from the Earth's gravity pulling on it, or mgh. At the instant the ball left the ground at height h_1 its potential energy E_{p1} is mgh_1. At its highest point, its potential energy E_{p2} is mgh_2. Applying the law of conservation of energy and assuming no friction in the air, these add up to form the following equations:

Potential and kinetic energy

$$E_{k1} + E_{p1} = E_{k2} + E_{p2}$$

or

$$\frac{1}{2}mv_1^2 + mgh_1 = 0 + mgh_2.$$

In this idealized example the kinetic energy of the ball at ground level is converted into work in raising the ball to h_2 where its gravitational potential energy has been increased by $mg(h_2 - h_1)$. As the ball falls back to the ground level h_1, this gravitational potential energy is converted back into kinetic energy and its total energy at h_1 again is $\frac{1}{2}mv_1^2 + mgh_1$. In this chain of events the kinetic energy of the ball is unchanged at h_1; thus the work done on the ball by the force of gravity acting on it in this cycle of events is zero. This system is said to be a conservative one.

Varying degrees of conversion in real systems. Although the total amount of energy in an isolated system remains unchanged, there may be a great difference in the quality of different forms of energy. Many forms of energy, in theory, can be transformed completely into work or into other forms of energy. This is true for mechanical energy and electrical energy. The random motions of constituent parts of a material associated with thermal energy, however, represent energy that is not available completely for conversion into directed energy.

The French engineer Sadi Carnot described (in 1824) a theoretical power cycle of maximum efficiency for converting thermal into mechanical energy. He demonstrated that this efficiency is determined by the magnitude of the temperatures at which heat energy is added and waste heat is given off during the cycle. A practical engine operating on the Carnot cycle has never been devised, but the Carnot cycle determines the maximum efficiency of thermal energy conversion into any form of directed energy. The Carnot criterion renders 100 percent efficiency impossible for all heat engines. In effect, it constitutes the basis for what is now the second law of thermodynamics.

The so-called Carnot efficiency

(R.L.Se./C.R.R./Ed.)

History of energy-conversion technology

EARLY ATTEMPTS TO HARNESS NATURAL FORMS OF ENERGY

Early humans first made controlled use of an external, nonanimal energy source when they discovered how to use fire. Burning dried plant matter (primarily wood) and animal waste, they employed the energy from this biomass for heating and cooking. The generation of mechanical energy to supplant human or animal power came very much later—only about 2,000 years ago—with the development of simple devices to harness the energy of flowing water and of wind.

Waterwheels. The earliest machines were waterwheels, first used for grinding grain. They were subsequently adopted to drive sawmills and pumps, to provide the bellows action for furnaces and forges, to drive tilt hammers or trip-hammers for forging iron, and to provide direct me-

Diverse applications

chanical power for textile mills. Until the development of steam power during the Industrial Revolution at the end of the 18th century, waterwheels were the primary means of mechanical power production, rivaled only occasionally by windmills. Thus, many industrial towns, especially in early America, sprang up at locations where water flow could be assured all year.

The oldest reference to a water mill dates to about 85 BC, appearing in a poem by an early Greek writer celebrating the liberation from toil of the young women who operated the querns (primitive hand mills) for grinding corn. According to the Greek geographer Strabo, King Mithradates VI of Pontus in Asia used a hydraulic machine, presumably a water mill, by about 65 BC.

Early vertical-shaft water mills drove querns where the wheel, containing radial vanes or paddles and rotating in a horizontal plane, could be lowered into the stream. The vertical shaft was connected through a hole in the stationary grindstone to the upper, or rotating, stone. The device spread rapidly from Greece to other parts of the world, because it was easy to build and maintain and could operate in any fast-flowing stream. It was known in China by the 1st century AD, was used throughout Europe by the end of the 3rd century, and had reached Japan by the year 610. Users learned early that performance could be improved with a millrace and a chute that would direct the water to one side of the wheel.

A horizontal-shaft water mill was first described by the Roman architect and engineer Vitruvius about 27 BC. It consisted of an undershot waterwheel in which water enters below the centre of the wheel and is guided by a millrace and chute. The waterwheel was coupled with a right-angle gear drive to a vertical-shaft grinding wheel. This type of mill became popular throughout the Roman Empire, notably in Gaul, after the advent of Christianity led to the freeing of slaves and the resultant need for an alternative source of power. Early large waterwheels, which measured about 1.8 metres (six feet) in diameter, are estimated to have produced about three horsepower, the largest amount of power produced by any machine of the time. The Roman mills were adopted throughout much of medieval Europe, and waterwheels of increasing size, made almost entirely of wood, were built until the 18th century.

Energy from ocean tides

In addition to flowing stream water, ocean tides were used to drive waterwheels. Tidal water was allowed to flow into large millponds, controlled initially through lock-type gates and later through flap valves. Once the tide ebbed, water was let out through sluice gates and directed onto the wheel. Sometimes the tidal flow was assisted by building a dam across the estuary of a small river. Although limited in operation to ebbing tide conditions, tidal mills were widely used by the 12th century. The earliest recorded reference to tidal mills is found in the *Domesday Book* (1086), which also records more than 5,000 water mills in England south of the Severn and Trent rivers. (Tidal mills also were built along the Atlantic coast in Europe and centuries later on the eastern seaboard of the United States and in Guyana, where they powered sugarcane-crushing mills.)

The first analysis of the performance of waterwheels was published in 1759 by John Smeaton, an English engineer. Smeaton built a test apparatus with a small wheel (its diameter was only 0.61 metre) to measure the effects of water velocity, as well as head and wheel speed. He found that the maximum efficiency (work produced divided by potential energy in the water) he could obtain was 22 percent for an undershot wheel and 63 percent for an overshot wheel (*i.e.*, one in which water enters the wheel above its centre; see Figure 1). In 1776 Smeaton became the first to use a cast-iron wheel, and two years later he introduced cast-iron gearing, thereby bringing to an end the all-wood construction that had prevailed since Roman times. Based on his model tests, Smeaton built an undershot wheel for the London Bridge waterworks that measured 4.6 metres wide and that had a diameter of 9.75 metres. The results of Smeaton's experimental work came to be widely used throughout Europe for designing new wheels.

Influence of Smeaton's work

During the mid-1700s a reaction waterwheel for generating small amounts of power became popular in the rural areas of England. In this type of device, commonly known as a Barker's mill, water flowed into a rotating vertical tube before being discharged through nozzles at the end of two horizontal arms. These directed the water out tangentially, much in the way that a modern rotary lawn sprinkler does. A rope or belt wound around the vertical tube provided the power takeoff.

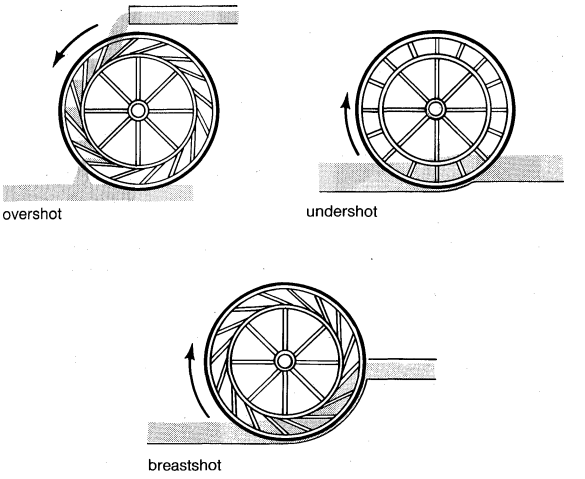

Figure 1: Some major types of waterwheels.

Early in the 19th century Jean-Victor Poncelet, a French mathematician and engineer, designed curved paddles for undershot wheels to allow the water to enter smoothly. His design was based on the idea that water would run up the surface of the curved vanes, come to rest at the inner diameter, and then fall away with practically no velocity. This design increased the efficiency of undershot wheels to 65 percent. At about the same time, William Fairbairn, a Scottish engineer, showed that breast wheels (*i.e.*, those in which water enters at the 10- or two-o'clock position) were more efficient than overshot wheels and less vulnerable to flood damage. He used curved buckets and provided a close-fitting masonry wall to keep the water from flowing out sideways. In 1828 Fairbairn introduced ventilated buckets in which gaps at the bottom of each bucket allowed trapped air to escape. Other improvements included a governor to control the sluice gates and spur gearing for the power takeoff.

During the course of the 19th century, waterwheels were slowly supplanted by water turbines (see *Water turbines* below). Water turbines were more efficient; design improvements eventually made it possible to regulate the speed of the turbines and to run them fast enough to drive electric generators. This fact notwithstanding, waterwheels gave way slowly, and it was not until the early 20th century that they became largely obsolescent. Yet, even today some waterwheels still survive; in the early 1970s there were more than 1,000 grain mills in use in Portugal alone. Equipped with submerged bearings, these modern waterwheels certainly are more sophisticated than their predecessors, though they bear a remarkable likeness to them.

Windmills. Windmills, like waterwheels, were among the original prime movers that replaced animal muscle as a source of power. They were used for centuries in various parts of the world, converting the energy of the wind into mechanical energy for grinding grain, pumping water, and draining lowland areas.

First known wind-powered device

The first known wind device was described by Hero of Alexandria (*c.* 1st century AD). It was modeled on a water-driven paddle wheel and was used to drive a piston pump that forced air through a wind organ to produce sound. The earliest known references to wind-driven grain mills, found in Arabic writings of the 9th century AD, refer to a Persian millwright of AD 644, although windmills may actually have been used earlier. These mills, erected near what is now the Iran–Afghanistan border, had a vertical shaft with paddlelike sails radiating outward and were located in a building with diametrically opposed openings

for the inlet and outlet of the wind. Each mill drove a single set of stones without gearing. The first mills were built with the millstones above the sails, patterned after the early waterwheels from which they were derived. Similar mills were known in China by the 13th century.

Windmills with vertical sails on horizontal shafts reached Europe through contact with the Arabs. Adopting the ideas from contemporary waterwheels, builders began to use fabric-covered, wood-framed sails located above the millstone, instead of a waterwheel below, to drive the grindstone through a set of gears. The whole mill with all its machinery was supported on a fixed post so that it could be rotated and faced into the wind. The millworks were initially covered by a boxlike wooden frame structure and later often by a "round-house," which also provided storage. A brake wheel on the shaft allowed the mill to be stopped by a rim brake. A heavy lever then had to be raised to release the brake, an early example of a fail-safe device. Mills of this sort first appeared in France in 1180, in areas of Syria under the control of the crusaders in 1190, and in England in 1191. The earliest known illustration is from the Windmill Psalter made in Canterbury, Eng., in the second half of the 13th century.

Emergence of the tower mill

The large effort required to turn a post-mill into the wind probably was responsible for the development of the so-called tower mill in France by the early 14th century (see Figure 2). Here, the millstone and the gearing were placed in a massive fixed tower, often circular in section and built of stone or brick. Only an upper cap, normally made of wood and bearing the sails on its shaft, had to be rotated. Such improved mills spread rapidly throughout Europe and later became popular with early American settlers.

The Low Countries of Europe, which had no suitable streams for waterpower, saw the greatest development of windmills. Dutch hollow post-mills, invented in the early 15th century, used a two-step gear drive for drainage pumps. An upright shaft that had gears on the top and bottom passed through the hollow post to drive a paddle-wheel-like scoop to raise water. The first wind-driven sawmill, built in 1592 in the Netherlands by Cornelis Cornelisz, was mounted on a raft to permit easy turning into the wind.

At first both post-mills and the caps of tower mills were turned manually into the wind. Later small posts were placed around the mill to allow winching of the mill with a chain. Eventually winches were placed into the caps of tower mills, engaged with geared racks and operated from inside or from the ground by a chain passing over a wheel. Tower mills had their sail-supporting or tail pole normally inclined at between 5° and 15° to the horizontal. This aided the distribution of the huge sail weight on the tail bearing and also provided greater clearance between the sails and the support structure. Windmills became progressively larger, with sails from about 17 to 24 metres in diameter already common in the 16th century. The material of construction, including all gearing, was wood, although eventually brass or gunmetal came into use for the main bearings. Cast-iron drives were first introduced in 1754 by John Smeaton, the aforementioned English engineer. Little is known about the actual power produced by these mills. In all likelihood only from 10 to 15 horsepower was developed at the grinding wheels. A 50-horsepower mill was not built until the 19th century. The maximum efficiency of large Dutch mills is estimated to have been about 20 percent.

Invention of the fantail

In 1745 Edmund Lee of England invented the fantail, a ring of five to eight vanes mounted behind the sails at right angles to them. These were connected by gears to wheels running on a track around the cap of the mill. As the wind changed direction, it struck the sides of the fantail vanes, realigning them and thereby turning the main sails again squarely into the wind. Fabric-on-wood-frame sails were sometimes replaced by all-wood sails with removable sections. Early sails had a constant angle of twist; variable twist sails resembling a modern airplane propeller were developed much later.

A major problem with all windmills was the need to feather the sails or reduce sail area so that if the wind suddenly increased during a storm the sails would not be ripped apart. In 1772 Andrew Meikle, a Scottish millwright, invented the spring sail, a shutter arrangement similar to a venetian blind in which the sails were controlled by a spring. When the wind pressure exceeded a preset amount, the shutters opened to let some of the wind pass through. In 1789 Stephen Hooper of England introduced roller blinds that could all be simultaneously adjusted with a manual chain from the ground while the mill was working. This was improved upon in 1807 by Sir William Cubitt, who combined Meikle's shutters with Hooper's remote control by hanging varying weights on the adjustment chain, thus making the control automatic. These so-called patent sails, however, found acceptance only in England and northern Europe.

Even though further improvements were made, especially in speed control, the importance of windmills as a major power producer began to decline after 1784, when the first flour mill in England successfully substituted a steam engine for wind power. Yet, the demise of windmills was slow; at one time in the 19th century there were as many as 900 corn (maize) and industrial windmills in the Zaan district of the Netherlands, the highest concentration known. Windmills persisted throughout the 19th century in newly settled or less-industrialized areas, such as the central and western United States, Canada, Australia, and New Zealand. They also were built by the hundreds in the West Indies to crush sugarcane.

Use of wind pumps

The primary exception to the steady abandonment of windmills was resurgence in their use in rural areas for pumping water from wells. The first wind pump was introduced in the United States by David Hallay in 1854. After another American, Stewart Perry, began constructing wind pumps made of steel and equipped with metal vanes in 1883, this new and simple device spread around the world.

Wind-driven pumps remain important today in many rural parts of the world. They continued to be used in large numbers, even in the United States, well into the 20th century until low-cost electric power became readily available in rural areas. Although rather inefficient, they are rugged and reliable, need little attention, and remain a prime source for pumping small amounts of water wherever electricity is not economically available. (For the development of the modern wind turbine, see *Wind turbines* below.) (R.W./Fr.L.)

DEVELOPMENTS OF THE INDUSTRIAL REVOLUTION

Steam engines. The rapid growth of industry in Britain from about the mid-18th century (and somewhat later in various other countries) created a need for new sources of motive power, particularly those independent of geographic location and weather conditions. This situation, together with certain other factors, set the stage for the development and widespread use of the steam engine, the first practical device for converting thermal energy to mechanical energy.

Papin's experimental work on steam power

The foundations for the use of steam power are often traced to the experimental work of the French physicist Denis Papin. In 1679 Papin invented a type of pressure cooker, a closed vessel with a tightly fitting lid that confined steam until high pressure was generated. Observing that the steam in the vessel raised the lid, he conceived the idea of using steam to power a piston and cylinder engine.

Thomas Savery, an English inventor and military engineer, studied Papin's work and built a steam-driven suction machine for removing water from coal mines. Savery's machine (patented in 1698) consisted of a boiler, a closed, water-filled reservoir, and a series of valves. Steam was introduced into the reservoir, and the pressure of the steam forced the water out through a one-way outlet valve until the vessel was empty. Water was then sprayed over the surface of the vessel to condense the steam and create a vacuum capable of drawing up more water through a valve below. Unfortunately the vacuum created was not perfect, and so water could only be lifted to a limited height.

Newcomen engine. Some years later another English engineer, Thomas Newcomen, developed a more efficient steam pump consisting of a cylinder fitted with a piston—a design inspired by Papin's aforementioned idea. When the cylinder was filled with steam, a counterweighted pump plunger moved the piston to the extreme upper end of the stroke. With the admission of cooling water, the steam condensed, creating a vacuum. The atmospheric pressure in the mine acted on the piston and caused it to move down in the cylinder, and the pump plunger was lifted by the resulting force (see Figure 3).

Because Savery had obtained a broad patent for his steam device, Newcomen could not patent his engine. He thus entered into a partnership with Savery, and together they built, in 1712, the first piston-operated steam pump. Several years later Smeaton improved the Newcomen engine, almost doubling its efficiency. Although engines of this kind converted only about 1 percent of the thermal energy in the steam to mechanical energy, they remained unrivaled for more than 50 years.

First piston-operated steam pump

Watt's engine. In 1765 James Watt, a Scottish instrument maker and inventor, modified a Newcomen engine by adding a separate condenser to make it unnecessary to heat and cool the cylinder with each stroke. Because the cylinder and piston remained at steam temperature while the engine was operating, fuel costs dropped by about 75 percent.

Watt entered into a partnership with Matthew Boulton, who owned a factory in Soho, near Birmingham, Eng. At Boulton's insistence he set out to develop a new kind of engine that rotated a shaft instead of providing simple up-and-down motion. He found a way to obtain an inflexible connection between piston and rod (beam) and invented special gear arrangements to convert the up-and-down movement of the beam into circular motion. A heavy flywheel was added to smooth out the variations in the force delivered to the engine shaft by the action of the piston in the cylinder. The flow of steam to the engine was regulated by a governor connected to the flywheel. In addition, Watt applied steam to both sides of the piston to produce greater uniformity of effort and increased power.

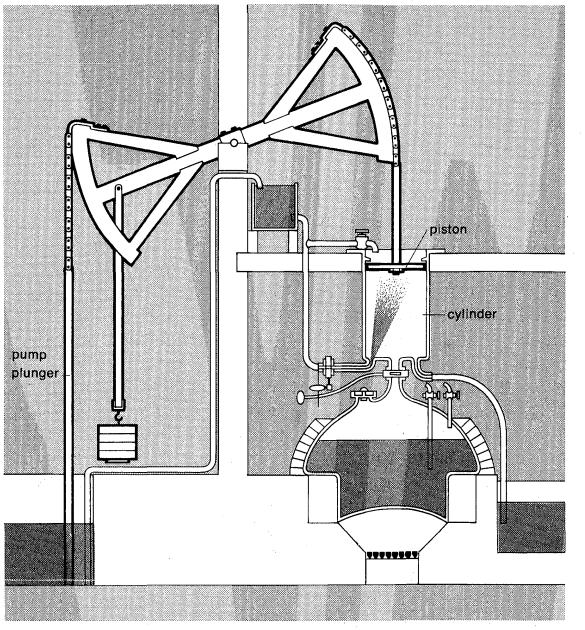

Figure 3: Newcomen engine (see text).

Widespread use of Watt's rotative steam engine

Although far more difficult to build, Watt's rotative engine opened up an entirely new field of application: it enabled the steam engine to be used to operate rotary machines in factories and cotton mills. The rotative engine was widely adopted; it is estimated that by 1800 Watt and Boulton had built 500 engines, of which less than 40 percent were pumps and the rest were of the rotative type.

High-pressure steam engines. Although Watt understood the advantages of utilizing the expansive power of steam within a cylinder, he refused to use steam under high pressure for reasons of safety. This limited the application of steam engines. By the early years of the 19th century, however, the American inventor Oliver Evans had built a stationary high-pressure steam engine for driving a rotary crusher to produce pulverized limestone for agricultural use. Within a few years Evans had designed lighter-weight high-pressure steam engines that could do various other tasks, such as drive sawmills, sow grain, and power a dredge. From 1806 to about 1816 he produced more than 100 steam engines that were employed with screw presses for processing paper, cotton, and tobacco.

Other major advances in the use of high-pressure steam were achieved by Richard Trevithick in England during the early years of the 19th century. Trevithick built the world's first steam-powered railway locomotive in 1803. Two years later he adapted his high-pressure steam engine to drive an iron-rolling mill and to propel a barge with the help of paddle wheels.

First steam locomotive engine

Watt's engine was able to convert only a little more than 2 percent of the thermal energy in steam to work. The improvements introduced by Evans, Trevithick, and others (*e.g.*, three separate expansion cycles and higher steam temperatures) increased the efficiency of the steam engine to roughly 17 percent by 1900. Yet, within the next decade the steam engine was supplanted for various important applications by the more efficient steam turbine (see *Steam turbines* below). Owing to technological advances and the use of high-temperature steam, steam turbines have attained an efficiency of thermal energy conversion of approximately 40 percent. (E.B.Wo./Ed.)

Stirling engine. Many of the early high-pressure steam

boilers exploded because of poor materials and faulty methods of construction. The resultant casualties and property losses motivated Robert Stirling of Scotland to invent a power cycle that operated without a high-pressure boiler. In his engine (patented in 1816), air was heated by external combustion through a heat exchanger and then was displaced, compressed, and expanded by two pistons. Stirling also conceived the idea of a regenerator to store thermal energy during part of the cycle and then return this energy to the working fluid. A successful Stirling engine was built for factory use in 1843, but general use was restricted by the high cost of the device. Nevertheless, until about 1920, small engines of this type were used to pump water on farms and to generate electricity for small communities.

External-combustion engine

Since the Stirling engine is efficient, produces less pollution than most other kinds of engines, and operates on virtually any kind of fuel, efforts have been made intermittently since the late 1930s to reduce its manufacturing costs. Modern versions of the Stirling engine employ pressurized hydrogen or helium instead of air. Although attempts were made as recently as the 1970s to adapt the device to power automobiles, its only commercial application at present is use as a cryogenic refrigerator.

Internal-combustion engines. While the steam engine remained dominant in industry and transportation during much of the 19th century, engineers and scientists began developing other sources and converters of energy. One of the most important of these was the internal-combustion engine. In such a device a fuel and oxidizer are burned within the engine and the products of combustion act directly on piston or rotor surfaces. By contrast, an external-combustion device, such as the steam engine, employs a secondary working fluid that is interposed between the combustion chamber and power-producing elements. By the early 1900s the internal-combustion engine had replaced the steam engine as the most broadly applied power-generating system not only because of its higher thermal efficiency (there is no transfer of heat from combustion gases to a secondary working fluid that results in losses in efficiency) but also because it provided a low-weight, reasonably compact, self-contained power plant.

First practical internal-combustion engine

The German engineer Nikolaus August Otto is generally credited with having built the first practical internal-combustion engine (1876), though several rudimentary devices had appeared earlier in the century. In 1885 Gottlieb Daimler, another German engineer, modified the four-cycle Otto engine so that it burned gasoline (instead of coal powder) and built the first successful high-speed internal-combustion engine. Within several decades the gasoline engine found wide application in motorcycles, automobiles, and small trucks (see *Gasoline engines* below).

Another type of internal-combustion engine was introduced by Rudolf Diesel, also of Germany, in the early 1890s. Named for its inventor, the diesel engine was more efficient than engines of the Otto variety and was fueled by heavy oil, which is cheaper and less volatile than gasoline. As a result, it was adopted as the primary power plant for submarines, railway locomotives, and heavy machinery (see *Diesel engines* below).

An internal-combustion engine quite different from the reciprocating piston type was developed around the turn of the century. This was the gas-turbine engine, the first successful version of which was built in 1903 in France. Modern gas turbines have been used for electric power generation and various other purposes, but its primary application has been jet propulsion. In a gas-turbine system compressed air, heated by the combustion of petroleum, is used to turn a turbine to drive the compressor while excess energy accelerates the exhaust gas to high velocity for producing thrust (see *Gas-turbine engines* and *Jet engines* below).

Early studies of rocket propulsion systems

Another form of propulsive engine, the rocket, attracted increasing attention during the final decades of the 19th century due in part to the imaginative portrayals of space travel fabricated by Jules Verne and other science-fiction writers. From about 1880, various scientists and inventors began investigating theoretical problems of rocket motion and propulsion system design. By the mid-1920s Robert H. Goddard of the United States had developed experimental rockets employing liquid and solid propellants (see *Rockets* below).

Electric generators and motors. Other important energy-conversion devices emerged during the 19th century. During the early 1830s the English physicist and chemist Michael Faraday discovered a means by which to convert mechanical energy into electricity on a large scale. While engaged in experimental work on magnetism, Faraday found that moving a permanent magnet into and out of a coil of wire induced an electric current in the wire. This process, called electromagnetic induction, provided the working principle for electric generators.

During the late 1860s Zénobe-Théophile Gramme, a French engineer and inventor, built a continuous-current generator. Dubbed the Gramme dynamo, this device contributed much to the general acceptance of electric power. By the early 1870s Gramme had developed several other dynamos, one of which was reversible and could be used as an electric motor. Electric motors, which convert electrical energy to mechanical energy, run virtually every kind of machine that uses electricity.

The Gramme dynamo

All of Gramme's machines were direct-current (DC) devices. It was not until 1888 that Nikola Tesla, a Serbian-American inventor, introduced the prototype of the present-day alternating-current (AC) motor (see *Electric generators and electric motors* below).

Direct energy-conversion devices. Most of these energy converters, sometimes called static energy-conversion devices, use electrons as their "working fluid" in place of the vapour or gas employed by such dynamic heat engines as the external-combustion and internal-combustion engines mentioned above. In recent years, direct energy-conversion devices have received much attention because of the necessity to develop more efficient ways of transforming available forms of primary energy into electric power. Four such devices—the electric battery, the fuel cell, the thermoelectric generator (or at least its working principle), and the solar cell—had their origins in the early 1800s.

Electrochemical generation of electricity

The battery, invented by the Italian physicist Alessandro Volta about 1800, changes chemical energy directly into an electric current. A device of this type has two electrodes, each of which is made of a different chemical. As chemical reactions occur, electrons are released on the negative electrode and made to flow through an external circuit to the positive electrode. The process continues until the circuit is interrupted or one of the reactants is exhausted. The forerunners of the modern dry cell and the lead-acid storage battery appeared during the second half of the 19th century (see *Batteries* below).

The fuel cell, another electrochemical producer of electricity, was developed by William Robert Grove, a British physicist, in 1839. In a fuel cell, continuous operation is achieved by feeding fuel (*e.g.*, hydrogen) and an oxidizer (oxygen) to the cell and removing the reaction products (see *Fuel cells* below).

Thermoelectricity

Thermoelectric generators are devices that convert heat directly into electricity. Electric current is generated when electrons are driven by thermal energy across a potential difference at the junction of two conductors made of dissimilar materials. This effect was discovered by Thomas Johann Seebeck, a German physicist, in 1821. Seebeck observed that a compass needle near a circuit made of different conducting materials was deflected when one of the junctions was heated. He investigated various materials that produce electric energy with an efficiency of 3 percent. This efficiency was comparable to that of the steam engines of the day. Yet, the significance of the discovery of the thermoelectric effect went unrecognized as a means of producing electricity because of Seebeck's misinterpretation of the phenomenon as a magnetic effect caused by a difference in temperature. A basic theory of thermoelectricity was finally formulated during the early 1900s, though no functional generators were developed until much later (see *Thermoelectric power generators* below).

Conversion of solar energy into electric power

In a solar cell, radiant energy drives electrons across a potential difference at a semiconductor junction in which the concentrations of impurities are different on the two sides of the junction. What is often considered the first

genuine solar cell was built in the late 1800s by Charles Fritts, who used junctions formed by coating selenium (a semiconductor) with an extremely thin layer of gold (see *Exploiting renewable energy sources* below).

MODERN DEVELOPMENTS

The 20th century brought a host of important scientific discoveries and technological advances, including new and better materials and improved methods of fabrication. These developments permitted the enhancement and refinement of many of the energy-conversion devices and systems that had been introduced during the previous century, as exemplified by the remarkable evolution of jet engines and rockets. They also gave rise to entirely new technologies.

Discovery and application of nuclear energy. *Fission reactors.* Scientists first learned of the tremendous energy bound in the nucleus of the atom during the early years of the century. In 1942 they succeeded in unleashing that energy on a large scale by means of what was called an atomic pile. This was the first nuclear fission reactor, a device designed to induce a self-sustaining and controlled series of fission reactions that split heavy nuclei to release their energy. It was built for the U.S. Manhattan Project undertaken to develop the atomic bomb. Shortly after World War II, reactors were built for submarine propulsion and for commercial power production. The first full-scale commercial nuclear power plant was opened in 1956 at Calder Hall, Eng. In a power generation system of this kind, much of the energy released by the fissioning of heavy nuclei (principally those of the radioactive isotope uranium-235) takes the form of heat, which is used to produce steam. This steam drives a turbine, the mechanical energy of which is converted to electricity by a generator (see *Nuclear fission reactors* below).

First nuclear reactor

Fusion reactors. In the late 1930s Hans A. Bethe, a German-born physicist, recognized that the fusion of hydrogen nuclei to form deuterium releases energy. Since that time scientists have sought to harness such thermonuclear reactions for practical energy production. Much of their work has centred on the use of magnetic fields and electromagnetic forces to confine plasma, an exceedingly hot gas composed of unbound electrons, ions, and neutral atoms and molecules. Plasma is the only state of matter in which thermonuclear reactions can be induced and sustained to generate usable amounts of thermal energy. The difficulty is in confining plasma long enough for this to happen. Although researchers have made significant headway toward constructing fusion reactors capable of such confinement, no device of this kind has been developed sufficiently for commercial application (see *Fusion reactors* below).

Other conversion technologies. Energy requirements for space vehicles led to an intensive investigation, from 1955 on, of all possible energy sources. Direct energy-conversion devices are of interest for providing electric power in spacecraft because of their reliability and their lack of moving parts. Besides solar cells, fuel cells, and thermoelectric generators, thermionic power converters have received considerable attention for space applications. Thermionic generators are designed to convert thermal energy directly into electricity. The required heat energy may be supplied by chemical, solar, or nuclear sources, the latter being the preferred choice for current experimental units (see *Thermionic power converters* below).

Energy-conversion research associated with the space program

Another direct energy converter with considerable potential is the magnetohydrodynamic (MHD) power generator. This system produces electricity directly from a high-temperature, high-pressure electrically conductive fluid—usually an ionized gas—moving through a strong magnetic field. The hot fluid may be derived from the combustion of coal or other fossil fuel. The first successful MHD generator was built and tested during the 1950s. Since that time developmental efforts have progressed steadily, culminating in a Soviet project to build an MHD power plant in the city of Ryazan, located about 180 kilometres (112 miles) southeast of Moscow (see *Magnetohydrodynamic power generators* below).

Exploiting renewable energy sources. Growing concern over the world's ever-increasing energy needs and the prospect of rapidly dwindling reserves of oil, natural gas, and uranium fuel have prompted efforts to develop viable alternative energy sources. The volatility and uncertainty of the petroleum fuel supply were dramatically brought to the fore during the energy crisis of the 1970s caused by the abrupt curtailment of oil shipments from the Middle East to many of the highly industrialized nations of the world. It also has been recognized that the heavy reliance on fossil fuels has had an adverse impact on the environment. Gasoline engines and steam-turbine power plants that burn coal or natural gas emit substantial amounts of sulfur dioxide and nitrogen oxides into the atmosphere. When these gases combine with atmospheric water vapour, they form sulfuric acid and nitric acids, giving rise to highly acidic precipitation. The combustion of fossil fuels also releases carbon dioxide. The amount of this gas in the atmosphere has steadily risen since the mid-1800s largely as a result of the growing consumption of coal, oil, and natural gas. More and more scientists believe that the atmospheric buildup of carbon dioxide (along with that of other industrial gases such as methane and chlorofluorocarbons) may induce a greenhouse effect, raising the surface temperature of the Earth by increasing the amount of heat trapped in the lower atmosphere. This condition could bring about climatic changes with serious repercussions for natural and agricultural ecosystems. (For a detailed discussion of acid rain and the greenhouse effect, see the articles ATMOSPHERE: *Effects of human activity on atmospheric composition and their ramifications* and HYDROSPHERE, THE: *Acid rain* and *Buildup of greenhouse gases.*)

Growing concern over depletion of fuel resources and environmental pollution

Many countries have initiated programs to develop renewable energy technologies that would enable them to reduce fossil-fuel consumption and its attendant problems. Fusion devices are believed to be the best long-term option, since their primary energy source would be the hydrogen isotope deuterium abundantly present in ordinary water. Other technologies that are being actively pursued are those designed to make wider and more efficient use of the energy in sunlight, wind, moving water, and terrestrial heat (*i.e.,* geothermal energy). The amount of energy in such renewable and virtually pollution-free sources is large in relation to world energy needs, yet at the present time only a small portion of it can be converted to electric power at reasonable cost.

A variety of devices and systems has been created to better tap the energy in sunlight. Among the most efficient are photovoltaic systems that transform radiant energy from the Sun directly into electricity by means of silicon or gallium arsenide solar cells. Large arrays consisting of thousands of these semiconductor cells can function as central power stations (see *Solar cells* below). Other systems, which are still under development, are designed to concentrate solar radiation not only to generate electric power but also to produce high-temperature process heat for various applications. These systems employ a number of different components, including large parabolic concentrators and heat engines of the Stirling engine type (see above). Another approach involves the use of flat-plate solar collectors to provide space heating for commercial and residential buildings.

Although wind is intermittent and diffuse, it contains tremendous amounts of energy. Sophisticated wind turbines have been developed to convert this energy to electric power. The utilization of wind energy systems grew discernibly during the 1980s. For example, more than 15,000 wind turbines are now in operation in Hawaii and California at specially selected sites. Their combined power rating of 1,500 megawatts is roughly equal to that of a conventional steam-turbine power installation (see *Wind turbines* below).

Renewal of interest in wind power

Converting the energy in moving water to electricity has been a long-standing technology. Yet, hydroelectric power plants are estimated to provide only about 2 percent of the world's energy requirements. The technology involved is simple enough: hydraulic turbines change the energy of fast-flowing or falling water into mechanical energy that drives power generators, which produce electricity

(see *Water turbines* below). Hydroelectric power plants, however, generally require the building of costly dams. Another factor that limits any significant increase in hydroelectric power production is the scarcity of suitable sites for additional installations except in certain regions of the world.

In certain coastal areas of the world, as, for example, the Rance River estuary in Brittany, Fr., hydraulic turbine-generator units have been used to harness the great amount of energy in ocean tides (see *Tidal plants* below). At most such sites, the capital costs of constructing damlike structures with which to trap and store water are prohibitive, however.

Geothermal energy flows from the hot interior of the Earth to the surface in steam or hot water most often in areas of active volcanism. Geothermal reservoirs with temperatures of 180° C or higher are suitable for power generation. The earliest commercial geothermal power plant was built in 1904 in Larderello, Italy. Today, steam from wells drilled to depths of hundreds of metres drives the plant's turbine generators to produce about 190 megawatts of electricity. Geothermal plants have been built in a number of other countries, including Japan, Mexico, New Zealand, the Soviet Union, and the United States. The principal U.S. plant, located at The Geysers north of San Francisco, can generate up to 1,900 megawatts, though production may be restricted to prolong the life of the steam field. (C.R.R./Ed.)

First commercial geothermal power plant

MAJOR ENERGY-CONVERSION DEVICES AND SYSTEMS

Turbines

A turbine is a machine that converts the energy stored in a fluid into mechanical energy. This conversion is generally accomplished by passing the fluid through a system of stationary passages or vanes that alternate with passages consisting of finlike blades attached to a rotor. By arranging the flow so that a tangential force, or torque, is exerted on the rotor blades, the rotor will turn, and work can be extracted. Turbines can be classified into four general types according to the fluids used: water, steam, gas, and wind. Although the same principles apply to all turbines, their specific designs differ sufficiently to merit separate descriptions.

Classification of turbines

A water turbine uses the potential energy resulting from the difference in elevation between an upstream water reservoir and the turbine-exit water level (the tailrace) to convert this so-called head into work. Water turbines are the modern successors of simple waterwheels, which date back about 2,000 years (see *Waterwheels* above). Today, the primary use of water turbines is for electric power generation.

The greatest amount of electrical energy comes, however, from steam turbines coupled to electric generators. The turbines are driven by steam produced in either a fossil-fuel-fired or a nuclear-powered generator. The energy that can be extracted from the steam is conveniently expressed in terms of the enthalpy change across the turbine. Enthalpy reflects both thermal and mechanical energy forms in a flow process and is given by the sum of the internal thermal energy and the product of pressure times volume. The available enthalpy change through a steam turbine increases with the temperature and pressure of the steam generator and with reduced turbine-exit pressure.

Enthalpy

For gas turbines, the energy extracted from the fluid also can be expressed in terms of the enthalpy change, which for a gas is nearly proportional to the temperature drop across the turbine. In gas turbines the working fluid is air mixed with the gaseous products of combustion. Most gas-turbine engines include at least a compressor, a combustion chamber, and a turbine. These are usually mounted as an integral unit and operate as a complete prime mover on a so-called open cycle where air is drawn in from the atmosphere and the products of combustion are finally discharged again to the atmosphere. Since successful operation depends on the integration of all components, it is important to consider the whole device, which is actually an internal-combustion engine, rather than the turbine alone. For this reason, gas turbines will be treated in the section *Internal-combustion engines.*

The energy available in wind can be extracted by a wind turbine to produce electric power or to pump water from wells. Wind turbines are the successors of windmills, which were important sources of power from the late Middle Ages through the 19th century (see *Windmills* above). (Fr.L.)

WATER TURBINES

Principal types

Water turbines are generally divided into two categories: (1) impulse turbines used for high heads of water and low flow rates and (2) reaction turbines normally employed for heads below about 450 metres and moderate or high flow rates. These two classes include the main types in common use—namely, the Pelton impulse turbine and the reaction turbines of the Francis, propeller, Kaplan, and Deriaz variety. Turbines can be arranged with either horizontal or, more commonly, vertical shafts. Wide design variations are possible within each type to meet the specific local hydraulic conditions. Today, most hydraulic turbines are used for generating electricity in hydroelectric installations.

Impulse turbines. In an impulse turbine the potential energy, or the head of water, is first converted into kinetic energy by discharging water through a carefully shaped nozzle. The jet, discharged into air, is directed onto curved buckets fixed on the periphery of the runner to extract the water energy and convert it to useful work.

Modern impulse turbines are based on a design patented in 1889 by the American engineer Lester Allen Pelton. The free water jet strikes the turbine buckets tangentially. Each bucket has a high centre ridge so that the flow is divided to leave the runner at both sides. Pelton wheels are suitable for high heads, typically above about 450 metres with relatively low water flow rates. For maximum efficiency the runner tip speed should equal about one-half the striking jet velocity. The efficiency (work produced by the turbine divided by the kinetic energy of the free jet) can exceed 91 percent when operating at 60–80 percent of full load.

Pelton turbines

The power of a given wheel can be increased by using more than one jet. Two-jet arrangements are common for horizontal shafts (see Figure 4). Sometimes two separate runners are mounted on one shaft driving a single electric generator. Vertical-shaft units may have four or more separate jets.

If the electric load on the turbine changes, its power output must be rapidly adjusted to match the demand. This

Fox Photos Ltd.

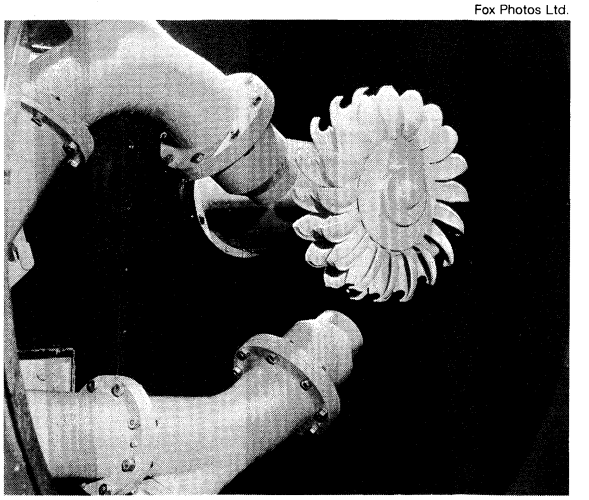

Figure 4: Pelton water turbine with twin jets.

requires a change in the water flow rate to keep the generator speed constant. The flow rate through each nozzle is controlled by a centrally located, carefully shaped spear or needle that slides forward or backward as controlled by a hydraulic servomotor.

Proper needle design assures that the velocity of the water leaving the nozzle remains essentially the same irrespective of the opening, assuring nearly constant efficiencies over much of the operating range. It is not prudent to reduce the water flow suddenly to match a load decrease. This could lead to a destructive pressure surge (water hammer) in the supply pipeline, or penstock. Such surges can be avoided by adding a temporary spill nozzle that opens while the main nozzle closes or, more commonly, by partially inserting a deflector plate between the jet and the wheel, diverting and dissipating some of the energy while the needle is slowly closed.

Turgo impulse turbines

Another type of impulse turbine is the turgo type. The jet impinges at an oblique angle on the runner from one side and continues in a single path, discharging at the other side of the runner. This type of turbine has been used in medium-sized units for moderately high heads.

Reaction turbines. In a reaction turbine, forces driving the rotor are achieved by the reaction of an accelerating water flow in the runner while the pressure drops. The reaction principle can be observed in a rotary lawn sprinkler where the emerging jet drives the rotor in the opposite direction. Due to the great variety of possible runner designs, reaction turbines can be used over a much larger range of heads and flow rates than impulse turbines. Reaction turbines typically have a spiral inlet casing that includes control gates to regulate the water flow. In the inlet a fraction of the potential energy of the water may be converted to kinetic energy as the flow accelerates. The water energy is subsequently extracted in the rotor.

There are, as noted above, four major kinds of reaction turbines in wide use: the Kaplan, Francis, Deriaz, and propeller type. In fixed-blade propeller and adjustable-blade Kaplan turbines (named after the Austrian inventor Victor Kaplan), there is essentially an axial flow through the machine. The Francis- and Deriaz-type turbines (after the British-born American inventor James B. Francis and the Swiss engineer Paul Deriaz, respectively) use a "mixed flow," where the water enters radially inward and discharges axially. Runner blades on Francis and propeller turbines consist of fixed blading, while in Kaplan and Deriaz turbines the blades can be rotated about their axis, which is at right angles to the main shaft.

Propeller-type turbines

Axial-flow machines. Fixed propeller-type turbines are generally used for large units at low heads, resulting in large diameters and slow rotational speeds. As the name suggests, a propeller-type turbine runner looks like the very large propeller of a ship except that it serves the opposite purpose: power is extracted in a turbine, whereas it is fed into a marine propeller. The central shaft, or hub, may have the propeller blades bolted to it during on-site assembly, thus permitting shipment by sections for a large runner. At low heads (below about 24 metres), vertical-shaft propeller turbines typically have a concrete spiral inlet casing of rectangular cross section. Inlet guide vanes are either mounted on a ring or, in large units, set individually directly into the concrete. The flow passage can be increased or decreased by servomotor-driven wicket gates. The kinetic energy leaving the runner can be partially recaptured by a draft tube, a conical diffusing exit section where the velocity is decreased while the pressure is increased. This leads to improved efficiency by keeping the loss of kinetic energy in the exit, or tail, section of the installation to a minimum.

Propeller turbines are used extensively in North America, where low heads and large flow rates are common. For example, there are 32 propeller turbines in the Moses–Saunders Power Dam on the St. Lawrence River between New York and Ontario—16 operated by the United States and 16 by Canada, with each turbine rated at 50,000 kilowatts. With such large plants it is possible to run each turbine at or near its most efficient output by switching complete units in or out as the load fluctuates, in addition to regulating each unit.

If the head or the water flow rate tends to vary seasonally, as occurs in many river systems, an installation with only a few propeller turbines might have to operate all units at partial output under average flow and load conditions. The energy-conversion efficiency of a conventional propeller turbine decreases rapidly once the turbine load drops below 75 percent of its rating. This performance loss can be minimized by varying the inlet-blade angle of the runner to match the runner-inlet conditions more accurately with the water velocity for a given flow. In such a Kaplan turbine (Figure 5) each blade can be swiveled about a post at right angles to the main turbine shaft, thus producing a variable pitch. The angle of the blades is controlled by an oil-pressure operated servomotor, usually mounted in the rotor hub with the oil fed through the generator and turbine shaft. The servo-control system, which also drives the gates through a cam or rocker arrangement, is designed to adjust angles and inlet flows to match the electrical load while keeping the main shaft with its directly coupled generator rotating at constant speed. Runners with four to six blades are common, though more blades may be used for high heads. British manufacturers have developed Kaplan designs for heads up to 58 metres.

Kaplan turbines

By courtesy of The English Electric Co. Ltd.

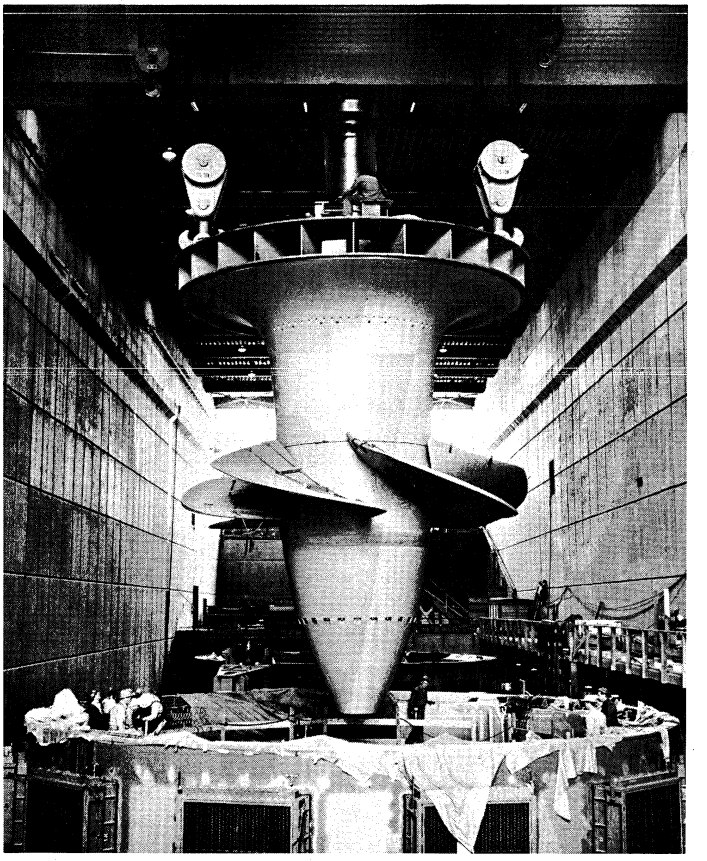

Figure 5: A 131,000-horsepower Kaplan water-turbine runner.

Although the usual turbine installation has a vertical shaft, some also have been designed with horizontal shafts. In a horizontal bulb arrangement, the generator is embedded in a nacelle, corresponding to the thick body of a light bulb, while the blades are set around a hub corresponding to the thinner bulb socket. This design is suitable for medium-sized machines operating at very low heads when an almost straight-through water flow is desirable. The Rance River tidal plant in France employs this kind of arrangement (see *Tidal plants* below).

Francis turbines

Mixed-flow turbines. Francis turbines are probably used most extensively because of their wider range of suitable heads, characteristically from three to 600 metres. At the high-head range, the flow rate and the output must be large; otherwise the runner becomes too small for reasonable fabrication. At the low-head end, propeller turbines are usually more efficient unless the power output is also

small. Francis turbines reign supreme in the medium-head range of 120 to 300 metres and come in a wide range of designs and sizes. They can have either horizontal or vertical shafts, the latter being used for machines with diameters of about two metres or more. Vertical-shaft machines usually occupy less space than horizontal units, permit greater submergence of the runner with a minimum of deep excavation, and make the tip-mounted generator more easily accessible for maintenance. Horizontal-shaft units are more compact for smaller sizes and allow easier access to the turbine, although removal of the generator for repair becomes more difficult as size increases.

The most common form of Francis turbine has a welded, or cast-steel, spiral casing. The casing distributes water evenly to all inlet gates; up to 24 pivoted gates or guide vanes have been used. The gates operate from fully closed to wide open, depending on the power output desired. Most are driven by a common regulating speed ring and are pin-connected in such a fashion that no damage will occur if debris blocks one of the gate passages. The regulating ring is rotated by one or two oil-pressure servomotors that are controlled by the speed governor.

Slow, high-power units have a nearly radial set of blades, while in fast and lower-powered units the curved blades reach from the radial inlet to almost the axial outlet (see Figure 6). Once the overall blade dimensions (inlet and exit diameters and blade height) have been defined, the blades are designed for a smooth entry of the water flow at the inlet and minimum water swirl at the exit. The number of blades can vary from seven to 19. Runners for low-head units are usually made of cast mild steel, sometimes with stainless-steel protection added at locations subject to cavitation (see below). All stainless-steel construction is more commonly used for high heads. Large units can be welded together on-site, using an appropriate combination of various preformed steel sections to provide carefully shaped, finished water passages. Francis turbines allow for very large, high-output units. The Grand Coulee hydroelectric power plant on the Columbia River in Washington state has the largest single runner in the United States, a device capable of producing 716,000 kilowatts at a head of 93 metres. The world's largest hydroelectric power installation, the Itaipú plant on the Paraná River between Brazil and Paraguay, is scheduled to have 18 Francis turbines capable of producing 740,000 kilowatts each at heads between 118.4 and 126.7 metres while rotating at slightly above 90 revolutions per minute (rpm).

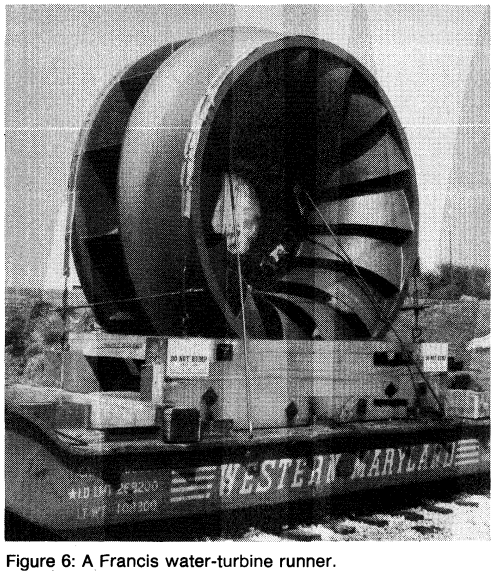

Figure 6: A Francis water-turbine runner.

Deriaz-type mixed-flow turbine

A mixed-flow turbine of the Deriaz type uses swiveled, variable-pitch runner blades that allow for improved efficiency at part loads in medium-sized machines (see Figure 7). The Deriaz design has proved useful for higher heads and also for some pumped storage applications (see below). It has the advantage of a lower runaway (sudden loss of load) speed than a Kaplan turbine, which results in significant savings in generator costs. Very few Deriaz turbines, however, have actually been built. The first non-reversible Deriaz turbine, capable of producing 22,750 kilowatts with a head of 55 metres, was installed in an underground station at Culligran, Scot., in 1958.

Other design considerations. *Output and speed control.* If the load on the generator is decreased, a turbine will tend to speed up unless the flow rate can be reduced accordingly. Similarly, an increase of load will cause the turbine to slow down unless more water can be admitted. Since electric-generator speeds must be kept constant to a high degree of precision, this leads to complex controls. These must take into account the large masses and inertias of the metal and the flowing water, including the water in the inflow pipes (or penstocks), that will be affected by any change in the wicket gate setting. If the inlet pipeline is long, the closing time of the wicket gate must be slow enough to keep the pressure increase caused by a reduction in flow velocity within acceptable limits. If the closing or opening rate is too slow, control instabilities may result. To assist regulation with long pipelines, a surge chamber is often connected to the pipeline as close to the turbine as possible. This enables part of the water in the line to pass into the surge chamber when the wicket gates are rapidly closed or opened. Medium-sized reaction turbines may also be provided with pressure-relief valves through which some water can be bypassed automatically as the governor starts to close the turbine. In some applications, both relief valves and surge chambers have been used.

Cavitation. According to Bernoulli's principle (derived by the Swiss mathematician Daniel Bernoulli), as the flow velocity of the water increases at any given elevation, the pressure will drop. There is a danger that in high-velocity sections of a reaction turbine, especially near the exit, the pressure can become so low that the water flashes over into small vapour bubbles, which then collapse suddenly. This so-called cavitation leads to erosion pitting as well as to vibrations and must be avoided by the careful shaping of all blade passages and of the exit passage or draft tube.

Problems associated with cavitation

Turbine selection on the basis of specific speed. Initial turbine selection is usually based on the ratio of design variables known as the power specific speed. In U.S. design practice this is given by

$$N = \frac{nP^{1/2}}{H^{5/4}},$$

where n is in revolutions per minute, P is the output in horsepower, and H is the head of water in feet. Turbine types can be classified by their specific speed, N, which always applies at the point of maximum efficiency. If N ranges from one to 20, corresponding to high heads and

low rotational speeds, impulse turbines are appropriate. For N between 10 and 90, Francis-type runners should be selected, with slow-running, near-radial units for the lower N values and more rapidly rotating mixed-flow runners for higher N values. For N up to 110, Deriaz turbines may be suitable. If N ranges from 70 to the maximum of 260, propeller or Kaplan turbines are called for.

Using the specific speed formula, a turbine designed to deliver 100,000 horsepower (74,600 kilowatts) with a head of 40 feet (12.2 metres) operating at 72 revolutions per minute would have a specific speed of 226, suggesting a propeller or Kaplan turbine. It can also be shown that the flow rate would have to be about 24,500 cubic feet per second (694 cubic metres per second) at a turbine efficiency of 90 percent. The runner diameter will be about 33 feet (10 metres). This illustrates the large sizes required for high-power, low-head installations and the low rotational speed at which these turbines have to operate to stay within the permissible specific speed range.

Turbine model testing. Before building large-scale installations, the design should be checked out with turbine model tests, using geometrically similar models of small and intermediate size, all operating at the same specific speed. Allowances must be made for the effects of friction, determined by the Reynolds number (density × rotational speed × runner diameter squared/viscosity) and for possible changes in scaled roughness and clearance dimensions. Friction effects are less important for large units, which tend to be more efficient than smaller ones.

Applications. *Electric power generation.* Water turbines are used almost exclusively for generating electric power that can be transmitted through high-voltage power lines to population centres. The United States, the Soviet Union, and Canada lead in hydroelectric power production, though many other countries also have major production facilities. Until the late 1950s most single turbogenerator units had capacities of less than 150,000 kilowatts. By the late 1980s construction costs and the need for reliability pointed toward 250,000- to 300,000-kilowatt units, although some recent installations were equipped with turbines capable of up to 750,000 kilowatts.

Pumped storage. Electricity must be used as soon as it is generated; there are no economical means of storing large quantities of electric energy. Thus hydroelectric plants built for near-maximum power consumption during daytime peak hours would have to operate at low efficiency during nighttime or weekend off-hours. To avoid this, water can be pumped to a second, higher reservoir during off-hours for storage in the form of potential energy and then fed back through power-generating turbines at times of high demand. Even though this system does not generate new energy (there actually is a reduction in energy due to losses involved in pump and turbine operation as well as in the electric motor and generator), pumped hydro-storage often becomes economical when compared with the cost of constructing additional turbines for peak power demands.

Use of reversible-pump turbines

Modern pumped storage units in the United States normally use reversible-pump turbines that can be run in one direction as pumps and in the other direction as turbines. These are coupled to reversible electric motor/generators. The motor drives the pump during the storage portion of the cycle, while the generator produces electricity during discharge from the upper reservoir.

Most reversible-pump turbines are of the Francis type. The complexity of the unit, however, increases significantly as compared to a turbine alone. In spite of the higher costs for both hydraulic and electrical controls and support equipment, the total installed cost will be less than for completely separate pump-motor and turbine-generator assemblies with dual water passages.

Some very economical pumped storage plants have heads exceeding 300 metres. In the past this was considered too high for single-stage pumps, and the use of separate multistage, nonreversible units was required. Satisfactory reversible single-stage pump turbines, however, have been developed that can operate at 700-metre heads, though most installations have smaller head differences between the upper and lower reservoirs.

For medium heads, Deriaz turbines have had some success because they allow ready adjustment of the runner-blade angles to match the opposite requirements of pumping and power generation. The pumping load can also be varied with Deriaz-type units, which cannot be done with a Francis runner. A further advantage of a Deriaz-type machine is that the runner blades can be closed to form a smooth cone, a feature that permits pump start-up with minimum load while the unit is submerged in water.

An early major Deriaz reversible-pump turbine system was installed at plants on both the Canadian and U.S. sides of Niagara Falls; this made it possible to provide "side storage" at night without impairing the tourist attraction of the falls by reducing the flow during the day. The Tuscarora plant on the U.S. side uses 12 pump turbines at heads between 18.3 to 29 metres.

Pumped storage has become widespread in industrialized nations. In the United States alone more than 30 pumped hydropower stations were in operation by the mid-1980s. The largest plant is located in Bath County, Va., where six pump-turbines have a total capacity of 2.1 million kilowatts. This amount of power can be generated over an 11-hour period.

Tidal plants. Although the majority of hydroelectric plants depend on the impoundment of rivers, tidal power still could play a role, albeit minor, in electric power generation during the coming years. Areas where the normal tide runs high, such as in the Bay of Fundy between the United States and Canada or along the English Channel, can allow water to flow into a dam-controlled basin during high tide and discharge it during low tide to produce intermittent power. One such plant is located in France on the estuary of the Rance River near Saint-Malo in Brittany. There, a reservoir has been created by a barrage four kilometres inland from the river mouth to make use of tides ranging from about 3.4 to 13.4 metres. The power station is equipped with 24 reversible bulb-type propeller turbines coupled to reversible motor/generators, each having a capacity of 10,000 kilowatts. Pumped storage is used if the tidal outflow through the plant falls below peak power demands. A pilot tidal plant with a 40,000-kilowatt capacity has been built in the Soviet Union on the Barents Sea. If this facility proves economical, it may lead to the construction of other tidal plants on the northern and eastern Soviet coasts.

Rance River tidal plant

Cost of hydroelectric power. Although large hydroelectric plants can be operated economically, the cost of land acquisition and of dam and reservoir construction must be included in the total cost of power, since these outlays generally account for about half of the total initial cost. Most large plants serve multiple purposes: hydropower generation, flood control, storage of drinking water, and the impounding of water for irrigation. By properly prorating construction costs to the non-power-producing utility of the unit, electricity can be sold very cheaply. In the Pacific Northwest region of the United States, such accounting has given hydroelectric plants an apparent cost advantage over fossil-fueled units.

History of water turbine technology. Experiments on the mechanics of reaction wheels conducted by the Swiss mathematician Leonhard Euler and his son Albert in the 1750s found application about 75 years later. In 1826 Jean-Victor Poncelet of France proposed the idea of an inward-flowing radial turbine, the direct precursor of the modern water turbine. This machine had a vertical spindle and a runner with curved blades that was fully enclosed. Water entered radially inward and discharged downward below the spindle.

Precursor of the modern water turbine

A similar machine was patented in 1838 by Samuel B. Howd of the United States and built subsequently. Howd's design was improved on by James B. Francis, who added stationary guide vanes and shaped the blades so that water could enter shock-free at the correct angle. His runner design, which came to be known as the Francis turbine (see above), is still the most widely used for medium-high heads. Improved control was proposed by James Thomson, a Scottish engineer, who added coupled and pivoted curved guide vanes to assure proper flow directions even at part load.

A radial outward-flow turbine had been proposed in 1824 by the French engineering professor Claude Burdin and his former student Benoît Fourneyron. This device had a vertical axis carrying a runner with curved blades through which the water left almost tangentially. Fixed guide vanes, curved in the opposite direction, were mounted in an annulus inside the runner. Unfortunately the design made it difficult to support the runner and to take power off the turbine wheel. The first successful version of the turbine was built by Fourneyron in 1827. More than 100 such machines were subsequently built all over the world; they achieved efficiencies up to 75 percent at full load with heads up to 107 metres. In 1844 Uriah A. Boyden added an outlet diffuser to recover part of the kinetic energy exiting the device and thereby further improved efficiency. Outward-flow turbines, however, are inherently unstable, and speed control is difficult. Moreover, the construction of outward-flow turbines is very complex as compared to that of Francis-type runners, and this fact led to their eventually being supplanted by the latter.

Francis turbines were augmented by the development of the Pelton wheel (1889) for small flow rates and high heads and by propeller turbines, first built by Kaplan in 1913, for large flows at low heads. Kaplan's variable-pitch propeller turbine, which still bears his name, was manufactured after 1920. These units, together with the Deriaz mixed-flow turbine (invented in 1956), constitute the arsenal of modern water turbines.

By the mid-19th century, water turbines were widely used to drive sawmills and textile mill equipment, often through a complex system of gears, shafts, and pulleys. After the widespread adoption of the steam engine they did not, however, become a major factor in power generation until the advent of the electric generator made hydroelectric power possible.

The world's first hydroelectric central station

The world's first hydroelectric central station was built in 1882 in Appleton, Wis., only three years after Thomas Edison's invention of the light bulb. Its output of 12.5 kilowatts was used to light two paper mills and a house. Thereafter hydroelectric power development spread rapidly, though even by 1910 most units delivered only a few hundred to a few thousand kilowatts. Installations with more than 100,000-kilowatt capacity were not built until the 1930s. One of the first large U.S. plants was installed at Hoover Dam on the Colorado River between Nevada and Arizona. It began operating in 1936 and eventually included 17 Francis turbines capable of delivering from 40,000 to 130,000 kilowatts of power, along with two 3,000-kilowatt Pelton wheels.

Pumped-storage hydropower in the United States

The first pumped storage plant with a capacity of 1,500 kilowatts was built near Schaffhausen, Switz., in 1909. It made use of a separate pump and turbine, resulting in a relatively large and only barely economical system. The first U.S. plant, built on the Rocky River in Connecticut in 1929, was also only marginally economical. In the United States major work on pumped-storage hydropower began in the mid-1950s, following the success of a plant at Flatiron, Colo. Built in 1954, this facility was equipped with a reversible-pump turbine having a capacity of 9,000 kilowatts.

In highly industrialized countries, such as the United States and the nations of western Europe, most potential sites for hydropower have already been tapped. Environmental concerns relating to the impact of large dams on the upstream watercourse and to the possible effect on aquatic life add to the likelihood that only a few large hydraulic plants will be built in the future.

From about the 1940s to the early 1970s, many small U.S. hydroelectric facilities (primarily those of less than 1,000-kilowatt capacity) were, in fact, closed down because high maintenance and supervision costs made them uneconomical compared to power plants that burn fossil fuels. Even though the increase in fossil-fuel costs since 1973 has led to the rehabilitation of some of these abandoned plants, only a marked increase in fuel prices, coupled with specific needs for irrigation or flood control, is likely to lead to significant new hydroelectric plant construction.

It is estimated that about 75 percent of the potential waterpower in the contiguous United States has already been developed, with the drainage area of the Columbia River in the Pacific Northwest leading in both developed and potential additional power. As of the late 1980s, hydroelectric power met about 13 percent of the total demand for electrical energy in the United States, though this amounts to only 3 percent of the combined U.S. energy usage for mechanical power, heat, light, and refrigeration.

The above considerations do not necessarily apply to such remote areas as Alaska, northern Canada, and parts of the Soviet Union, or to developing nations in regions of the Himalayas, Africa, and South America. In these areas it is estimated that only 23 percent of the potential waterpower has been developed. For example, less than 1 percent of the estimated 167 million kilowatts available in Alaska has been harnessed to date. Other river basins with large remaining potential capacities include the Fraser River in Canada, the Orinoco in Venezuela, the Brahmaputra in India, and the Yenisey–Angara in the Soviet Union. Turbine capacities for some of these remote areas may possibly exceed the current maximum of 740,000 kilowatts per unit.

STEAM TURBINES

A steam turbine consists of a rotor resting on bearings and enclosed in a cylindrical casing. The rotor is turned by steam impinging against attached vanes or blades on which it exerts a force in the tangential direction. Thus a steam turbine could be viewed as a complex series of windmill-like arrangements, all assembled on the same shaft.

Predominance in power generation and propulsion of high-speed vessels

Because of its ability to develop tremendous power within a comparatively small space, the steam turbine has superseded all other prime movers, except hydraulic turbines, for generating large amounts of electricity and for providing propulsive power for large, high-speed ships. Today, units capable of generating more than 1.3 million kilowatts of power can be mounted on a single shaft.

Classifications. Large steam turbines are complex machines that can be classified in various ways. One approach centres on whether rotation is achieved by impulse forces or by reaction forces (see below). This distinction may become somewhat blurred, since many modern machines employ a combination of both methods.

Condensing and noncondensing turbines. Steam turbines are often divided into two types: condensing and noncondensing. In devices of the first type, steam is condensed at below atmospheric pressure so as to gain the maximum amount of energy from it. In noncondensing turbines, steam leaves the turbine at above atmospheric pressure and is then used for heating or for other required processes before being returned as water to the boiler. Compared to the fuel needed for simply converting water into steam (saturated steam), relatively little additional fuel has to be expended to increase the steam generator exit pressure and, especially, the temperature in order to produce superheated steam, which then is used to drive a turbine. Noncondensing turbines are thus an economical means of generating power (cogeneration) when large amounts of heating or process steam are already needed.

In condensing turbines, substantial quantities of cooling water are required to carry away the heat released during condensation. While noncondensing turbines exhaust steam at or above atmospheric pressure, condensing turbines can condense at pressures of 90 to 100 kilopascals (13 to 14.5 pounds per square inch) below atmospheric pressure. This allows for a much larger expansion of the steam and a larger change in enthalpy (see above), resulting in higher work output and greater efficiency. All central station plants, where efficiency is a prime consideration, employ condensing turbines.

Steam extraction. Steam turbines differ according to whether or not a portion of the steam is extracted from intermediate portions of the turbine. Extraction may be carried out to partially reheat the water fed back to the boiler and thereby significantly increase the efficiency of the power plant. In light of this, turbines may be classified as (1) straight-through turbines, in which there is no extraction (or bleeding), (2) bleeder or extraction turbines, and (3) controlled-(or automatic-) extraction turbines.

Increasing power plant efficiency

In bleeder turbines no effort is made to control the pres-

sure of the extracted steam, which varies in almost direct proportion to the load carried by the turbine. Extraction also reduces the steam flow to the condenser, allowing the turbine exhaust area to be reduced. Controlled-extraction turbines are designed for withdrawing variable amounts of constant-pressure steam irrespective of the load on the turbine. They are frequently selected for industrial use when steam at fixed intermediate pressures is demanded by process operations. Since both extraction pressures and turbine speed should be kept constant, a complex system is required for controlling steam flow, which increases the cost. Controlled-extraction turbines may be designed for both condensing and noncondensing operations.

Reheat and nonreheat turbines. If high-pressure, high-temperature steam is partially expanded through a turbine, the efficiency can be increased by returning the steam to the steam generator and reheating it to approximately its original temperature before feeding it back to the turbine. Single reheat turbines are common in the electric utility industry. For very large units, double reheating may be employed. Nonreheat turbines are currently limited mostly to industrial plants and small utilities.

Multiflow and compound arrangements. Steam entering a turbine at a high pressure and temperature—say, 24,100 kilopascals gauge, or 3,500 pounds per square inch gauge (where gauge denotes pressure above atmospheric value), and 600° C—can have a volume increase of more than a thousandfold if it is expanded to below atmospheric condenser pressures. To keep the steam velocity through the turbine essentially constant, the annular flow area would have to increase more than a thousandfold, necessitating very large diameter casings and excessively long turbine blades near the exit. In large turbines this problem is alleviated by splitting the low-pressure stream into a number of parallel flow sections, as illustrated in Figures 8 and 9 for four-flow units.

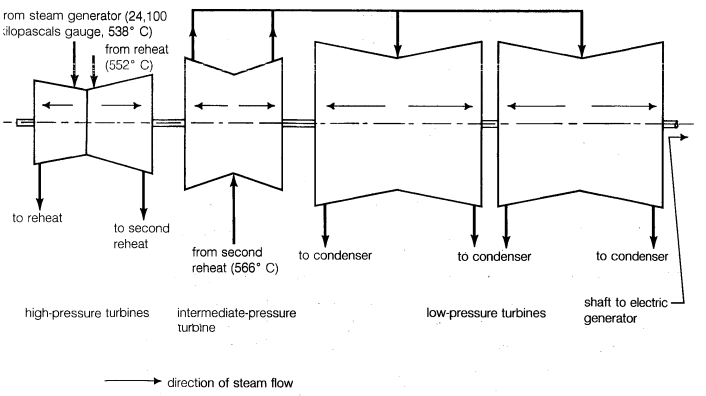

Figure 8: *Schematic of a 3,600-rpm, tandem-compound, four-flow, double-reheat steam turbine.* This unit can produce 725,000 kilowatts with inlet steam at 24,100 kilopascals gauge at 538° C and double reheats to 552° C and 566° C, respectively. The exit blades (or buckets) are 85 centimetres long. The heat rate (see text) at 100 percent of rated output is 7,490 British thermal units per kilowatt-hour (Btu/kWh), 7,950 Btu/kWh at 50 percent output, and 9,330 Btu/kWh at 25 percent output. The first reheat occurs at about 7,140 kilopascals gauge and the second at approximately 2,340 kilopascals gauge when operating at full power.

Tandem-compound and cross-compound turbines

This flow splitting also leads to another method of classification that differentiates between having the whole machine assembled along a single shaft with one generator (tandem-compound turbines), as illustrated in the figures, or utilizing two shafts, each with its own generator (cross-compound turbines).

Principal components. The main parts of a steam turbine are (1) the rotor that carries the blading to convert the thermal energy of the steam into the rotary motion of the shaft, (2) the casing, inside of which the rotor turns, that serves as a pressure vessel for containing the steam (it also accommodates fixed nozzle passages or stator vanes through which the steam is accelerated before being directed against and through the rotor blading), (3) the speed-regulating mechanism, and (4) the support system, which includes the lubrication system for the bearings that support the rotor and also absorb any end thrust developed.

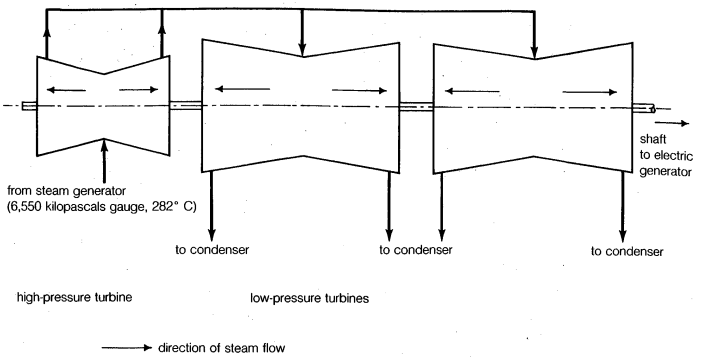

Figure 9: *Schematic of a 1,800-rpm, tandem-compound, four-flow, nonreheat steam turbine for nuclear applications.* The unit is rated at 847,000 kilowatts with steam entering at 6,550 kilopascals gauge and a temperature of about 282° C, which is typical for nuclear power plants. The exit buckets are 96.5 centimetres long. The heat rate is 9,810 Btu/kWh at full output and about 10,400 Btu/kWh at 40 percent output. Similarly, six-flow units operating with steam at 7,580 kilopascals gauge and about 293° C can produce 1,325,000 kilowatts. In this case the exit blades measure 109 centimetres long.

Design considerations. *Blading design.* The turbine blading must be carefully designed with the correct aerodynamic shape to properly turn the flowing steam and generate rotational energy efficiently. The blades also have to be strong enough to withstand high centrifugal stresses and must be sized to avoid dangerous vibrations. Various types of blading arrangements have been proposed, but all are designed to take advantage of the principle that when a given mass of steam suddenly changes its velocity, a force is then exerted by the mass in direct proportion to the rate of change of velocity.

Impulse and reaction blading

Two types of blading have been developed to a high degree of perfection: impulse blading and reaction blading. The principle of impulse blading is illustrated in the schematic diagram of Figure 10 for a first stage. A series of stationary nozzles allows the steam to expand to a lower pressure while its velocity and kinetic energy increase. The steam is then directed to the moving passages or buckets where the kinetic energy is extracted. Since there is ideally no pressure drop and no acceleration in the blade passage, the magnitude of the velocity vector in the blades should remain constant. This also implies that the cross-sectional area normal to the flow remains constant, giving rise to the typical shape of a symmetrical impulse blade—namely, thick at the middle and sharp at the ends.

Figure 10 also includes the velocity diagrams for such a stage. Velocities are vectors that are added by the parallelogram law (see ANALYSIS: *Vector and tensor analysis*). The relative velocity of the fluid with reference to the blade at inlet (or exit) added vectorially to the (tangential) velocity of the blade must give the absolute velocity as seen by the stationary passages. That the kinetic energy at the nozzle exit (proportional to the square of the nozzle-leaving velocity) is much larger than that at the blade exit is apparent from the figure. In an ideal impulse stage, this change of kinetic energy is fully converted into useful work. For minimum exit kinetic energy in a symmetrical impulse blade, the rotor velocity should be about one-half of the entering steam velocity.

In an idealized reaction stage, about one-half of the enthalpy drop per stage is effected in the stator passage and the other half in the rotor passage. This implies that the pressure drop is also almost equal in both the stationary and the rotary passages, which tend to look like mirror images of each other. If the flow velocity is subsonic (below the velocity of sound in the fluid), an expanding passage flow will increase its velocity as the pressure drops while the cross-sectional area decreases simultaneously, thus leading to the curved nozzle shape shown in Figure 11.

Since there is no pressure drop in an idealized impulse stage, pressure forces on the rotor play no role in this type of

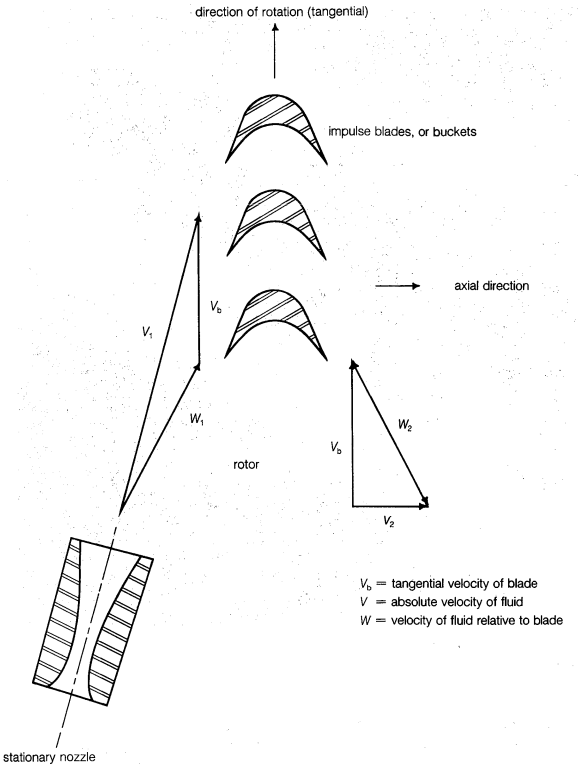

Figure 10: *Schematic of an impulse stage with velocity diagrams.*
The first stage, including a convergent-divergent inlet nozzle, is shown. Ideally there is no change in the magnitude of the relative velocities W between inlet and exit (which are designated by subscripts 1 and 2, respectively). The large inlet absolute velocity V_1 has been reduced to a small absolute exit velocity V_2, which ideally is in the axial direction.

arrangement. By contrast, in a reaction stage, the effect of the changing pressure exerts a net force in the tangential direction (thus turning the wheel) and also in the axial direction. The latter tends to push the rotor into the ends of the casing, requiring a thrust bearing to absorb the axial load. In large turbines the axial load can be reduced by admitting the steam flow in the middle and expanding in both axial directions, as shown in Figures 8 and 9.

There is no need to match the increase of fluid velocity in the stator to that in the rotor (50 percent reaction). Other

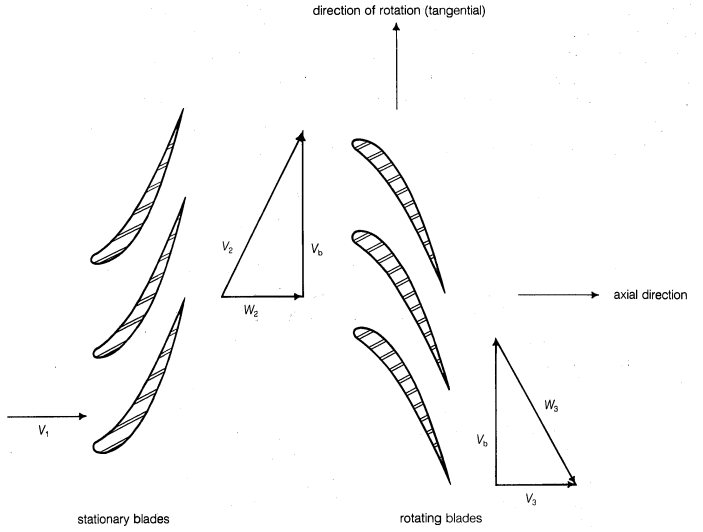

Figure 11: *An idealized 50-percent reaction stage for a steam turbine with velocity diagrams.*
Here, V is absolute velocity of fluid, V_b is blade velocity, and W is velocity of fluid relative to blade. Subscript 1 signifies entering stationary blade (stator), subscript 2 indicates leaving stator or entering rotor, and subscript 3 signifies leaving rotor.

widely used combinations that fall between pure impulse and 50 percent reaction staging have been developed.

The large length of low-pressure blades imposes special requirements on stiffness in addition to aerodynamic shaping. The tangential velocity of the blade near the hub is much smaller than at the blade tip, while the axial through-flow velocity is maintained nearly constant. To match the flow, the blades must be twisted to have the correct approach angle for the incoming steam (see Figure 12) and at the same time avoid possible resonant vibrations.

Turbine staging. Only a small fraction of the overall pressure drop available in a turbine can be extracted in a single stage consisting of a set of stationary nozzles or vanes and moving blades or buckets. In contrast to water turbines where the total head is extracted in a single runner (see above), the steam velocities obtained from the enthalpy drop between steam generator and condenser would be prohibitively high. In addition, the volume increase of the expanding steam requires a large increase in the annular flow area to keep the axial through-flow velocity nearly constant. To this must be added limitations on blade length and blade-tip velocities to avoid excessive centrifugal stresses. In practice, the steam expansion is therefore broken up into many small segments or stages, each with a range of velocities and an appropriate blade size to permit efficient conversion of the thermal energy in the steam to mechanical energy. In modern turbines, three types of staging are employed, either separately or in combination: (1) pressure (or impulse) staging, (2) reaction staging, and (3) velocity-compound staging.

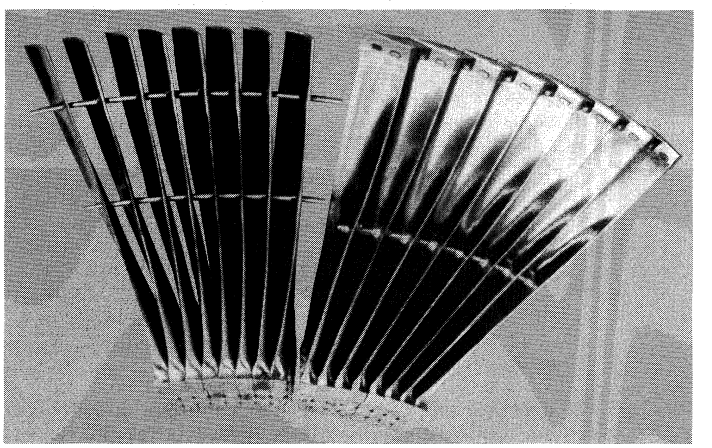

Figure 12: Large low-pressure steam turbine blades.

Pressure staging

Pressure staging uses a number of sequential impulse stages similar to those illustrated in Figure 10, except that the stationary passages also become highly curved nozzles. Pressure-staged turbines can range in power capacity from a few to more than 1.3 million kilowatts. Some manufacturers prefer to build units with impulse stages simply to reduce thrust-bearing loads. An example of a large turbine using impulse staging is shown in Figure 13. Such units may have as many as 20 sequential stages.

Reaction staging

Reaction staging is similar to pressure staging, except that a greater number of reaction stages are required. The first turbine stage, however, is often an impulse stage for controlling the steam flow and for rapidly reducing the pressure in stationary nozzles from its high steam generator value, thereby lowering the pressure that the casing has to withstand. Reaction turbines require about twice as many stages as impulse-staged turbines for the same change in steam enthalpy. The cost and size of the turbines, however, are about the same because blading for pressure staging must withstand greater forces and must therefore be more rigidly constructed. Reaction turbines also have large axial thrust and require heavy-duty thrust bearings.

Velocity-compound staging

In velocity-compound staging a set of stationary nozzles is followed by two sets of moving blades with a stationary row of impulse blades between them to redirect the flow. Ideally this allows twice as much power to be extracted than from a single impulse stage for a given blade-tip

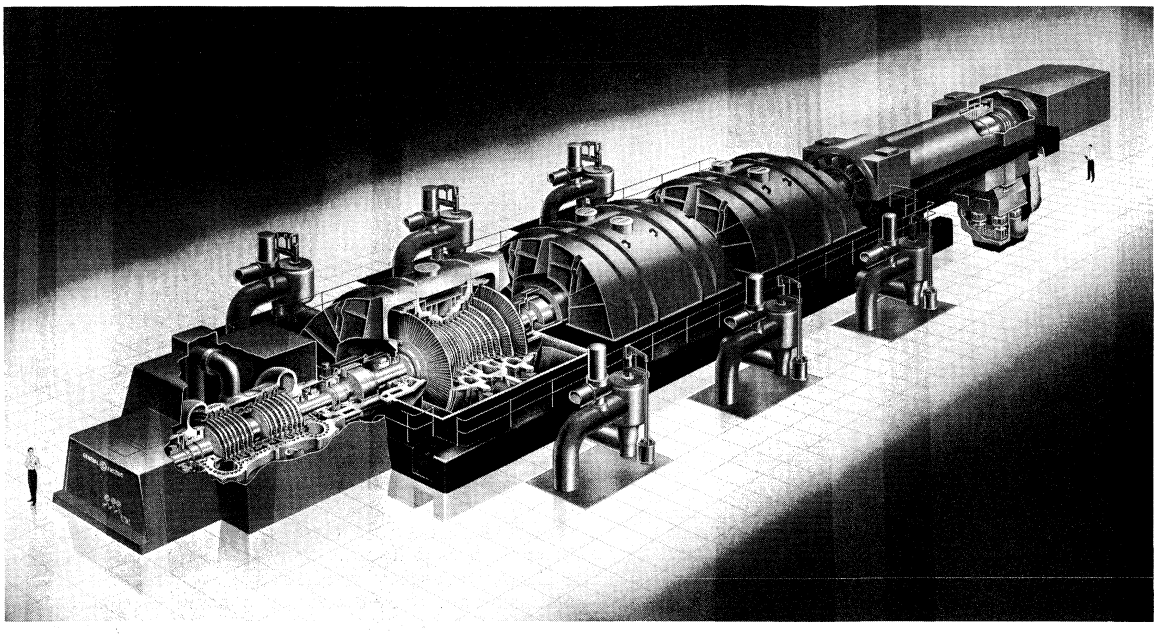

Figure 13: Rendering of an installed 1,800-revolution-per-minute tandem-compound, six-flow, nuclear steam turbine-generator unit rated at more than one million kilowatts.

velocity. It also permits a large pressure drop through the stationary nozzles. Velocity-compounding is well suited for small turbines; it is also sometimes used as the first stage in large turbines for control purposes. The inherent high steam velocities, however, tend to result in high losses and poor stage efficiencies.

Power development. The theoretical maximum power produced by a turbine can be computed from the mass flow rate of the steam multiplied by the ideal enthalpy drop per unit mass between the steam generator exit and the condenser conditions. The actual power produced, however, is less because of friction, turbulence, leakage around the blade tips, and other losses. For the same maximum blade-tip velocity, pressure staging produces about twice as much ideal power per stage as reaction staging, while velocity-compound staging produces about four times as much.

The stage efficiency—*i.e.,* the amount of work that is actually produced in each stage as compared to the maximum possible amount—can be higher for reaction stages than for impulse stages due to generally lower flow velocities and associated losses. The greater number of stages required, however, results in an overall turbine efficiency that is about the same for both. Efficient stages also require carefully designed seals along the rotor shaft and opposite the rotating blade tips to avoid leakage past the blades.

Control. A turbine driving an electric generator must run at constant speed. In the United States where 60-cycle-per-second alternating current is used, this usually means 3,600 or 1,800 revolutions per minute. (In countries that use 50-cycle current, 3,000 or 1,500 revolutions per minute are the norm.) When the electric power demand on the generator, or the load, changes, the turbine must respond immediately to keep the speed constant. The inlet enthalpy is determined by the exit conditions of the steam generator and the exit enthalpy by the condenser pressure. Neither of these can be varied rapidly. With a fixed enthalpy drop per unit mass, the power output thus can only be controlled by varying the mass flow rate. This is achieved by opening or closing valves leading to the turbine inlet stage. Under partial load, the reduced steam flow results in lower axial velocities along the turbine and thereby alters the velocity diagrams somewhat. Since efficient operation requires a careful match between all velocity directions and blade inlet shapes, part-load operation decreases the efficiency of the turbine.

Overall performance characteristics. The performance of a steam turbine is conventionally measured in terms of its heat rate—*i.e.,* the amount of heat that has to be supplied to the feedwater in order to produce a specified generator power output. In the United States the heat rate is given by the heat input in Btus per hour for each kilowatt-hour of electricity produced by the turbogenerator assembly. The heat rate depends on the steam generator exit temperature and pressure, the condenser pressure, the efficiency of the turbine in converting the thermal energy of the steam into work, the mechanical and bearing losses, the exhaust loss due to the kinetic energy of the steam leaving the final turbine stage, and the generator losses. The lower the heat rate, the less the thermal energy required and the better the efficiency. At constant condenser pressure, the heat rate can be decreased by about 11 percent when going from steam generator exit conditions of 10,000 kilopascals gauge and 538° C to 24,100 kilopascals gauge and 538° C, with a subsequent reheat temperature of 538° C. The higher pressure, however, necessitates costlier equipment to contain the steam and to maintain the same reliability. Part-load operation, with its attendant loss of efficiency, always leads to higher heat rates.

Heat rate

History of steam turbine technology. *Early precursors.* The first device that can be classified as a reaction steam turbine is the aeolipile proposed by Hero of Alexandria, during the 1st century AD. In this device, steam was supplied through a hollow rotating shaft to a hollow rotating sphere. It then emerged through two opposing curved tubes, just as water issues from a rotating lawn sprinkler. The device was little more than a toy, since no useful work was produced.

Another steam-driven machine, described in 1629 in Italy, was designed in such a way that a jet of steam impinged on blades extending from a wheel and caused it to rotate by the impulse principle. Starting with a 1784 patent by James Watt, the developer of the steam engine, a number of reaction and impulse turbines were proposed, all adaptations of similar devices that operated with water. None were successful except for the units built by William Avery of the United States after 1837. In one such Avery turbine two hollow arms, about 75 centimetres long, were attached at right angles to a hollow shaft through which steam was supplied. Nozzles at the outer end of the arms allowed the steam to escape in a tangential direction, thus producing the reaction to turn the wheel. About 50 of these turbines were built for sawmills, cotton gins, and woodworking shops, and at least one was tried on a locomotive. While the efficiencies matched those of contemporary steam engines, high noise levels, difficult speed regulation, and frequent need for repairs led to their abandonment.

Avery turbine

Development of modern steam turbines. No further developments occurred until the end of the 19th century when various inventors laid the groundwork for the modern steam turbine. In 1884 Sir Charles Algernon Parsons, a British engineer, recognized the advantage of employing a large number of stages in series, allowing extraction of the thermal energy in the steam in small steps. Parsons also developed the reaction-stage principle according to which a nearly equal pressure drop and energy release takes place in both the stationary and moving blade passages. In addition, he subsequently built the first practical large marine steam turbines. During the 1880s Carl G.P. de Laval of Sweden constructed small reaction turbines that turned at about 40,000 revolutions per minute to drive cream separators. Their high speed, however, made them unsuitable for other commercial applications. De Laval then turned his attention to single-stage impulse turbines that used convergent-divergent nozzles, such as the one in Figure 14. From 1889 to 1897 de Laval built many turbines with capacities from about 15 to several hundred horsepower. His 15-horsepower turbines were the first employed for marine propulsion (1892). C.E.A. Rateau of France first developed multistage impulse turbines during the 1890s. At about the same time, Charles G. Curtis of the United States developed the velocity-compounded impulse stage.

By 1900 the largest steam turbine-generator unit produced 1,200 kilowatts, and 10 years later the capacity of such machines had increased to more than 30,000 kilowatts. This far exceeded the output of even the largest steam engines, making steam turbines the principal prime movers in central power stations after the first decade of the 20th century. Following the successful installation of a series of 68,000-horsepower turbines in the transatlantic passenger liners *Lusitania* and *Mauretania,* launched in 1906, steam turbines also gained preeminence in large-scale marine applications, first with vessels burning fossil fuels and then with those using nuclear power. Steam generator pressures increased from about 1,000 kilopascals gauge in 1895 to 1,380 kilopascals gauge by 1919 and then to 9,300 kilopascals gauge by 1940. Steam temperatures climbed from about 180° C (saturated steam) to 315° C (superheated steam) and eventually to 510° C over the same time period, while heat rates decreased from about 38,000 to below 10,000 Btus per kilowatt-hour.

The steam turbine as the principal prime mover in large power stations

Recent developments and trends. By 1940, single turbine units with a power capacity of 100,000 kilowatts were common. Ever-larger turbines (with higher efficiencies) have been constructed during the last half of the century, largely because of the steadily rising cost of fossil fuels. This required a substantial increase in steam generator pressures and temperatures. Some units operating with supercritical steam at pressures as high as 34,500 kilopascals gauge and at temperatures of up to 650° C were built before 1970. Reheat turbines that operate at lower pressures (between 17,100 to 24,100 kilopascals gauge) and temperatures (540–565° C) are now commonly installed to assure high reliability. Steam turbines in nuclear power plants, which are still being constructed in a number of countries outside of the United States, typically operate at about 7,580 kilopascals gauge and at temperatures of up to 295° C to accommodate the limitations of reactors. Turbines that exceed one-million-kilowatt output require exceptionally large, highly alloyed steel blades at the low pressure end.

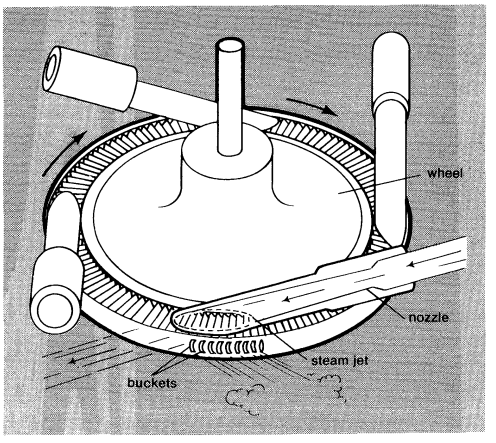

Figure 14: De Laval turbine, showing how the steam is formed into a jet by a specially shaped nozzle and is then deflected by the buckets or vanes on the wheel, causing the wheel to rotate.

Slightly more efficient units with a power capacity of more than 1.3 million kilowatts may eventually be built, but no major improvements are expected within the next few decades, primarily because of the temperature limitations of the materials employed in steam generators, piping, and high-pressure turbine components and because of the need for very high reliability.

Although the use of large steam turbines is tied to electric power production and marine propulsion, smaller units may be used for cogeneration when steam is required for other purposes, such as for chemical processing, powering other machines (*e.g.,* compressors of large central air-conditioning systems serving many buildings), or driving large pumps and fans in power stations or refineries. However, the need for a complete steam plant, including steam generators, pumps, and accessories, does not make the steam turbine an attractive power device for small installations. (R.A.B./Fr.L.)

WIND TURBINES

Modern wind turbines extract energy from the wind, mostly for electricity generation, by rotation of a propeller-like set of blades that drive a generator through appropriate shafts and gears. The older term windmill is often still used to describe this type of device, although electric power generation rather than milling has become the primary application. As was noted earlier, windmills, together with waterwheels, were widely used from the Middle Ages to the 19th century during the course of which they were supplanted by steam engines and steam turbines. Though they continued to be used for pumping water in rural areas, wind turbines practically disappeared in the 20th century as the internal-combustion engine and electricity provided more reliable and usually less expensive power. Interest in wind turbines for electricity generation was rekindled by the oil crisis of the mid-1970s. High initial costs, intermittent operation, and maintenance costs, however, have prevented wind turbines from becoming a significant factor in commercial power production.

Modern version of the windmill

Types of wind turbines. *Horizontal axis machines.* The best-known machines of this type are the so-called American farm windmills that came into wide use during the 1890s. Such devices consist of a rotor, which may have up to 20 essentially flat sheet-metal blades and a tail vane that keeps the rotor facing into the wind by swiveling the entire rotor assembly. Governing is automatic and overspeeding is avoided by turning the wheel off the wind direction, thus reducing the effective sail area while keeping the speed constant. A typical pump can deliver about 38 litres (10 gallons) per minute to a height of 30 metres at a wind velocity of 6.7 metres per second (15 miles per hour).

Modern wind turbines have from one to four metal blades that operate at much higher rotor-tip speeds than windmills. Each blade is twisted like an airplane propeller. An automatic governor rotates the blades about their support axis to maintain constant generator speed. The Jacobs three-bladed windmill, used widely between 1930 and 1960, could deliver about one kilowatt of power at a wind speed of 6.25 metres per second, a typical average wind velocity in the United States about 18 metres above ground.

High rotor-tip speeds

More recently, large horizontal-shaft, two-bladed turbines have been developed in the United States. The first such device, a unit equipped with a rotor measuring 11.6 metres in diameter, was installed near Sandusky, Ohio, in 1976; its power output was rated at 100 kilowatts. The most recent type of machine, first installed on the island of Oahu in Hawaii, has a rotor diameter of 122 metres with its axis about 76 metres above ground. Its output rating is 6,200 kilowatts at a wind speed of 13 metres per second.

Vertical-axis machines. Devices of this kind, which had

Savonius rotor

not been used since the early Middle Ages, found a new application after the Finnish engineer S.J. Savonius invented a new type of rotor in 1922. Known as the Savonius rotor, it consists of semicircular blades that can be constructed from little more than the two sections of an oil drum, cut in half along its vertical axis, and welded together with an offset from the axis to form an open S (see Figure 15). An advanced version of this machine installed at Manhattan, Kan., during the 1970s generated five kilowatts of electric power in a 12-metre-per-second wind.

By courtesy of Gary Johnson, Ph.D.

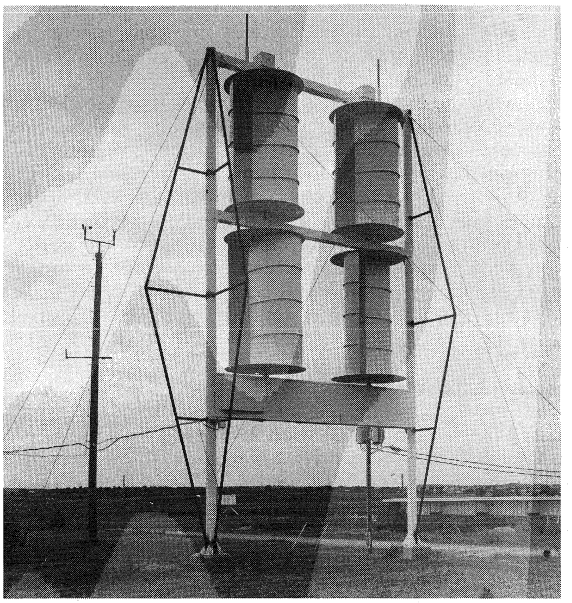

Figure 15: A Savonius rotor.

The most recent vertical wind turbine is based on a machine patented in 1931 by the French engineer G.J.M. Darrieus. Its two blades consist of twisted metal strips tied to the shaft at the top and bottom and bowed out in the middle similar to the blades on a food mixer. A Darrieus turbine with aluminum blades erected in 1980 by the Sandia National Laboratories in New Mexico produced 60 kilowatts in a wind blowing slightly more than 120 metres per second. Turbines of this variety are not self-starting and require an external motor for start-up. Several models of Darrieus turbines have been built since the construction of the Sandia unit (see Figure 16).

Wind farms. A wind farm is a cluster of wind turbines (up to several hundred) erected in areas where there is a nearly steady prevalent wind; such areas generally occur near mountain passes. Wind farms comprised of propeller-type units have been set up in Hawaii, California, and New Hampshire (see Figure 17). Capacities range from 10 to 500 kilowatts per unit. During 1984 the total output of all U.S. wind farms exceeded 150 million kilowatt-hours; the entire output was fed into the electric utility network. Though seemingly substantial, this amounted to less than $^{1}/_{100,000}$ of the total electric power generated in the United States.

Limitations on wind power. Not all the kinetic energy of the wind can be extracted because there must be a finite velocity as the air leaves the blading. It can be shown that the maximum efficiency (energy extracted divided by energy available in the captured wind area) obtainable is about 59 percent, although actual wind turbines extract only a portion of this amount. Currently, the maximum efficiency obtainable with a propeller-type windmill is roughly 47 percent; this occurs when the propeller-tip speed is between five and six times the wind velocity. For a given rotor speed, it drops rapidly as the wind velocity decreases. The power obtainable varies as the square of the rotor diameter and the cube of the wind velocity. Thus the theoretical maximum energy obtainable from a rotor with a diameter of 30 metres in a wind with a speed of 14 metres per second would be about 690 kilowatts. If the wind speed decreases to 7 metres per second, the theoretical maximum drops to about 86 kilowatts. At this lower wind speed, it would require more than 17,000 wind turbines (with rotors of 30 metres across) operating at an efficiency of 40 percent to match the output of a single large one-million-kilowatt central power station. When these limitations are coupled to the need for suitable sites with steady winds, it becomes apparent that wind turbines alone will not play a major role in meeting the power demands of an industrialized nation.

Amount of kinetic energy extracted from the wind

Development of wind turbines. The origin and development of the traditional windmill and other predecessors of modern wind turbines were described above in *History of energy-conversion technology.* The emergence and evolution of wind-driven devices for electric power generation are briefly surveyed here.

The development of the electric generator aroused some interest in the wind as a "free" power source. The first windmill to drive a generator was built in 1890 by P. LaCour in Denmark, using patent sails and twin fantails on a steel tower.

Adopting the ideas gained from airfoil and aircraft propeller designs, windmill designers and manufacturers began to replace broad windmill sails with a few slender propeller-like blades. In 1931 the first propeller wind turbine was erected in the Crimea. From the 1940s, experimental twin-blade turbines were constructed in the United States and later in Scotland and France. In The Netherlands a few old-fashioned mills were adapted to generate electricity. Today, wind turbines for electric power generation are most commonly propeller-type machines. (Fr.L.)

Internal-combustion engines

An internal-combustion (IC) engine is any of a group of devices in which the reactants of combustion (oxidizer and fuel) and the products of combustion serve as the working fluids of the engine. Such an engine gains its energy from heat released during the combustion of the nonreacted working fluids, the oxidizer–fuel mixture. This process occurs within the engine and is part of the thermodynamic cycle of the device. Useful work generated by an IC engine results from the hot, gaseous products of combustion acting on moving surfaces of the engine, such as the face of a piston, a turbine blade, or a nozzle.

Major classes of IC engines

Internal-combustion engines are divided into two groups: continuous-combustion engines and intermittent-combustion engines. The continuous-combustion engine is characterized by a steady flow of fuel and oxidizer into the engine. A stable flame is maintained within the engine (*e.g.,* jet engine). The intermittent-combustion engine is characterized by periodic ignition of air and fuel and is commonly referred to as a reciprocating engine. Discrete volumes of air and fuel are processed in a cyclic manner. Gasoline piston engines and diesel engines are examples of this second group.

Internal-combustion engines can be delineated in terms of a series of thermodynamic events. In the continuous-combustion engine, the thermodynamic events occur simultaneously as the oxidizer and fuel, and the products of combustion flow steadily through the engine. In the intermittent-combustion engine, by contrast, the events occur in succession and are repeated for each full cycle.

With the exception of rockets (both solid-rocket motors and liquid-propellant rocket engines), internal-combustion engines ingest air, then either compress the air and introduce fuel into the air or introduce fuel and compress the air–fuel mixture, burn the air–fuel mixture, extract work from the hot, gaseous products of combustion by expansion, and ultimately exhaust the products of combustion. Their operation can be contrasted with that of external-combustion engines (*e.g.,* steam engines), in which the working fluid does not chemically react and energy gain is achieved solely through heat transfer to the working fluid by way of a heat exchanger.

Examples of IC engines

Internal-combustion engines are the most broadly applied and widely used power-generating devices currently in existence. Examples include gasoline (or spark-ignition [SI]) engines, diesel engines (sometimes referred to as compression-ignition [CI] engines), gas-turbine engines, and rocket propulsion systems.

The most common internal-combustion engine is the four-stroke gasoline-powered, homogeneous-charge, spark-ignition engine. This is because of its outstanding performance as a prime mover in the ground-transportation industry. Spark-ignition engines also are used in the aeronautics industry; however, aircraft gas turbines have become the prime movers in this sector due to the emphasis of the aeronautics industry on range, speed, and passenger comfort. The domain of internal-combustion engines also includes such exotic devices as supersonic combustion ramjet engines (scramjets), as typified by the space plane, and sophisticated rocket engines and motors, as those used on the U.S. Space Shuttle and other space vehicles.

It is the versatility and cost—both capital and operational—of conventional internal-combustion engines that have led to their widespread use in contemporary energy production. (C.L.P.II)

GASOLINE ENGINES

General characteristics. The gasoline engine is an intermittent-combustion engine. It is powered by the combustion of a premixed charge of air and gasoline, which is ignited electrically by a spark.

Most gasoline engines are of the so-called reciprocating piston type, but recent developments suggest that superior performance in some respects may be obtained from either rotary piston or turbine types (see below). Several terms are unique to the reciprocating piston engine. The piston–cylinder arrangement defines all terms relative to the size, location, and position of the piston within the cylinder (see Figure 18). Bore is the inner diameter of the cylinder. The volume at bottom dead centre (VBDC) is defined as the volume occupied between the cylinder head and the piston face when the piston is farthest from the cylinder head. The volume at top dead centre (VTDC) is that volume occupied when the piston is closest to the cylinder head; the distance between the piston face and cylinder head at VTDC is called the clearance. The distance traveled by the piston between its VTDC and VBDC locations is the stroke. The compression ratio of a reciprocating engine is

Basic terms

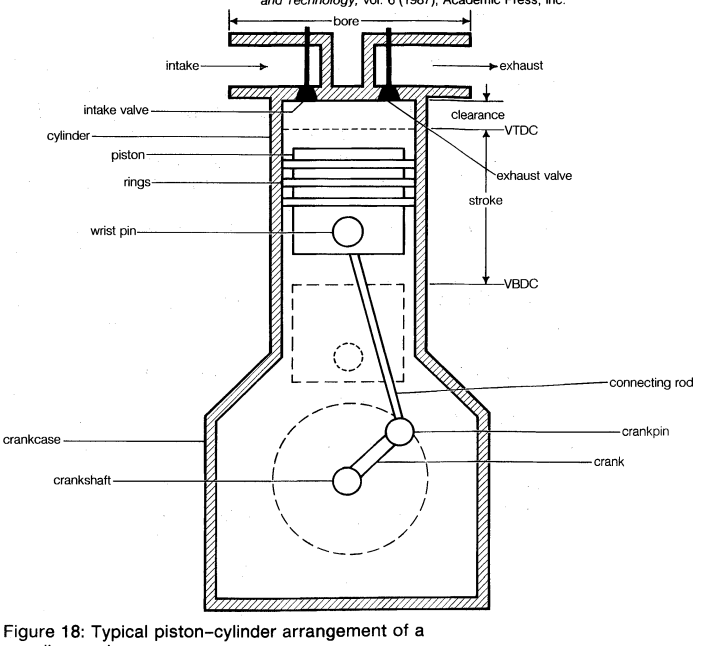

Figure 18: Typical piston–cylinder arrangement of a gasoline engine.

the ratio of VTDC to VBDC normalized to the VTDC value—*i.e.*, (VBDC/VTDC):1.

In all internal-combustion engines the products of combustion act directly on piston or rotor surfaces, whereas the external-combustion engine employs a secondary working fluid that is interposed between the combustion chamber and the power-producing elements. Fundamentally, the steam engine operates with a high-pressure working medium produced by utilizing the expansion accompanying the vaporization of a liquid (see above); by contrast, the internal-combustion engine utilizes the large volume of high-temperature combustion products that, when confined, become a high-pressure gaseous medium.

Combustion processes

Classification. The many types of internal-combustion engines can be grouped in a number of different ways on the basis of similarities among them. Important methods of classification include application, type of fuel and method of injection, ignition, reciprocating piston or rotary, cylinder arrangement, strokes per cycle, cooling system, and valve type and location. These various classifications will be discussed further as the various engine types are described.

Valve type and arrangement. Valves for controlling intake and exhaust may be located overhead, on one side, side and overhead, or on opposite sides of the cylinder. These are all the so-called poppet or mushroom valves consisting of a stem with one end enlarged to form a head that permits flow through a passage surrounding the stem when raised from its seat and prevents flow when the head is moved down to contact the valve seat formed in the cylinder block.

Another group of engines uses sliding valves that are usually of the sleeve type surrounding the cylinder bore.

Pressure application. Some power plants use the same combustion principle but apply the pressure resulting from combustion to different mechanical elements. There are, for example, gas-turbine engines in which the products of combustion are directed through nozzles against the blades of a turbine rotor to cause it to rotate. In the jet engine the products of combustion simply flow through a nozzle, and the reaction force tends to move the nozzle in the opposite direction.

Rotary engines

The Wankel and Tri-Dyne engines (see below) burn the fuel within the engine; they are rotary and do not have conventional cylinders fitted with reciprocating pistons. Instead, the gas pressure acts on surfaces formed by the configuration of a rotor. Both gas-turbine and jet engines have combustion furnaces separate from the power-producing units. The power is produced by the action of the products of combustion on the blades of the turbine or the interior wall of the jet nozzle (see *Gas-turbine engines* and *Jet engines* below).

Comparison with other engines. When the gasoline engine is compared with other types, certain similarities and differences as well as some advantages and disadvantages become apparent. The diesel engine and the gas engine (an engine utilizing a gas such as propane as the fuel) have a good deal in common with the gasoline engine, since they are all cylinder-and-piston engines that burn air–fuel mixtures in contact with moving components. The important difference that distinguishes the diesel engine is that it has no spark-ignition system. The diesel is heavier and more expensive per horsepower of output, but it has a longer life and operates at less cost per horsepower-hour because it burns less fuel. (For more specific details, see *Diesel engines* below.)

The gas engine

The gas engine has much in common with the gasoline engine; in fact, in some instances their differences are very slight at best. Structurally, the difference lies primarily in the substitution of a gas-mixing valve for a carburetor. The cylinder and piston configurations are the same. In general, gases have better antiknock qualities than gasoline (see below), permitting slightly higher compression ratios without knock or other combustion difficulties.

From the standpoint of application, the gas engine burning natural gas, manufactured gas, or industrial by-product gas is limited primarily to stationary power plant use because it must remain connected to the gas pipeline. If, however, the fuel is liquefied petroleum gas, sometimes called bottled gas, the containers of gas can be carried in a vehicle, leading to much flexibility in applications. The present obstacle is that facilities are not readily available for replenishing the gas supply. Dual carburetors have been produced experimentally that make it possible to operate an engine on either liquefied petroleum gas or gasoline; thus dual gas–gasoline engines are a distinct possibility.

Engine types. Of the different techniques for recovering the power from the combustion process the most important so far has been the four-stroke cycle, a conception now more than 100 years old.

Four-stroke cycle. The four-stroke cycle is illustrated in Figure 19. With the inlet valve open, the piston first descends on the intake stroke. An explosive mixture of gasoline vapour and air is drawn into the cylinder by the partial vacuum thus created. The mixture is compressed as the piston ascends on the compression stroke with both valves closed. As the end of the stroke is approached, the charge is ignited by an electric spark. The power stroke follows, with both valves still closed and the gas pressure, due to the expansion of the burned gas, pressing on the piston crown. During the exhaust stroke, the ascending piston forces the spent products of combustion through the open exhaust valve. The cycle then repeats itself. Each cycle thus requires four strokes of the piston—intake, compression, power, and exhaust—and two revolutions of the crankshaft.

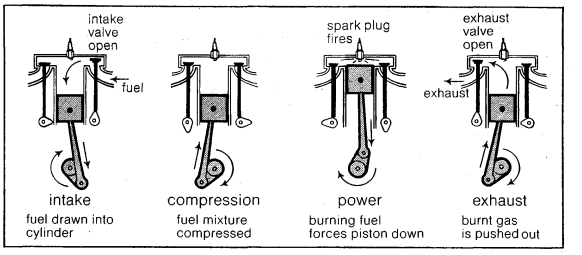

Figure 19: Strokes of the four-stroke cycle.

A disadvantage of the four-stroke cycle is that only half as many power strokes are completed as in the two-stroke cycle (see below) and only half as much power can be expected from an engine of a given size at a given operating speed. The four-stroke cycle, however, provides more positive clearing out of exhaust gases (scavenging) and reloading of the cylinders, reducing the amount of loss of fresh charge to the exhaust.

Two-stroke cycle. In the original two-stroke cycle (as developed in 1878), the compression and power stroke of the four-stroke cycle are carried out without the inlet and exhaust strokes, thus requiring only one revolution of the crankshaft to complete the cycle. Figure 20 illustrates the two-stroke-cycle engine of a so-called uniflow type in which the fresh fuel mixture is forced into the cylinder through circumferential ports by a rotary blower. The exhaust gases pass through poppet valves in the cylinder head that are opened and closed by a cam-follower mechanism. The valves are timed to begin opening toward the end of the power stroke after the cylinder pressure has dropped appreciably. The inlet ports in the cylinder wall start to uncover after the exhaust opening has decreased the cylinder pressure to the inlet pressure produced by the blower. The exhaust valves are allowed to remain open for a few

Uniflow two-stroke-cycle engine

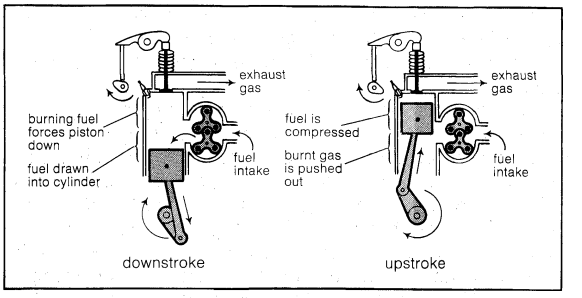

Figure 20: Blower-scavenged, two-stroke-cycle engine with uniflow scavenging.

degrees of crank rotation after the inlet ports have been covered by the rising piston on the compression stroke, thus allowing the persistency of flow more thoroughly to scavenge the cylinder. The compression and power strokes are similar to those of the four-stroke engine.

Crankcase compression

A simplified version of the two-stroke-cycle engine was developed some years later (introduced in 1891) by using crankcase compression to pump the fresh charge into the cylinder. Instead of intake ports extending entirely around the lower cylinder wall, this engine has intake ports only halfway around; a second set of ports starts a little higher in the cylinder wall in the other half of the cylinder bore. These larger ports lead to the exhaust system. The inlet ports connect to a transfer passage leading to the fully enclosed crankcase. A spring-loaded inlet valve admits air into the crankcase on the upward, or compression, stroke of the piston. Air trapped in the crankcase is compressed by the descent of the piston on its power stroke. The piston thus uncovers the exhaust ports near the end of the power stroke and slightly later it uncovers the inlet or transfer port on the opposite side of the cylinder to admit the compressed fresh mixture from the crankcase. The top face of the piston is designed to provide a deflector or baffle that directs the fresh load upward on the inlet side of the cylinder and then downward on the exhaust side, thus pushing the spent gases of the previous cycle out through the exhaust port on that side. This outflow continues after the inlet ports are covered by the rising piston on the compression stroke until the exhaust ports are covered and compression of the fresh load begins. This loading process, called loop scavenging, is the simplest known method of replacing the exhaust products with a fresh mixture and completing the cycle with only compression and power strokes.

Loop scavenging

Such a system is used in many small gasoline engines (*e.g.,* small outboard motors) and for gasoline-powered appliances. A disadvantage is that the return flow of the gases causes a slight loss of fresh charge through the exhaust ports. Because of this loss, carburetor engines operating on the two-stroke cycle lack the fuel economy of four-stroke engines. The loss can be avoided by equipping them with fuel-injection systems (see below) instead of carburetors and injecting the fuel directly into the cylinders after scavenging. Such an arrangement is attractive as a means of attaining high power output from a relatively small engine, and development of the turbocharger (see below *Supercharger*) for this application holds promise of further improvement.

Opposed-piston engine. The opposed-piston engine also provides uniflow scavenging. This engine (Figure 21A) has two pistons moving in opposite directions in the same cylinder. Two sets of ports extending entirely around the cylinder bore are so located that one set is covered and uncovered by one piston and the other set is controlled by the second piston. A second crankshaft, to which the upper pistons are attached, is located at the top of the engine and the two shafts are connected by gears.

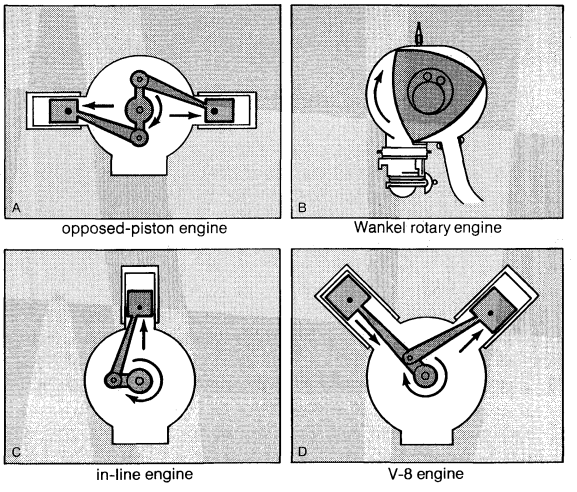

Figure 21: Certain types of gasoline engines.

The opposed-piston design has two major advantages: reciprocating masses move in opposite directions, providing excellent balance; and the poppet valves necessary in other uniflow-scavenged two-stroke-cycle engines are eliminated.

Wankel rotary engine. A rotary-piston internal-combustion engine developed in Germany is radically different in structure from conventional reciprocating piston engines. The engine was conceived by Felix Wankel, a specialist in the design of sealing devices, and experimental units were built and tested by a German firm beginning in 1956. Instead of pistons that move up and down in cylinders, the Wankel engine has an equilateral triangular orbiting rotor (see Figure 21B). The rotor turns in a closed chamber and the three apexes of the rotor maintain a continuous sliding contact with the curved inner surface of the casing. The curve-sided rotor forms three crescent-shaped chambers between its sides and the curved wall of the casing. The volumes of the chambers vary with the rotor motion. Maximum volume is attained in each chamber when the side of the rotor forming it is parallel with the minor diameter of the casing, and the volume is reduced to a minimum when the rotor side is parallel with the major diameter. Shallow pockets recessed in the flank of the rotor control the shape of the combustion chambers and establish the compression ratio of the engine.

Action of the rotor

In turning about its central axis the rotor must follow a circular orbit about the geometric centre of the casing. The necessary orbiting rotation is attained by means of a central bore in the rotor in which an internal gear is fitted to mesh with a stationary pinion fixed immovably to the centre of the casing. The rotor is guided by fitting its central bore to an eccentric formed on the output shaft that passes through the centre of the stationary pinion. This eccentric also harnesses the rotor to the shaft so that torque is applied when gas pressure is exerted against the rotor flanks as the fuel and air charges burn. A 3-to-1 gear ratio causes the output shaft to turn three times as fast as the rotor turns about the eccentric. Each quarter turn of the rotor completes an expansion or a compression, permitting intake, compression, expansion, and exhaust to be accomplished during one turn of the rotor. The only moving parts are the rotor and the output shaft.

The fuel mixture is supplied by a carburetor and enters the combustion chambers through an intake port in one of the end plates of the casing. An exhaust port is formed in one of the flattened sides of the casing wall and a spark plug is located in a pocket communicating with the chambers through a small throat in the opposite side of the casing wall.

The rotor and its gears and bearings are lubricated and cooled by oil circulating through the hollow rotor. The apex vanes are lubricated by a small amount of oil added to the fuel in proportions as low as 1 to 200. Water is circulated through cooling jackets in the casing, the entrance to which is located adjacent to the spark plug where the temperature tends to be highest.

Maintaining pressure-tight joints by suitable seals at the apexes and on the end faces of the rotor is a major design problem. Radial sliding vanes are fitted in slots at the three apex edges and kept in contact with the casing by expander springs. The end faces of the rotor are sealed by arc-shaped segmental rings fitted in grooves close to the curved edges of the rotor and pressed against the casing by flat springs.

Advantages of the Wankel engine

The major advantages of the Wankel engine are its small space requirements and low weight per horsepower, smooth and vibrationless operation, quiet operation, and low manufacturing costs resulting from mechanical simplicity. The absence of inertial forces from reciprocating parts and the elimination of spring-closed poppet valves permit operation at much higher speed than is practical for reciprocating piston engines, an advantage because shaft speed must be high for optimum performance. The induction of fresh fuel mixture and exhaust are more effective because the ports are opened and closed more rapidly than with poppet valves, and gas flow through them is almost continuous. Heat transfer and the resulting cooling requirement are low because the jacketed surface is small. Fuel economy is at least as good as that of conventional

gasoline engines, providing knock-free combustion with a wider range of permissible fuels. Lower weight and a lower centre of gravity make it much safer in an automobile in the event of a collision. There are approximately one third as many parts in a Wankel engine as in a typical six-cylinder automobile engine.

Tri-Dyne rotary engine. The Tri-Dyne engine, a British design, consists of three rotors (Figure 22). The large, triangular central rotor is called the power rotor. The other two are a combustion rotor and a barrier valve. The power rotor turns in the opposite direction from the combustion rotor and barrier valve. It has three curved lobes that fit into three semicircular cavities in the periphery of each of the two smaller rotors. The three are geared together by spur-shaped gears on the end of each rotor; all of them turn at the same speed. The motion is entirely rotary with no eccentricity. The three cavities in the combustion rotor form the combustion chambers and the profiles of all three rotors are such that, while not actually touching each other, they interact to connect these cavities alternately with the inlet and exhaust pipes and isolate them during the combustion process. It is not necessary that the cavities be positively sealed because of the high speed of operation. Clearance of 0.1 millimetre (0.004 inch) is provided between the interacting surfaces. Two spark plugs are installed in the casing at a point where they communicate with the combustion rotor cavities as they pass at the instant of firing. The advantage of the Tri-Dyne engine over the Wankel engine lies in the elimination of the seals that the latter requires at the apexes of its triangular rotor that limit the speed at which it can operate and that are difficult to lubricate.

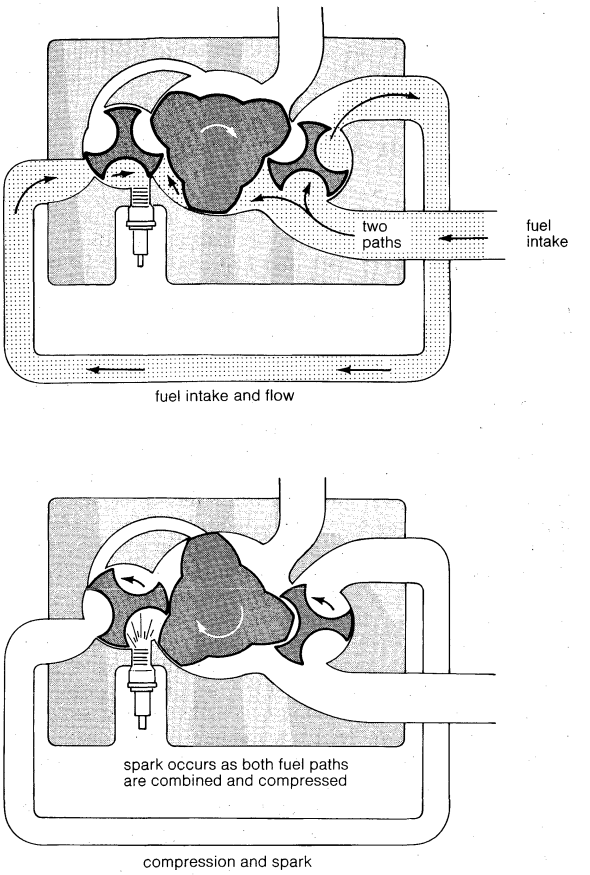

Figure 22: Simplified sketches showing operating principles of the Tri-Dyne engine.

Engine construction and operation. The overall structure of a gasoline engine depends almost entirely upon the intended application. Many components require only slight modification. Apart from the type of cycle (two- or four-stroke) the provision for mounting is the main structural difference among automotive, marine, stationary, and aviation engines. When a clutch and transmission are used, as in automobiles, the engine is commonly of the so-called unit-power-plant type with a bell-shaped housing surrounding the flywheel and attached to the rear flange of the cylinder block integral with, or attached to, the transmission gear case. The clutch is incorporated in the flywheel of the engine. Three-point suspension is used in such engines; that is to say, projections on each side of the bell housing fit into the vehicle side frame members and a central tubular extension at the centre of the front end of the cylinder block attaches to the front cross member of the frame. This construction permits some flexing of the vehicle frame without stressing the basic structure of the engine.

Unit-power-plant type

The following description of general engine construction indicates the essential components of an engine and introduces the nomenclature of the various parts. The four-stroke-cycle automobile engine is used as the basic type. Figure 23 shows a cross section of a typical automobile engine with the principal parts indicated.

Cylinder block. The main structural member of all automotive engines is a cylinder block that usually extends upward from the centre line of the main support for the crankshaft to the junction with the cylinder head. The block serves as the structural framework of the engine and carries the mounting pad by which the engine is supported in the chassis. Large, stationary power-plant engines and marine engines are built up from a foundation or bedplate and have upper and lower crankcases that are separate from the cylinder assemblies. The cylinder block of an automobile engine is a casting with appropriate machined surfaces and threaded holes for attaching the cylinder head, main bearings, oil pan, and other units.

Crankcase

The crankcase is formed by the portion of the cylinder block below the cylinder bores and the stamped metal oil pan that forms the lower enclosure of the engine and also serves as a lubricating oil reservoir or sump.

The cylinders are openings of circular cross section that extend through the upper portion of the block with interior walls bored and polished to form smooth, accurate bearing surfaces. The cylinders of heavy-duty engines are usually fitted with removable liners made of metal that is more wear-resistant than that used in the block casting.

There are two arrangements of cylinders in common automotive use—the vertical or in-line type (Figure 21C) and the V type (Figure 21D). The in-line engine has a single row of cylinders extending vertically upward from the crankcase and aligned with the crankshaft main bearings. The V type has two rows of cylinders, usually forming an angle of 60° or 90° between the two banks. V-8 engines (eight cylinders) are usually of the 90° type. Some small 6-cylinder aviation engines have horizontally opposed cylinders.

A passage bored lengthwise in the block houses the camshaft that operates the valves. A gear or chain compartment for the camshaft drive from the crankshaft is formed between the front or rear end of the block and a cover plate. The bell housing is formed at the rear of the cylinder block to enclose the flywheel and provide for

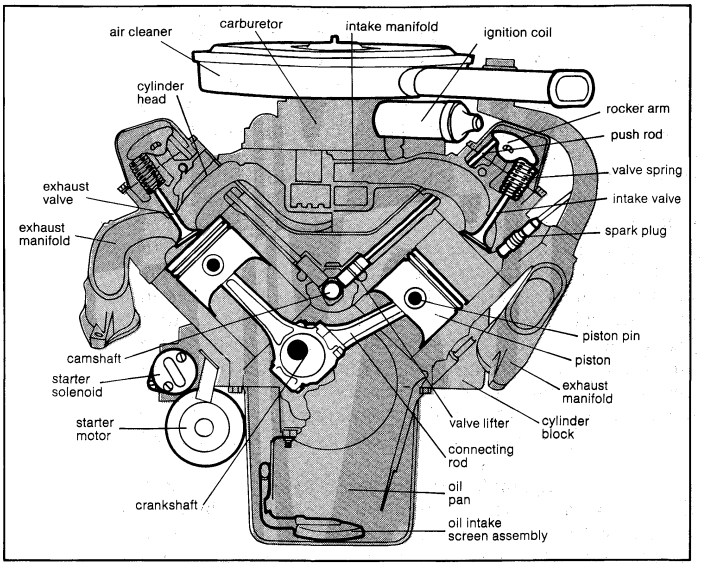

Figure 23: Cross section of a V-8 engine.

attachment of a transmission housing. Water jackets are formed around the cylinders with suitable cored connecting passages for circulation of the coolant.

Block design

The design of the cylinder block is affected by the location of the valves of the four-stroke-cycle engine and by the provision of cylinder ports in the two-stroke type. An overhead-valve engine, which has largely replaced the L-head type, has its valves entirely in the cylinder head. The cylinder block of the L-head engine is extended to one side of the cylinder bores, with the valve seats and passages for inlet and exhaust, together with the valve guides, formed in this extension of the block. The cylinder head then becomes merely a water-jacketed cover, providing threaded locations for the spark plugs and with its underside so profiled that a combustion chamber of desired size and shape is formed above each cylinder bore. The shape of the space forming the combustion chamber when the piston is at its closest approach to the cylinder head and volume contained therein in relation to the piston displacement volume are extremely important in their effect on performance. The cylinder head of the valve-in-head engine is narrower and deeper and carries the valve seats, valve guides, and valve ports.

Combustion chamber. The size of the combustion chamber relative to the volume displaced by the piston establishes the compression ratio of the engine. The piston displacement is the volume swept by the piston during one stroke and is equal to the cross-sectional area of the cylinder multiplied by the length of the stroke. The larger volume above the piston at the lowest point in its stroke, divided by the combustion-chamber volume when the piston is at its highest point, is the compression ratio of the engine. The larger volume is the sum of the piston-displacement volume and the combustion-chamber volume. The compression ratio may thus be expressed as the ratio of the sum of the piston displacement volume and the combustion-chamber volume to the combustion-chamber volume. Compression ratio is the most important factor affecting the theoretical efficiency of the engine cycle. Because increasing the compression ratio is the best way to improve efficiency, compression ratios on automobile engines have tended to increase. This requires stronger, more durable materials.

Importance of compression ratio

Pistons. The pistons are cup-shaped cylindrical castings of steel or aluminum alloy. The upper, closed end, called the crown, forms the lower surface of the combustion chamber and receives the force applied by the combustion gases. The outer surface is machined to fit the cylinder bore closely and is grooved to receive piston rings that seal the gap between the piston and the cylinder wall. In the upper piston grooves there are plain compression rings that prevent the combustion gases from blowing past the piston. The lower rings are vented to distribute and limit the amount of lubricant on the cylinder wall. Piston pin supports (bosses) are cast in opposite sides of the piston and hardened steel pins fitted into these bosses pass through the upper end of the connecting rod.

Connecting rod and crankshaft. A forged steel connecting rod connects the piston to a throw (offset portion) of the crankshaft and converts the reciprocating motion of the piston to the rotating motion of the crank. The lower, larger end of the rod is bored to take a precision bearing insert lined with Babbitt or other bearing metal and closely fitted to the crankpin. V-type engines usually have opposite cylinders staggered sufficiently to permit the two connecting rods that operate on each crank throw to be side by side. Some larger engines employ fork-and-blade rods with the rods in the same plane and cylinders exactly opposite each other.

V-type engines

Each connecting rod in an in-line engine or each pair of rods in a V-type engine is attached to a throw of the crankshaft. Each throw consists of a crankpin with a bearing surface, on which the connecting rod bearing insert is fitted, and two radial cheeks that connect it to the portions of the crankshaft that turn in the main bearings, supported by the cylinder block. Sufficient throws are provided to serve all the cylinders, and the angles between them equal the angular firing intervals between the cylinders. The throws of a six-cylinder, four-stroke-cycle crankshaft are spaced 120° apart so that the six cylinders fire at equal intervals in two full rotations of the shaft. Those of an eight-cylinder engine are 90° apart. The position of each throw along the shaft depends upon the firing order of the cylinders. Firing sequence is chosen to distribute the power impulses along the length of the engine to minimize vibration. Consideration is also given to the fluid flow pattern in the intake and exhaust manifolds. The standard firing order for a six-cylinder engine is 1-5-3-6-2-4, which illustrates the practice of alternating successive impulses between the front and rear valves of the engine whenever possible. Balance is further improved by adding counterweights to the crankshaft to offset the eccentric masses of metal in the crank throws.

The crankshaft design also establishes the length of the piston stroke because the radial offset of each throw is equal to half the stroke imparted to the piston. The ratio of the piston stroke to the cylinder bore diameter is an important design consideration. In the early years of engine development, no logical basis for the establishment of this ratio existed, and a range from unity to 1½ was used by different manufacturers. As engine speeds increased, however, and it became apparent that friction horsepower increased with piston speed rather than with crankshaft rotating speed, there began a trend toward short-stroke engines. Strokes were shortened to as much as 20 percent less than the bores.

Crank-throw layout

From the requirement for the two-cylinder engine a general rule for the layout of the throws of four-stroke-cycle multicylinder crankshafts can be expressed. Regardless of the number of cylinders, two pistons must arrive at top dead centre (see above) in unison so that a second cylinder is ready to fire exactly 360° after each cylinder fires. Half of the cylinders then will fire during each turn of the crankshaft. To follow this rule, there must be an even number of cylinders in order that there may be pairs of cylinders whose pistons move in unison.

An eight-cylinder engine fires each time its crankshaft makes a quarter turn if the intervals between impulses are equal. The crankshaft for an eight-cylinder, in-line engine is designed with each of its eight throws a quarter turn away from another throw.

For best lengthwise balance, the cylinders whose pistons are in phase are the first and last cylinders of an in-line engine, the second and next to the last, continuing in that order with crank throws that are in alignment equidistant from the centre of the engine.

Valves, pushrods, and rocker arms. The valve-in-head engine has pushrods that extend upward from the cam followers to rocker arms mounted on the cylinder head that contact the valve stems and transmit the motion produced by the cam profile to the valves. Clearance (usually

termed tappet clearance) must be maintained between the ends of the valve stems and the lifter mechanism to assure proper closing of the valves when the engine temperature changes. This is done by providing pushrod length adjustment or by the use of hydraulic lifters.

Noisy and erratic valve operation can be eliminated with entirely mechanical valve lifter linkage only if the tappet clearance between the rocker arms and the valve stems is closely maintained at the specified value for the engine as measured with a thickness gauge. Hydraulic valve lifters, now commonly used on automobile engines, eliminate the need for periodic adjustment of clearance.

Hydraulic valve lifters

The hydraulic lifter comprises a cam follower that is moved up and down by contact with the cam profile, and an inner bore into which the valve lifter is closely fitted and retained by a spring clip. The valve lifter, in turn, is a cup closed at the top by a freely moving cylindrical plug that has a socket at the top to fit the lower end of the pushrod. This plug is pushed upward by a light spring that is merely capable of taking up the clearance between the valve stem and the rocker arm. A small hole is drilled in the bottom of the valve-lifter cup to admit lubricating oil that enters the cam follower from the engine lubricating system through a passage in the cylinder block. A small steel ball serves as a check valve to admit the oil into the valve-fitter cup but prevent its escape. When the clearance in the entire linkage between the cam profile and the valve stem is being taken up by the spring in the valve lifter, oil flows into the lifter chamber past the ball check and is trapped there to maintain this no-clearance condition as the engine operates. Expansion or contraction of the valve linkage is compensated by oil seepage from the lifter to correct for expansion of parts and oil flow into the chamber if clearance tends to be produced between the pushrod and the lifter. Complete closure of the valve is then assured at all times without tappet noise.

The intake valve must be open while the piston is descending on the intake stroke of the piston, and the exhaust valve must be open while the piston is rising on the exhaust stroke. It would seem, therefore, that the opening and closing of the two valves would occur at the appropriate top and bottom dead-centre points of the crankshaft. The time required for the valves to open and close, however, and the effects of high speed on the starting and stopping of the flow of the gases requires that for optimum performance the opening events occur before the crankshaft dead-centre positions and that the closing events be delayed until after dead centre.

Valve timing

All four valve events, inlet opening, inlet closing, exhaust opening, and exhaust closing, are accordingly displaced appreciably from the top and bottom dead centres. Opening events are earlier and closing events are later to permit ramps to be incorporated in the cam profiles to allow gradual initial opening and final closing to avoid slamming of the valves. Ramps are provided to start the lift gradually and to slow the valve down before it contacts its seat. Early opening and late closure are also for the purpose of using the inertia or persistence of flow of the gases to assist in filling and emptying the cylinder.

Camshaft. The camshaft, which opens and closes the valves, is driven from the crankshaft by a chain drive or gears on the front end of the engine. Because one turn of the camshaft completes the valve operation for an entire cycle of the engine and the four-stroke-cycle engine makes two crankshaft revolutions to complete one cycle, the camshaft turns half as fast as the crankshaft. It is located above and to one side of the crankshaft, which places it directly under the valves of the L-head engine or the pushrods that extend down from the rocker arms of the valve-in-head engine. Because of the long pushrods and the rocker arms, the speed of the valve-in-head engine is limited to that at which the cam followers can remain in contact with the cams when the valves are closing. Above that limiting speed the valves are said to float and their motion tends to become erratic. For this reason, the overhead-camshaft engine is increasing in popularity. Located immediately above the valves, this type of camshaft is driven either by a vertical shaft and bevel gears or by a cog belt.

Overhead camshafts

Flywheel. The cycle of the internal-combustion engine is such that torque (turning force) is applied only intermittently as each cylinder fires. Between these power impulses the pistons rising on compression and the opposition to rotation caused by the load carried by the engine apply negative torque. The alternating acceleration caused by the power impulse and deceleration caused by compression results in nonuniform rotation. To counter this tendency to slow down and speed up is the function of the flywheel, attached to one end of the crankshaft. The flywheel consists of a heavy circular cast-iron disk with a hub for attachment to the engine. Its heavy rotating mass has sufficient momentum to oppose all changes in its rotational speed and to force the crankshaft to turn steadily at this speed. The engine thus runs smoothly with no evidence of rotational pulsations. The outer rim of the flywheel usually carries gear teeth so as to mesh with the starter motor. The driving component of a clutch or fluid coupling for the transmission may be incorporated in the flywheel.

Bearings. The crankshaft has bearing surfaces on each crank throw and three or more main bearings. These are heavily loaded because of the reciprocating forces at each cylinder applied to the crankshaft and the weight of the crankshaft and flywheel. All but the smallest engines use split shell bearings, usually made of bronze with Babbitt-metal linings. The surface material is sufficiently soft to minimize the possibility of scoring the crankshaft in the event of inadequate lubrication. The smallest engines usually have cast Babbitt bearings. A small amount of bearing clearance is necessary to permit an oil film to separate the surfaces.

Ignition. Electric ignition systems may be classified as magneto and battery-and-coil systems. Although these are similar in basic principle, the magneto is self-contained and requires only the spark plugs and connecting wires to complete the system, whereas the battery-and-coil system involves several separate components. The circuit consists of a battery, one terminal of which is grounded while the other leads through a switch to the primary winding of the coil, and then to a circuit breaker where it is again grounded. Rotation of the circuit-breaker cam opens and closes the primary circuit. The secondary circuit, consisting of several thousand turns of fine wire, leads to the rotor of the distributor, which acts as a rotary switch, selecting the spark plug to be placed in the circuit. Each plug is connected to one of the outer terminals of the distributor to receive an electrical impulse in proper sequence. When the primary circuit is broken, a high potential (up to 20,000 volts) is developed in the secondary winding and conducted to the appropriate spark plug.

Spark plug

The spark plug is an important component of the ignition system and is the one that must operate under the most severe conditions. Because it is exposed to combustion-chamber temperatures and pressures and contaminating products of combustion, it requires more service attention and is usually the shortest-lived component of the gasoline engine. It consists of a steel shell threaded to fit a standard 14-millimetre hole in the cylinder head. A copper gasket insures a gastight fit between cylinder head and plug. A fused ceramic insulating element is molded into the plug body and the steel centre electrode passes through the insulator up to the connector to which the high-voltage lead from the distributor is attached. The other electrode is welded to the metal body of the plug, which is grounded to the cylinder head.

It is essential that the spark gap be as specified for the particular engine. Gauges are available to aid in making this adjustment by bending the ground electrode as required. Manufacturers specify gaps ranging from 0.508 to 1.016 millimetres between the centre electrode and the ground electrode. If the plug gap is too large, the possibility of misfiring increases. If the gap is too small, the spark will not be sufficiently intense. Gap growth from erosion of the electrodes may be corrected. The high voltage for the spark plug may also be produced by a capacitor discharge ignition system. Such a system consists of a source of 250 to 300 volts direct-current power applied to a storage capacitor, a device for storing an electric charge.

Capacitor ignition system

A lead from the capacitor goes to one side of the spark coil primary through cam-actuated breaker points or an electronic switching device. At the instant this switching device establishes a contact, the capacitor discharges through the primary of the spark coil and an instantaneous high voltage is delivered to the distributor and thence to the spark plug.

The capacitor discharge system stem provides a more intense spark, thus improving starting a cold or flooded engine. It continues to fire the plugs when they are fouled by carbon or other deposits or when the spark gap has widened because of erosion of the points. Other notable advantages include increased spark plug life, improved firing over a wider speed range, and better moisture tolerance.

A magneto is a fixed-magnet, alternating-current generator designed to generate sufficient voltage to fire the spark plugs. A high-tension magneto is entirely self-contained and requires only spark plugs, wires, and switches to do what is required in meeting ignition requirements.

Carburetor. The gasoline carburetor is a device that introduces fuel into the air stream as it flows into the engine. A simple carburetor is shown diagrammatically in Figure 24. Gasoline is maintained in the float chamber by the float-actuated valve at a level slightly below the outlet of the jet. Air flows downward through the throat, past the throttle valve, and into the intake manifold. A throat is formed by the reduced diameter, and acceleration of the air through this smaller passage causes a decrease in pressure proportional to the amount of air flowing. This decrease in throat pressure results in fuel flow from the jet into the air stream. Any increase in air flow caused by change in engine speed or throttle position increases the pressure differential acting on the fuel and causes more fuel to flow.

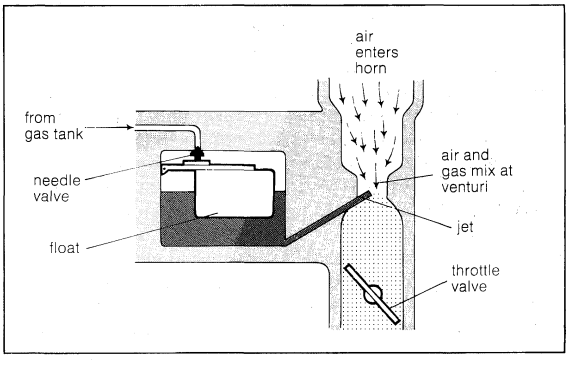

Figure 24: A simple carburetor.

The volume ratio of air to fuel established by the throat and fuel jet sizes will be maintained with increased flow, but the weight of fuel per kilogram (or pound) of air increases because the air expands to a lower density as the throat pressure decreases. This enriching tendency necessitates the inclusion of a compensating device in a practical carburetor. Carburetor design is further complicated by the need for an enriching device to provide a maximum-power ratio at full throttle, a choke to facilitate starting a cold engine, an idling system to provide the special needs of light-load operation, and an accelerating device to supply additional fuel while the throttle is being opened.

Fuel injection. Gasoline-injection systems in which the fuel is forcefully injected into the cylinder by a pump were available for airplane engines before World War II and were extensively used then in aircraft. The performance of engines with such equipment was excellent, but the much greater cost of fuel-injection systems compared with that of carburetors limited their application.

The above-mentioned form of fuel preparation is termed cylinder-head injection. Such a system, employed in stratified-charge engines, involves the injection of fuel directly into each cylinder under high pressure. It is well-suited for this type of engine, which is designed to permit operation under very fuel-lean conditions. Examples of stratified engines include the divided-chamber, axially stratified-charge, and direct-injection varieties (Figure 25).

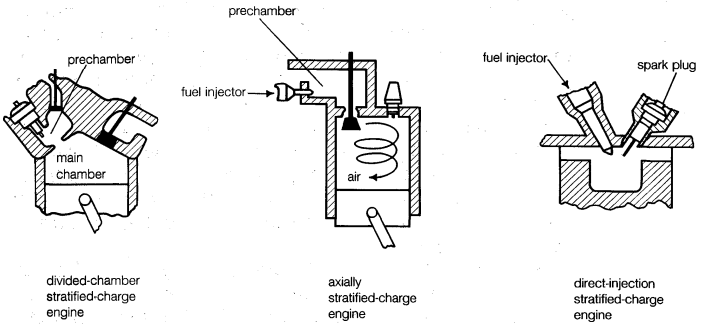

Figure 25: Stratified-charge engine design.

From R.A. Meyers (ed.), *Encyclopedia of Physical Science and Technology*, vol 6 (1987), Academic Press, Inc.

Efforts to simplify and lower the cost of fuel-injection equipment without impairing performance have yielded multicylinder pumps that can compete in cost with four-barrel carburetors. Gasoline-injection equipment may consist of distributor systems employing a single pump for all of the cylinders, or multipumps.

Advantages of fuel injection

The principal advantages of gasoline injection over carburetors are improved fuel economy because of more accurate fuel and air proportioning, greater power because of the elimination of fuel heating, elimination of inlet icing, and more uniform and direct delivery of fuel load to the cylinders.

Supercharger. The efficiency of the charging process in an automotive engine usually rises to a peak of slightly more than 80 percent at about half the rated speed of the engine and then decreases considerably at higher speed. This change in air charge per cycle with engine speed is reflected in proportionate changes in the torque, or turning effort, applied to the crankshaft and causes the power that the engine can deliver at full throttle to reach a maximum as engine speed increases. At speeds above this peaking speed, the air charge introduced per cycle falls off so rapidly that less power is developed than at lower speeds. The inability of the engine to draw in a full charge of fresh air at high speeds limits the power output of the engine.

Supercharging overcomes this disadvantage by the use of a pump or blower to raise the pressure of the air supplied to the cylinders, increasing the weight of charge. The loss in power suffered by unsupercharged engines at high altitudes can be largely restored; it is also possible to more than double the power of an engine by supercharging. Increased charge density and temperature, resulting from supercharging, increase the tendency for combustion knock or roughness in the spark-ignition engine and thus necessitates an undesirable decrease in compression ratio or the use of an antiknock fuel.

Turbocharger

The supercharging blower may be geared to the crankshaft, in which case the power consumed in driving it is added to the friction loss of the engine. A turbocharger employs a gas turbine operated by the exhaust gases to drive a centrifugal blower. The turbocharged engine not only gains increased power capacity but also operates at improved fuel economy. Airplane engines are usually supercharged both by geared blowers and by turbochargers to provide the large pumping capacity needed at high altitude.

Since compressing air prior to introducing it into the cylinder increases the charge-air temperature, the mass of air that can be introduced into the engine is less than that which would be possible if the compressed air were at ambient temperature. Consequently, engine charge-air coolers, commonly referred to as either intercoolers or aftercoolers, are used to reduce the temperature of the charge air. Both air-to-coolant and air-to-air type coolers are available.

Cooling system. The cylinders of internal-combustion engines require cooling because of the inability of the engine to convert all of the energy released by combustion into useful work. Liquid cooling is employed in most gasoline engines, whether the engines are for use in automobiles or elsewhere. The liquid is circulated around

the cylinders to pick up heat and then through a radiator to dissipate the heat. Usually a thermostat is located in the circulating system to maintain the design jacket temperature—71° to 82° C. The cooling system is usually pressurized to raise the boiling point of the coolant so that a higher outlet temperature can be maintained to improve thermal efficiency and increase the heat transfer capacity of the radiator. A pressure cap on the radiator maintains this pressure by valves that open outwardly at the design pressure and inwardly to prevent a vacuum as the system cools.

Some engines, particularly aviation engines and small units for mowers, chain saws, and other tools, are air cooled. Air cooling is accomplished by forming thin metal fins on the exterior surfaces of the cylinders to increase the rate of heat transfer by exposing more metal surface to the cooling air. Air is forced to flow rapidly through the spaces between the fins by ducting air toward the engine.

Air cooling

Lubrication system. Lubrication is employed to reduce friction by interposing a film between rubbing parts. The lubrication system must continuously replace the films.

The lubricants commonly employed are refined from crude oil after the fuels have been removed. Their viscosities must be appropriate for each engine and the oil must be suitable for the severity of the operating conditions. Oils are improved with additives that reduce oxidation, inhibit corrosion, and act as detergents to disperse deposit-forming gums and solid contaminants. Various systems of numbers are used to designate oil viscosity; the lower the number, the lighter the body of the oil. Certain oils contain additives that oppose their change in viscosity between the winter and summer.

Oil filters, if regularly serviced, can remove solid contaminants from crankcase oil, but chemical reactions may form liquids that are corrosive and damaging. Depletion of the additives also limits the useful life of lubricating oils.

The lubrication system is fed by the oil sump that forms the lower enclosure of the engine. Oil is taken from the sump by a pump, usually of the gear type, and delivered under pressure to a system of passages or channels drilled through the engine. In some instances a so-called full-flow filter runs the length of the engine between the pump and the main oil passage. In other engines bypass filters continuously bleed off a small quantity of oil and return the filtered oil to the sump.

Oil is supplied under pressure to crankshaft and camshaft main bearings. Adjacent crank throws are drilled to enable the oil to flow from the supply at the main bearings to the crankpins. Leaking oil from all of the crankshaft bearings is sprayed on the cylinder walls, cams, and up into the pistons to lubricate the piston pins. Additional passages intersect the cam-follower openings and supply oil to hydraulic valve lifters when used. A spring-loaded pressure-relief valve maintains the pressure at the proper level.

Exhaust system. Exhaust gases from an internal-combustion engine are passed through a muffler to suppress audible vibrations. When the exhaust valve opens, the pressure in the engine causes an initial gas outflow at explosive velocity. Successive discharges from the cylinders set up pressure pulsations that produce a sharp barking sound. The muffler damps out or absorbs these pulsations so that the gases leave the outlet as a relatively smooth, quiet stream.

Mufflers of early design contained sets of baffles that reversed the flow of the gases or otherwise caused them to follow devious paths so that interference between the pressure waves reduced the pulsations. The mufflers most commonly used in modern motor vehicles employ resonating chambers connected to the passages through which the gases flow. Gas vibrations are set up in each of these chambers at the fundamental frequency determined by its dimensions. These vibrations cancel or absorb those present in the exhaust stream of about the same frequency. Several such chambers, each tuned to one of the predominant frequencies present in the exhaust stream, effectively reduce noise.

Emission control devices for reducing air pollution are added to the exhaust system. Beds of a suitable catalyst (a material for promoting desirable reactions) are placed in a mufflerlike chamber to reduce unburned hydrocarbons, carbon monoxide, and, in some instances, nitrogen oxides in the exhaust output. This device, called the catalytic converter, is used in conjunction with various other kinds of emission control systems.

Emission control

The reactor system for controlling emission is composed of a belt-driven air compressor connected to small nozzles installed in the exhaust manifold facing the outlet from each exhaust valve. A small jet of air is thus directed toward the red-hot outflowing combustion products to provide oxygen to consume the hydrocarbons and carbon monoxide.

Fuels. Gasoline was originally considered dangerous and was discarded and destroyed at early refineries, which were manufacturing kerosene for lamps. As the gasoline engine developed, gasoline and the engine were harmonized to attain the best possible matching of characteristics. The most important properties of gasoline are its volatility and antiknock quality. Volatility is a measure of the ease of vaporization of gasoline in the carburetor.

Volatility and antiknock quality

To suit the needs of a modern engine a gasoline must have the volatility for which the fuel system of the engine was designed and antiknock quality sufficient to avoid knock under normal operation. Although other specifications must also be met, volatility and knock rating are the most important. The size and structural arrangement of the molecules principally determine the knocking tendency of a gasoline as well as its volatility.

Tetraethyl lead, added to gasolines for many years to improve antiknock fueling, has been found to contaminate the exhaust gases with poisonous lead oxides, and the practice is ending. Lower compression ratios and improved combustion-chamber designs are eliminating the need for extremely high antiknock gasolines.

Lubricating oil is added to gasoline used in crankcase-compression two-stroke cycle engines.

Performance. The performance of an engine is expressed in terms of power, speed, and fuel economy. The three quantities are evaluated with a dynamometer, a laboratory device that applies a controllable load in the form of resistance to the turning of the crankshaft and also measures the torque exerted at the shaft coupling. The resistance imposed by a dynamometer may be so adjusted that the desired engine speed is established at any throttle position. It is thus possible to run the engine at various speeds throughout its operating range, to maintain these operating conditions continuously, and to measure the precise load and speed at which each run is made. Additional test equipment permits measurement of the exact quantity of fuel consumed as well as the duration of the runs. From these data the power–speed–economy relationships can be calculated and performance plotted.

The power produced by an engine is, as explained earlier, expressed in horsepower. When the power developed is measured by means of a dynamometer or similar braking device, it is called brake horsepower. This is the power actually delivered by the engine and is therefore the capacity of the engine. The power developed in the combustion chambers of the engine is greater than the delivered power because of friction and other mechanical losses. This power loss, called the friction horsepower, can be evaluated by "motoring" the engine (driving it in a forward direction) with a suitable dynamometer when no fuel is being burned. The power developed in the cylinder can then be found by adding the friction horsepower to the brake horsepower. This quantity is the indicated horsepower of the engine, so called from an instrument known as the engine indicator, which is used to measure the pressure on the piston and thus calculate the power developed in the cylinder.

Power measurements

Mechanical efficiency is defined as brake horsepower in percent of indicated horsepower and is usually between 70 percent and 90 percent within the normal operating speed range.

A quantity called brake mean effective pressure is obtained by multiplying the mean effective pressure of an engine by its mechanical efficiency. This is a commonly used index expressing the ability of the engine, per unit of cylinder bore, to develop useful pressure in the cylinders

and delivery power. If the power delivered is increased by any change other than an increase in speed or cylinder dimensions, its brake mean effective pressure increases proportionately.

Applications. Gasoline engines can be built to meet the requirements of practically any conceivable power-plant application. In some instances, however, other kinds of engines or electric motors have certain advantages. The important applications for which the gasoline engine is most likely to be chosen in preference to other types are in the areas of passenger automobiles, small trucks and buses, aircraft, outboard and small inboard marine units, moderate-sized stationary pumping, lighting plant, machine tool and similar installations, and power tools.

Development of gasoline engines. While attempts to devise heat engines were made in ancient times, the steam engine of the 18th century was the first successful type. The internal-combustion engine, which followed in the 19th century as an improvement over the steam engine for many applications, cannot be attributed to any single inventor. The piston, thought to date as far back as 150 BC, was used by metalworkers in pumps for blowing air. The piston (and cylinder) was basic to the steam engine, which brought the component to a high state of efficiency. The steam engine, however, suffered from low thermal efficiency, great weight and bulk, and inconvenience of operation, all of which were primarily traceable to the necessity of burning the fuel in a furnace separate from the engine. It became evident that a self-contained power unit was desirable.

Early use of the piston

As early as the 17th century, several experimenters first tried to use hot gaseous products to operate pumps. By 1820 an engine was built in England in which hydrogen–air mixtures were exploded in a chamber. The chamber was then cooled to create a vacuum acting on a piston. The sale of such gas engines began in 1823. They were heavy and crude but contained many essential elements of later, more successful devices. In 1824 the French engineer Sadi Carnot published his now classic pamphlet "Reflections on the Motive Power of Heat," which outlined fundamental internal-combustion theory. Over the next several decades inventors and engineers built engines that used pressure produced by the combustion of fuels rather than a vacuum and engines in which the fuel was compressed before burning. None of them succeeded in developing an operational system, however. Finally, in 1860 Étienne Lenoir of France marketed an engine that operated on illuminating gas and provided reasonably satisfactory service. The Lenoir engine was essentially a converted double-acting steam engine with slide valves for admitting gas and air and for discharging exhaust products. Although the Lenoir engine developed little power and utilized only about 4 percent of the energy in the fuel, hundreds of these devices were in use in France and Britain within five years. They were used for powering water pumps and printing presses and for completing certain other tasks that required only limited power output.

The ideal operating cycle

A major theoretical advance occurred with the publication in 1862 of a description of the ideal operating cycle of an internal-combustion engine. The author, the French engineer Alphonse Beau de Rochas, laid down the following conditions as necessary for optimum efficiency: maximum cylinder volume with minimum cooling surface, maximum rapidity of expansion, maximum ratio of expansion, and maximum pressure of the ignited charge. He described the required sequence of operations as (1) suction during an entire outstroke of the piston, (2) compression during the following instroke, (3) ignition of the charge at dead centre and expansion during the next outstroke (the power stroke), and (4) expulsion of the burned gases during the next instroke. The engine Beau de Rochas described thus had a four-stroke cycle, in contrast to the two-stroke cycle (intake-ignition and power-exhaust) of the Lenoir engine. Beau de Rochas never built his engine, and no four-stroke engine appeared for more than a decade. Finally in 1876 the German engineer Nikolaus A. Otto built an internal-combustion unit based on Beau de Rochas's principle. (Otto's firm, Otto and Langen, had produced and marketed an improved two-stroke engine several years earlier.) The four-stroke Otto engine was an immediate success. In spite of its great weight and poor economy, nearly 50,000 engines with a combined capacity of about 200,000 horsepower were sold in 17 years, followed by the rapid development of a wide variety of engines of the same type. Manufacture of the Otto engine in the United States began in 1878, following the grant to Otto of a U.S. patent in 1877.

The Otto engine

Eight years later Gottlieb Daimler and Wilhelm Maybach, former associates of Otto, developed the first successful high-speed four-stroke engine and invented a carburetor that made it possible to use gasoline for fuel. They employed their engine to power a bicycle (perhaps the world's first motorcycle) and later a four-wheeled carriage. At about the same time, another German mechanical engineer, Carl Benz, built a one-cylinder gasoline engine to power what is often considered the first practical automobile. The engines built by Daimler and Benz were fundamentally the same as today's basic gasoline engine. For information about subsequent enhancements and advances, see TRANSPORTATION: *Modern automotive systems.* (O.C.C./C.L.P.II)

DIESEL ENGINES

General characteristics. The diesel engine is an intermittent-combustion piston–cylinder device. It operates as either a two-stroke or four-stroke cycle (see *Gasoline engines* above); however, unlike the spark-ignition engine, the diesel engine induces only air into the combustion chamber on its intake stroke. The air is heated as compression occurs during the compression stroke. Diesel engines are typically constructed with compression ratios in the range 14:1 to 22:1. Both two-stroke and four-stroke engine designs can be found among engines with bores (cylinder diameters) less than 600 millimetres. Engines with bores of greater than 600 millimetres are almost exclusively two-stroke cycle systems.

The diesel engine gains its energy by burning fuel injected or sprayed into the compressed, hot air charge within the cylinder. The air must be heated to a temperature greater than the temperature at which the injected fuel can ignite. Fuel sprayed into air that has a temperature higher than the "auto-ignition" temperature of the fuel spontaneously reacts with the oxygen in the air and burns. Air temperatures are typically in excess of 526° C; however, at engine start-up, supplemental heating of the cylinders is usually required, since the temperature of the air within the cylinders is determined by both the engine's compression ratio and its current operating temperature. Diesel engines are sometimes called compression-ignition engines because initiation of combustion relies on air heated by compression rather than on an electric spark.

Ignition by compression of air charge

In a diesel engine, fuel is introduced as the piston approaches the top dead centre of its stroke (see *Gasoline engines* above). The fuel is introduced under high pressure either into a precombustion chamber (Figure 26) or directly into the piston–cylinder combustion chamber. With the exception of small, high-speed systems, diesel engines use direct injection.

Direct injection

Diesel-engine fuel-injection systems are typically designed to provide injection pressures in the range of seven to 70 megapascals (1,000 to 10,000 pounds per square inch). There are, however, a few higher pressure systems.

Precise control of fuel injection is critical to the performance of a diesel engine. Since the entire combustion process is controlled by fuel injection, injection must begin at the correct piston position (*i.e.,* crank angle). At first, the fuel is burned in nearly a constant-volume process while the piston is near top dead centre. As the piston moves away from this position, fuel injection is continued, and the combustion process then appears as a nearly constant-pressure process.

The combustion process in a diesel engine is heterogeneous—that is to say, the fuel and air are not premixed prior to initiation of combustion. Consequently, rapid vaporization and mixing of fuel in air is very important to thorough burning of the injected fuel. This places much emphasis on injector nozzle design, especially in direct-injection engines.

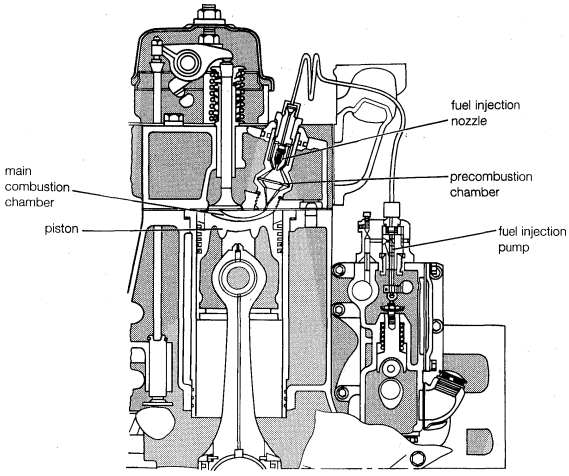

Figure 26: Diesel engine equipped with a precombustion chamber.

From H.A. Sorensen, *Energy Conversion Systems*, copyright © 1983 by John Wiley & Sons, Inc.; reprinted by permission of John Wiley & Sons, Inc.

Engine work is obtained during the power stroke. The power stroke includes both the constant-pressure process during combustion and the expansion of the hot products of combustion after fuel injection ceases.

Diesel engines are often turbocharged and aftercooled (see *Supercharger* above). Addition of a turbocharger and aftercooler can enhance the performance of a diesel engine both in terms of power and efficiency.

High efficiency of diesel engines

The most outstanding feature of the diesel engine is its efficiency. By compressing air, rather than using an air–fuel mixture, the diesel engine is not limited by the preignition problems that plague high-compression spark-ignition engines. Thus higher compression ratios can be achieved with diesel engines than with the spark-ignition variety; commensurately, higher theoretical cycle efficiencies, when compared to the latter, can often be realized. It should be noted that for a given compression ratio, the theoretical efficiency of the spark-ignition engine is greater than that of the compression-ignition engine; however, in practice, it is possible to operate compression-ignition engines at compression ratios high enough to produce efficiencies greater than those attainable with spark-ignition systems. Furthermore, diesel engines do not rely on throttling the intake mixture to control power. As such, the idling and reduced power efficiency of the diesel is far superior to that of the spark-ignition engine.

High pollutant emissions

The principal drawback of diesel engines is their emission of air pollutants. These engines typically discharge high levels of particulate matter (soot), reactive nitrogen compounds (commonly designated NO_x), and odour compared to spark-ignition engines. Consequently, in the small engine category (see below), consumer acceptance is low.

Major types of diesel engines. There are three basic size groups of diesel engines based on power—namely, small, medium, and large. The small engines have power output values of less than 188 kilowatts, or 252 horsepower. This is the most commonly produced diesel-engine type. These engines are used in automobiles, light trucks, and some agricultural and construction applications, and as small stationary electrical power generators (such as those on pleasure craft) and as mechanical drives. They are typically direct-injection, in-line, four- or six-cylinder engines. Many are turbocharged with aftercoolers.

Medium engines have power capacities ranging from 188 to 750 kilowatts, or 252 to 1,006 horsepower. The majority of these engines are used in heavy-duty trucks (those of the class 6, 7, and 8 variety). They are usually direct-injection, in-line, six-cylinder turbocharged/aftercooled engines. Some V-8 and V-12 engines also belong to this size group.

Large diesel engines have power ratings in excess of 750 kilowatts. These unique engines are used for marine, locomotive, and mechanical drive applications and for electrical power generation. In most cases, they are direct-injection, turbocharged/aftercooled systems. They may operate at as low as 500 revolutions per minute when good reliability and durability are critical.

Engine structure and components. As noted earlier, diesel engines are designed to operate on either the two- or four-stroke cycle. In the typical four-stroke-cycle engine (Figure 27), the intake and exhaust valves and the fuel-injection nozzle are located in the cylinder head. Often dual valve arrangements, two intake and two exhaust valves, are employed.

Dual valve arrangement

Use of the two-stroke cycle can eliminate the need for one or both valves in the engine design. Scavenging and intake air is usually provided through ports in the cylinder liner. Exhaust can be either through valves located in the cylinder head or through ports in the cylinder liner. Engine construction is simplified when using a port design instead of one requiring exhaust valves.

Diesel engine starting. A diesel engine is started by driving it from some external power source until conditions have been established under which the engine can run by its own power. The most positive starting method is by admitting air at about 1.7 to nearly 2.4 megapascals to each of the cylinders in turn on their normal firing stroke. The compressed air becomes heated sufficiently to ignite the fuel. Other starting methods involve auxiliary equipment and include admitting blasts of compressed air to an air-activated motor geared to rotate a large engine's flywheel; supplying electric current to an electric starting motor, similarly geared to the engine flywheel; or by means of a small gasoline engine geared to the engine flywheel. The selection of the most suitable starting method depends on the physical size of the engine to be started, the nature of the connected load, and whether or not the load can be disconnected during starting.

Fuel for diesels. Petroleum products normally used as fuel for diesel engines are distillates composed of heavy hydrocarbons, with at least 12 to 16 carbon atoms per molecule. These heavier distillates are taken from crude oil after the more volatile portions used in gasoline are removed. The boiling points of these heavier distillates range from 177° to 343° C. Thus, their evaporation temperature is much higher than that of gasoline, which has fewer carbon atoms per molecule. Specifications for diesel fuels published in 1970 listed three grades: the first was a volatile distillate recommended for high-speed engines with frequent and wide variations in load and speed; the second, a distillate for high-speed engines in services with high loads and uniform speeds; and the third, a fuel for low- and medium-speed engines in service with sustained loads.

Distillates composed of heavy hydrocarbons

Water and sediment in fuels can be harmful to engine operation; clean fuel is essential to efficient injection systems. Fuels with a high carbon residue can be handled best by engines of low-speed rotation. The same applies to those with high ash and sulfur content. The cetane number, which defines the ignition quality of a fuel, is ascertained by adjusting a mixture of cetane and alpha-methyl-naphthalene until it has the same ignition quality as the fuel being tested. The percentage of cetane in this mixture is then the cetane number of the fuel under test. For the first two grades of diesel fuel described above, the minimum cetane number is 40; for the third grade, the minimum is 30, representing 30 percent cetane in the fuel.

Development of diesel engines. *Early work.* Rudolf Diesel, a German engineer, conceived the idea for the

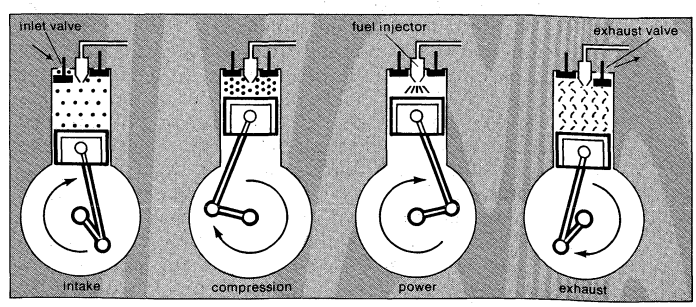

Figure 27: *Four-stroke diesel engine.*
The sequence of cycle events is shown here.

engine that now bears his name after seeking a device to increase the efficiency of the Otto engine (see *Development of gasoline engines* above). Diesel realized that the electric ignition process of the gasoline engine could be eliminated if, during the compression stroke of a piston–cylinder device, compression could heat air to a temperature higher than the auto-ignition temperature of a given fuel. Diesel proposed such a cycle in his patents of 1892 and 1893.

Originally, either powdered coal or liquid petroleum was proposed as fuel. Diesel saw powdered coal, a by-product of the Saar coal mines, as a readily available fuel. Compressed air was to be used to introduce coal dust into the engine cylinder; however, controlling the rate of coal injection was difficult, and after the experimental engine was destroyed by an explosion, Diesel turned to liquid petroleum. He continued to introduce the fuel into the engine with compressed air.

First commercial diesel engine

The first commercial engine built on Diesel's patents was installed in St. Louis, Mo., by Adolphus Busch, a brewer who had seen one on display at an exposition in Munich and had purchased a license from Diesel for the manufacture and sale of the engine in the United States and Canada. The engine operated successfully for years and was the forerunner of the Busch–Sulzer engine that powered many submarines of the U.S. Navy in World War I. Another diesel engine used for the same purpose was the Nelseco, built by the New London Ship and Engine Company in Groton, Conn.

The diesel engine became the primary power plant for submarines during World War I. It was not only economical in the use of fuel but also proved reliable under wartime conditions. Diesel fuel, less volatile than gasoline, was more easily stored and handled.

At the end of the war many men who had operated diesels were looking for peacetime jobs. Manufacturers began to adapt diesels for the peacetime economy. One modification was the development of the so-called semidiesel that operated on a two-stroke cycle at a lower compression pressure and made use of a hot bulb or tube to ignite the fuel charge. These changes resulted in an engine less expensive to build and maintain.

Fuel-injection technology. One objectionable feature of the full diesel was the necessity of a high-pressure, injection air compressor. Not only was energy required to drive the air compressor, but the sudden expansion of the air compressed to 6.9 megapascals when it entered the cylinder in which the pressure was only about 3.4 to 4.1 megapascals resulted in a refrigerating effect that delayed ignition. Diesel had needed high-pressure air with which to introduce powdered coal into the cylinder; when liquid petroleum replaced powdered coal as fuel, a pump could be made to take the place of the high-pressure air compressor.

Substitution of pumps for air compressors

There were a number of ways in which a pump could be used. In England the Vickers Company used what was called the common-rail method, in which a battery of pumps maintained the fuel under pressure in a pipe running the length of the engine with leads to each cylinder. From this rail (or pipe) fuel-supply line, a series of injection valves admitted the fuel charge to each cylinder at the right point in its cycle. Another method employed cam-operated jerk, or plunger-type, pumps, to deliver fuel under momentarily high pressure to the injection valve of each cylinder at the right time.

The elimination of the injection air compressor was a step in the right direction, but there was yet another problem to be solved: the engine exhaust contained an excessive amount of smoke, even at outputs well within the horsepower rating of the engine and even though there was enough air in the cylinder to burn the fuel charge without leaving a discoloured exhaust that normally indicated overload. Engineers finally realized that the problem was that the momentarily high-pressure injection air exploding into the engine cylinder had diffused the fuel charge more efficiently than the substitute mechanical fuel nozzles were able to do, with the result that without the air compressor, the fuel had to search out the oxygen atoms to complete the combustion process, and since oxygen makes up only 20 percent of the air, each atom of fuel had only one chance in five of encountering an atom of oxygen. The result was improper burning of the fuel.

The usual design of a fuel-injection nozzle introduced the fuel into the cylinder in the form of a cone spray, with the vapour radiating from the nozzle, rather than in a stream or jet. Very little could be done to diffuse the fuel more thoroughly. Improved mixing had to be accomplished by imparting additional motion to the air, most commonly by induction-produced air swirls or a radial movement of the air, called squish, or both, from the outer edge of the piston toward the centre. Various methods have been employed to create this swirl and squish. Best results are apparently obtained when the air swirl bears a definite relation to the fuel-injection rate. Efficient utilization of the air within the cylinder demands a rotational velocity that causes the entrapped air to move continuously from one spray to the next during the injection period, without extreme subsidence between cycles.

Swirl or squish

Price's engine. In 1914 a young American engineer, William T. Price, began to experiment with an engine that would operate with a lower compression ratio than that of the diesel and at the same time would not require either hot bulbs or tubes. As soon as his experiments began to show promise, he applied for patents.

In Price's engine the selected compression pressure of nearly 1.4 megapascals did not provide a high enough temperature to ignite the fuel charge when starting. Ignition was accomplished by a fine wire coil in the combustion chamber. Nichrome wire was used for this because it could easily be heated to incandescence when an electric current was passed through it. The experimental engine had a single horizontal cylinder with a bore of 43 centimetres and a stroke (maximum piston movement) of 48 centimetres and operated at 257 revolutions per minute. Because the nichrome wire required frequent replacement, the compression pressure was raised to 2.4 megapascals, which did provide a temperature high enough for ignition when starting. Some of the fuel charge was injected before the end of the compression stroke in an effort to increase the cycle timing and to keep the nichrome wire glowing hot.

In the meantime many engines of the two-stroke cycle, semidiesel type were being installed. Some were used to produce electricity for small municipalities, while others were installed in water pumping plants. Many provided power for tugs, fishing boats, trawlers, and workboats.

In the early 1920s the General Electric Company suggested to the Ingersoll–Rand Company, for whom Price was working, that they cooperate in the building of a diesel-electric locomotive. At that time many of the locomotives in service were powered by gasoline engines. A diesel-electric locomotive with Price's engine was completed in 1924 and placed in service for switching purposes in New York City. The success of this locomotive resulted in orders from railroads, factories, and open-pit mines. The engine used in most of these installations was a six-cylinder, 25-centimetre bore, 30-centimetre stroke system, rated 300 brake horsepower at 600 revolutions and weighing 6,800 kilograms.

Diesel-electric locomotive

Subsequent developments and applications. Many diesel engines were purchased for marine propulsion. The diesels, however, normally rotated faster than was desirable for the propellers of large ships because the high speeds of the huge propellers tended to create hollowed-out areas within the water around the propeller (cavitation), with resultant loss of thrust. The problem did not exist, however, with smaller propellers, and diesel engines proved especially suitable for yachts, in which speed is desired. The problem was solved by utilizing a diesel-electric installation in which the engines were connected to direct-current generators that furnished the electricity to drive an electric motor connected to the ship's propeller. There were also many installations in which the diesel was connected either directly or through gears to the propeller. When diesel engines of larger horsepower and slower rotation speeds became available, they were installed in cargo and passenger ships.

The diesel engine became the predominant power plant for military equipment on the ground and at sea during World War II. Since then it has been adopted for

use in heavy construction machinery, high-powered farm tractors, and most large trucks and buses. Diesel engines also have been installed in hospitals, telephone exchanges, airports, and various other facilities to provide emergency power during electrical power outages. In addition, they have been used in automobiles, albeit on a limited scale. Although diesels provide better fuel economy than gasoline engines, they do not run as smoothly as the latter and emit higher levels of pollutants. (L.V.A./C.L.P.II)

GAS-TURBINE ENGINES

General characteristics. Although the term gas turbine literally refers only to a turbine that employs a gas as the working fluid, it is conventionally used to describe a complete internal-combustion engine consisting of at least a compressor, a combustion chamber, and a turbine. Useful work or propulsive thrust can be obtained from the engine. It may drive a generator, pump, or propeller or, in the case of a pure jet aircraft engine, develop thrust by accelerating the turbine exhaust flow through a nozzle. Large amounts of power can be produced by a gas-turbine engine which, for the same output, is much smaller and lighter than a reciprocating internal-combustion engine. Reciprocating engines depend on the up-and-down motion of a piston, which must then be converted to rotary motion by a crankshaft arrangement, whereas a gas turbine delivers rotary shaft power directly. Although conceptually the gas-turbine engine is a simple device, the components for an efficient unit must be carefully designed and manufactured from costly materials because of the high temperatures and stresses encountered during operation. Thus, gas-turbine engine installations are usually limited to large units where they become cost-effective.

Differences between gas-turbine and reciprocating engines

Gas-turbine engine cycles. *Idealized simple open-cycle gas-turbine engine.* Most gas turbines operate on an open cycle in which air is taken from the atmosphere, compressed in a centrifugal or axial-flow compressor, and then fed into a combustion chamber. Here, fuel is added and burned at an essentially constant pressure with a portion of the air. Additional compressed air, which is bypassed around the burning section and then mixed with the very hot combustion gases, is required to keep the combustion chamber exit (in effect, the turbine inlet) temperature low enough to allow the turbine to operate continuously. If the unit is to produce shaft power, the combustion products (mostly air) are expanded in the turbine to atmospheric pressure. Most of the turbine output is required to operate the compressor; only the remainder is available to supply shaft work to a generator, pump, or other device. In a jet engine the turbine is designed to provide just enough output to drive the compressor and auxiliary devices. The stream of gas then leaves the turbine at an intermediate pressure (above local atmospheric pressure) and is fed through a nozzle to produce thrust. A simplified schematic for a gas turbine engine is given in Figure 28. Pressure–volume relations are also shown in the diagram.

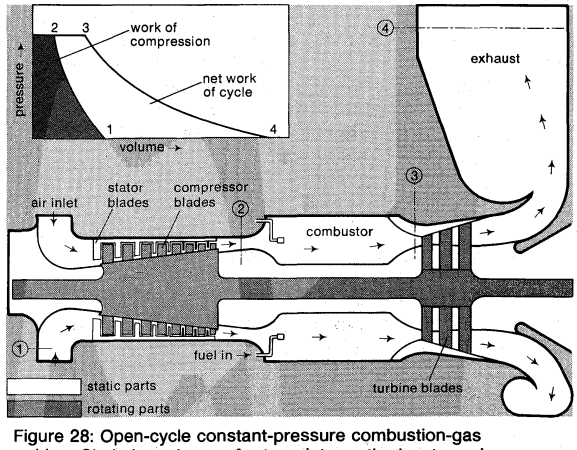

Figure 28: Open-cycle constant-pressure combustion-gas turbine. Circled numbers refer to points on the inset graph of the pressure-volume relationship during a working cycle (see text).

An idealized gas-turbine engine operating without any losses on this simple Brayton cycle is considered first. If, for example, air enters the compressor at 15° C and atmospheric pressure and is compressed to one megapascal, it then absorbs heat from the fuel at a constant pressure until the temperature reaches 1,100° C prior to expansion through the turbine back to atmospheric pressure. This idealized unit would require a turbine output of 1.68 kilowatts for each kilowatt of useful power with 0.68 kilowatt absorbed to drive the compressor. The thermal efficiency of the unit (net work produced divided by energy added through the fuel) would be 48 percent.

Brayton cycle

Actual simple open-cycle performance. If for a unit operating between the same pressure and temperature limits the compressor and the turbine are only 80 percent efficient (*i.e.,* the work of an ideal compressor equals 0.8 times the actual work, while the actual turbine output is 0.8 times the ideal output), the situation changes drastically even if all other components remain ideal. For every kilowatt of net power produced, the turbine must now produce 2.71 kilowatts while the compressor work becomes 1.71 kilowatts. The thermal efficiency drops to 25.9 percent. This illustrates the importance of highly efficient compressors and turbines. Historically it was the difficulty of designing efficient compressors, even more than efficient turbines, that delayed the development of the gas-turbine engine. Modern units can have compressor efficiencies of 86–88 percent and turbine efficiencies of 88–90 percent at design conditions.

Efficiency and power output can be increased by raising the turbine-inlet temperature. All materials lose strength at very high temperatures, however, and since turbine blades travel at high speeds and are subject to severe centrifugal stresses, turbine-inlet temperatures above 1,100° C require special blade cooling. It can be shown that for every maximum turbine-inlet temperature there is also an optimum pressure ratio. Modern aircraft gas turbines with blade cooling operate at turbine-inlet temperatures above 1,370° C and at pressure ratios of about 30:1.

Increasing efficiency and power output

Intercooling, reheating, and regeneration. In aircraft gas-turbine engines attention must be paid to weight and diameter size. This does not permit the addition of more equipment to improve performance. Accordingly, commercial aircraft engines operate on the simple Brayton cycle idealized above. These limitations do not apply to stationary gas turbines where components may be added to increase efficiency. Improvements could include (1) decreasing compression work by intermediate cooling, (2) increasing turbine output by reheating after partial expansion, or (3) decreasing fuel consumption by regeneration.

The first improvement would involve compressing air at nearly constant temperature. Although this cannot be achieved in practice, it can be approximated by intercooling (*i.e.,* by compressing the air in two or more steps and water-cooling it between steps back to its initial temperature). Cooling decreases the volume of air to be handled and, with it, the compression work required.

The second improvement involves reheating the air after partial expansion through a high-pressure turbine in a second set of combustion chambers before feeding it into a low-pressure turbine for final expansion. This process is similar to the reheating used in a steam turbine.

Both approaches require considerable additional equipment and are used less frequently than the third improvement. Here, the hot exhaust gases from the turbine are passed through a heat exchanger, or regenerator, to increase the temperature of the air leaving the compressor prior to combustion. This reduces the amount of fuel needed to reach the desired turbine-inlet temperature. The increase in efficiency is, however, tied to a large increase in initial cost and will be economical only for units that are run almost continuously.

Use of regenerators

Major components of gas-turbine engines. *Compressor.* Early gas turbines employed centrifugal compressors, which are relatively simple and inexpensive. They are, however, limited to low pressure ratios and cannot match the efficiencies of modern axial-flow compressors. Accordingly, centrifugal compressors are used today primarily in small industrial units.

An axial-flow compressor is the reverse of a reaction turbine (see *Steam turbines* above). The blade passages, which look like twisted, highly curved airfoils, must exert a tangential force on the fluid with the pressures on one side of the blade higher than on the other. For subsonic flow, an increase in pressure requires the flow area to also increase, thus reducing the flow velocity between the blade passages and diffusing the flow. A typical compressor stage is shown schematically in Figure 29 with corresponding velocity diagrams. A simple passage flow interpretation, however, is not enough for design purposes. Here, a row of compressor blades must be viewed as a set of closely spaced, highly curved airfoil shapes with which airflow strongly interacts. There will not only be a rise in pressure along the blades but a variation between them as well. Flow friction, leakage, wakes produced by the previous sets of blades, and secondary circulation or swirl flows all contribute to losses in a real unit. Tests of stationary blade assemblies, known as cascades, can be performed in special wind tunnels, but actual blade arrangements in a rotating assembly require special test setups or rigs.

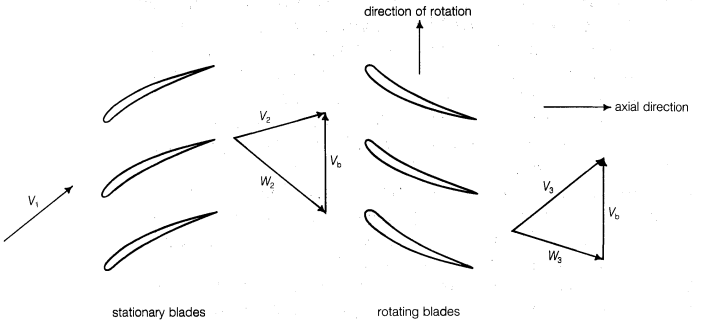

Figure 29: *Typical axial-flow compressor stage with velocity diagrams.*
Here, V is the absolute velocity of fluid, V_b is the blade velocity, and W is the velocity of fluid relative to the blade. Subscript 1 denotes entry into stationary blade (stator), subscript 2 signifies exit from stator or entry into rotor, and subscript 3 indicates exit from rotor.

Blades must be designed not only to have the correct aerodynamic shape but also to be light and not prone to critical vibrations. Recent advances in compressor (and turbine) blade design have been aided by extensive computer programs.

While moderately large expansion-pressure ratios can be achieved in a reaction-turbine stage, only relatively small pressure increases can be handled by a compressor stage—typically pressure ratios per stage of 1.35 or 1.4 to 1 in a modern design. Thus, compressors require more stages than turbines. If higher stage pressure ratios are attempted, the flow will tend to separate from the blades, leading to turbulence, reduced pressure rise, and a "stalling" of the compressor with a concurrent loss of engine power. Unfortunately, compressors are most efficient close to this so-called surge condition, where small disturbances can disrupt operation. It remains a major challenge to the designer to maintain high efficiency without stalling the compressor.

As the air is compressed, its volume decreases. Thus the annular passage area should also decrease if the through-flow velocity is to be kept nearly constant—*i.e.*, the blades have to become shorter at higher pressures. An optimum balance of blade-tip speeds and airflow velocities often requires that the rotational speed of the front, low-pressure end of the compressor be less than that of the high-pressure end. This is achieved in large aircraft gas turbines by "spooled" shafts where the shaft for the low-pressure end, driven by the low-pressure portion of the turbine, is running at a different speed within the hollow high-pressure compressor/turbine shaft, with each shaft having its own bearings. Both twin- and triple-spool engines have been developed.

Combustion chamber. Air leaving the compressor must first be slowed down and then split into two streams. The smaller stream is fed centrally into a region where atomized fuel is injected and burned with a flame held in place by a turbulence-generating obstruction. The larger, cooler stream is then fed into the chamber through holes along a "combustion liner" (a sort of shell) to reduce the overall temperature to a level suitable for the turbine inlet. Combustion can be carried out in a series of nearly cylindrical elements spaced around the circumference of the engine called cans, or in a single annular passage with fuel-injection nozzles at various circumferential positions. The difficulty of achieving nearly uniform exit-temperature distributions in a short aircraft combustion chamber can be alleviated in stationary applications by longer chambers with partial internal reversed flow.

Turbine. The turbine is normally based on the reaction principle with the hot gases expanding through up to eight stages using one- or two-spooled turbines. In a turbine driving an external load, part of the expansion frequently takes place in a high-pressure turbine that drives only the compressor while the remaining expansion takes place in a separate, "free" turbine connected to the load.

One- or two-spooled turbines

High-performance aircraft engines usually employ multiple spools. A recent large aircraft-engine design operating with an overall pressure ratio of 30.5:1 uses two high-turbine pressure stages to drive 11 high-pressure compressor stages on the outer spool, rotating at 9,860 revolutions per minute, while four low-pressure turbine stages drive the fan for the bypass air as well as four additional low-pressure compressor stages through the inner spool turning at 3,600 revolutions per minute (see below). For stationary units, a total of three to five total turbine stages is more typical.

High temperatures at the turbine inlet and high centrifugal blade stresses necessitate the use of special metallic alloys for the turbine blades. (Such alloys are sometimes grown as single crystals.) Blades subject to very high temperatures also must be cooled by colder air drawn directly from the compressor and fed through internal passages. Two processes are currently used: (1) jet impingement on the inside of hollow blades, and (2) bleeding of air through tiny holes to form a cooling blanket over the outside of the blades.

Control and start-up. In a gas-turbine engine driving an electric generator, the speed must be kept constant regardless of the electrical load. A decrease in load from the design maximum can be matched by burning less fuel while keeping the engine speed constant. Fuel flow reduction will lower the exit temperature of the combustion chamber and, with it, the enthalpy drop available to the turbine. Although this reduces the turbine efficiency slightly, it does not affect the compressor, which still handles the same amount of air. The foregoing method of control is substantially different from that of a steam turbine, where the mass flow rate has to be changed to match varying loads.

An aircraft gas-turbine engine is more difficult to control. The required thrust, and with it engine speed, may have to be changed as altitude and aircraft speed are altered. Higher altitudes lead to lower air-inlet temperatures and pressures and reduce the mass flow rate through the engine. Aircraft now use complex computer-driven controls to adjust engine speed and fuel flow while all critical conditions are monitored continuously.

For start-up, gas turbines require an external motor which may either be electric or, for stationary applications, a small diesel engine.

External motor for start-up

Other design considerations. Many other aspects enter into the design of a modern gas-turbine engine, of which only a few examples can be given. Much attention must be paid, especially in a multispool unit, to the design of all bearings, including the thrust bearings that absorb axial forces, and to the lubrication system. As an engine is started up and becomes hot, components elongate or "grow," thereby affecting passage clearances and seals. Other considerations include bleeding air from the compressor and ducting it for turbine-blade cooling or for driving accessories.

Applications. By far the most important use of gas turbines is in aviation, where they provide the motive power for jet propulsion. Because of the significance of this application and the diversity of modern jet engines, the

subject will be dealt with at length in a separate section of the article. The present discussion will touch on the use of gas turbines in electric power generation and in certain industrial processes, as well as consider their role in marine, locomotive, and automotive propulsion.

Electric power generation. In the field of electric power generation, gas turbines must compete with steam turbines in large central power stations and with diesel engines in smaller plants. Even though the initial cost of a gas turbine is less than either alternative for moderately sized units, its inherent efficiency is also lower. Yet, a gas-turbine unit requires less space, and it can be placed on-line within minutes, as opposed to a steam unit that requires many hours for start-up. As a consequence, gas-turbine engines have been widely used as medium-sized "peak load" plants to run intermittently during short durations of high power demand on an electric system. In this case, initial costs, rather than fuel charges, become the prime consideration.

Advantages of a gas turbine

Early commercial stationary plants employed aircraft units operating at reduced turbine-inlet temperatures. The high rotational speed of aircraft turbines required special gearing to drive electric generators. More recently, special units have been designed for direct operation (in the United States) at 3,600 revolutions per minute. Units in sizes up to 200,000 kilowatts have been built, although the majority of installations are less than 100,000 kilowatts. These turbines have operated up to 6,000 hours per year on either liquid fuels or natural gas. Typical turbine-inlet temperatures for large units range from about 980° to 1,260° C with turbine blade cooling used at the higher temperatures.

Efficiency can be improved by adding a regenerator to exploit the high turbine exhaust temperatures (typically about 480° to 590° C). Alternatively, if the gas turbine serves as a peak-load unit for a continuously running steam power plant, the hot exhaust gases can be used to preheat by means of a heat exchanger the combustion air entering a steam boiler. A modern development involves feeding the gas turbine exhaust directly into a steam generator where additional fuel is burned, producing steam of moderate pressure for a steam turbine. An overall thermal efficiency of nearly 50 percent is claimed for these combined units, making them the most fuel-efficient power plants currently available.

Use as a peak-load unit for a steam power plant

Industrial uses. With sizes typically ranging from 1,000 to 50,000 horsepower, industrial gas-turbine engines can be used for many applications. These include driving compressors for pumping natural gas through pipelines, where a small part of the pumped gas serves as the fuel. Such units can be automated so that only occasional on-site supervision is required. A gas turbine can also be incorporated in an oil refining process called the Houdry process, in which pressurized air is passed over a catalyst to burn off accumulated carbon. The hot gases then drive a turbine directly without a combustion chamber. The turbine, in turn, drives a compressor to pressurize the air for the process. Small portable gas turbines with centrifugal compressors also have been used to operate pumps.

Marine propulsion. In this area of application, the gas-turbine engine has two advantages over steam- and diesel-driven plants: it is lightweight and compact. During the early 1970s a ship powered by a gas turbine capable of 20,000 horsepower was successfully tested at sea by the U.S. Navy over a period of more than 5,000 hours. Gas turbines were subsequently selected to power various new U.S. naval vessels.

Use in naval vessels

Locomotive propulsion. During the 1950s and '60s, manufacturers of locomotives built a number of vehicles powered by gas-turbine engines that use heavy oil. Although gas-turbine locomotives have had moderate success for long sustained runs, they have not been able to make significant inroads against diesel locomotives under normal running conditions, especially after increases in the relative cost of heavy fuel oils. Moreover, the inherent low efficiency of a simple open-cycle gas turbine becomes even worse at part-load or during idling when considerable fuel is needed to drive the compressor while producing little or no useful power.

Automotive propulsion. Gas-turbine engines were proposed for use in automobiles from the early 1960s. In spite of their small size and weight for a given power output and their low exhaust emissions compared to gasoline engines, the disadvantages of high manufacturing costs, low thermal efficiency, and poor part-load and idling performance have proven gas-turbine cars to be uneconomical and impractical.

Development of gas turbines. *Origins.* The earliest device for extracting rotary mechanical energy from a flowing gas stream was the windmill (see above). It was followed by the smokejack, first sketched by Leonardo da Vinci and subsequently described in detail by John Wilkins, an English clergyman, in 1648. This device consisted of a number of horizontal sails that were mounted on a vertical shaft and driven by the hot air rising from a chimney. With the aid of a simple gearing system, the smokejack was used to turn a roasting spit.

The smokejack

Various impulse and reaction air-turbine drives were developed during the 19th century. These made use of air, compressed externally by a reciprocating compressor, to drive rotary drills, saws, and other devices. Many such units are still being used, but they have little in common with the modern gas-turbine engine, which includes a compressor, combustion chamber, and turbine to make up a self-contained prime mover. The first patent to approximate such a system was issued to John Barber of England in 1791. Barber's design called for separate reciprocating compressors whose output air was directed through a fuel-fired combustion chamber. The hot jet was then played through nozzles onto an impulse wheel. The power produced was to be sufficient to drive both the compressor and an external load. No working model was ever built, but Barber's sketches and the low efficiency of the components available at the time make it clear that the device could not have worked even though it incorporated the essential components of today's gas-turbine engine.

Although many devices were subsequently proposed, the first significant advance was covered in an 1872 patent granted to F. Stolze of Germany. Dubbed the fire turbine, his machine consisted of a multistage, axial-flow air compressor that was mounted on the same shaft as a multistage, reaction turbine. Air from the compressor passed through a heat exchanger, where it was heated by the turbine exhaust gases before passing through a separately fired combustion chamber. The hot compressed air was then ducted to the turbine. Although Stolze's device anticipated almost every feature of a modern gas-turbine engine, both compressor and turbine lacked the necessary efficiencies to sustain operation at the limited turbine-inlet temperature possible at the time.

Developments of the early 20th century. The first successful gas turbine, built in Paris in 1903, consisted of a three-cylinder, multistage reciprocating compressor, a combustion chamber, and an impulse turbine. It operated in the following way: Air supplied by the compressor was burned in the combustion chamber with liquid fuel. The resulting gases were cooled somewhat by the injection of water and then fed to an impulse turbine. This system, which had a thermal efficiency of about 3 percent, demonstrated for the first time the feasibility of a practical gas-turbine engine.

First successful gas turbine

Two other devices with intermittent gas action, both developed at about the same time, deserve mention. A 10,000-revolutions-per-minute unit built in Paris in 1908 had four explosion chambers located on the periphery of a de Laval impulse turbine. Each chamber, containing air and fuel, was fired sequentially to provide a nearly continuous flow of high-temperature, high-pressure gases that were fed through nozzles to the turbine wheel. The momentary partial vacuum created by the hot gases rushing from the explosion chamber was used to draw in a new charge of air.

Of greater significance was the "explosion" turbine developed by Hans Holzwarth of Germany, whose initial experiments started in 1905. In this system, a compressor introduced a charge of air and fuel into a constant-volume combustion chamber. After ignition, the hot, high-pressure gas escaped through spring-loaded valves into nozzles directed against the blading of a turbine. The valves re-

mained open until the gas was discharged, at which point a fresh charge was brought into the combustion chamber. Since the pressure increase in the compressor was only about one-fourth of the maximum pressure reached after combustion, the unit could operate even though the compressor efficiency was low. Holzwarth and various collaborators continued to develop the explosion turbine for more than 30 years until it was eventually superseded by the modern gas-turbine engine.

System featuring both a rotating compressor and a turbine

To be successful, a steady-flow engine based on the ideas first proposed by Stolze depends not only on high efficiencies (more than 80 percent) for both the rotating compressor and the turbine but also on moderately high turbine-inlet temperatures. The first successful experimental gas turbine using both rotary compressors and turbines was built in 1903 by Aegidus Elling of Norway. In this machine, part of the air leaving a centrifugal compressor was bled off for external power use. The remainder, which was required to drive the turbine, passed through a combustion chamber and then through a steam generator where the hot gas was partially cooled. This combustion gas was cooled further (by steam injected into it) to 400° C, the maximum temperature that Elling's radial-inflow turbine could handle. The earliest operational turbine of this type delivered 11 horsepower. Many subsequent improvements led to another experimental Elling turbine, which by 1932 could produce 75 horsepower. It employed a compressor with 71-percent efficiency and a turbine with an efficiency of 82 percent operating at an inlet temperature of 550° C. Norway's industry, however, was unable to capitalize on these developments, and no commercial units were built. The first industrial success did not come until 1936, when the Swiss firm of Brown Boveri independently developed a gas turbine for the Houdry process (see above).

Also during the mid-1930s a group headed by Frank Whittle at the British Royal Aircraft Establishment (RAE) undertook efforts to design an efficient gas turbine for jet propulsion of aircraft. The unit produced by Whittle's group worked successfully during tests; it was determined that a pressure ratio of about 4 could be realized with a single centrifugal compressor running at roughly 17,000 revolutions per minute. Shortly after Whittle's achievement, another RAE group, led by A.A. Griffith and H. Constant, began developmental work on an axial-flow compressor. Axial-flow compressors, though much more complex and costly, were better suited for detailed blade-design analysis and could reach higher pressures and flow rates and, eventually, higher efficiencies than their centrifugal counterparts.

Independent parallel developments in Germany, initiated by Hans P. von Ohain working with the manufacturing firm of Ernst Heinkel, resulted in a fully operational jet aircraft engine that featured a single centrifugal compressor and a radial-inflow turbine. This engine was successfully tested in the world's first jet-powered airplane flight on Aug. 27, 1939. Subsequent German developments directed by Anselm Franz led to the Junkers Jumo 004 engine for the Messerschmitt Me-262 aircraft, which was first flown in 1942. In Germany as well as in Britain, the search for higher temperature materials and longer engine life was aided by experience gained in developing aircraft turbosuperchargers.

Use in military aircraft

Before the end of World War II gas-turbine jet engines built by Britain, Germany, and the United States were flown in combat aircraft. Within the next few decades both propeller-driven gas-turbine engines (turboprops) and pure jet engines developed rapidly, with the latter assuming an ever larger role as airplane speeds increased.

Recent trends. Because of the significant advances in gas-turbine engine design in the years following World War II, it was expected that such systems would become an important prime mover in many areas of application. However, the high cost of efficient compressors and turbines, coupled with the continued need for moderate turbine-inlet temperatures, have limited the adoption of gas-turbine engines. Their preeminence remains assured only in the field of aircraft propulsion for medium and large planes that operate at either subsonic or supersonic speeds. As for electric power generation, large central power plants that use steam or hydraulic turbines are expected to continue to predominate. The prospects appear bright, nonetheless, for medium-sized plants employing gas-turbine engines in combination with steam turbines. Further use of gas-turbine engines for peak power production is likely as well. These turbine engines also remain attractive for small and medium-sized, high-speed marine vessels and for certain industrial applications. (Fr.L.)

JET ENGINES

General characteristics. The prime mover of virtually all jet engines is a gas turbine. Variously called the core, gas producer, gasifier, or gas generator, the gas turbine converts the energy derived from the combustion of a liquid hydrocarbon fuel to mechanical energy in the form of a high-pressure, high-temperature airstream. This energy is then harnessed by what is termed the propulsor (*e.g.*, airplane propeller and helicopter rotor) to generate a thrust with which to propel the aircraft.

Principles of operation. *The prime mover.* The gas turbine operates on the Brayton cycle in which the working fluid is a continuous flow of air ingested into the engine's inlet (see *Gas-turbine engine cycles* above). As shown in Figure 30, the air is first compressed by a turbocompressor to a pressure ratio of typically 10 to 40 times the pressure of the inlet airstream. It then flows into a combustion chamber, where a steady stream of the hydrocarbon fuel, in the form of liquid spray droplets and vapour or both,

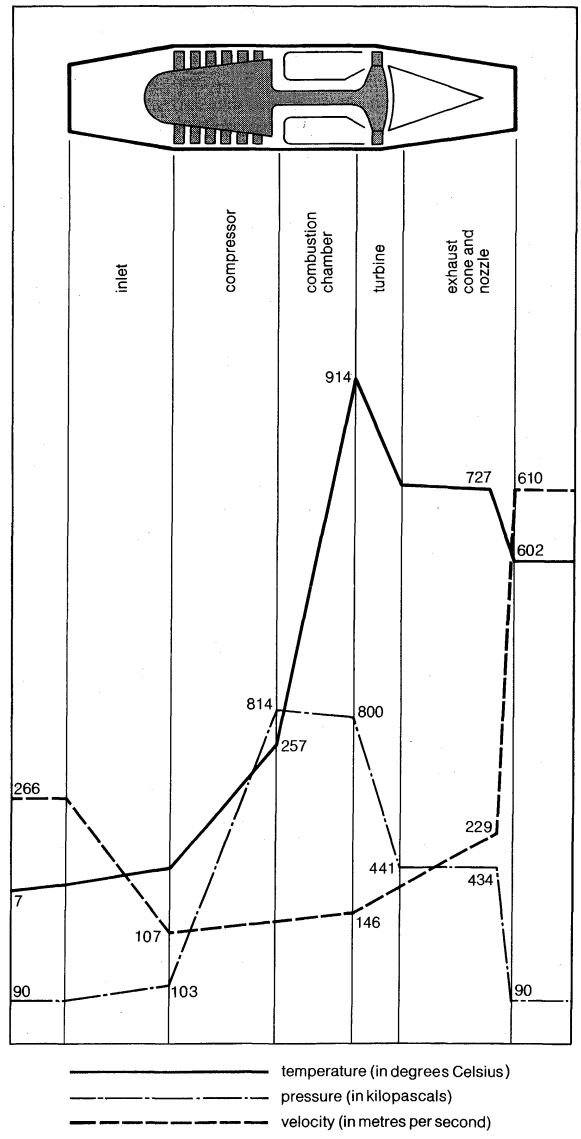

Figure 30: Cross section of a turbojet and (below) graph of typical operating conditions for its working fluid.

is introduced and burned at approximately constant pressure. This gives rise to a continuous stream of high-pressure combustion products whose average temperature is typically from 980° to 1,540° C or higher. This stream of gases flows through a turbine, which is linked by a torque shaft to the compressor and which extracts energy from the gas stream to drive the compressor. Because heat has been added to the working fluid at high pressure, the gas stream that exits from the gas generator after having been expanded through the turbine contains a considerable amount of surplus energy—*i.e.*, gas horsepower—by virtue of its high pressure, high temperature, and high velocity, which may be harnessed for propulsion purposes.

Gas horsepower

The heat released by burning a typical jet fuel in air is approximately 43,370 kilojoules per kilogram (18,650 British thermal units per pound) of fuel. If this process were 100 percent efficient, it would then produce a gas power for every unit of fuel flow of 7.45 horsepower/(pounds per hour), or 12 kilowatts/(kilograms per hour). In actual fact, certain practical thermodynamic limitations, which are a function of the peak gas temperature achieved in the cycle, restrict the efficiency of the process to about 40 percent of this ideal value. The peak pressure achieved in the cycle also affects the efficiency of energy generation. This implies that the lower limit of specific fuel consumption (SFC) for an engine producing gas horsepower is 0.336 (pound per hour)/horsepower, or 0.207 (kilogram per hour)/kilowatt. In actual practice, the SFC is even higher than this lower limit because of inefficiencies, losses, and leakages in the individual components of the prime mover.

Because weight and volume are at a premium in the overall design of an aircraft and because the power plant represents a large fraction of any aircraft's total weight and volume, these parameters must be minimized in the engine design. The airflow that passes through an engine is a representative measure of the engine's cross-sectional area and hence its weight and volume. Therefore, an important figure of merit for the prime mover is its specific power—the amount of power that it generates per unit of airflow. This quantity is a very strong function of the peak gas temperature in the core at the discharge of the combustion chamber. Modern engines generate from 150 to 250 horsepower/(pound per second), or 247 to 411 kilowatts/(kilogram per second).

Specific power

The propulsor. The gas horsepower generated by the prime mover in the form of hot, high-pressure gas is used to drive the propulsor, enabling it to generate thrust for propelling or lifting the aircraft. The principle on which such a thrust is produced is based on Newton's second law of motion. This law generalizes the observation that the force (F) required to accelerate a discrete mass (m) is proportional to the product of that mass and the acceleration (a). In effect,

$$F = ma = \frac{wa}{g},$$

where the mass is taken as the weight (w) of the object divided by the acceleration due to gravity (g) at the place where the object was weighed. In the case of a jet engine, one is generally dealing with the acceleration of a steady stream of air rather than with a discrete mass. Here, the equivalent statement of the second law of motion is that the force (F) required to increase the velocity of a stream of fluid is proportional to the product of the rate of mass flow (M) of the stream and the change in velocity of the stream,

$$F = M(V_j - V_0) = \frac{W(V_j - V_0)}{g},$$

where the inlet velocity (V_0) relative to the engine is taken to be the flight velocity and the discharge velocity (V_j) is the exhaust or jet velocity relative to the engine. W is the rate of weight flow of working fluid (*i.e.*, air or products of combustion) divided by the acceleration of gravity in the place where the weight flow is measured. The relatively small effect of the weight flow of fuel in creating a difference between the weight flow of the inlet and exhaust streams is intentionally disregarded.

One thereby infers that the components of a propulsor must exert a force F on the stream of air flowing through the propulsor if this device accelerates the airstream from the flight velocity V_0 to the discharge velocity V_j. The reaction to that force F is ultimately transmitted by the mounts of the propulsor to the aircraft as propulsive thrust.

There are two general approaches to converting gas horsepower to propulsive thrust. In one, a second turbine (*i.e.*, a low-pressure, or power, turbine) may be introduced into the engine flow path to extract additional mechanical power from the available gas horsepower. This mechanical power may then be used to drive an external propulsor, such as an airplane propeller or helicopter rotor. In this case, the thrust is developed in the propulsor as it energizes and accelerates the airflow through the propulsor—*i.e.*, an airstream separate from that flowing through the prime mover.

Use of a second turbine

In the second approach, the high-energy stream delivered by the prime mover may be fed directly to a jet nozzle, which accelerates the gas stream to a very high velocity as it leaves the engine, as is typified by the turbojet. In this case, the thrust is developed in the components of the prime mover as they energize the gas stream.

In other types of engines, such as the turbofan, thrust is generated by both approaches: A major part of the thrust is derived from the fan, which is powered by a low-pressure turbine and which energizes and accelerates the bypass stream (see below). The remaining part of the total thrust is derived from the core stream, which is exhausted through a jet nozzle.

Just as the prime mover is an imperfect device for converting the heat of fuel combustion to gas horsepower, so the propulsor is an imperfect device for converting the gas horsepower to propulsive thrust. There is generally a great deal of energy left in the high-temperature, high-velocity jet stream exiting from the propulsor that is not fully exploited for propulsion. The efficiency of a propulsor, propulsive efficiency η_p, is the portion of the available energy that is usefully applied in propelling the aircraft compared to the total energy of the jet stream. For the simple but representative case of the discharge airflow equal to the inlet gas flow, it is found that

Propulsive efficiency

$$\eta_p = \frac{2V_0}{V_j + V_0}.$$

Although the jet velocity V_j must be larger than the aircraft velocity V_0 to generate useful thrust, a large jet velocity that exceeds flight speed by a substantial margin can be very detrimental to propulsive efficiency. Maximum propulsive efficiency is approached when the jet velocity is almost equal to (but, of necessity, slightly higher than) the flight speed. This fundamental fact has given rise to a large variety of jet engines, each designed to generate a specific range of jet velocities that matches the range of flight speeds of the aircraft that it is supposed to power (see Figure 31).

The net assessment of the efficiency of a jet engine is the measurement of its rate of fuel consumption per unit of thrust generated (*e.g.*, in terms of pounds, or kilograms, per hour of fuel consumed per pounds, or kilograms, of thrust generated). There is no simple generalization of the value of specific fuel consumption of a thrust engine. It is

Specific fuel consumption

Adapted from *Aerospace America* (October 1984)

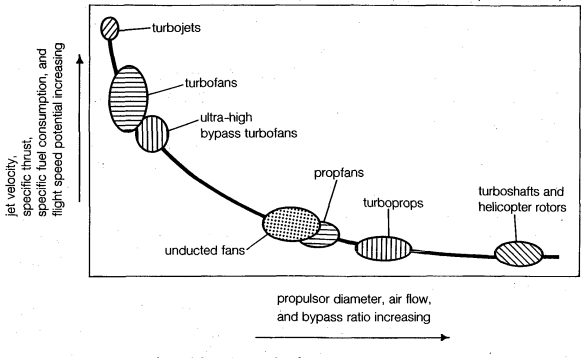

Figure 31: Effect of varying jet velocity on engine design and operation.

not only a strong function of the prime mover's efficiency (and hence its pressure ratio and peak-cycle temperature) but also of the propulsive efficiency of the propulsor (and hence of the engine type). It also is a strong function of the aircraft flight speed and the ambient temperature (which is in turn a strong function of altitude, season, and latitude).

Basic engine types. Achieving a high propulsive efficiency for a jet engine is dependent on designing it so that the exiting jet velocity is not greatly in excess of the flight speed. At the same time, the amount of thrust generated is proportional to that very same velocity excess that must be minimized. This set of restrictive requirements has led to the evolution of a large number of specialized variations of the basic turbojet engine, each tailored to achieve a balance of good fuel efficiency, low weight, and compact size for duty in some band of the flight speed–altitude–mission spectrum. There are two major general features characteristic of all the different engine types, however. First, in order to achieve a high propulsive efficiency, the jet velocity, or the velocity of the gas stream exiting the propulsor, is matched to the flight speed of the aircraft—slow aircraft have engines with low jet velocities and fast aircraft have engines with high jet velocities. Second, as a result of designing the jet velocity to match the flight speed, the size of the propulsor varies inversely with the flight speed of the aircraft—slow aircraft have very large propulsors, as, for example, the helicopter rotor—and the relative size of the propulsor decreases with increasing design flight speed—turboprop propellers are relatively small and turbofan fans even smaller.

Although the turbojet is the simplest jet engine and was invented and flown first among all the engine types, it seems useful to examine the entire spectrum of engines in the order of the flight-speed band in which they serve, starting with the slowest—namely, the turboshaft engine, which powers helicopters.

Turboshaft engines. The helicopter is designed to operate for substantial periods of time hovering at zero flight speed. Even in forward flight, helicopters rarely exceed 240 kilometres per hour or a Mach number of 0.22. (The Mach number is the ratio of the velocity of the aircraft to the speed of sound.) The principal propulsor is the helicopter rotor, which is driven by one or more turboshaft engines (Figure 32) in all modern helicopters of large size. As was previously noted, the propulsor is designed to give a very low discharge or jet velocity and is by the same token very large for a given size aircraft when compared to the propulsors of higher-speed aircraft. The prime mover of a helicopter is a core engine whose gas horsepower is extracted by a power turbine, which then drives the helicopter rotor via a speed-reducing (and combining) gearbox. The power turbine is usually located on a spool separate from the gas generator; thus its rotative speed and that of the helicopter rotor which it drives are independent of the rotative speed of the gas generator. This allows the rotor speed to be varied or kept constant independently of the gas-generator speed, which must be varied to modulate the amount of power generated.

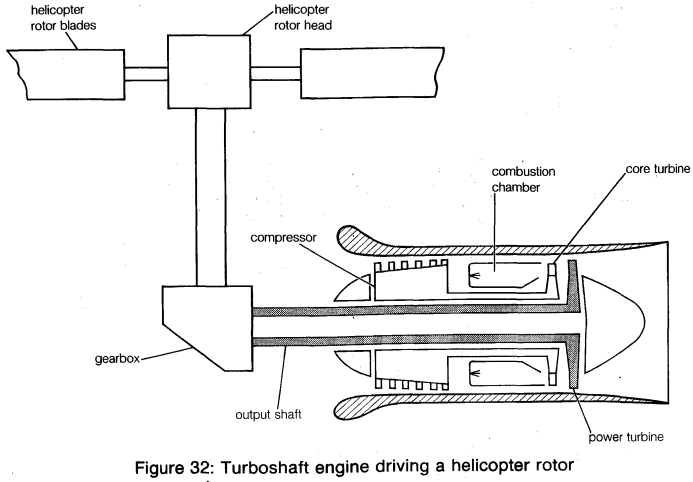

Figure 32: Turboshaft engine driving a helicopter rotor as propulsor.

Turboprops, propfans, and unducted fan engines. The turboprop is the power plant that occupies the next band of flight speeds in the flight spectrum, from a Mach number of 0.2 to 0.7. The propulsor is a propeller with a somewhat higher discharge, or jet velocity, than that of the helicopter rotor to match the flight speed, and it has a proportionately smaller area than the latter for a similarly sized aircraft. As shown in Figure 33, the prime mover is a turboshaft engine (very similar to the one that drives a helicopter rotor except for a different gearbox) designed to provide a somewhat higher rotative speed for the propeller, which turns faster than the helicopter rotor having a much larger diameter. The control mode of the turboprop also is somewhat different from that of a helicopter's turboshaft engine. In a helicopter the pilot calls for power by manipulating the pitch of the rotor blades (a greater pitch taking a bigger "bite" of air and so demanding more power to maintain rotative speed). The engine's control responds by increasing fuel to the engine to maintain output shaft speed. In a turboprop, the pilot calls for power by selecting fuel flow to the prime mover. The propeller control responds by varying propeller pitch to attain a greater "pull" while maintaining a preselected propeller rotative speed.

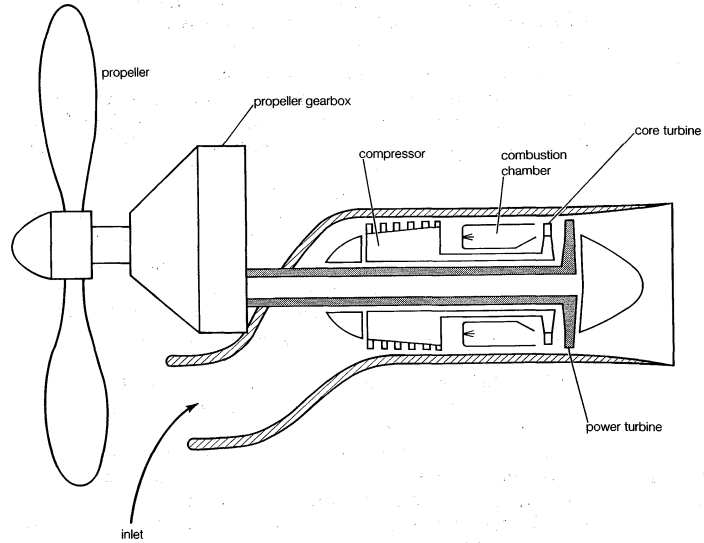

Figure 33: Turboprop engine driving a single rotation propeller as propulsor; tractor arrangement.

Trends in turboprop design

A recent trend in turboprop design has been the evolution of propellers for efficient operation at transonic flight speeds (those approximating the speed of sound), much higher than previously achieved—up to Mach numbers of 0.85. This usually involves a higher disk loading (*i.e.*, a higher discharge velocity from the propeller) in order to permit the use of a smaller diameter propeller. This trend has been accompanied by an increase in the number of blades in the propeller (from six to 12 instead of the more common two to four blades in lower-speed propellers). The blades are scimitar-shaped, with swept-back leading edges at the blade tips to accommodate the large Mach numbers encountered by the propeller tip at high rotative and flight speeds. Such high-speed propulsors are called propfans.

Another variation of the propulsor involves the application of two concentric propellers on the same centreline, driven by the same prime mover through a gearbox that causes each propeller to rotate in a direction opposite the other. Such counter-rotating propellers are capable of significantly higher propulsive efficiency and higher disk loading than conventional propellers.

Counter-rotating propellers

In most turboprop installations the prime mover is mounted on the wing, and the plane of the propeller is forward of the prime mover (the so-called tractor layout). Modern high-speed aircraft may find it more advantageous to mount the engine more toward the rear of the aircraft, with the plane of the propeller aft of the engine. These ar-

rangements are referred to as "pusher" layouts. A recently developed engine layout, identified as the unducted fan (or UDF; trademark), provides a set of very high-efficiency counter-rotating propeller blades, each blade mounted on one of either of two sets of counter-rotating low-pressure turbine stages and achieving all the advantages of the arrangement without the use of a gearbox (see Figure 34).

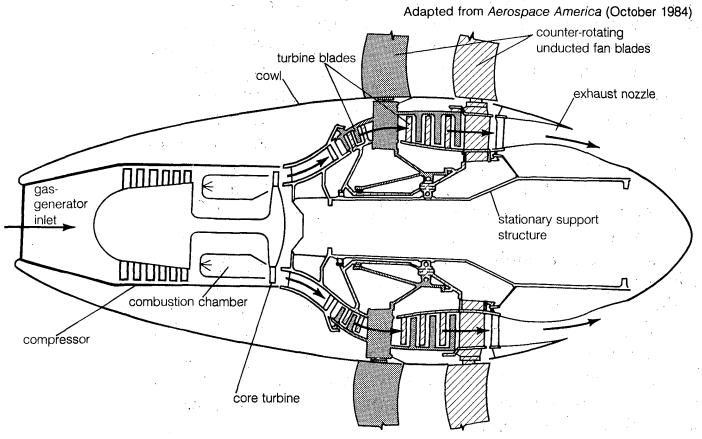

Figure 34: An unducted fan engine (UDF; trademark) with counter-rotating propellers, or unducted fan blades; pusher arrangement.

Medium-bypass turbofans, high-bypass turbofans, and ultrahigh-bypass engines. Moving up in the spectrum of flight speeds to the transonic regime—Mach numbers from 0.75 to 0.9—the most common engine configurations are turbofan engines, such as those in Figures 35A and 35B. In a turbofan, only a part of the gas horsepower generated by the core is extracted to drive a propulsor, which usually consists of a single low-pressure-ratio, shrouded turbocompression stage. The fan is generally placed in front of the core inlet so that the air entering the core first passes through the fan and is partially compressed by it. Most of the air, however, bypasses the core (hence the designation bypass stream) and goes directly to an exhaust nozzle. The core stream, with some modest fraction of the gas horsepower remaining (not extracted to drive the fan) proceeds directly to its own exhaust nozzle.

Bypass ratio

A key parameter for classifying the turbofan is its bypass ratio, defined as the ratio of the mass flow rate of the bypass stream to the mass flow rate entering the core. Since the highest propulsion efficiencies are obtained by the engines with the highest bypass ratios, one would expect to find all engines of that design in this flight speed regime. (Some of the variation derives from historical evolution.) In actuality, however, one finds engines with a broad spectrum of bypass ratios, including medium-bypass engines (with bypass ratios from 2 to 4), high-bypass engines (with bypass ratios from 5 to 8), and ultrahigh-bypass engines, so-called UBEs (with bypass ratios from 9 to 15 or higher). A whole generation of low- and medium-bypass engines has completely supplanted the first generation of aircraft powered by (zero-bypass) turbojet engines. Moreover, that generation was itself supplanted by a third generation of medium- and high-bypass turbofan engines. There are several other reasons why engines with less than the highest bypass ratios hypothetically achievable are still in use. Very high bypass ratios involve the use of fans with very large diameters, which in turn entail very heavy components; this increases the difficulty of installing the engine on aircraft and maintaining sufficient ground clearance. In addition, the weight and complexity of the apparatus required to reverse the direction of the bypass stream (to achieve thrust reversal in order to shorten the aircraft's landing roll) also increases with the bypass ratio. The long-term trend, however, is definitely toward higher and higher bypass ratios.

There are several unique features and ancillary devices found in turbofan engines. As shown in Figure 35A, ultrahigh-bypass engines may have a gearbox between the drive turbine and the fan to simplify the design of the small-diameter turbine (with the attendant high rotative speed) without compromising the performance of the very large-diameter fan (with the attendant low rotative speed). Variable-pitch fan blades are generally required for thrust reversal in such ultrahigh-bypass fans, while in medium- and high-bypass engines the thrust reversing is usually accomplished by introducing blocker doors into the bypass stream. In high- and medium-bypass turbofans such as is shown in Figure 35B, a small but significant improvement in propulsive efficiency can be achieved by mixing the airstream of the hot core and cold bypass streams before the total airstream enters a single jet nozzle.

Provisions for thrust reversing

Low-bypass turbofans and turbojets. In the next higher regime of aircraft flight speed, the low supersonic range from Mach numbers above 1 up to 2 or 3, one finds the application of the simple turbojet (with no bypass stream) and the low-bypass turbofan engine (with a bypass ratio up to 2), such as that pictured in Figure 36.

Although the low-bypass turbofan has the same general appearance as a turbofan with a larger bypass ratio, certain special features are unique to low-bypass engines. The lower total flow in the fan generally involves a higher fan pressure ratio (for equivalent amounts of energy available from the drive turbine), and so such a fan usually has more than one (*i.e.*, two or three) turbocompressor stages. Engines designed to operate at the low supersonic range generally have insufficient thrust in other flight regimes or modes where they must operate for short durations, as, for instance, acceleration through transonic speed, takeoff from high-altitude airports under conditions of extremely high temperatures and high gross weight, or combat maneuvers at high supersonic flight speed. Rather than installing a larger engine to meet these requirements, it is more effective to add an afterburner to a turbofan engine as a means of thrust augmentation (see Figure 36). The

Use of an afterburner

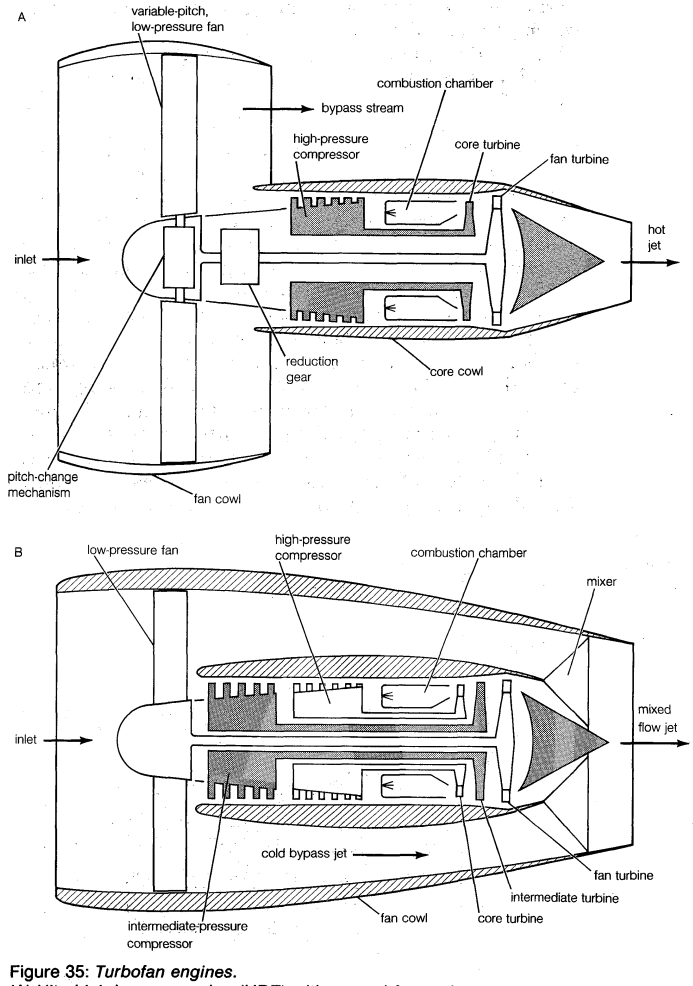

Figure 35: *Turbofan engines.*

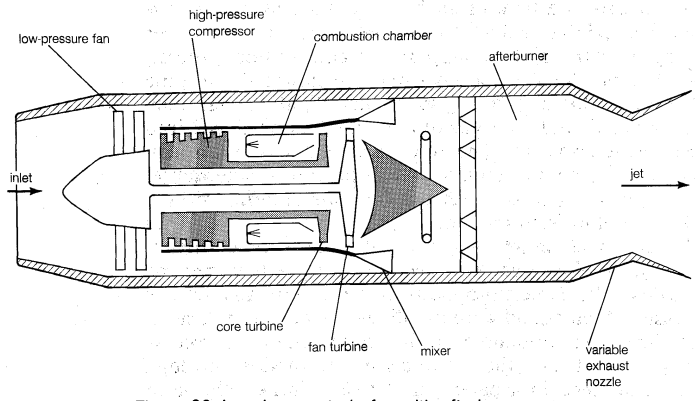

Figure 36: Low-bypass turbofan with afterburner.

afterburner is a secondary combustion system that operates in the exhaust stream of the engine before the stream is introduced into the exhaust nozzle. Such a device is not as fuel-efficient as the main turbofan section of the engine because heat addition occurs at a lower pressure than in the main burner. The afterburner, however, is relatively simple and lightweight, since it does not contain any rotating machinery. For the same reason, it may be operated to a much higher discharge temperature (typically 1,760° C), so that it is capable of augmenting the thrust of the turbofan by as much as 50 percent.

The afterburner in a turbofan usually requires a mixer for mixing the relatively cool bypass air with the hot core stream; the cooler air is otherwise difficult to burn in the low-pressure environment of an afterburner. Also, in both the turbojet and the turbofan with an afterburner, the exhaust nozzle must have a variable throat area to accommodate the large variations in volumetric flow rate between the very hot exhaust stream from the operating afterburner and the cooler airstream discharged from the engine when the afterburner is not in use. Engines intended for supersonic flight generally have a much lower compression-pressure ratio than higher-bypass machines intended for subsonic or transonic operation. A major contributor to this tendency is the additional pressure ratio developed in the engine's inlet as it slows down or diffuses the very high-speed airstream that is ingested as the engine's working fluid—the ram effect. At transonic flight speed this pressure ratio is almost 2:1, so that the engine's compressor may be built to provide that much less pressure where peak pressure is otherwise limiting.

Ram effect

Early generations of jet-propelled aircraft in this low supersonic flight regime were powered by turbojet engines, but subsequent generations built for the same flight regime have largely been equipped with low-bypass turbofans. This substitution of engine type was undertaken primarily because such aircraft expend a great deal of their fuel at subsonic flight speed (*e.g.*, in takeoff, climb, loiter, acceleration, approach, and landing), where the turbofan provides an advantage in propulsive efficiency.

Ramjets and supersonic combustion ramjets. As has been seen, ram pressure plays an increasingly important role in the thermodynamic cycle of power and thrust generation of the jet engine at supersonic flight speeds. For flight speeds above Mach 2.5 or 3, the ram-pressure ratio becomes so high that a turbocompressor is no longer necessary for efficient thrust generation. Indeed, the pressure ratio eventually rises to such high values that the associated high ram temperatures make it difficult or impossible to place high-speed rotating machinery in the flow path without prohibitive amounts of cooling provision. This combination of circumstances gives rise to the ramjet, a jet engine in which the pressure increase is attributable only to the ram effect of the high flight speed; no turbomachinery is involved, and the main thrust producer is an afterburner (see Figure 37).

Absence of a turbine

Ramjets are lightweight and simple power plants, making them ideal candidates for supersonic flight vehicles that are launched from other flight vehicles at extremely high speed. They are less suitable for use in vehicles that must be sufficiently self-powered for subsonic takeoff, climb, and acceleration to supersonic flight speed; the subsonic ram pressure is insufficient to produce any reasonable amount of thrust, and so alternative propulsion devices must be provided.

In the flight regime of Mach 4 or 5, it is usually efficient to decelerate the inlet airstream to subsonic velocity before it enters the combustion system. At still higher Mach numbers, such deceleration becomes more difficult and costly in terms of pressure losses, and it is necessary to make provision for the combustion chamber to burn its fuel in the supersonic airstream. Such specialized ramjets are called scramjets (for supersonic combustion ramjets) and are projected to be fueled by a cryogenically liquified gas (*e.g.*, hydrogen or methane) instead of a liquid hydrocarbon. The primary reason for doing so is to exploit the greater heat release per unit weight of fuels that have a higher ratio of hydrogen to carbon atoms than ordinary fractions of petroleum even though this gain is partly negated by the higher volume per unit of heat release of those same fuels. Another incentive for employing a very cold fuel is that it may be used as a heat sink for cooling a very high-speed (and hence very hot) engine and aircraft structure. The scramjet has an unusual feature: the inlet deceleration and exhaust acceleration occur largely outside the enclosed engine inlet and exhaust ducts against external aircraft surfaces in front of and to the rear of the engine. In effect, the engine itself is little more than a sophisticated supersonic combustion chamber.

Scramjets

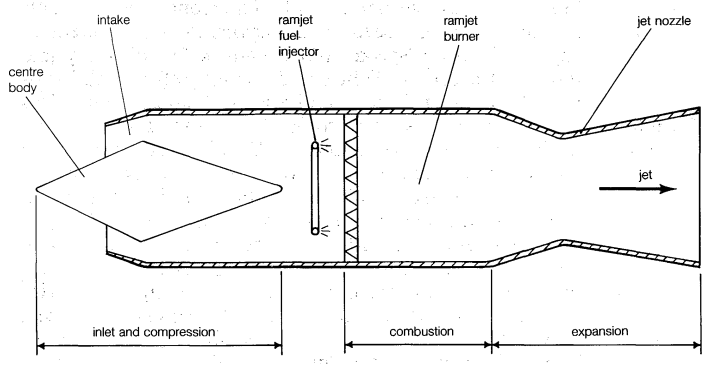

Figure 37: Arrangement of a ramjet.

Hybrid engine types. It is possible to tailor an engine configuration so that the engine is well suited for operation within a given band of the flight spectrum. To have an engine that will perform well in more than one band of the flight spectrum or in more than one regime of operation, it may be necessary to configure the power plant so that it can be converted from one engine type to another by means of variable geometry built into the engine components.

Vertical and short takeoff and landing (V/STOL) propulsion systems. Propulsion systems that provide aircraft with the capability of both vertical and conventional forward flight represent a formidable challenge to the engine designer. V/STOL aircraft have several major categories of engine arrangement. They are as follows:

Vertical and forward flight capability

1. As in a helicopter, the propulsor may consist of a rotor that is driven by one or more turboshaft engines and is installed in such a way as to provide vertical thrust. The entire aircraft must be tilted to give the thrust vector a forward component to achieve forward flight. This arrangement has certain limitations in terms of effectiveness, as borne out by the relative inefficiency of forward flight above a Mach number of 0.2.

2. The propulsors may be mounted on pivots so that they can be rotated from the position in which they give vertical thrust in a takeoff, hover, climb, descent, or landing maneuver and pivoted 90° to provide thrust for conventional forward flight (as in the tilt-rotor aircraft). The prime mover that drives the propulsor may either be tilted with the propulsor or be fixed in the wing and drive the tilting propulsor via a rotating shaft through the pivot axis. In some configurations, the entire wing of the aircraft, carrying fixed engines and propulsors, may be tilted as a single assembly.

3. The engines may be fixed in a position required to produce thrust for forward flight. Their exhaust systems, however, have built-in variable geometry, making it possible to vector the exhaust nozzle (or nozzles) or divert the exhaust gases by means of valves and auxiliary ducts to nozzles mounted in such a way as to provide vertical thrust or lift.

4. The aircraft may include two different sets of engines or propulsors (or both), fixed in position, with one set installed for forward flight and the other for vertical thrust (*i.e.*, the lift engines).

5. The aircraft may use a convertible engine. Such an engine has a single prime mover that is arranged to drive a fan for efficient forward propulsion, to drive a shaft that turns the main helicopter rotor, or to drive both a fan and a shaft. In order to convert from horizontal to vertical flight, variable-pitch fan blades or variable-pitch stators (or both) unload the fan, thereby making mechanical power available to drive the helicopter rotor for vertical movement.

Variable-cycle engines. For aircraft designed to fly mixed missions (*i.e.*, at subsonic, transonic, and supersonic flight speeds) with low levels of fuel consumption, it is desirable to have an engine with the characteristics of both a high-bypass engine (for subsonic flight speed) and a low-bypass engine (for supersonic flight speed). This requirement is typical for such high-speed commercial airliners as the Concorde, a type of supersonic transport built by the British and French. The Concorde is capable of traveling over oceans and unpopulated land areas at supersonic cruise speeds, but it cannot fly efficiently and quietly at subsonic flight speed for takeoff, ascent, cruising over populated areas, and approach and landing. This dual function is expected to be accomplished in the future by the variable-cycle engine (VCE). If the components of an engine are designed to accommodate the extreme limits of flow, pressure ratio, and other conditions involved in both high-bypass and low-bypass operation, the engine may be operated at either extreme of bypass ratio or at any bypass ratio between those extremes by means of a valve (or valves) in the bypass stream (in conjunction with a variable exhaust nozzle). When the valves are closed, they restrict the flow in the bypass stream to achieve low bypass for supersonic flight. When the valves are open, the bypass is increased to its maximum value for efficient subsonic flight.

Multiple flight-speed capability

Turboramjets. As noted above, the ramjet provides a simple and efficient means of propulsion for aircraft at relatively high supersonic flight speeds. It is, however, quite inefficient at transonic flight speeds and is completely ineffective at subsonic velocities. The turboramjet, shown in Figure 38, has been developed to overcome this inadequacy. In this system, a turbofan engine is built into the inlet of a ramjet engine to charge the latter with a pressurized stream of air at subsonic flight speed where ram pressure is insufficient for effective ramjet operation. During supersonic flight the fan blades, if they are of variable pitch, may be feathered so that they do not interfere with the flow of ram air to the ramjet. A separate inlet to the core engine that drives the fan may be closed off so as not to expose the turbomachinery to the hostile environment of the high-temperature ram air.

Built-in turbofan engine

Another variation of the turboramjet does without the core inlet and the core compressor altogether. Instead, the aircraft carries a tank of an oxidizer, such as liquid oxygen. The oxidizer is fed into the core combustion chamber along with the fuel to support the combustion process, which generates the hot gas stream to power the turbine that drives the fan. During supersonic flight, the fan may be feathered, and a surplus of fuel may be introduced into the core combustor. The unburned fuel passes through the fan turbine and undergoes combustion in the ramjet burner when it mixes with the fresh air entering via the bypass stream from the fan. (F.F.E.)

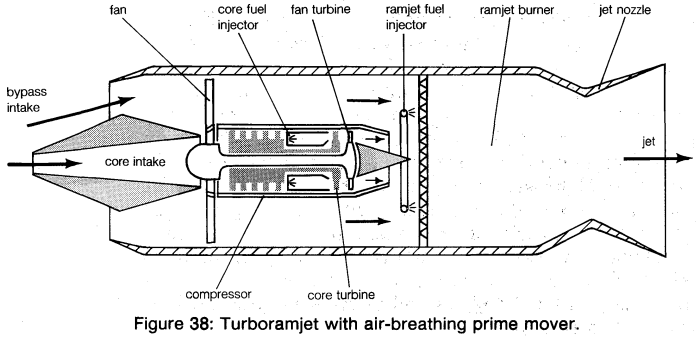

Figure 38: Turboramjet with air-breathing prime mover.

Development of jet engines. Like many other inventions, jet engines were envisaged long before they became a reality. The earliest proposals were based on adaptations of piston engines and were usually heavy and complicated. The first to incorporate a turbine design was conceived as early as 1921, and the essentials of the modern turbojet were contained in a patent in 1930 by Frank Whittle in England. His design was first tested in 1937 and achieved its first flight in May 1941. In Germany, parallel but completely independent work followed issuance of a patent in 1935. It proceeded more rapidly, and the very first flight of a turbojet-powered aircraft, a Heinkel HE-178, came in August 1939. By the end of World War II these prototype aircraft had developed into a few operational turbojet squadrons in the German, British, and U.S. air forces.

In the military area, jet fighter aircraft developed rapidly and were in use during the Korean War (1950–53), flying at speeds of 1,000 kilometres per hour. During the next decade they overcame the sound barrier and established normal operations up to more than twice the speed of sound (Mach 2). Bomber and transport jet aircraft were also able to reach and cruise at supersonic speeds.

Emergence of supersonic jet aircraft

The first civil jet transport, the British de Havilland Comet, flew in 1949, and regular transatlantic jet services were started in 1958 with the Comet 4 and the American Boeing 707. By 1974 more than 90 percent of hours flown throughout the world were flown by jets; the first supersonic airliner, the British-French Concorde, flying at more than twice the speed of sound, entered regular service in January 1976.

During the 1980s various major aircraft manufacturers undertook programs to develop fuel-saving propfan and unducted-fan propulsion systems. Some authorities believe that the next generation of commercial air transport may very well be powered by such advanced-technology propeller engines. (A.D.B./F.F.E.)

ROCKETS

General characteristics and principles of operation. The rocket constitutes a form of jet propulsion (see *Jet engines* above). It differs from the turbojet and other "air-breathing" engines in that all of the exhaust jet consists of the gaseous combustion products of "propellants" carried on board. Like the turbojet engine, the rocket develops thrust by the rearward ejection of mass at very high velocity.

The fundamental physical principle involved in rocket propulsion was formulated by Newton. According to his third law of motion, the rocket experiences an increase in momentum proportional to the momentum carried away in the exhaust,

$$M\Delta v_R = \mathring{m} v_e \Delta t = F\Delta t, \qquad (1)$$

where M is the rocket mass, Δv_R is the increase in velocity of the rocket in a short time interval, Δt, $\mathring{m}$ is the rate of mass discharge in the exhaust, v_e is the exhaust velocity (relative to the rocket), and F is force. The quantity $\mathring{m} v_e$ is the propulsive force, or thrust, produced on the rocket by exhausting the propellant,

$$F = \mathring{m} v_e . \qquad (2)$$

Evidently thrust can be made large by using a high mass discharge rate or high exhaust velocity. Employing high $\mathring{m}$ uses up the propellant supply quickly (or requires a large supply), and so it is preferable to seek high values of v_e. The value of v_e is limited by practical considerations, determined by how the exhaust is accelerated in the engine and what energy supply is available for the purpose.

Most rockets derive their energy in thermal form by combustion of condensed-phase propellants at elevated

Combustion of chemical propellants in conventional rockets

pressure. The gaseous combustion products are exhausted through a nozzle that converts part of the thermal energy to kinetic energy. The maximum amount of energy available is limited to that provided by combustion or by practical considerations imposed by the high temperature involved. Higher energies are possible if other energy sources (*e.g.*, electric arc or microwave heating) are used in conjunction with the chemical propellants on board the rockets, and extremely high energies are achievable when the exhaust is accelerated by electromagnetic means. As yet, these more exotic systems have not found application because of technical reasons but probably will be used in some future space missions where requisite electrical power sources can be shared by propulsion and other mission requirements (see *Other systems* below).

The exhaust velocity is a figure of merit for rocket propulsion because it is a measure of thrust per unit mass of propellant consumed—*i.e.*,

$$\frac{F}{\dot{m}} = v_e. \tag{3}$$

Values of v_e are in the range 2,000 to 5,000 metres per second for chemical propellants, while values two or three times that are claimed for electrically heated propellants. Values up to 40,000 metres per second are predicted for systems using electromagnetic acceleration. In engineering circles, notably in the United States, the exhaust velocity is widely expressed in units of pound thrust per pound weight per second, which is referred to as specific impulse. (In the International System of Units [SI], the unit of specific impulse is newton-seconds per kilogram.) Values in the range 185 to 465 seconds are analogous to the range of exhaust velocities noted above for chemical propellants.

Specific impulse

In a typical chemical-rocket mission, anywhere from 50 to 95 percent or more of the takeoff mass is propellant. This can be put in perspective by the equation for burnout velocity (gravity-free flight),

$$v_b = v_e \ln \frac{M_o}{M_s + M_{\text{pay}}}$$

$$= v_e \ln \frac{1}{\left(\frac{M_s}{M_p}\right)\left(\frac{M_p}{M_o}\right) + \left(\frac{M_{\text{pay}}}{M_o}\right)}. \tag{4}$$

In this expression, M_s/M_p is the ratio of propulsion system and structure weight to propellant weight, with a typical value of 0.09 (the symbol ln represents natural logarithm). M_p/M_o is the ratio of propellant weight to all-up takeoff weight, with a typical value of 0.90. A typical value for v_e for a hydrogen–oxygen system is 3,536 metres per second. From the above equation, the ratio of payload mass to takeoff mass (M_{pay}/M_o) can be calculated. For a low Earth orbit, v_b is about 7,544 metres per second, which would require M_{pay}/M_o to be 0.0374. In other words, it would take a 1,337,000-kilogram takeoff system to put 50,000 kilograms in a low orbit around the Earth. This is an optimistic calculation because equation (4) does not take into account the effect of gravity, drag, or directional corrections during ascent, which would double the takeoff mass. From equation (4) it is evident that there is a direct trade-off between M_s and M_{pay}, so that every effort is made to design for low structural mass, and M_s/M_p is a second figure of merit for the propulsion system. While the various mass ratios chosen depend strongly on the mission, rocket payloads generally represent a small part of the takeoff weight.

Multiple staging

A technique called multiple staging is used in many missions to minimize the size of the takeoff vehicle. A launch vehicle carries a second rocket as its payload, to be fired after burnout of the first stage (which is left behind). In this way, the inert components of the first stage are not carried to final velocity, with the second-stage thrust being more effectively applied to the payload. Most spaceflights use at least two stages. The strategy is extended to more stages in missions calling for very high velocities. The U.S. Apollo manned lunar missions used a total of six stages.

The unique features of rockets that make them useful include the following:

1. Rockets can operate in space as well as in the atmosphere of the Earth.
2. They can be built to deliver very high thrust (a modern heavy space booster has a takeoff thrust approaching 4.5 million kilograms).
3. The propulsion system can be relatively simple.
4. The propulsion system can be kept in a ready-to-fire state (important in military systems).
5. Small rockets can be fired from a variety of launch platforms, ranging from packing crates to shoulder launchers to aircraft (there is no recoil).

These features explain not only why all speed and distance records are set by rocket systems (air, land, space) but also why rockets are the exclusive choice for spaceflight. They also have led to a transformation of warfare, both strategic and tactical. Indeed, the emergence and advancement of modern rocket technology can be traced to weapon developments during and since World War II, with a modest but growing portion being funded through "space agency" initiatives such as the Ariane, Apollo, and Space Shuttle programs.

Chemical rockets. Rockets that employ chemical propellants come in different forms, but all share analogous basic components. These are (1) a combustion chamber where condensed-phase propellants are converted to hot gaseous reaction products, (2) a nozzle to accelerate the gas to high exhaust velocity, (3) propellant containers, (4) a means of feeding the propellants into the combustion chamber, (5) a structure to support and protect the parts, and (6) various guidance and control devices.

Basic parts of a chemical rocket

Chemical rocket propulsion systems are classified into two general types according to whether they burn solid or liquid propellants. Solid systems are usually called motors and liquid systems are referred to as engines. Some developmental work has been carried out on so-called hybrid systems, in which the fuel is a solid and the oxidizer is a liquid, or vice versa. The characteristics of such systems differ greatly depending on the requirements of a given mission.

Solid-rocket motors. The principal features of a solid-rocket motor (SRM) are shown in Figure 39. The propellant consists of one or more pieces mounted directly in the motor "case," which serves both as a propellant tank and combustion chamber. The propellant is usually arranged to protect the motor case from heating. Most modern propellant charges are formed by pouring a viscous mix into the motor case with suitable mold fixtures. The propellant solidifies (usually by polymerization) and the mold fixtures are removed, leaving the propellant bonded to the motor case with a suitably shaped perforation down the middle. During operation the solid burns on the exposed surfaces. These burn away at a predictable rate to give the desired thrust.

The motor case generally consists of a steel or aluminum tube; it has a head-end dome that contains an igniter

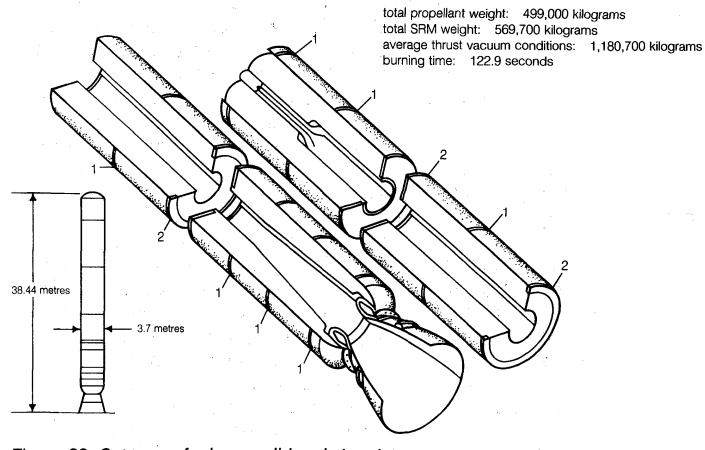

Figure 39: *Cutaway of a large solid-rocket motor.*
This type of motor, used on the U.S. Space Shuttle, consists of four segments and a nozzle assembly that are mated together at the launch site. The numbers indicate joints in the steel case: (1) "factory joints," which are case-segment joints assembled before propellant casting, and (2) "field joints," which are assembled subsequently. The Shuttle motors are recovered at sea, refurbished, and reused.

and an aft-end dome that houses or supports the nozzle. Motor cases ordinarily have insulation on their interior surfaces, especially those not covered by propellant, for protection against thermal degradation. When a mission requires particularly lightweight components, motor cases are often made by filament winding of high-strength fibres on a suitable form. The filaments are held in place by continuous application and curing of plastic during winding. In motor cases, the front and aft domes are wound as integral parts of the case, with suitable openings and fixtures included to permit removal of the (collapsible) motor case form, loading of propellant, and attachment of igniter and nozzle. No matter what type of motor construction is involved, provisions must be made for attaching the structures that connect to the rest of the vehicle and to the launching pad or vehicle. In nearly all applications, the motor case constitutes the main structural component of the rocket and must be designed accordingly.

Propellants for solid-rocket motors are made from a wide variety of substances, selected for low cost, acceptable safety, and high performance. The selection is strongly affected by the specific application. Typical ingredients are

Propellant materials

ammonium perchlorate (a granular oxidizer), powdered aluminum (a fuel), and polybutadiene-acrylonitrile-acrylic acid (a fuel that is liquid during mixing and that polymerizes to a rubbery binder during curing). This combination is used in major U.S. space boosters (*e.g.*, the Space Shuttle and the Titan). Higher performance is achieved by the use of more energetic oxidizers (*e.g.*, cyclotetramethylene tetranitramine [HMX]) and by energetic plasticizers in the binder or by energetic binders such as a nitrocellulose–nitroglycerin system. In military systems, low visibility of the exhaust plume has sometimes been a requirement, which precludes the use of aluminum powder or very much ammonium perchlorate and makes it necessary to use other materials such as HMX and high-energy binder systems that yield combustion products involving mainly carbon, oxygen, hydrogen, and nitrogen.

Propellant charges must meet a variety of often conflicting requirements. From a performance standpoint, they should burn inward at the burning surface in a consistent and predictable manner that is not unduly sensitive to pressure or bulk temperature at a rate typically in the range of 0.2 to 20 centimetres per second. They should be as dense as possible (to maximize the amount of propellant in a given motor size) while still producing reaction products of low molecular weight and high temperature (to maximize exhaust velocity). From a practical standpoint, propellants must be insensitive to accidental ignition stimuli and amenable to safe manufacturing and loading in the motor. Once they have been loaded in the motor, they must achieve and retain the mechanical properties necessary to maintain structural integrity under shipping, storage, and flight conditions. Since the energetic materials used in high-performance propellants are often explosives, manufacturing the propellant to a safe form is a complex technology involving special facilities and strict safety guidelines. To a degree this is true also of less sensitive propellants (*e.g.*, ammonium perchlorate–aluminum–polymeric binder propellants) used in intermediate-performance systems, such as the Space Shuttle booster motors.

Nozzle

The principal requirement for a nozzle is that it be able to produce an optimum flow of the exhaust gas from combustion chamber pressure to exterior pressure (or thereabouts), a function that is accomplished by proper contouring and sizing of the conduit. The contour is initially convergent to a "throat" section. The velocity of the exhaust gas in this region is equal to the local velocity of sound, and the throat cross-sectional area controls the mass discharge rate (and hence the operating pressure). Beyond the throat, the channel is divergent and the flow accelerates to high supersonic speeds with a corresponding pressure decrease. Contours are often carefully designed so that shock waves do not form. (Shock waves slow the flow and degrade thrust.)

The details of nozzle design depend strongly on application. Most applications require at least some use of insulation or special high-temperature materials (*e.g.*, graphite) in order to protect the load-carrying structures from thermal degradation. Many applications require that the direction of the exhaust flow be controllable over a few degrees in order to provide for "steering." This is accomplished in a variety of ways that frequently complicate the design considerably and increase nozzle weight.

The ignition system

The igniter in a solid-rocket motor provides a means of heating the surface of the propellant charge to a high enough temperature to induce combustion. At the same time, the igniter is usually designed to produce some initial pressure increase in the motor to assure more reproducible start-up. The igniter consists of a container of material like a metal–oxidizer mixture that is more easily and quickly ignited than the propellant; it is initiated by an electric squib or other externally energized means. The igniter case is designed to be sealed until fired and to disperse hot and burning products when pressurized by its own burning. In large motors the igniter may feed into a miniature motor containing a fast-burning propellant charge, which exhausts into the main motor to produce ignition and pressurization. Most ignition systems include some kind of "arming" feature that prevents ignition by unintended stimuli.

Thrust levels of solid rockets

The thrust level of a solid rocket is determined by the rate of burning of the propellant charge (mass rate in equation [2]), which is determined by the surface area (S_c) that is burning and the rate (r) at which the surface burns into the solid. The designer chooses a charge geometry that will vary with time during burning in the manner needed for a particular mission and chooses a propellant formulation that gives the desired burning rate. This means that the thrust-time function is not amenable to much intentional modification after manufacture, and most missions using solid-rocket motors are designed to take advantage of the predictability of the thrust-time function rather than to regulate thrust during flight. The lack of real-time control on thrust is compensated for by the ability to achieve extraordinarily high mass-flow rates without the propellant pumps ordinarily used in liquid-propellant rockets. The thrust levels occurring in practice depend on motor operating pressure, which in turn is shown in internal ballistic theory to depend on motor and propellant properties according to the equation

$$p = \left(\rho_p \frac{C}{C_d} \frac{S_c}{A_t}\right)^{1/(1-n)}, \tag{5}$$

where A_t is nozzle throat area, C_d is a nozzle discharge coefficient (that depends on the thermochemical properties of the propellant reaction products), ρ_p is the density of the solid propellant, and C and n are constants in an equation that gives the approximate dependence of burning rate of the propellant on pressure,

$$r = Cp^n. \tag{6}$$

The thrust is then given by an engineering equation,

$$F = C_F A_t p = C_F \left(\rho_p \frac{CS_c}{C_d A_t}\right)^{1/(1-n)} A_t, \tag{7}$$

where C_F depends on nozzle geometry, thermochemical properties, and to a lesser degree on external pressure. Typical values of the quantities in this equation are given in Table 1.

Table 1: Typical Values of Internal Ballistic Variables in Equation (7)

ρ_p	C_d	S_c/A_t	C	n	C_F	coefficient of $A_t(C_F p)$
kg/m^3	s/m	—	$N^{-1}m^{1+2n}s^{-1}$	—	—	N/m^2
1,762	6.1×10^{-4}	200	4.45×10^{-5}	0.35	1.5	8.21×16^6

In most applications, the need to minimize the mass of motor components is a major design consideration. This need is so important that it is often "bought" at the expense of low safety margins and sometimes by the use of exotic construction and structural materials. These considerations are constantly weighed against the cost of mission failures. With the advent of manned flight and payloads sometimes costing $1 billion or more, the thinking on safety margins and acceptable propulsion-system cost is changing.

Liquid-propellant rocket engines. Liquid-propellant systems carry the propellant in tanks external to the combustion chamber. Most of these engines use a liquid oxidizer and a liquid fuel, which are transferred from their respective tanks by pumps. The pumps raise the pressure well above the operating pressure of the engine, and the propellants are then injected into the engine in a manner that assures atomization and rapid mixing. Liquid-propellant engines have certain features that make them preferable to solid systems in many applications. These features include (1) higher attainable exhaust velocities (v_e), (2) higher mass fractions (propellant mass divided by mass of inert components), and (3) control of operating level in flight (throttleability), sometimes including stop-and-restart capability and emergency shutdown. Also, in some applications it is an advantage that propellant loading is delayed until shortly before launch time, a measure that the use of a liquid propellant allows. These features tend to promote the use of liquid systems in many upper-stage applications where high v_e and high propellant mass fraction are particularly important. Liquid systems also have been used extensively as first-stage launch vehicles for space missions, as, for example, in the Saturn (U.S.), Ariane (European), and Energia (Soviet) launch systems. Many intercontinental ballistic missile (ICBM) systems employ liquid-propellant engines, but solid systems have been widely adopted for these applications in the United States because of their suitability for launch on short notice. The relative merits of solid and liquid propellants in heavy launch vehicles are still under debate and involve not only propulsion performance but also issues related to logistics, capital and operating costs of launch sites, recovery and reuse of flight hardware, and so forth.

Distinctive features

The typical components of a liquid-rocket propulsion system are the engine, fuel tanks, and vehicle structure with which to hold these parts in place and connect to payload and launch pad (or vehicle). The fuel and oxidizer tanks are usually of very lightweight construction, as they operate at low pressure. In some applications, the propellants are cryogenic (*i.e.,* they are substances like oxygen and hydrogen that are gaseous at ambient temperature and must be tanked at very low temperature to be in the liquid state).

Principal components

The liquid-propellant engine itself (Figure 40) consists of a main chamber for mixing and burning the fuel and oxidizer, with the fore end occupied by fuel and oxidizer manifolds and injectors and the aft end comprised of the nozzle. Integral to the main chamber is a coolant jacket through which liquid propellant (usually fuel) is circulated at rates high enough to allow the engine to operate continuously without an excessive increase of temperature in the chamber. Engine operating pressures are usually in the range 1,000 to 10,000 kilopascals (10 to 100 atmospheres). The propellants are supplied to the injector manifold at a somewhat higher pressure, usually by high-capacity turbopumps (one for the fuel and another for the oxidizer). From the outside, a liquid-propellant engine often looks like a maze of plumbing, which connects the tanks to the pumps, carries the coolant flow to and from the cooling jackets, and conveys the pumped fluids to the injector. In addition, engines are generally mounted on gimbals so that they can be rotated a few degrees for thrust direction control, and appropriate actuators are connected between the engine (or engines) and the vehicle structure to constrain and rotate the engine.

Each of the main engines of the U.S. Space Shuttle (shown in Figure 40) employs liquid oxygen (LO_2) and liquid hydrogen (LH_2) propellants. These engines represent a very complex, high-performance variety of liquid-propellant rocket. Not only does each have a v_e value of 3,630 metres per second but is also capable of thrust-magnitude control over a significant range (2–1). Moreover, the Shuttle engines are part of the winged orbiter, which is designed to carry both crew and payload for up to 20 missions.

Main engines of the Space Shuttle

At the opposite extreme of complexity and performance is a hydrazine thrustor used for attitude control of conventional flight vehicles and unmanned spacecraft. Such a system may employ a valved pressure vessel in place of a pump, and the single propellant flows through a catalyst bed that causes exothermic (heat-releasing) decomposition. The resulting gas is exhausted through a nozzle that is suitably oriented for the required attitude correction. Systems of this kind also are used as gas generators for turbopumps on larger rockets.

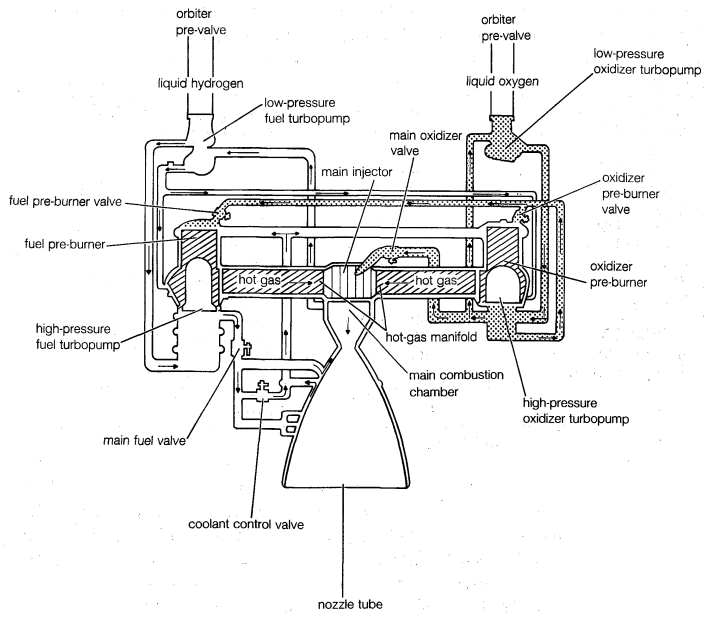

Figure 40: Flow diagram for the Space Shuttle main engine (SSME). Three such engines are mounted on the orbiter.

Most liquid-propellant rockets use bipropellant systems—*i.e.,* those in which an oxidizer and a fuel are tanked separately and mixed in the combustion chamber. Desirable properties for propellant combinations are low molecular weight and high temperature of reaction products (for high exhaust velocity), high density (to minimize tank weight), low hazard factor (*e.g.,* corrosivity and toxicity), and low cost. Choices are based on trade-offs according to the applications. For example, liquid oxygen is widely used because it is a good oxidizer for a number of fuels (giving high flame temperature and low molecular weight) and because it is reasonably dense and relatively inexpensive. It is liquid only below −183° C, which somewhat limits its availability, but it can be loaded into insulated tanks shortly before launch (and replenished or drained in the event of launch delays). Liquid fluorine or ozone are better oxidizers in some respects but involve more hazard and higher cost. The low temperatures of all of these systems require special design of pumps and other components, and the corrosivity, toxicity, and hazardous characteristics of fluorine and ozone have apparently thus far prevented their use in operational systems. Other oxidizers that have seen operational use are nitric acid (HNO_3) and nitrogen tetroxide (N_2O_4), which are liquids under ambient conditions. While they are somewhat noxious chemicals, they are useful in applications where the rocket must be in a near ready-to-fire condition over an extended period of time, as in the case of long-range ballistic missiles.

Predominance of bipropellant systems

Liquid hydrogen is usually the best fuel from the standpoint of high exhaust velocity, and it might be used exclusively were it not for the cryogenic requirement and its low density. Such hydrocarbon fuels as alcohol and kerosene are often preferred because they are liquid under ambient conditions and denser than liquid hydrogen in addition to being more "concentrated" fuels (*i.e.,* they have more fuel atoms in each molecule). The values of exhaust velocity are determined by the relative effects of higher flame (combustion) temperatures and molecular weights of reaction products (as compared to liquid oxygen and liquid hydrogen).

Hydrocarbon fuels

In practice, a variety of choices of propellant systems have been made in major systems, as shown in Table 2. In flights where cryogenic propellants can be utilized (*e.g.,* ground-to-earth-orbit propulsion), liquid oxygen is usually

Table 2: Liquid Propellants in Various Flight Vehicles

rocket	oxidizer	fuel
German V-2	liquid oxygen	ethyl alcohol–water (75%–25%)
Atlas ICBM	liquid oxygen	RP-1 (kerosene)
Delta		
First stage	liquid oxygen	RP-1 (kerosene)
Second stage	nitrogen tetroxide	hydrazine–UDMH* (50%–50%)
Saturn		
First stage	liquid oxygen	RP-1 (kerosene)
Second stage	liquid oxygen	liquid hydrogen
Third stage	liquid oxygen	liquid hydrogen
Apollo Lunar Module	nitrogen tetroxide	hydrazine–UDMH* (50%–50%)
Space Shuttle		
Main engines	liquid oxygen	liquid hydrogen
Orbital Maneuvering System	nitrogen tetroxide	monomethyl hydrazine
Ariane 4, first stage	nitrogen tetroxide	UDMH*
Energia, first stage		
Core	liquid oxygen	liquid hydrogen
Cluster	liquid oxygen	kerosene

*Unsymmetrical dimethylhydrazine.

used as the oxidizer. In first stages either a hydrocarbon or liquid hydrogen is employed, while the latter is usually adopted for second stages. In ICBMs and other similar guided missiles that must stand ready for launch on short notice, noncryogenic (or "storable") propellant systems are used, as, for instance, an oxidizer–fuel mixture of nitrogen tetroxide and hydrazine–unsymmetrical dimethylhydrazine (also designated UDMH; $[CH_3]_2\ NNH_2$). Systems of this sort also find application on longer duration flights such as those involving the Space Shuttle Orbital Maneuvering System and the Apollo Lunar Module. Solid motors have proved useful on long-duration flights, but liquid systems are often preferred because of the need for stop–start capability or thrust control.

Possible use of energy sources independent of the propellant fluid

Other systems. As suggested earlier, systems using energy sources independent of the propellant fluid have been studied, and they offer promise for some future missions. In certain systems the propellant is heated at elevated pressure by independent means and then accelerated by exhaust through a nozzle. In others the propellant is accelerated by electromagnetic means, in which case at least part of the fluid must be electrically charged first. In these systems the energy source may be nuclear, solar, or beamed energy from an independent source. The outlook for most current missions is that on-board energy sources of this kind would be too heavy, especially for high-thrust missions. There are, however, missions such as manned flights to other planets where sustained low thrust from on-board energy sources would shorten mission duration greatly, saving both time and consumable materials. Such a mission would very likely originate from Earth orbit, with flight system and on-board materials being transported to Earth orbit by chemical rocket propulsion. Electrically heated fluids would probably be used in missions involving manned space stations, where low-thrust capability is needed to control orbit and station attitude. Consideration is even being given to the use of waste products as propellants; these could be heated electrically from power systems already on board for station operational needs.

Use of black powder as a propellant

Development of rockets. The technology of rocket propulsion appears to have its origins in the period AD 1200–1300 in Asia, where the first "propellant" (a mixture of saltpetre, sulfur, and charcoal called black powder) had been in use for about 1,000 years for other purposes. As is so often the case with the development of technology, the early uses were primarily military. Powered by black powder charges, rockets served as bombardment weapons, culminating in effectiveness with the Congreve rockets (named for William Congreve, a British officer who was instrumental in their development) of the early 1800s. Performance of these early rockets was poor by modern standards because the only available propellant was black powder, which is not ideal for propulsion. Military use of rockets declined from 1815 to 1936 because of the superior performance of guns.

During the period 1880–1930 the idea of using rockets for space travel grew in public interest. Stimulated by the conceptions of such fiction writers as Jules Verne, the Russian scientist Konstantin E. Tsiolkovsky worked on theoretical problems of propulsion-system design and rocket motion and on the concept of multistage rockets. Perhaps more widely recognized are the contributions of Robert H. Goddard, an American scientist and inventor who from 1908 to 1945 conducted a wide array of rocket experiments. He independently developed ideas similar to those of Tsiolkovsky about spaceflight and propulsion and implemented them, building liquid- and solid-propellant rockets. His developmental work included tests of the world's first liquid-propellant rocket in 1926. Goddard's many contributions to the theory and design of rockets earned him the title of father of modern rocketry. A third pioneer, Hermann Oberth of Germany, developed much of the modern theory for rocket and spaceflight independent of Tsiolkovsky and Goddard. He not only provided inspiration for visionaries of spaceflight but played a pivotal role in advancing the practical application of rocket propulsion that led to the development of rockets in Germany during the 1930s.

The contributions of Tsiolkovsky, Goddard, and Oberth

Due to the work of these early pioneers and a host of rocket experimenters, the potential of rocket propulsion was at least vaguely perceived prior to World War II, but there were many technical barriers to overcome. Development was accelerated during the late 1930s and particularly during the war years. The most notable achievements in rocket propulsion of this era were the German liquid-propellant V-2 rocket and the Me-163 rocket-powered airplane. (Similar developments were under way in other countries but did not see service during the war.) A myriad of solid-propellant rocket weapons also were produced, and tens of millions were fired during combat operations by German, British, and U.S. forces (see WAR, THE TECHNOLOGY OF: *Rockets and missile systems*). The main advances in propulsion that were involved in the wartime technology were the development of pumps, injectors, and cooling systems for liquid-propellant engines and high-energy solid propellants that could be formed into large pieces with reliable burning characteristics.

From 1945 to 1955 propulsion development was still largely determined by military applications. Liquid-propellant engines were refined for use in supersonic research aircraft, intercontinental ballistic missiles (ICBMs), and high-altitude research rockets. Similarly, developments in solid-propellant motors were in the areas of military tactical rocket applications and high-altitude research. Bombardment rockets, aircraft interceptors, antitank weapons, and air-launched rockets for air and surface targets were among the primary tactical applications. Technological advances in propulsion included the perfection of methods for casting solid-propellant charges, development of more energetic solid propellants, introduction of new structural and insulation materials in both liquid and solid systems, manufacturing methods for larger motors and engines, and improvements in peripheral hardware (*e.g.*, pumps, valves, engine-cooling systems, and direction controls). By 1955 most missions called for some form of guidance, and larger rockets generally employed two stages. While the potential for spaceflight was present and contemplated at the time, financial resources were directed primarily toward military applications.

The next decade witnessed the development of large solid-propellant rocket motors for use in ICBMs, a choice motivated by the perceived need to have such systems in ready-to-launch condition for long periods of time. This resulted in a major effort to improve manufacturing capabilities for large motors, lightweight cases, energetic propellants, insulation materials that could survive long operational times, and thrust-direction control. Enhancement of these capabilities led to a growing role for solid-rocket motors in spaceflight. Between 1955 and 1965 the vision of the early pioneers began to be realized with the achievement of Earth-orbiting satellites and manned spaceflight. The early missions were accomplished with liquid-propulsion systems adapted from military rockets. The first successful "all-civilian" system was the Saturn launch vehicle for the Apollo Moon-landing program, which used five 680,000-kilogram-thrust liquid-propellant engines in the first stage. Since then, liquid systems have been employed by most countries for spaceflight applications, though solid boost-

ers have been combined with liquid engines in various first stages of U.S. launch vehicles (those of the Titan 34D, Delta, and Space Shuttle) and solid-rocket motors have been used for several systems for transfer from low Earth orbit to geosynchronous orbit. In such systems, the lower performance of solid-propellant motors is accepted in exchange for the operational simplicity that it provides.

Since 1965, missions have drawn on an ever-expanding technology base, using improved propellants, structural materials, and designs. Present-day missions may involve a combination of several kinds of engines and motors, each chosen according to its function. Because of the performance advantages of energetic propellants and low structural mass, propulsion systems are operated near their safe limits, and one major challenge is to achieve reliability commensurate with the value of the (sometimes human) payload. (E.W.P.)

Nuclear fission reactors

A nuclear reactor is a device in which a nuclear fission chain reaction takes place under controlled conditions. Such devices are used as research tools, as systems for producing radioisotopes, and most prominently as energy sources. The latter are commonly called power reactors.

Fission is the process in which a heavy nucleus splits into two smaller fragments. A large amount of energy is released in this process, and this energy is the basis of fission power systems. The nuclear fragments are in very excited states and emit neutrons and other forms of radiation. The neutrons can then cause new fissions, which in turn yield more neutrons, and so forth. Such a continuous self-sustaining series of fissions constitutes a fission chain reaction. For a detailed discussion of nuclear fission, see ATOMS: *Fundamentals of the fission process.*

In an atomic bomb the chain reaction is designed to increase in intensity until much of the material has fissioned. This increase is very rapid and produces the extremely sharp, tremendously energetic explosions characteristic of such bombs. In a nuclear reactor the chain reaction is maintained at a controlled, nearly constant level. Nuclear reactors are so designed that they cannot explode like atomic bombs.

Energy release

Most of the energy of fission—about 85 percent of it—is released within a very short time after the process occurs. The rest of the energy comes from the radioactive decay of fission products, which is what the fragments are called after they have emitted neutrons. Radioactive decay continues when the fission chain has been stopped, and its energy must be dealt with in any proper reactor design.

PRINCIPLES OF OPERATION

Chain reaction and criticality. The course of a chain reaction is determined by the probability that a neutron released in fission will cause a subsequent fission. If on the average less than one neutron causes another fission, the rate of fission will decrease with time and ultimately drop to zero. This situation is called subcritical. When an average of one neutron from a fission causes another fission, the fission rate is steady and the reactor is critical. A critical reactor is what is usually desired. When more than one neutron causes a subsequent fission, fission rate and power increase and the situation is termed supercritical. In order to be able to increase power, reactors are designed to be slightly supercritical when all controls are removed.

Reactivity

Reactor control. A parameter called reactivity is positive when a reactor is supercritical, zero at criticality, and negative when the reactor is subcritical. Reactivity can be controlled in various ways: by adding or removing fuel; by changing the fraction of neutrons that leaks from the system; or by changing the amount of an absorber that competes with the fuel for neutrons. Control is generally accomplished by varying absorbers, which are commonly in the form of movable elements—control rods—or sometimes by changing the concentration of the absorber in a reactor coolant. Leakage changes are usually automatic; for example, an increase of power may cause coolant to boil (see below), which in turn increases neutron leakage and reduces reactivity. This, and other types of negative power-reactivity feedbacks, are vital aspects of safe reactor design.

Reactor control is facilitated by the presence of delayed neutrons. These neutrons are emitted by fission products some time after fission has occurred. The fraction of delayed neutrons is small, but there is a sufficient number of such neutrons for the types of changes needed to regulate an operating reactor, and so the chain reaction must "wait" for them before it can respond. This eases operation considerably.

Fissile and fertile materials. All heavy nuclides can fission if they are in an excited enough state, but only a few fission readily when struck by slow (low-energy) neutrons. Such species of atoms are called fissile. The most important of these are uranium-233 (^{233}U), uranium-235 (^{235}U), plutonium-239 (^{239}Pu), and plutonium-241 (^{241}Pu). The only one that occurs in usable amounts in nature is uranium-235, which makes up a mere 0.711 percent of natural uranium by weight. Uranium-233 can be produced by neutron capture in natural thorium (^{232}Th); that is to say, when a nucleus of thorium-232 absorbs a neutron, it becomes uranium-233. Similarly, plutonium-239 is created by neutron capture in uranium-238 (^{238}U; the principal constituent of naturally occurring uranium), and plutonium-241 is formed when a neutron is absorbed into plutonium-240 (^{240}Pu). Plutonium-240 builds up over time in most power reactors. Thorium-232, uranium-238, and plutonium-240 are termed fertile materials because they can be transformed into fissile materials.

A power reactor contains both fissile and fertile materials. The fertile materials replace fissile materials that are destroyed by fission. This permits the reactor to run longer before the amount of fissile material decreases to the point where criticality can no longer be maintained.

Heat removal. The energy of fission is quickly converted to heat, the bulk of which is deposited in the fuel. A coolant is therefore required to remove this heat. The most common coolant is water, but any fluid can be used. Heavy water (deuterium oxide), air, carbon dioxide, helium, liquid sodium, sodium-potassium alloy (called NaK), molten salts, and hydrocarbons have all been used in reactors or reactor experiments. Some research reactors are operated at very low power and have no need for a dedicated cooling system; in such units the small amount of heat that is generated is removed by conduction and convection to the environment. Very high power reactors must have extremely sophisticated cooling systems to remove heat quickly and reliably; otherwise, the heat will build up in the reactor fuel and melt it.

Coolant

Shielding. An operating reactor is a powerful source of radiation, since fission and subsequent radioactive decay produce neutrons and gamma rays, both of which are highly penetrating radiations. A reactor must have special shielding around it to absorb this radiation in order to protect technicians and other reactor personnel. In a popular class of research reactors known as "swimming pools," this shielding is provided by placing the reactor in a large, deep pool of water. In other kinds of reactors, the shield consists of a thick concrete structure around the reactor system. The shield also may contain heavy metals, such as lead or steel, for more effective absorption of gamma rays, and heavy aggregates may be used in the concrete itself for the same purpose.

Critical concentration and size. Not every arrangement of material containing fissile fuel can be brought to criticality. Even if there were no leakage of neutrons from a reactor, a critical concentration of fissile material must be present. Otherwise, absorption of neutrons by other constituents of the reactor will be too high to permit a critical chain reaction to proceed. Similarly, even if there is a high enough concentration for criticality, the reactor must be large enough so that not too many neutrons leak out before being absorbed. This imposes a critical size limit on a reactor of a given concentration.

Although the only useful fissile material in nature, uranium-235, is found in natural uranium, there are just a few combinations and arrangements of this and other materials that can be brought to criticality. To increase the range of feasible reactor designs, enriched uranium can

Use of enriched uranium fuel

be used. Most of today's power reactors employ enriched uranium fuel in which the percentage of uranium-235 has been increased to 3 to 4 percent. This is about five times the concentration in natural uranium. Large plants for enriching uranium exist in several countries; enrichment has now become a commercial enterprise (see below).

Thermal, intermediate, and fast reactors. Reactors are conveniently classified according to the typical energies of the neutrons that cause fission. Neutrons emanating in fission are very energetic; their average energy is around two million electron volts (MeV), 80 million times higher than the energy of atoms in ordinary matter at room temperature. As the neutrons collide with nuclei in a reactor, they lose energy. The choice of reactor materials and of fissile material concentrations determines how much they are slowed down by these collisions before causing fission.

In a thermal reactor, enough collisions are permitted to occur so that most of the neutrons reach thermal equilibrium with the atoms of the reactor at energies of a few hundredths of an electron volt. Neutrons lose energy most efficiently by colliding with light atoms such as hydrogen (mass 1), deuterium (mass 2), beryllium (mass 9), and carbon (mass 12). Materials that contain atoms of this kind—water, heavy water, beryllium metal and oxide, and graphite—are deliberately incorporated into the reactor for this reason and are known as moderators. Since water and heavy water also can function as coolants, they can do double duty in thermal reactors.

Moderators

One disadvantage of thermal reactors is that at low energies uranium-235 and plutonium-239 not only can be fissioned by thermal (or slow) neutrons but also can capture neutrons without undergoing fission. This destroys fissile atoms without any fission to show for it. When neutrons of higher energy cause fission, fewer of these captures occur. To achieve this, a reactor can be built to operate without a moderator. Then, depending on how many collisions take place with heavier atoms before fission occurs, the typical fission-causing neutrons can have energies in the range of 0.5 electron volt to thousands of electron volts (intermediate reactors) or several hundred thousand electron volts (fast reactors). Such reactors require higher concentrations of fissile material to reach criticality than do thermal reactors but are more efficient at converting fertile material to fissile material. Indeed, they can be designed to produce more than one new fissile atom for each fissile atom destroyed. Such reactors are called breeders. Breeder reactors may become particularly important if the world demand for nuclear power turns out to be a long-term one, since their fuel is manufactured from very abundant fertile materials.

Breeder reactors

REACTOR DESIGN AND COMPONENTS

There are a large number of ways in which a reactor may be designed and constructed, and many types have been experimentally realized. Over the years, nuclear engineers have developed reactors with solid fuels and liquid fuels, thick reflectors and no reflectors, forced cooling circuits and natural conduction or convection heat-removal systems, and so on. Most reactors, however, have certain basic components. These are described below.

Core. All reactors have a core, a central region that contains the fuel, fuel cladding, coolant, and, where separate from the latter, moderator. It is in the core that fission occurs and the resulting neutrons migrate.

Fuel elements

The fuel is usually heterogeneous—*i.e.*, it consists of elements containing fissile material along with a diluent. This diluting agent may be fertile material or simply material that has good mechanical and chemical properties and that does not readily absorb neutrons. The diluted fissile material is enclosed in a cladding—a substance that isolates the fuel from the coolant and keeps the radioactive fission products contained.

Fuel types. Different kinds of reactors use different types of fuel elements. For example, the light-water reactor (LWR), which is the most widely used variety for commercial power generation in the United States, employs a fuel consisting of pellets of sintered uranium dioxide loaded into cladding tubes of zirconium alloy that measure about one centimetre in diameter and roughly three to four metres long. These tubes, called pins, are bundled together into a fuel assembly, with the pins arranged in a square lattice. The uranium used in the fuel is 3- to 4-percent enriched. Since light (ordinary) water tends to absorb more neutrons than do other moderators, such enrichment is crucial. The CANDU (Canadian deuterium-uranium) reactor, which is the principal type of heavy-water reactor, uses natural uranium compacted into pellets. These pellets are inserted in tubes arranged in a lattice. Such a fuel assembly measures about one metre in length, and several assemblies are arranged end-to-end within a channel inside the reactor core.

In a high-temperature graphite reactor the fuel is made of small spherical particles containing uranium dioxide at the centre with concentric shells of carbon, silicon carbide, and carbon around them. (These shells serve as microscopic cladding.) The particles are mixed with graphite and encased in a macroscopic graphite cladding. In a sodium-cooled fast reactor, commonly called a liquid-metal reactor (LMR), the fuel consists of dioxide pellets (French design) or uranium-plutonium-zirconium metal alloy pins (U.S. design) in steel cladding.

The most common type of fuel used in research reactors consists of plates of a uranium-aluminum alloy with an aluminum cladding. The uranium is enriched to 20 percent, and silicon, along with aluminum, are included in the "meat" of the plate. A common variety of research reactor, known as TRIGA (from training, research, and isotope-production reactors–General Atomic), employs a fuel of mixed uranium and zirconium hydride in zirconium cladding.

Coolants and moderators. A variety of substances, including light water, heavy water, air, carbon dioxide, helium, liquid sodium, liquid sodium-potassium alloy, and hydrocarbons (oils), have been used as coolants. Such substances are good conductors of heat and serve to carry the thermal energy produced by fission from the core to the steam-generating equipment of the nuclear power plant.

In many cases, the same substance functions as both coolant and moderator, as in the case of light and heavy water. The moderator slows down the fast (high-energy) neutrons emitted in fission to speeds at which they are more likely to induce fission. In doing so, the moderator helps initiate and sustain a fission chain reaction.

Reflector. A reflector is a region of unfueled material surrounding the core. Its function is to scatter neutrons that leak from the core and thereby return some of them to the core. This reduces core size and smooths out the power density. The reflector is particularly important in research reactors, since it is the region in which much of the experimental apparatus is located. Some reflectors are located inside the core as central islands in which high neutron intensities can be achieved for experimental purposes. In most types of power reactors, a reflector is less important, because the reactors are large and do not leak many neutrons. Yet, as it serves to keep the power density uniform, such an unfueled zone of moderator material is left around the core. The liquid-metal reactor represents a special case. Most sodium-cooled reactors are deliberately built to allow a large fraction of their neutrons—those not needed to maintain the chain reaction—to leak from the core. These neutrons are valuable because they can produce new fissile material if they are absorbed by fertile material. Thus, fertile material—generally depleted uranium or its dioxide—is placed around the core to catch the leaking neutrons. Such an absorbing reflector is referred to as a blanket or a breeding blanket.

Reducing the leakage of neutrons

Reactor control elements. All reactors need special elements for control. Although control can be achieved by varying parameters of the coolant circuit or by varying the amount of absorber dissolved in the coolant or moderator, by far the most common method involves the use of special absorbing assemblies—namely, control rods or sometimes blades. Typically a reactor is equipped with three types of rods for different purposes: (1) safety rods for starting up and shutting down the reactor, (2) regulating rods for adjusting the reactor's power rate, and (3) shim rods for compensating for changes in reactivity as fuel is depleted by fission and capture.

Control rods

The most important function of the safety rods is to shut down the reactor, either when such a shutdown is scheduled or in case of a real or suspected emergency. These rods contain enough absorber to terminate a chain reaction under any conceivable condition. They are withdrawn before fuel is loaded and remain available in case a loading error requires their action. After the fuel is loaded, the rods are inserted, to be withdrawn again when the reactor is ready for operation. The mechanism by which they are moved is designed to be fail-safe in the sense that if there is a mechanical failure the safety rods will fall by gravity into the reactor. In some cases, moreover, the safety rods have an automatic feature, such as a fuse, which releases them by virtue of physical effects independent of electronic signals.

Regulating rods are deliberately designed to affect reactivity only by a small degree. It is assumed that at some time the rods might be totally withdrawn by mistake, and the idea is to keep the added reactivity in such cases well within sensible limits. A well-designed regulating rod will add so little reactivity when it is removed that the delayed neutrons will continue to control the rate of power increase.

Shim rods are designed to compensate for the effects of burnup (*i.e.,* energy production). Reactivity changes resulting from burnup can be large, but they occur slowly over periods of days to years, as compared to the seconds-to-minutes range over which safety actions and routine regulation take place. Therefore, shim rods may control a significant amount of reactivity, but they will work perfectly well under constraints on their speed of movement. A common way in which shims are operated is by inserting or removing them as regulating rods reach the end of their most useful position range. When this happens, shim rods are moved so that the regulating rods can be reset.

The functions of shim and safety rods are sometimes combined in rods that have low rates of withdrawal but that can be rapidly inserted. This is usually done when the effect of burnup is to decrease reactivity. The rods are only partially inserted at the outset of operation, but the reactor can be quickly shut down by lowering them all the way into the core (scramming). As operation proceeds, the rods are moved farther out so that there is a greater shutdown reactivity margin.

The amount of shim control required can be reduced by the use of a burnable "poison." This is a neutron-absorbing material, such as boron or gadolinium, which will burn off faster than the fissile material does. At the beginning of operation, this controls the extra reactivity that has been built into the fuel to compensate for the amount of fuel consumed. At the end of an operating period, the absorber material will have been almost completely destroyed by neutron capture.

Structural components. These are the parts of a reactor system that hold the reactor together and permit it to function as a useful energy source. The most important structural component is usually the reactor vessel. In both the light-water reactor and the high-temperature gas-controlled reactor (HTGR), a pressure vessel is used so that the coolant can be contained and operated under conditions appropriate for power generation—namely, high temperature and pressure. Within the reactor vessel are structural grids for holding the reactor core and solid reflectors; coolant channels; control-rod guide channels; internal thermohydraulic components (*e.g.,* pumps or steam circulators) in some cases; instrument tubes; and parts of safety systems.

Pressure vessel

Coolant system. The function of a power reactor installation is to extract the heat of nuclear fission and convert it to useful power, generally electricity. The coolant system plays a pivotal role in performing this function. A coolant fluid enters the core at low temperature and leaves it at higher temperature. This higher temperature fluid is then directed to conventional thermodynamic components where the heat is converted into electrical power. In most light-water, heavy-water, and gas-cooled power reactors, the coolant is maintained at high pressure. Sodium and organic coolants operate at atmospheric pressure.

Research reactors have very simple heat removal systems in which coolant is run through the reactor and the heat that is removed is transferred to ambient air or to water without going through a power cycle. In research reactors of the lowest power running at only a few kilowatts, this may involve simple heat exchange to tap water or to a pool of water cooled with ambient air. During operation at higher power levels, the heat is usually removed by means of a small natural-draft cooling tower.

Containment system. Reactors are designed with the expectation that they will operate safely without releasing radioactivity to their surroundings. It is, however, recognized that accidents can occur. An approach using multiple barriers has been adopted to deal with such accidents. These barriers are, successively, the fuel cladding, primary vessel, and thick shielding. As a final barrier, the reactor is housed in a containment structure. This consists basically of the reactor building, which is designed and tested to prevent any radioactivity that escapes from the reactor from being released to the environment. As a consequence, the containment structure must be at least nominally airtight. In practice, it must be able to maintain its integrity under circumstances of a drastic nature, such as accidents in which most of the contents of the reactor core are released to the building. It has to withstand pressure buildups and damage from debris propelled by an explosion within the reactor, and it must pass a test to demonstrate that it will not leak more than a small fraction of its contents over a period of several days, even when its internal pressure is well above that of the surrounding air. The most common form of containment building is a cylindrical structure with a spherical dome, which is characteristic of LWR systems. This is much more typical of nuclear plants than the large cooling tower that is often used as a symbol for nuclear power. (It should be noted that cooling towers are found at large modern coal- and oil-fired power stations as well.)

Reactors other than those of the LWR type also have containment structures, but they vary in shape and construction. When it can be justified that major pressure buildups are not to be expected, the containment can be any form of airtight structure. In the United States, containment structures are required for all commercial power reactors and all high-power research reactors. In general, low-power research reactors are exempt, based on the common assumption that an accident in such systems will not lead to a widespread release of radioactivity. Reactors operated by the U.S. Department of Energy and by the armed services also are exempt, a matter which has caused considerable controversy. Some of these have containment structures, while others do not.

Relative integrity of containment

The concept of containment originated in the United States during the 1950s and has been generally accepted throughout much of the world. The Soviet bloc countries, however, did not concur with this view, and when containment was provided it was generally not up to Western standards. For example, Chernobyl Unit 4, which suffered a catastrophic explosive accident and fire in 1986, merely had an internal structure that could only withstand the loss of function of a single pressure tube. Though called containment, this was a misnomer by Western standards.

The most severe test of a containment system occurred during an accident in the United States in 1979 at Three Mile Island Unit 2, near Harrisburg, Pa. In this installation, a stoppage of core cooling resulted in the destruction, including partial melting, of the entire core and the release of a large part of its radioactivity to the enclosure around the reactor. In spite of a hydrogen deflagration that also occurred during the accident, the containment structure prevented all but a very small amount of radioactivity from entering the environment and must be credited with having prevented a major radioactive release and its consequences.

TYPES OF REACTORS

Most of the world's existing reactors are power reactors. There also are many research reactors, and the navies of many nations include submarines and surface ships driven by propulsion reactors. There are several types of power reactors, but only one, the light-water reactor, is widely

used. Accordingly, this variety is discussed in considerable detail here. Other significant types are briefly described, as are research and propulsion reactors. Some attention is also given to the prospective uses of reactors for space travel and for certain industrial purposes.

Power reactors. *Light-water reactor.* As noted above, LWRs are power reactors that are cooled and moderated with ordinary water. There are two basic types: the pressurized-water reactor (PWR) and the boiling-water reactor (BWR). In the first type, high-pressure, high-temperature water removes heat from the core and is then passed to a steam generator. Here the heat of the coolant is transferred to a stream of water in the generator (the secondary loop in Figure 41B), causing the water to boil and slightly superheat. The steam generated by this serves as the working fluid in a steam-turbine cycle (see *Steam turbines* above).

Pressurized-water reactor and boiling-water reactor

In a boiling-water reactor, water passing through the core is allowed to boil at intermediate pressure, and the steam from the reactor is used directly in the power cycle (see Figure 41A). Although the BWR seems simpler, the PWR has advantages with regard to fuel utilization and power density, and the two concepts have been economically competitive with each other since the 1960s. Both these light-water reactors are fueled with uranium dioxide pellets in zirconium alloy cladding (see above). The BWR fuel is slightly less enriched, but the PWR fuel produces more energy before being discharged, and so these two aspects balance each other out economically. Because the BWR operates at lower pressure, it has a thinner pressure vessel than the PWR; however, because its power density is somewhat lower, the BWR's vessel has a larger diameter for the same reactor power. The internal system of a BWR is more complex, since there are internal recirculation pumps and complex steam separation and drying equipment within its vessel. Though the internals of the PWR are simpler, a BWR power plant is smaller because it has no steam generators. In fact, the steam generators—there are usually four of them in a big PWR plant—are larger than the reactor vessel itself. The control rods of a typical PWR are inserted from the top (through the reactor head), while those of a BWR are inserted from the bottom.

Refueling operation

Light-water reactors are refueled by removing the reactor head—after lowering and unlatching the safety rods in the case of a PWR. This exposes the reactor to visual observation. The pressure vessel is filled to the top with water, and, since the core is near the bottom of the vessel, the water acts as a shield for this operation. Then, the fuel assemblies to be removed are lifted up into a shielded cask within which they are transferred to a storage pool for cooling while they are still highly radioactive. Many of the remaining assemblies are then shifted within the core, and finally fresh fuel is loaded into the empty fuel positions. The purpose of shifting fuel at the time of reload is to achieve an optimal reactivity and power distribution for the next cycle of operation. Reloading is a time-consuming operation. In principle, it could be accomplished in three weeks, but in practice the plant undergoes maintenance during reload, which can take considerably more time—up to a few months. Utilities schedule maintenance and reload during the spring and fall when electricity demand is lowest and the system usually has reserve capacity.

Storage pools for spent fuel

The discharged fuel stored in the storage pool is not only highly radioactive but also continues to produce energy. This energy is removed by natural circulation of the water in the storage pool. Originally it was expected that this spent fuel could be shipped out for reprocessing within two years, but this option is currently practiced only in France. In the United States, storage pools have continued to receive spent fuel, and some of the pools are filling up. Options available to nuclear plant operators are to store the spent fuel more densely than originally planned, to build new pools, or to store the oldest, no longer very hot fuel in above-ground silos (dry storage). Ultimately this fuel will be transferred to the U.S. Department of Energy for reprocessing or waste disposal or both, but this may not happen until the year 2003 or perhaps later if a viable disposal program is not established.

During the 1970s light-water reactors represented the cheapest source of new electricity in most parts of the world, and it still is economical in Japan, Korea, Taiwan, and France and many other European countries. In the United States, however, strict regulation of light-water reactors during the 1980s, coupled with a decrease in reactor research and development activity, have made

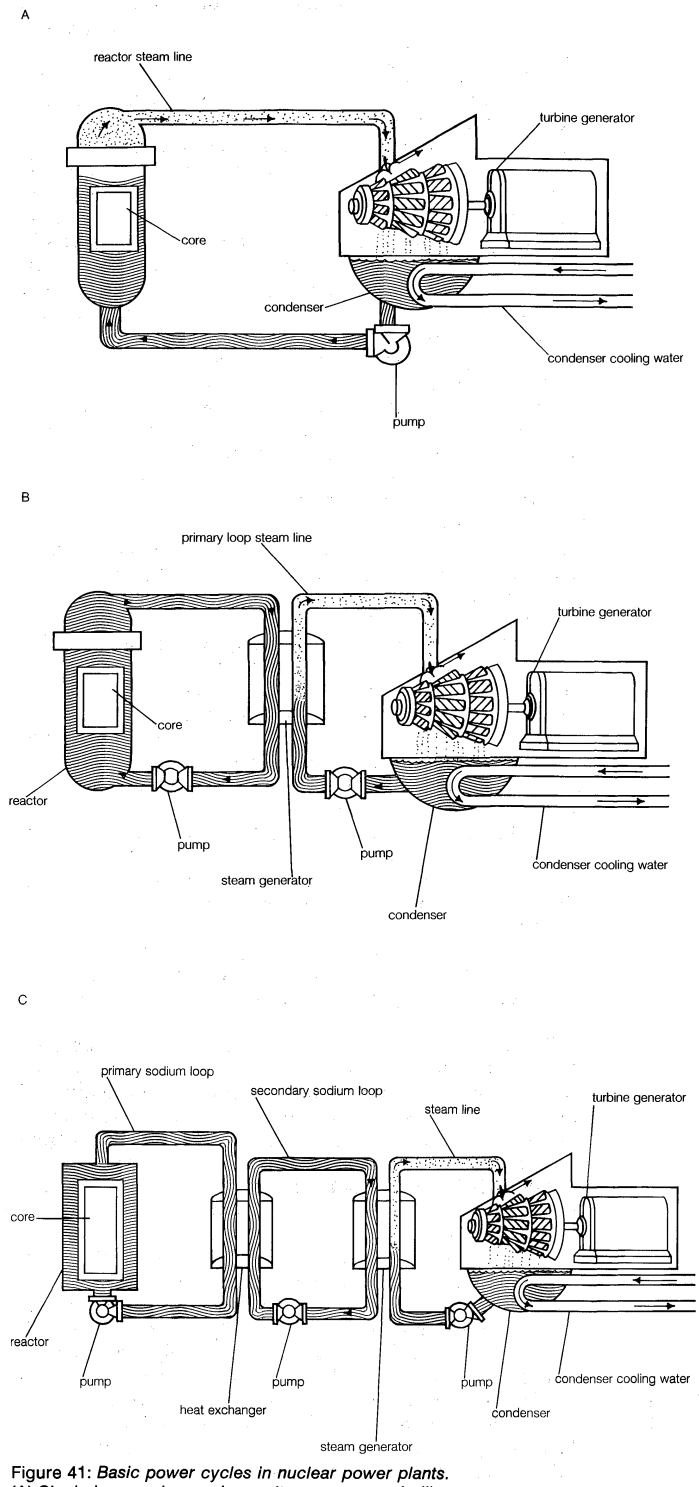

Figure 41: *Basic power cycles in nuclear power plants.* (A) Single-loop cycle; as shown, it represents a boiling-water reactor (BWR), but it could also represent a direct-cycle, high-temperature gas-cooled reactor (HTGR) if the word helium were substituted for the word steam. (B) Two-loop cycle; the primary loop depicted here could constitute a pressurized-water reactor (PWR), a CANDU pressurized heavy-water reactor (PHWR), or a helium HTGR. (C) Three-loop cycle; this is found only in sodium-cooled reactors where an intermediate loop of nonradioactive sodium is provided between the radioactive primary loop and the steam generator.

From the U.S. Department of Energy in R.A. Knief, *Nuclear Energy Technology* (1981), McGraw-Hill, Inc.

the competitive nature of new light-water reactor installations problematic. Plants that have been exceptionally well managed during construction and operation remain competitive; unfortunately, these are not the rule. New designs, developed abroad, may alter this situation, however.

Most recent light-water reactors have had electric capacity ratings of 1,000 megawatts or more. These are not very suitable for the utility industry, which has had only a slow growth in base-load demand since about 1975. Therefore, as of 1989, advanced light-water reactors in the 600-megawatt capacity range were also being considered.

High-temperature gas-cooled reactor. The HTGR, as mentioned above, is fueled with a mixture of graphite and fuel-bearing microspheres. There are two competitive designs of this reactor type: (1) a German system that uses spherical fuel elements of tennis-ball size loaded into a graphite silo and (2) an American version in which the fuel is loaded into precisely located graphite hexagonal prisms. In both variants, the coolant consists of helium pressurized to about 100 bars. In the German system the helium passes through interstices in the bed of the spherical fuel elements, while in the American system it passes through holes in the graphite prisms. Both are capable of operating at very high temperature, since graphite has an extremely high sublimation temperature and helium is completely inert chemically. The hot helium can be used directly as the working fluid in a high-temperature gas turbine, or its heat can be utilized to generate steam for a water cycle. Experimental prototypes of both the American and German designs have been built, but no commercial plants were on order as of 1989.

Sodium-cooled systems

Liquid-metal reactors. Sodium-cooled, fast-neutron-spectrum reactors received much attention during the 1960s and '70s when it appeared that their breeding capabilities would soon be needed to supply fissile material to a rapidly expanding nuclear industry. When it became clear in the 1980s that this was not a realistic expectation, enthusiasm slackened. The developmental work of the previous decades, however, resulted in the construction of a number of liquid-metal reactors around the world—in the United States, the Soviet Union, France, Britain, Japan, and Germany. Most liquid-metal reactors are fueled with uranium dioxide or mixed uranium–plutonium dioxides. In the United States, however, the greatest success has been with metal fuels. While some liquid-metal reactors are of the loop type, equipped with heat exchangers and pumps outside the primary reactor vessel, others are of the pool variety featuring a large volume of primary sodium in a pool that also contains the primary pumps and primary-to-secondary heat exchanger. In all types, the heat extracted from the core by primary sodium is transferred to a secondary, nonradioactive sodium loop, which serves as the heat source for a steam generator and turbine. The pool type seems to have some advantage in terms of safety in that the large volume of primary sodium heats up only slowly even if no power is extracted; thus, the reactor is effectively isolated from upsets in the balance of the plant. The reactor core in all such systems is a tightly packed bundle of fuel in steel cladding through which the sodium coolant flows to extract the heat. Most liquid-metal reactors are breeders or are capable of breeding, which is to say that they all produce more fissile material than they consume.

Natural uranium fuel

CANDU reactor. Canada focused its developmental efforts on reactors that would utilize abundant domestic natural uranium as fuel without having to resort to enrichment services that could be supplied only by other countries. The result of this policy was CANDU—the line of natural uranium-fueled reactors moderated and cooled by heavy water. A reactor of this kind consists of a tank, or calandria vessel, containing cold heavy water at normal pressure. The calandria is pierced by pressure tubes made of zirconium alloy, in which the natural uranium fuel is placed and the heavy water coolant is circulated. Power is obtained by transferring the heat from the exiting hot pressurized heavy water to a steam generator and then running the steam from the latter through a conventional turbine cycle. The fuel assembly of a CANDU reactor, which consists of a bundle of short zirconium alloy-clad tubes containing natural uranium dioxide pellets, can be changed while the system is running. A new assembly is simply pushed into one end of a pressure tube and the old one collected as it drops out at the other end. This feature has given the CANDU higher capacity factors than other reactor types. Several countries have purchased CANDU reactors for the same reason that they were developed by Canada—to be independent of imported enrichment services.

Advanced gas-cooled reactor. The advanced gas-cooled reactor (AGR) was developed in Britain as the successor to reactors of the Calder Hall class, which combined plutonium production and power generation. Calder Hall was the first nuclear station to feed an appreciable amount of power into a civilian network. It was fueled with slugs of natural uranium metal canned in aluminum, cooled with carbon dioxide, and employed a moderator consisting of a block of graphite pierced by fuel channels. In the advanced gas-cooled reactor, fuel pins clad in Zircaloy (trademark for alloys of zirconium having low percentages of chromium, nickel, iron, and tin) and loaded with 2-percent enriched uranium dioxide are placed into zirconium-alloy channels that pierce a graphite moderator block. The enriched fuel permits operation to economic levels of fuel burnup. A coolant of carbon dioxide transports heat to a steam generator, activating a steam-turbine cycle. Although a number of advanced gas-cooled reactors have been built in Britain, they have been less trouble-free and more costly than expected, and no new ones are planned.

Other power reactor types. A large variety of reactor types have been built and operated on an experimental basis. A few examples include organic liquid-cooled and -moderated reactors that can operate like a pressurized-water reactor without requiring high pressures in the primary circuit; sodium-cooled, graphite-moderated reactors; and heavy-water reactors built in a pressure-vessel design.

Research reactors. *Water-cooled, plate-fuel reactor.* This is the most common type of research reactor. It uses enriched uranium fuel in plate assemblies (see above) and is cooled with water. Water-cooled, plate-fuel reactors operate over a wide range of thermal power levels, from a few kilowatts to hundreds of megawatts. The systems with the lowest power ratings are usually operated at universities and used primarily for teaching, while those with the highest are used by major research laboratories chiefly for materials testing and research.

Pool-type reactors

A common form of the water-cooled, plate-fuel reactor is the pool reactor, in which the reactor core is positioned at the bottom of a large, deep pool of water. This has the advantage of simplifying both observation and the placement of channels from which beams of neutrons can be extracted. At lower thermal power levels, no pumping is required and the cooling water circulates by natural convection. A heat exchanger is usually located at the top of the pool, where the hottest water is stratified. At higher operating power levels, pumping becomes necessary to augment the natural circulation.

Most pool reactors use the water of the pool as a reflector (see above), but some have blocks of a solid moderator (canned graphite or beryllium metal) around the core that serves as an inner reflector. Graphite and beryllium create a large peak in slow neutron intensity a short distance from the core, which is an advantage when beams of slow neutrons are to be extracted or when such neutrons are used for irradiating materials.

Tank-type reactors

At higher power levels, it becomes more convenient to employ a tank-type reactor because it is simpler to control the flow path of pumped water in such a system. Low-power teaching reactors also are available in the tank form. The core and reflector arrangement in tank-type, plate-fuel research reactors is the same as in the pool-type systems and has the same variations; however, solid concrete shielding is employed around the sides instead of the water shield characteristic of the latter.

TRIGA reactors. The TRIGA system is an increasingly popular variety of research reactor. It is another tank-type, water-cooled system, but its fuel differs from that employed by the above-mentioned research reactors. The fuel

assembly of the TRIGA consists of zirconium-clad rods of mixed uranium and zirconium hydrides. The virtue of this fuel is that it exhibits an extremely large negative power-reactivity coefficient—so large that the reactor can be made strongly supercritical for an instant, causing its power to rise very rapidly, after which it quickly shuts itself down. The resulting power pulse is useful for a number of dynamic experiments. The total energy released in a pulse is not a problem, since the automatic shutdown occurs very quickly and the energy release is proportional to both peak power and pulse duration.

Other research reactors. As in the case of power reactors, a number of different reactor types have seen service as research reactors, and some are still in operation. The variety is so great as to defy cataloging. There have been homogeneous (fueled solution cores), fast, graphite-moderated, heavy-water-moderated, and beryllium-moderated reactors, as well as those adapted to use fuels left over from power reactor experiments. The design of research reactors is much more fluid and sensitive to a greater variety of special research demands than is design for other applications.

Ship propulsion reactors. The original, and still the major, naval application of nuclear energy is the propulsion of submarines. The chief advantage of using nuclear reactors for submarine propulsion is that they, unlike fossil-fuel combustion systems, require no air for power generation. Consequently, a nuclear-powered submarine can remain underwater indefinitely, whereas a conventional diesel-powered submarine must surface periodically to run its engines in air. Nuclear power confers a strategic advantage on naval surface vessels as well because it eliminates their dependence on refueling from vulnerable tankers.

Advantages of nuclear-powered naval craft

The design of U.S. naval nuclear power plants is classified for defense security purposes, and so only general information pertaining to them has been published. It is known that such power plants are fueled with highly enriched uranium and moderated and cooled with light water. The design of the first nuclear submarine power plant, that of the USS *Nautilus,* was heavily influenced by high-power research reactor design. Special features include the incorporation of a very large reactivity margin to accommodate long burnups without refueling and to permit restart after shutdown. For submarine use, the power plant also must be extremely quiet to avoid sonic detection. Various models have been developed to fit the specific requirements of different classes of submarines.

The nuclear power plants for U.S. aircraft carriers are believed to have been derived from the power plant designs for the largest submarines, but again the particulars of their design have not been published.

Besides the United States, Britain, France, and the Soviet Union have nuclear submarines. In each case, the design was developed in secret, but it is generally believed that they are all rather similar; the demands of the application usually lead to similar solutions. The Soviet Union also has a small fleet of nuclear-powered icebreakers, whose power plants are thought to be essentially the same as those in their earliest submarines. As with naval vessels, the ability to operate without refueling is an enormous advantage for Arctic icebreakers.

Nuclear-powered icebreakers

Prototypes of nuclear-powered commercial cargo ships were built and operated by the United States and West Germany but have now been decommissioned. These vessels did not operate very economically, and opposition to their docking in a number of major ports also was a factor in their decommissioning. The prototypes were powered by reactors of the pressurized-water type.

Production reactors. The very first nuclear reactors were built for the express purpose of manufacturing plutonium for nuclear weapons, and the euphemism of calling them production reactors has persisted to this day. At present, most of the material produced by such systems is tritium (^{3}H, or T), the fuel for hydrogen bombs. Plutonium has a long half-life, and so countries with arsenals of nuclear weapons using plutonium as fissile material generally have more than they expect to need. On the other hand, tritium has a half-life of only about 12 years; thus stocks of this radioactive hydrogen isotope have to be continuously replenished. The United States, for example, operates several reactors moderated and cooled by heavy water that produce tritium at the Savannah River facility in South Carolina.

The plutonium isotope that is most desirable for sophisticated nuclear weapons is plutonium-239. If plutonium-239 is left in a reactor for a long time after production, plutonium-240 builds up as an undesirable contaminant. Accordingly, a major feature of a production reactor is its capability for quick throughput of fuel at a low energy-production level. Any reactor that can be operated this way is a potential production reactor.

The world's first plutonium production reactors, built by the United States at Hanford, Wash., were fueled with natural uranium, moderated by graphite, and cooled by light water. It is believed that the early Soviet production reactors were the same sort, and the French and British versions differed only in that they were cooled with gas. As was noted above, the first significant power reactor, the Calder Hall reactor, was actually a dual-purpose production reactor.

Specialized reactors. Nuclear reactors have been developed to provide electric power and steam heat in far-removed, isolated areas. The Soviet Union, for instance, has installed smaller power reactors specially designed to supply both electricity and steam for heating to accommodate the needs of a number of remote Arctic communities. Independent developmental work on small automatically operated reactors with similar capabilities has been undertaken by Sweden and Canada.

Reactors have been developed to supply power and propulsion in space. The Soviet Union has been deploying small intermediate reactors in satellites for powering equipment and telemetry since the 1970s, but this policy has drawn criticism because at least one reactor-powered spacecraft has reentered the atmosphere and deposited radioactive debris in Canada. Developmental activity in the United States has been directed largely toward reactor applications for the Strategic Defense Initiative (SDI) and for such deep-space missions as manned exploration of other planets or the establishment of a permanent lunar base. Reactors for these applications would necessarily be high-temperature systems based on either the HTGR or the LMR design but that would use enriched fuel. A power cycle in space must be run at a very high temperature to minimize the size of the radiator from which heat is to be rejected. A reactor for space applications also has to be compact so that it can be shielded with a minimum amount of material.

Nuclear-powered spacecraft

Small pressurized-water reactors have been used in the past to provide power for remote bases in Greenland and Antarctica. Though they have been replaced with oil-fired power plants, it still appears feasible to employ nuclear power for such applications or even for more exotic ones, such as supplying power to permanent undersea camps.

Finally, concepts have been developed, notably in West Germany, for employing HTGR systems as sources of high-temperature heat for chemical process industries. An idea that has drawn particular attention involves the use of reactor-generated heat at the mouth of a coal mine to convert the coal into clean gas for delivery by pipeline. Such processes remain economically unattractive at present but may ultimately became feasible as natural sources of fluid fuels are exhausted.

REACTOR SAFETY

Nuclear reactors contain very large amounts of radioactive isotopes—mostly fission products but also such heavy elements as plutonium. If this radioactivity were to escape the reactor, its effects on the people in the vicinity would be severe. The deleterious effects of exposure to high levels of ionizing radiation would include increased rates of cancer and genetic defects, an increased number of developmental abnormalities in children exposed in the womb, and even death within a period of several days to months when irradiation is extreme (see RADIATION: *Major types of radiation injury*). For this reason, a major consideration in reactor design is ensuring that a significant release of radioactivity does not occur. This is ac-

Safeguarding against radioactive contamination of the environment

complished by a combination of preventive measures and mitigating measures. Preventive measures are those that are taken to avoid accidents, and mitigating measures are those that decrease the adverse consequences. Essentially, preventive measures are the set of design and operating rules that are intended to make certain that the reactor is operated safely, while mitigating measures are systems and structures that prevent such accidents as do occur from proceeding to a catastrophic conclusion. Among the most well-known preventive measures are the reports and inspections for double-checking that a plant is properly constructed; rules of operation; and qualification tests for operating personnel to ensure that they know their jobs. The mitigating measures include safety rod systems for quickly shutting down a reactor to prevent a runaway chain reaction; emergency cooling systems for removing the heat of radioactive decay in the event that normal cooling capability is lost; and the containment structure for confining any radioactivity that might escape the primary reactor system. An extreme mitigating measure is the exercising of plans to evacuate personnel who might otherwise be heavily exposed in a reactor installation.

Preventive measures. Since no human activity can be shown to be absolutely safe, all these measures cannot reduce the risks to zero, but it is the aim of the rules and safety systems to minimize the risk to the point where a reasonable individual would conclude they are trivial. What this *de minimis* risk value is, and whether it has been achieved by the nuclear industry, is a subject of bitter controversy, but it is generally accepted that independent regulatory agencies—the United States Nuclear Regulatory Commission (NRC) and similar agencies around the world—are the proper judges of such matters.

To help evaluate the risks from nuclear power plants, the U.S. Atomic Energy Commission (AEC) authorized a major safety study in 1972 (the AEC was disbanded in 1974 and its functions have been assumed by the NRC). The study was conducted with major assistance from a number of laboratories, and it involved the application

Probabilistic risk assessment

of probabilistic risk assessment (PRA) techniques for the first time on a system as complex as a large nuclear power reactor. This work resulted in the publication in 1975 of a report titled *Reactor Safety Study,* also known as WASH-1400. The most useful aspect of the study was its delineation of components and accident sequences (scenarios) that were determined to be the most significant contributors to severe accidents.

The *Reactor Safety Study* concluded that the risks of an accident that would injure a large number of people were extremely low for the light-water reactor systems analyzed. This conclusion, however, was subject to very large quantitative uncertainties and was challenged.

One basic problem with probabilistic risk assessment is that it cannot easily be confirmed by experience when the level of risk has been reduced to low values. That is to say, if probabilistic risk assessment predicts that a reactor is subject to, say, one failure in 10,000 years, there is no way to prove that statement with only a few, or even with 10,000, years of experience. Thus, the results of the *Reactor Safety Study* as to risk levels were not confirmable.

There matters stood until 1979, when Three Mile Island Unit 2 suffered a severe accident. Through a combination of operator errors, coupled with the failure of an important valve to operate correctly, cooling water to the core was lost, parts of the core were melted and the rest of it destroyed, and a large quantity of fission products was released from the primary reactor system to the interior of the containment structure. The containment vessel of the reactor building fulfilled its function, and only a small amount of radioactivity was released, demonstrating the wisdom of having this component. Still, a severe accident had occurred.

Many investigations of the Three Mile Island accident followed. Recommendations differed among them, but a common thread was that the human element was a much more important factor in safe operation than had been hitherto recognized. The human element pertained not only to the operating staff but also to the managements of nuclear plants and even to the NRC itself. Following the accident, therefore, many changes in operator training and in technical and inspectorate staffing were implemented, just as a number of hardware enhancements were introduced. It is generally believed that these changes have been effective in reducing the likelihood of the occurrence of accidents as severe as that at Three Mile Island. As a side issue to this, however, the operating costs of nuclear power plants have escalated sharply as more and more highly trained people have been added to the operating staffs.

One area where probabilistic risk assessment has proven useful is with regard to the licensing of new plants, either light-water reactor installations or those of less common reactor types. PRA has the virtue of comparing systems fairly reliably. With better computer hardware and software than were available in 1975, it has become feasible to do PRA analyses of individual plants and compare them. A standard protocol for the NRC in licensing new, and particularly new types of, plants has therefore been that they must demonstrate lower risks than light-water reactors, which have been accepted as the norm.

The significance of the human element, particularly as it relates to plant management and high-level regulatory decision making, was borne out again by the Chernobyl catastrophe of 1986. One of the four reactors in a nuclear power station about 100 kilometres north of Kiev exploded and caught fire as the result of an ill-conceived experiment (a test to see how long the steam turbines would run while coasting to a stop if the reactor would be abruptly shut down). Before the situation had been brought under control, 31 people had died (two from the blast and 29 from radiation exposure), an estimated 25 percent of the radioactive contents of the reactor had been released in a high cloud plume, 135,000 people had to be evacuated, and a large area surrounding the plant received fallout so great that it could not be farmed or pastured. Significant radiation was detected as far north as Scandinavia and as far west as Switzerland. It has been estimated that between 4,000 and 40,000 cases of cancer would ultimately result from this accident (besides the initial several hundred victims), mostly within the Soviet Union but some in areas far removed from there. Investigation of the accident placed the largest blame, as with the Three Mile Island mishap, on poor management both at the plant and within the government bureaucracy.

The Chernobyl disaster of 1986

Because all such nuclear plant accidents have basically resulted from human failings rather than from some intrinsic factor, most experts believe that nuclear energy can be a safe source of power. A review of the overall performance record shows that there had been, as of 1989, several thousand "reactor-years" of safe power-reactor operation in the Western world, with health effects less damaging than those associated with the extraction of an equal amount of power from coal. Incorporating the lessons learned from past accidents should certainly make future operations safer. There is, however, a condition on the conclusion that nuclear power is by and large a safe form of power. The facilities for generating this power must be designed, built, and operated to high standards by knowledgeable, well-trained professionals; and a regulatory mechanism capable of enforcing these standards must be in place.

Mitigating measures. Two of the principal safety measures, the safety rods and the containment structure, have already been described. Other major safety systems are the emergency core cooling system, which makes it possible to cool the reactor if normal cooling is disrupted, and the emergency power system, which is designed to supply electrical power in case the normal supply is disrupted so that detectors and vital pumps and valves can continue to be operated. An important part of the safety system is the strict adherence to design rules, some of which have been mentioned—namely, the reactor should have a negative power-reactivity coefficient; the safety rods must be injectable under all circumstances; and no single regulating rod should be able to add substantial reactivity rapidly. Another important design rule is that the structural materials used in the reactor must retain acceptable physical properties over their expected service life. Finally, construction is to be covered by stringent quality assurance

rules, and both design and construction must be in accordance with standards set by major engineering societies and accepted by the NRC.

Most probable accidents and risks

According to probabilistic risk assessment studies, three kinds of events are most responsible for the risks associated with light-water reactors—namely, station blackout, transient without scram, and loss of cooling. The nature of each of these mishaps is delineated, as are the proposed countermeasures and the anticipated risks.

In station blackout, a failure in the power line to which the station is connected is postulated. The proposed emergency defense is a secondary electrical system, typically a combination of diesel generators big enough to drive the pumps and a battery supply sufficient to run the instruments. The risk would be that of the emergency generators not accepting load when they are started up. In transient without scram, the event is insertion of reactivity, for example, by an unchecked withdrawal of shim rods. The protective response is the rapid and automatic insertion of the safety rods. The risk would be the safety rods not functioning properly. In loss of cooling, the event is a failure of the normal cooling system to operate, either because of a break in a coolant line or because of an operator error. The emergency response is activation of the emergency core cooling system, and the risk would be that the system fails to operate. The ultimate event in the chain that led to the Three Mile Island accident was loss of emergency cooling by operator action owing to a misinterpretation of what sort of accident was occurring. In all these cases, proper operator action as well as proper functioning of the appropriate backup system are important aspects of emergency response. A final backup capability that is coming into play is the use of computers in an advisory mode to help the operator understand what is happening and suggest proper responses.

Different reactor types pose different types of risk. For example, neither the pool-type liquid-metal reactor nor the high-temperature gas-cooled reactor are at major risk with regard to loss of cooling and perhaps not with regard to station blackout. However, the LMR, and perhaps the HTGR, are at some risk from events that might cause air or water to enter the coolant system. The hazard is that reactor materials, sodium or graphite, could chemically react with air and water. The hazard is greater with sodium in the LMR than it is with graphite in the HTGR.

Another type of risk arises from external events, such as the possibility that earthquakes might initiate one or another major accident. The earthquake risk is minimized by building plants away from faults and by making use of earthquake-resistant mechanical design and construction.

NUCLEAR FUEL CYCLE

No discussion of nuclear power can be complete without a brief exposition of the nuclear fuel cycle. The whole point of a reactor is, after all, to cause fission in nuclear fuel. Moreover, it has turned out that low cost of fueling is the chief reason for the economic competitiveness of nuclear power.

Principal steps of the fuel cycle

The principal steps of the fuel cycle are uranium mining and extraction from its ore (milling), uranium enrichment, fuel fabrication, loading and irradiation in the reactor (fuel management), unloading and cooling, reprocessing, waste packaging, and waste disposal (see Figure 42).

Uranium mining. Uranium is mined from ores whose uranium content is on the order of 0.1 percent (one part per thousand). Most ore deposits are at or near the surface, and whether they are mined by open-pit or deep-mining techniques depends on the depth of the deposit and whether it slopes downward. The ore is crushed and the uranium chemically extracted from it at the mouth of the mine. The residue remains radioactive as it contains long-lived radioactive daughter nuclei of uranium and has to be carefully managed to minimize the release of radioactive contaminants into the environment. The uranium concentrate, which consists of uranium compounds (typically 75 to 95 percent), is shipped to a chemical plant for further purification and chemical conversion.

Enrichment. There are several possible enrichment methods, but the only two that are used on a large scale

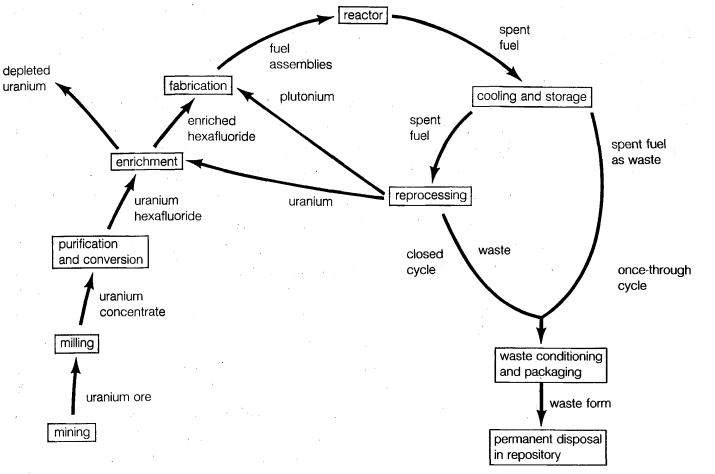

Figure 42: Light-water reactor fuel cycle.

are gaseous diffusion and gas centrifuging. In gaseous diffusion, natural uranium in the form of uranium hexafluoride gas (UF_6), a product of chemical conversion, is allowed to seep through a porous barrier. The molecules of $^{235}UF_6$ penetrate the barrier slightly faster than those of $^{238}UF_6$. Since the percentage of ^{235}U increases by only a very small amount after traversal of the barrier, the process must be repeated over and over in a large number of stages to obtain the desired amount of enrichment.

Gaseous diffusion

In gas centrifuging, the uranium hexafluoride gas is fed into a high-speed centrifuge. The lighter species of this mixture of gaseous molecules including ^{235}U tend to concentrate away from the wall, while the heavier ones accumulate along the wall. The degree of enrichment per stage in a centrifuge is greater than that obtained in a gaseous diffusion chamber, but the centrifuge is a more expensive piece of equipment.

Fabrication. This step involves the conversion of the suitably enriched product material to the chemical form desired for reactor fuel. As of the late 1980s the only fuel fabricated on a large scale was that for light-water reactors.

The chemical form prepared for the light-water reactor is uranium dioxide. Produced in the form of a ceramic powder, this compound is ground into a very fine flour and inserted into a die, where it is pressed into a pellet shape. Next the pellet is sintered in a furnace at 1,500–1,800° C. This sintering, similar to the firing of other ceramic ware, produces a dense ceramic pellet. Such pellets are loaded into prefabricated zirconium alloy cladding tubes, which are then filled with an inert gas and welded shut. These tubes, or pins, are bundled together with proper spacing assured by top and bottom grid plates through which the ends of the pins pass. Together with other necessary hardware, the bundle constitutes a fuel assembly (Figure 43).

Fuel management. Fuel is loaded into a reactor in a careful pattern so as to obtain the most energy production from it before it becomes no longer usable. Fresh fuel is more reactive than old fuel, and this reactivity is used to keep the reactor critical. Typically, a reactor is fueled in cycles, each cycle lasting one to two years, and a fuel batch is kept in the reactor for three or four cycles. At the end of each cycle, the oldest fuel is removed and fresh fuel loaded. The partially burned fuel that remains, however, is shuffled before the fresh fuel is installed. The objective of this procedure is to achieve a loading of maximum reactivity while keeping the power distribution among the different fuel assemblies within technical specifications.

Factors that limit energy production

Fuel burnup—that is, energy production—is limited by two factors. After significant burnup has occurred, the physical properties of the fuel become degraded and it is not prudent to continue to keep it in the reactor. Also, after some burnup, the old fuel no longer contributes useful reactivity to the reactor. The fuel design, including its initial enrichment, is such that these two limits are made to approximately coincide.

Unloading and cooling. Spent reactor fuel is extremely radioactive, and its radioactivity also makes it a source of

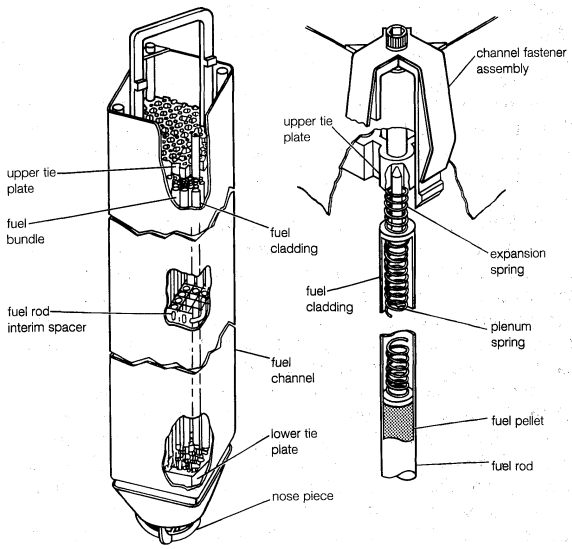

Figure 43: Fuel assembly.
From *General Description of a Boiling Water Reactor*, General Electric Co. (1974)

heat. When the spent fuel is removed from the reactor, it must continue to be both shielded and cooled. This is accomplished by placing the spent fuel in a water storage pool located next to the reactor. The water in the pool contains a large amount of dissolved boric acid, which is a heavy absorber of neutrons; this assures that the fuel assemblies in the pool will not go critical. (Pool water is also a common source of emergency cooling water for the reactor.) Pools vary in size; the older ones are only able to accommodate about 10 years worth of spent fuel. As the pools fill up, more spent fuel storage is needed. As noted earlier, additional storage space can be gained by loading spent fuel into the pool more densely than originally planned, by building a new pool, or by removing the oldest fuel assemblies from the existing pool and storing them in air-cooled concrete and steel silos located above ground. This last method becomes feasible after fuel has been stored for two or three years because radioactivity and heat generation decrease rapidly over this period. Dense storage in existing pools and silo storage both seem to be less expensive than building a new pool.

Reprocessing. Both the converted plutonium and residual uranium-235 in spent fuel can be recycled. Such materials can be recovered by chemically reprocessing the fuel. Equally as significant, reprocessing can reduce the volume and radioactivity of the waste material, which must ultimately be eliminated by some method of permanent disposal. Until 1975 it was generally assumed that after two to five years spent fuel would be delivered to a reprocessing plant. By that time, however, the cost of reprocessing had escalated to a point where its economics became questionable. Also, during the period 1976–81, it was U.S. policy, by presidential directive, not to reprocess. The directive has since been rescinded, but reprocessing is still not done commercially in the United States.

Policy and institutional arrangements are different in France and Britain. Commercial reprocessing plants exist in both countries and are processing spent fuel not only from nuclear plants in the host countries but also from those in others. The reprocessed plutonium can be used not only as fuel for planned future liquid-metal reactors but also to help fuel existing light-water reactors. In the latter application, the plutonium is utilized in mixed oxide form—a combination of uranium and plutonium dioxides having 3 to 6 percent plutonium.

Methodology

Reprocessing is accomplished by dissolving the spent fuel in nitric acid and contacting the acid solution with oil in which tributyl phosphate (TBP) is dissolved. TBP is a complexing agent for uranium and plutonium, forming compounds with them that bring them into the oil solution. A physical separation of the (immiscible) oil and acid serves to remove the desired products from the nitric acid solution, which still contains all the fission products. The uranium and plutonium can then be washed out of the TBP back into a water solution and separated from each other to the degree desired by means of various techniques. Thus, reprocessing produces three product streams: (1) a purified uranium product, (2) a plutonium product that may be either pure or mixed with uranium, and (3) a waste stream of fission products dissolved in nitric acid.

Waste conditioning. In the absence of reprocessing, the spent fuel is considered to be waste and must be prepared for disposal. This operation is to be performed in a separate facility, for which the Department of Energy has responsibility in the United States. As of 1998, the department is to begin receiving spent fuel from utilities largely on an "oldest-fuel-first" schedule. After brief storage, the fuel pins would be removed from their assemblies. End pieces that contain no fuel would be removed and the pins repacked into a dense lattice emplaced in a corrosion-resistant steel canister. A cover would be welded on and the canister covered with an overpack. This would represent the basic waste form for spent-fuel disposal.

Some waste exists in the form of the fission-product solution that arises from reprocessing. Reprocessed fuel from production reactors also generates this type of waste. The waste solution is completely evaporated, leaving behind the fission products in the solid residue, which is heated until all the constituent nitrate salts are converted to oxides. These oxides are then put into a glass-forming oven and mixed with materials that will produce a borosilicate glass. The fission-product oxides dissolve in the glass as it forms. The glass melt is subsequently poured into a steel canister, 200–400 millimetres in diameter and about one metre high, where it solidifies into a solid glass block. Once covered with an overpack of bentonite clay, the solid canister-like block is ready for disposal.

Waste solution from reprocessing

The glassmaking process for waste conditioning described here is operational on an industrial scale in France and has been tested in many other countries, including the United States.

Waste disposal. *Proposed method.* The waste disposal method currently being planned by all countries with nuclear power plants is called geologic disposal. This means that all conditioned nuclear wastes are to be deposited in mined cavities deep underground. Shafts are to be sunk into a solid rock stratum, with tunnel corridors extending horizontally from the central shaft region and tunnel "rooms" laterally from the corridors. The waste would be emplaced (probably by remotely controlled or robotic devices) in holes drilled into the floors of these rooms, after which the boreholes would be sealed and the rooms and corridors backfilled. When the entire operation is completed (perhaps after about 30 years of operation), the shafts too would be backfilled and sealed.

Geologic disposal method

Risks of nuclear waste disposal. Nuclear waste disposal is viewed quite differently by those who have studied it carefully and by the general public. When a holistic view of the process is taken, the risks seem extremely small, but it is one of the most feared aspects of the nuclear fuel cycle. A great deal of suspicion about the process arises from the numerous incidents of mismanagement of other types of waste, and these fears are encouraged by antinuclear activists. A number of basic observations on the process of geologic disposal point to the difficulty of resolving differences that are founded on perceptual discrepancies.

Nuclear waste retains its very intense level of radioactivity for several hundred years, but after 1,000 years have passed the remaining radioactivity, while persistent, is at a level comparable to, but greater than, that of a body of natural uranium ore. This separates the safety problem into two time periods: a first millennium during which it is crucial to ensure tight retention of the wastes in the repository, and a subsequent period during which it is only necessary to ensure that any release that occurs is small and slow.

There is general consensus that only impingement of groundwater and subsequent corrosion of the waste canisters, followed by dissolution of the waste, provides a route for the emergence of the waste in the surface environment. Water migrates slowly in most rock formations. Contrary to the popular belief that any dissolution of the waste and

discharge of the resulting solution to the environment will quickly lead to high-level contamination, only a low level is projected, even in worst-case scenarios.

Migration of radioactive species that has been observed at shallow burial sites for low-level radioactive waste is not an indication that similar migration can be expected in a deep underground repository. In addition to the near insolubility of the waste material, waste form engineering, particularly of corrosion-resistant containers, provides extra protection against such dispersal. Moreover, most of the dispersal problem in shallow disposal sites is caused by biochemical products that do not exist in deep formations; water found at depth is sterile.

Site selection

Finally, a great deal of care is to be expended in selecting the site of the repository. Site selection is probably the biggest problem, both politically and technically. Various conditions are mandatory: the repository must not be near a populated area, and the rock stratum selected must be deep (300 metres or more), dry, and naturally sealed from aquifers; and the water table should discharge only slowly into surface waters. Furthermore, the site must be in a tectonically inactive zone so that earthquakes will not break that seal.

The risk of high-level waste burial is almost certainly smaller than the risks of reactor accidents and even than the risks arising from improperly managed mine tailings. Nonetheless, the siting of a repository must be handled with political sensitivity, and the confirmation of acceptable hydrologic and geologic conditions must have a high degree of validity. There are many acceptable sites in principle, but confirming acceptability for any one of them is a large and expensive technical undertaking.

HISTORY OF REACTOR DEVELOPMENT

Soon after the discovery of nuclear fission was announced in 1939, it was also determined that the fissile isotope involved in the reaction was uranium-238 and that neutrons were emitted in the process. Newspaper articles reporting the discovery mentioned the possibility that a fission chain reaction could be exploited as a source of power. World War II, however, began in Europe in September of 1939, and physicists in fission research turned their thoughts to using the chain reaction in a bomb. It was quickly recognized that a high concentration of fissile material would be needed to accomplish this.

Inasmuch as fission had been first discovered in Germany, there was great fear, particularly among refugee physicists from Europe who had fled to America, France, and Britain, that Nazi Germany might develop just such a bomb. As a result, these three countries began working toward the development of atomic bombs, which at that point was still speculation. The most successful program was established in the United States, where President Franklin D. Roosevelt was persuaded by a letter from Albert Einstein to initiate a secret project devoted to this purpose. In early 1940 the U.S. government made funds available for research that eventually evolved into the Manhattan Project. After the fall of France to the German armies (1940), leading French researchers escaped to England and joined the ongoing British project. After the entry of the United States into the war in 1941, the British effort was transferred to the safer confines of North America. Though the British group participated in American research, it was chiefly concerned with initiating a research program in Canada.

The Manhattan Project

The Manhattan Project included work on uranium enrichment to procure uranium-235 in high concentrations and also research on reactor development. The goal was twofold: to learn more about the chain reaction for bomb design and to develop a way of producing a new element, plutonium, which was expected to be fissile and could be isolated from uranium chemically.

Reactor development was placed under the supervision of the leading experimental nuclear physicist of the era, Enrico Fermi. Fermi's project, begun at Columbia University and first demonstrated at the University of Chicago, centred on the design of a graphite-moderated reactor. It was soon recognized that heavy water was a better moderator and would be more easily used in a reactor, and this possibility was assigned to the Canadian research team since heavy-water production facilities already existed in Canada. Fermi's work led the way, and on Dec. 2, 1942, he reported having produced the first self-sustaining chain reaction. His reactor, later called Chicago Pile No. 1 (CP-1), was made of pure graphite in which uranium metal slugs were loaded toward the centre with uranium oxide lumps around the edges. This device had no cooling system, as it was expected to be operated for purely experimental purposes at very low power. CP-1 was subsequently dismantled and reconstructed at a new laboratory site in the suburbs of Chicago, the original headquarters of what is now Argonne National Laboratory. The device saw continued service as a research reactor until it was finally decommissioned in 1953.

Chicago Pile No. 1

On the heels of the successful CP-1 experiment, plans were quickly drafted for the construction of the first production reactors. These were the early Hanford reactors, which were graphite-moderated, natural uranium-fueled, water-cooled devices. As a backup project, a production reactor of air-cooled design was built at Oak Ridge, Tenn.; when the Hanford facilities proved successful, this reactor was completed to serve as the X-10 reactor at what is now Oak Ridge National Laboratory. Shortly after the end of World War II, the Canadian project succeeded in building a zero-power, natural uranium-fueled research reactor, the so-called ZEEP (Zero-Energy Experimental Pile). The first enriched-fuel research reactor was completed at Los Alamos, N.M., at about this time as enriched uranium-235 became available for research purposes (see Table 3). In 1947 a 100-kilowatt reactor with a graphite moderator and uranium metal fuel was constructed in England, and a similar one was built in France the following year.

Table 3: Notable Early Nuclear Reactors

name	location	power output*	distinction	start-up
CP-1 (Chicago Pile No. 1)	Chicago	low	first reactor	1942
ORNL Graphite, or Oak Ridge Graphite Reactor (X = 10)	Oak Ridge, Tenn.	3.8 MW	first megawatt-range reactor	1943
Y-Boiler (LOPO)	Los Alamos, N.M.	low	first enriched-fuel reactor	1944
CP-3 (Chicago Pile No. 3)	Chicago	300 kW	first heavy-water reactor	1944
ZEEP (Zero-Energy Experimental Pile)	Chalk River, Ont.	low	first Canadian reactor	1945
Hanford	Richland, Wash.	>100 MW	first high-power reactor	1945
Clementine	Los Alamos, N.M.	25 kW	first fast-neutron spectrum reactor	1946
NRX	Chalk River, Ont.	42 MW	first high-flux research reactor	1947
GLEEP	Harwell, Eng.	low	first British reactor	1947
ZOE (EL-1)	Châtillon, Fr.	150 kW	first French reactor	1948
EBR-1 (Experimental Breeder Reactor No. 1)	Idaho Falls, Idaho	1.4 MW	first breeder and first reactor system to produce electricity	1951
LITR (Low-Intensity Test Reactor)	Oak Ridge, Tenn.	3 MW	first plate-fuel reactor	1950
JEEP-1	Kjeller, Nor.	350 kW	first international reactor (Norway–Netherlands)	1951
STR (Submarine Thermal Reactor)	Idaho Falls, Idaho		submarine reactor prototype	1953
BORAX-III	Idaho Falls, Idaho	3.5 MW(e)	first U.S. reactor capable of significant electric power generation	1955
Calder Hall A	Calder Hall, Eng.	20 MW(e)	world's first reactor for large-scale commercial power production	1956

*Power output is thermal except where noted as MW(e), signifying electrical.

In 1953 President Dwight D. Eisenhower of the United States announced the Atoms for Peace program. This program established the groundwork for a formal U.S. nuclear power program and expedited international cooperation on nuclear power.

Development of commercial power reactors

The earliest U.S. nuclear power project had been started in 1946 at Oak Ridge, but the program was abandoned in 1948, with most of its personnel being transferred to the naval reactor program that produced the first nuclear-powered submarine, the *Nautilus*. After 1953 the U.S. nuclear power program was devoted to the development of several reactor types, of which three ultimately proved to be successful in the sense that they remain as commercial reactor types or as systems scheduled for future commercial use. These three were the fast breeder reactor (now called LMR); the pressurized-water reactor; and the boiling-water reactor. The first LMR was the Experimental Breeder Reactor, EBR-I, which was designed at Argonne National Laboratory and constructed at what is now the Idaho National Engineering Laboratory near Idaho Falls, Idaho. EBR-I was an early experiment to demonstrate breeding, and in 1951 it produced electricity from nuclear heat for the first time. As part of the U.S. nuclear power program, a much larger experimental breeder, EBR-II was developed and put into service (with power generation) in 1963. The principle of the boiling-water reactor was first demonstrated in a research reactor in Oak Ridge, but development of this reactor type was also assigned to Argonne, which built a series of experimental systems designated BORAX in Idaho. One of these, BORAX-III, became the first U.S. reactor to put power into a utility line on a continuous basis. A true prototype, the Experimental Boiling Water Reactor, was commissioned in 1957. The principle of the pressurized-water reactor had already been demonstrated in naval reactors, and the Bettis Atomic Power Laboratory of the naval reactor program was assigned to build a civilian prototype at Shippingport, Pa. This reactor, the largest of the power-reactor prototypes, is often hailed as the first commercial-scale reactor in the United States.

During the late 1950s and early 1960s a number of true commercial prototype nuclear power plants were built. Of these, the most successful was the light-water reactor system, although the advanced gas-cooled type remained the British standard for many years and the CANDU system prevailed in Canada. From the mid-1960s, larger units were ordered in the expectation of an ever-increasing commercial utilization of nuclear power, and by the early 1970s nuclear plant orders were coming in at such a rapid pace that the unit sizes were increased so as to reduce the number of separate projects that each vendor would have to staff for. By the later years of the decade, however, the surfeit of orders in the United States was followed by a large number of project cancellations. This phenomenon was the result of a sharp decrease over what had been projected as the rate of increase in base-load electricity demand for which the large nuclear plants were designed.

Escalating cost of building new nuclear plants

The new plants were not needed. Moreover, the cost of new nuclear plants had begun to escalate to the point where their economics became questionable. Public fears of nuclear power, stimulated by the Three Mile Island accident, also were a factor.

Similar scenarios have slowed the deployment of nuclear power in several countries besides the United States. On the other hand, France, Japan, South Korea, and Taiwan, which all have few alternative fuel resources, have continued building up their nuclear power capacity. (B.I.S.)

Electric generators and electric motors

A machine that converts mechanical energy into electrical energy is known as an electric generator. One that converts electrical energy into mechanical energy is an electric motor. Actually, the same machine can have energy flow in either direction. The same basic principles apply for both generators and motors. The designation as a generator or motor depends on the intended application.

Major uses

The major use of generators is to produce electrical power for distribution on transmission lines to domestic, commercial, and industrial customers. Generators also produce the electrical power required for automobiles, aircraft, ships, and trains.

Electric motors drive all sorts of mechanical devices. Typical examples are fans and windshield wipers on automobiles, elevators and air conditioners in office buildings, mixers and record players in homes, subway trains in cities, pumps in pipelines, and robots in industry.

Most electric machines rotate, often at high speed. Some, however, produce linear motion such as is required in rapid-transit vehicles.

BASIC PRINCIPLES OF OPERATION

Energy conversion by means of a magnetic field

Most electric machines convert energy by use of a magnetic field that allows force to be transmitted from a stationary to a moving part without physical connection. There are two basic principles exploited in generator and motor operation. The first, originally discovered by the French physicist André-Marie Ampère, states that an electrical conductor carrying a current at right angles to a magnetic field will experience a force at right angles to both the field and the current. The second principle, formulated on the basis of observations made by the English scientist Michael Faraday, states that a potential difference, or voltage, will be established between the ends of an electrical conductor that moves across or perpendicular to a magnetic field. These principles apply for a moving conductor in a stationary magnetic field. They apply equally for a stationary conductor with a moving magnetic field. The various configurations of electric machines consist of means of creating the magnetic field and placing current-carrying conductors in it in such a way as to produce force and voltage.

Elementary generators. These principles are demonstrated in the arrangement shown in Figure 44, where a loop of a conductor is rotated in a magnetic field. This field is created by the use of permanent magnets on each side, directing a horizontal field across a pair of air gaps. A central iron core and an outer iron yoke are used to provide an easy path for the magnetic field to close on itself and thus concentrate the field into the air gaps. Suppose the loop is rotated counterclockwise. In the left-hand section of the loop traveling downward across the field, positive electric charges will be forced toward the observer and negative charges will be forced away. On the right-hand section of the loop, the upward motion across the field forces negative charge toward the observer. The result is the establishment of a potential difference, or voltage, between the two terminals of the loop. This potential difference is proportional to the rate per second at which the magnetic field is being crossed by the two sides of the loop; that is to say, it depends on the density of the field, the length of conductor perpendicular to the field, and the velocity of the conductor perpendicular to the field.

If an electrical load such as a resistor is now connected

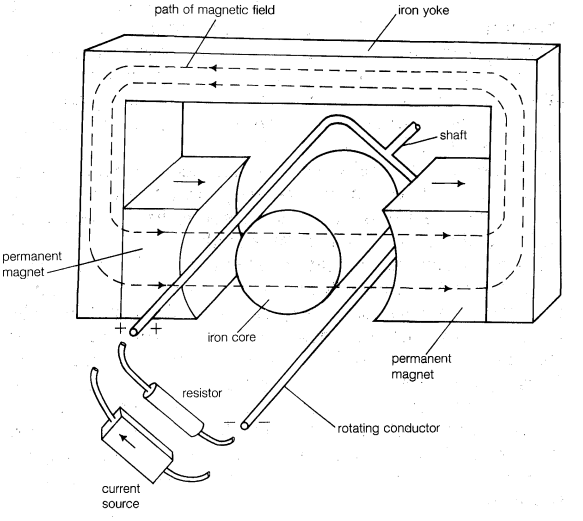

Figure 44: Elementary electric motor.

between the two terminals of the loop, an electric current will flow out of the positive terminal and into the negative terminal. This current will then interact with the magnetic field, resulting in an upward force on the left-hand conductor and a downward force on the right-hand one—*i.e.,* a force perpendicular to both the field and the current direction. To overcome this force and make the loop turn, mechanical torque must be applied to the shaft of the loop. The mechanical power input required will be the product of the force and the conductor velocity (ignoring any losses). Simultaneously, the electric power output to the load will be the product of the potential difference and the current. Ideally, if there were no power losses and no changes in stored energy in this system, the electrical power output would be equal to the mechanical power input. The machine would be acting as an ideal generator, converting mechanical energy into electrical energy.

Elementary motors. Consider now the situation where a source of electric current is attached, possibly through sliding contacts, to the loop terminals in place of the resistor so as to cause current to flow away from the observer in the left-hand side of the loop and toward the observer in the right-hand side. If the loop is rotating counterclockwise with the same velocity as before, the same potential difference will be established between the terminals (again ignoring any losses). Accordingly, there will be electrical power entering the loop equal to the product of the potential difference and the current. The current will interact with the magnetic field to produce a force, downward on the left-hand and upward on the right-hand conductor—*i.e.,* in the direction of the velocity in each case. Thus, there will be a mechanical output power equal to the force–velocity product. Again, ignoring losses and any change in stored energy, the electrical input power will be equal to the mechanical output power. The system will act as an ideal electric motor, converting electrical energy into mechanical energy.

According to the principles of mechanics, for each action there must be an equal and opposite reaction. Thus, in the system shown in Figure 44, the torque on the loop is balanced by an equal and opposite torque on the magnets and the iron yoke. The system can therefore act as a generator or a motor if the loop is held stationary and the magnet system is allowed to rotate.

Rotor and stator

Most, but not all, electric machines are based on the principles just described. A machine of this kind normally contains a rotating part, or rotor, and a stationary part, or stator. In Figure 44, the conductor loop can be fixed to the surface of a rotatable iron core to make up the rotor. In order to reduce the length of the air gaps across which the magnetic field must be produced, the conductor may in fact be imbedded in slots cut into the surface of the iron rotor. The magnetic field may be created by permanent magnets as shown or by electromagnets consisting of current-carrying coils around iron poles. In most machines, the stator is made approximately circular, with both upper and lower flux paths rather than with the one-sided yoke shown in Figure 44. The machine may equally consist of a magnet (permanent or electro-) on the rotor with conductors on the stator. For a permanent-magnet machine, this latter arrangement eliminates the need for sliding contacts or slip rings to connect the conductor loop to the external electric system.

The usual types of electric machine—induction, synchronous, and commutator—have much in common. They differ mainly in how the magnetic field is produced and how the conductors are arranged.

Other electromechanical phenomena. Other physical phenomena can be exploited to produce electromechanical energy converters, usually of a specialized nature. The force of attraction between bodies with opposite electric charges has been used in some electrostatic machines. These forces, however, are very small, even when high voltages are used. Another useful phenomenon is the

Utilization of the piezoelectric effect

piezoelectric effect in which a crystal deforms on application of an electric field. This phenomenon is utilized, for example, in an energy converter to produce underwater sound waves.

Some machines are based on the force of attraction between movable parts of an iron system that carries a magnetic field. These are commonly known as reluctance machines.

The electrical conductors in a machine need not be solid. The conductor can consist of a conducting liquid or gas. Such machines, classified as magnetohydrodynamic devices, can be used to produce electrical power (see *Magnetohydrodynamic power generators* below).

ELECTRIC GENERATORS

Electric generators, as noted above, transform mechanical power into electrical power. The mechanical power is usually obtained from a rotating shaft and is equal to the shaft torque multiplied by the rotational, or angular, velocity. The most significant generators are those used to provide power for transmission and distribution over electric power networks. The mechanical power is obtained from a number of sources: hydraulic turbines at dams or waterfalls; wind turbines; steam turbines using steam produced with heat from the combustion of fossil fuels or from the fission of heavy atomic nuclei; gas turbines burning gas directly in the turbine; or gasoline and diesel engines. The construction and the speed of the generator may vary considerably depending on the characteristics of the mechanical prime mover.

Sources of mechanical power for generators

Nearly all generators used to supply electric power networks generate alternating current, which reverses polarity at a fixed frequency (usually 50 or 60 cycles, or double reversals, per second). Since a number of generators are connected into a power network, they must operate at the same frequency for simultaneous generation. They are therefore known as synchronous generators or, in some contexts, alternators.

Synchronous generators. A major reason for selecting alternating current for power networks is that its continual variation with time allows the use of transformers. These devices convert electrical power at whatever voltage and current it is generated to high voltage and low current for long-distance transmission and then transform it down to a low voltage suitable for each individual consumer (typically 120 or 240 volts for domestic service). The particular form of alternating current used is a sine wave, which has the shape shown in Figure 45. This has been chosen because it is the only repetitive shape for which two waves displaced from each other in time can be added or subtracted and have the same shape occur as the result. The ideal is then to have all voltages and currents of sine shape. The synchronous generator is designed to produce this shape as accurately as is practical. This will become apparent as the major components and characteristics of such a generator are described below.

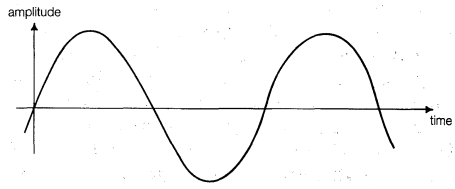

Figure 45: Sine wave.

Rotor. An elementary synchronous generator is shown in cross section in Figure 46. The central shaft of the rotor is coupled to the mechanical prime mover. The magnetic field is produced by conductors, or coils, wound into slots cut in the surface of the cylindrical iron rotor. This set of coils, connected in series, is thus known as the field winding. The position of the field coils is such that the outwardly directed or radial component of the magnetic field produced in the air gap to the stator is approximately sinusoidally distributed around the periphery of the rotor. In Figure 46, the field density in the air gap is maximum outward at the top, maximum inward at the bottom, and zero at the two sides, approximating a sinusoidal distribution.

Field winding

Stator. The stator of the elementary generator in Figure 46 consists of a cylindrical ring made of iron to provide an easy path for the magnetic flux. In this case, the stator contains only one coil, the two sides being accommodated

in slots in the iron and the ends being connected together by curved conductors around the stator periphery. The coil normally consists of a number of turns.

When the rotor is rotated, a voltage is induced in the stator coil. At any instant, the magnitude of the voltage is proportional to the rate at which the magnetic field encircled by the coil is changing with time—*i.e.*, the rate at which the magnetic field is passing the two sides of the coil. The voltage will therefore be maximum in one direction when the rotor has turned 90° from the position shown in Figure 46 and will be maximum in the opposite direction 180° later. The waveform of the voltage will be approximately of the sine form shown in Figure 45.

Frequency of electrical output and rotor speed

Frequency. The rotor structure of the generator in Figure 46 has two poles, one for magnetic flux directed outward and a corresponding one for flux directed inward. One complete sine wave is produced for each revolution of the rotor. The frequency of the electrical output, measured in hertz (cycles per second) is therefore equal to the rotor speed in revolutions per second. To provide a supply of electricity at 60 hertz, for example, the prime mover and rotor speed must be 60 revolutions per second, or 3,600 revolutions per minute. This is a convenient speed for many steam and gas turbines. For very large turbines, such a speed may be excessive for reasons of mechanical stress. In this case, the generator rotor is designed with four poles spaced at intervals of 90°. The voltage induced in a stator coil, which spans a similar angle of 90°, will consist of two complete sine waves per revolution. The required rotor speed for a frequency of 60 hertz is then 1,800 revolutions per minute. For lower speeds, a larger number of pole pairs can be used. The possible values of rotor speed, in revolutions per minute, are equal to $120f/p$, where f is the frequency and p the number of poles.

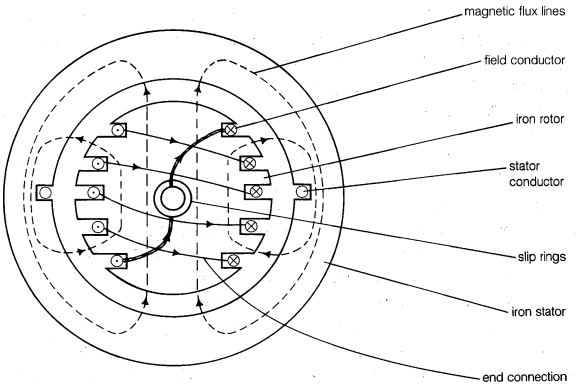

Figure 46: Elementary synchronous machine.

Stator windings. The maximum value of flux density in the air gap is limited by magnetic saturation in the stator and rotor iron, and it is typically about one tesla (weber per square metre). The effective, or root-mean-square (rms), voltage induced in one turn of a stator coil in a 60-hertz generator is about 170 volts for each metre squared of area encompassed by the coil (see below). Large synchronous generators are usually designed for a terminal voltage of several thousand volts. Each stator coil may therefore contain a number of insulated turns of conductor, and each stator winding may consist of a number of similar coils placed in sequential slots in the stator surface and connected in series as shown for the winding a-a' in Figure 47.

Phases. The voltages induced in individual coils in the distributed winding of Figure 47 are somewhat displaced in time from each other. As a result, the maximum winding voltage is somewhat less than the voltage per coil multiplied by the number of coils. The waveform is, however, still of approximately sine form. In the figure the winding a-a' spans two arcs, each of 60°. In order to make use of the whole periphery of the stator surface, two other similar windings are inserted. The voltage induced in winding b-b' will be equal in peak magnitude to that of a-a' but will be delayed in time by one-third of a cycle. The voltage in winding c-c' will be delayed by an additional third of

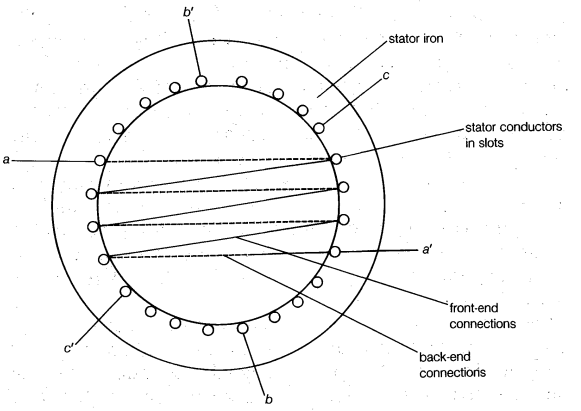

Figure 47: A three-phase winding on the stator (see text).

a cycle. This is known as a three-phase system of windings. The waveforms for the three windings, or phases, are shown in Figure 48.

Three-phase system of windings

The three-phase arrangement has a number of advantages. A single winding, or phase, requires two conductors for transmission of its electrical power to a load. At first glance, it might appear that six conductors would be required for the system in Figure 47. If, however, the waveforms of Figure 48 are considered to be those of the currents flowing in the three-phase windings, it will be seen that the sum of the three currents is zero at every instant in time. Thus, as long as the three phases are loaded equally, the terminals a', b', and c' of Figure 47 can be connected together to form a neutral point that may either be connected to ground or left open. The power of all three phases can be transmitted on three conductors. This connection is called a star, or wye, connection. Alternatively, since the three winding voltages also sum to zero at every instant, the three windings can be connected in series—a' to b, b' to c, and c' to a—to form a delta connection. The output can then be transmitted from only three conductors connected to the three junction points. Other advantages of the three-phase system will become evident in the discussion of electric motors below.

Field excitation. A source of direct current is required for the field winding, as sketched in Figure 46. In very small synchronous generators, this current may be supplied from an external source by fitting the generator shaft with two insulated copper rings, connecting the field coil ends to the rings and providing a connection to the external source through fixed carbon brushes bearing on the rings.

The power required for the field winding is that which is dissipated as heat in the winding resistance. In large generators, this is usually less than 1 percent of the generator rating, but in a generator with a capacity of 1,000 megavolt-amperes this will still be several megawatts. For most large synchronous generators, the field current is provided by another generator, known as an exciter, mounted on the same shaft. This may be a direct-current generator. In most modern installations, a synchronous generator is used as the exciter. For this purpose, the field windings of the exciter are placed on its stator and the phase windings on its rotor. A rectifier mounted on the rotating shaft is used to convert the alternating current to direct current. The field current of the main generator can then be adjusted by controlling the field current of the exciter.

Exciter

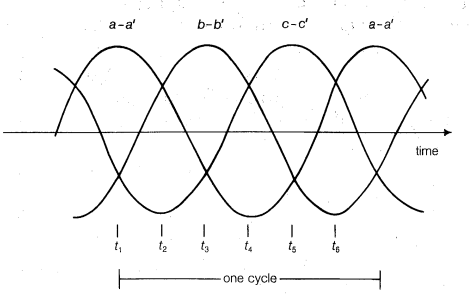

Figure 48: Waveforms of a three-phase system.

Generator rating. The capacity of a synchronous generator is equal to the product of the voltage per phase, the current per phase, and the number of phases. It is normally stated in megavolt-amperes (MVA) for large generators or kilovolt-amperes (kVA) for small generators. Both the voltage and the current are the effective, or rms, values (equal to the peak value divided by $\sqrt{2}$).

Voltage rating

The voltage rating of the generator is normally stated as the operating voltage between two of its three terminals—*i.e.,* the phase-to-phase voltage. For a winding connected in delta, this is equal to the phase-winding voltage. For a winding connected in wye, it is equal to $\sqrt{3}$ times the phase-winding voltage.

The capacity rating of the machine differs from its shaft power because of two factors—namely, the power factor and the efficiency. The power factor is the ratio of the real power delivered to the electrical load divided by the total voltage–current product for all phases. The efficiency is the ratio of the electrical power output to the mechanical power input. The difference between the two power values is the power loss consisting of losses in the magnetic iron due to the changing flux, losses in the resistance of the stator and rotor conductors, and losses from the winding and bearing friction. In large synchronous generators, these losses are generally less than 5 percent of the capacity rating. These losses must be removed from the generator by a cooling system to maintain the temperature within the limit imposed by the insulation of the windings.

High-speed synchronous generators. Generators driven by high-speed turbines are almost always constructed with horizontal shafts. The rotor diameter is usually limited to a maximum of about one metre because of the high centrifugal forces produced. The length of the rotor may be several metres. The rotor shaft and the field structure are made of a solid alloy steel forging in which slots are machined to accept the field coils, as shown in Figure 46. These coils are insulated typically with mica and glass laminate. The coils are held in place by nonmagnetic wedges in the tops of the slots.

The stator provides a path for the continuously varying magnetic flux. The stator core is therefore constructed of thin sheets, or laminations, of magnetic steel. The steel, being an electrical conductor, would tend to short-circuit the voltage induced in it if it were solid. Lamination breaks up the path along the length of the stator and keeps the power losses in the stator steel at an acceptable value. Slots are punched around the inside periphery of the laminations to accommodate the stator coils. In large generators, each stator coil normally contains only one turn.

High-speed generators are enclosed within a closed cylindrical stator housing that extends between the bearings at the two ends. They are cooled by hydrogen gas circulating within the housing and also frequently through ducts within the stator conductors. Very large generators are cooled by circulating water through the stator and rotor conductors.

The ratings of synchronous generators for large power systems extend up to about 2,000 megavolt-amperes. Smaller power systems use generators of lower rating (*e.g.,* 50 megavolt-amperes and up) since it is usually not desirable to have more than 10 percent of the total required system generation in one machine.

Waterwheel generators. Hydraulic turbines are of various types, the choice depending largely on the height of water fall and on the power rating (see *Water turbines* above). The range of speed for which hydraulic turbines give acceptable efficiency is much lower than for steam turbines. The rotational speed is generally in the range of 60 to 720 revolutions per minute. The construction of low-speed synchronous generators is substantially different from that of high-speed units. To produce power at 60 hertz, the number of rotor poles is in the range of 10 to 120 for the above speed range. For these machines the rotor poles are of the projecting, or salient, type. Figure 49 shows two poles of a 12-pole generator. Each pole, made of laminated magnetic steel, is encircled by a field coil. The pole is shaped so as to make the air-gap magnetic field distribution approximately sinusoidal.

Large hydraulic generators may have individual ratings in excess of 200 megavolt-amperes. They are mounted with a vertical shaft directly coupled to the turbine. The combination is usually supported on a single bearing, either above or below. The diameter is made relatively large to obtain a high peripheral velocity at low rotational speeds. The axial length of the generator is relatively short. The windings are frequently water-cooled. The rotor has to be designed to withstand a considerable overspeed condition that may arise if the generator loses its electrical load and there is a significant time delay in cutting off the water flow to the turbine.

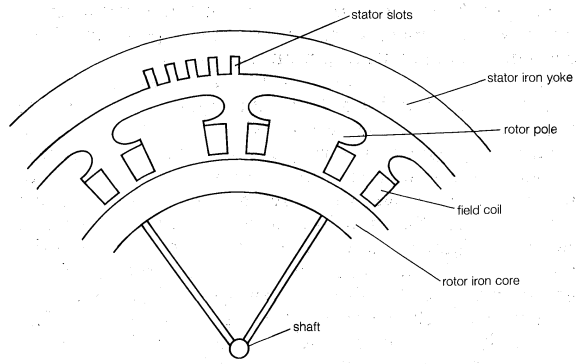

Figure 49: A two-pole cross section of a 12-pole, low-speed synchronous generator.

Generators for motor vehicles. Such vehicles as automobiles, buses, and trucks require a direct-voltage supply for ignition, lights, fans, and so forth. In modern vehicles the electric power is generated by an alternator mechanically coupled to the engine. The alternator normally has a rotor field coil supplied with current through slip rings. The stator is fitted with a three-phase winding. A rectifier is used to convert the power from alternating to direct form. A regulator is used to control the field current so that the output voltage of the alternator-rectifier is properly matched to the battery voltage as the speed of the engine varies.

Alternator-rectifier

Permanent-magnet generators. In small ratings, the magnetic field of the synchronous generator may be provided by permanent magnets. The rotor structure can consist of a ring of magnetic iron with magnets mounted on its surface, as in the four-pole structure shown in Figure 50. A magnet material such as neodymium-boron-iron or samarium-cobalt can provide a magnetic flux density in the air gap comparable to that produced with field windings, using a radial depth of magnet of about 10 millimetres. Other magnet materials such as ferrite can be used, but with a considerable reduction in air-gap flux density and a corresponding increase in generator dimensions.

Permanent-magnet generators are simple in that they require no system for the provision of field current. They are highly reliable. They do not, however, contain any means for controlling the output voltage, and this may vary with changes in load.

Induction generators. An induction machine (see *Induction motors* below) can operate as a generator if it is connected to an electric supply network operating at a substantially constant voltage and frequency. If torque is applied to the induction machine by a prime mover, it will tend to rotate somewhat faster than its synchronous

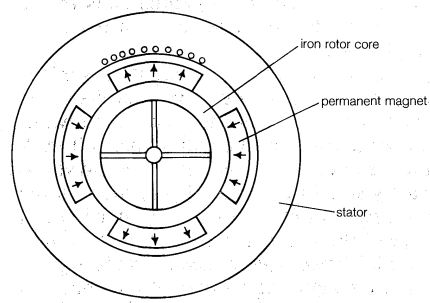

Figure 50: Cross section of a permanent-magnet generator.

speed, which is equal to 120 f/p revolutions per minute, where f is the supply frequency and p is the number of poles in the machine. The rotor conductors, moving faster than the air-gap field, will have induced currents that interact with the field to produce a torque with which to balance that applied by the prime mover. A stator current will then flow into the supply network delivering electrical power. The amount of power delivered is approximately proportional to the difference between the rotor speed and the field speed. This difference is typically of the order of 0.5 to 2 percent of rated speed at rated load.

An induction generator cannot normally provide an independent electrical power source because it does not contain a source of its own magnetic field. Stand-alone induction generators can, however, operate with the aid of appropriate loading capacitors.

Induction generators are frequently preferred over synchronous generators for small and remote hydroelectric sites because they are not subject to loss of synchronism following transient changes in the power system.

Special type of synchronous generator

Inductor alternators. An inductor alternator is a special kind of synchronous generator in which both the field and the output winding are on the stator. In the homopolar type of machine, the magnetic flux is produced by direct current in a field coil concentric with the shaft. In the heteropolar type, the field coils are in slots in the stator.

Voltage is generated in the output windings by pulsations in the flux in individual stator teeth. These pulsations are produced by use of a toothed rotor, which causes the reluctance of the air path from the rotor to each stator tooth to vary periodically with rotation.

Inductor alternators are useful as high-frequency generators. They also are useful in situations requiring high reliability, a feature achieved by their having no electrical connections to the rotor.

Direct-current generators. A direct-current (DC) generator is a rotating machine that supplies an electrical output with unidirectional voltage and current. The basic principles of operation are the same as those for synchronous generators. Voltage is induced in coils by the rate of change of the magnetic field through the coils as the machine rotates. This induced voltage is inherently alternating in form since the coil flux increases and then decreases, usually with a zero average value.

The field is produced by direct current in field coils or by permanent magnets on the stator. The output, or armature, windings are placed in slots in the cylindrical iron rotor. A simplified machine with only one rotor coil is shown in Figure 51. The rotor is fitted with a

Commutator

mechanical rotating switch, or commutator, that connects the rotor coil to the stationary output terminals. This commutator reverses the connections at the two instants in each rotation when the rate of change of flux in the coil is zero—*i.e.*, when the enclosed flux is maximum (positive) or minimum (negative). The output voltage is then unidirectional but is pulsating for the single case of one rotor coil. In practical machines, the rotor contains many coils symmetrically arranged in slots around the periphery and all connected in series. Each coil is connected to a segment on a multi-bar commutator. In this way, the output voltage consists of the sum of the induced voltages in a number of individual coils displaced around half the periphery. The magnitude of the output voltage is then approximately constant, containing only a small ripple due to the limited number of coils. The voltage magnitude is proportional to the rotor speed and the magnetic flux. Control of output voltage is normally provided by control of the direct current in the field.

For convenience in design, direct-current generators are usually constructed with four to eight field poles, partly to shorten the end connections on the rotor coils and partly to reduce the amount of magnetic iron needed in the stator. The number of stationary brushes bearing on the rotating commutator is usually equal to the number of poles but may be only two in some designs.

The field current for the generator may be obtained from an external source, such as a battery or a rectifier, as shown in Figure 52A. In this case, the generator is classed as separately excited. Alternatively, it may be noted that

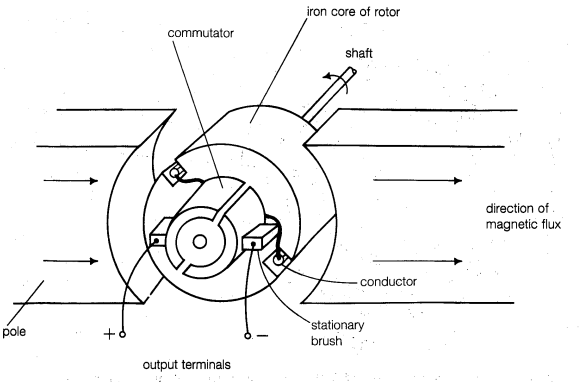

Figure 51: Direct-current generator.

the output of the DC generator is unidirectional and therefore may be used as a source to supply its own field current, as shown in Figure 52B. In this case, the generator is referred to as shunt-excited. It has the advantage of requiring no independent supply. Residual magnetic flux in the iron poles produces a small generated voltage when the machine is brought up to speed. This causes a field current that increases the flux and in turn the generated voltage. The voltage builds up until saturation in the iron limits the voltage produced. The stable value of generated voltage can be adjusted over a limited range by adjusting the value of a resistor placed in series with the field coil across the output terminals.

Shunt-excited DC generator

Direct-current generators were widely used prior to the availability of economical rectifier systems supplied by alternators. For example, they were commonly employed for charging batteries and for electrolytic purposes. In some applications, the direct-current generator retains an advantage over the alternator-rectifier in that it can operate as a motor as well, reversing the direction of power flow. An alternator, by contrast, must be fitted with a more complex rectifier-inverter system to accomplish power reversal.

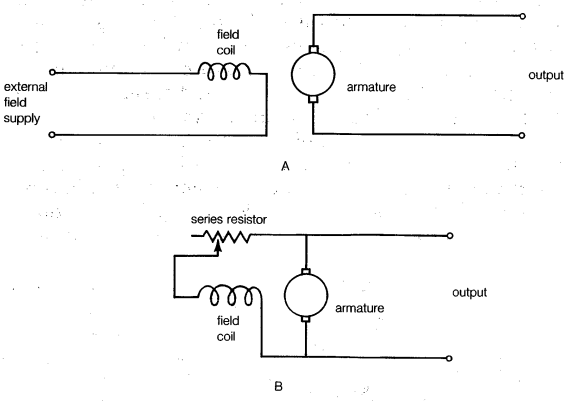

Figure 52: *Types of direct-current generators on the basis of source of field current.*

ELECTRIC MOTORS

Electric motors transform electrical power into mechanical power. In most instances, the electrical power is obtained from a power distribution network through appropriate control apparatus. In special situations, the electric supply may come from a battery, as, for example, in an automobile.

The basic principles of electric motors were discussed above. Most motors develop their mechanical torque by the interaction of conductors carrying current in a direction at right angles to a magnetic field. The various types of electric motor differ in the ways in which the conductors and the field are arranged and also in the control that can be exercised over mechanical output torque, speed, and position. Each of the major kinds is delineated below.

Differences between motor types

Induction motors. The simplest type of induction motor is shown in cross section in Figure 53. A three-phase

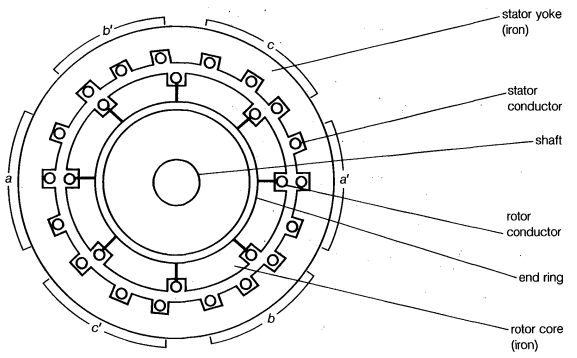

Figure 53: Cross section of a three-phase induction motor.

set of stator windings is inserted in slots in the stator iron. These windings may be connected either in a wye configuration, normally without external connection to the neutral point, or in a delta configuration. The rotor consists of a cylindrical iron core with conductors placed in slots around the surface. In the most usual form, these rotor conductors are connected together at each end of the rotor by a conducting end ring.

The basis of operation of the induction motor may be developed by first assuming that the stator windings are connected to a three-phase electric supply and that a set of three sinusoidal currents of the form shown in Figure 48 flow in the stator windings. Figure 54 shows the effect of the currents in producing a magnetic field across the air gap of the machine. For simplicity, only the central conductor loop for each phase winding is shown. At the instant t_1 in Figure 48, the current in phase a is maximum positive, while that in phases b and c is half that value negative. The result is a magnetic field with an approximately sinusoidal distribution around the air gap with a maximum outward value at the top and a maximum inward value at the bottom. At time t_2 in Figure 48 (*i.e.*, one-sixth of a cycle later), the current in phase c is maximum negative, while that in both phase b and phase a is half value positive. The result, as shown for t_2 in Figure 54 is again a sinusoidally distributed magnetic field but rotated 60° counterclockwise. Examination of the current distribution for t_3, t_4, t_5, and t_6 shows that the magnetic field continues to rotate as time progresses. The field completes one revolution in one cycle of the stator current. Thus, the combined effect of three sinusoidal currents, uniformly displaced in time and flowing in three stator windings uniformly displaced in angular position, is to produce a rotating magnetic field with a constant magnitude and a mechanical angular velocity that depends on the frequency of the electric supply.

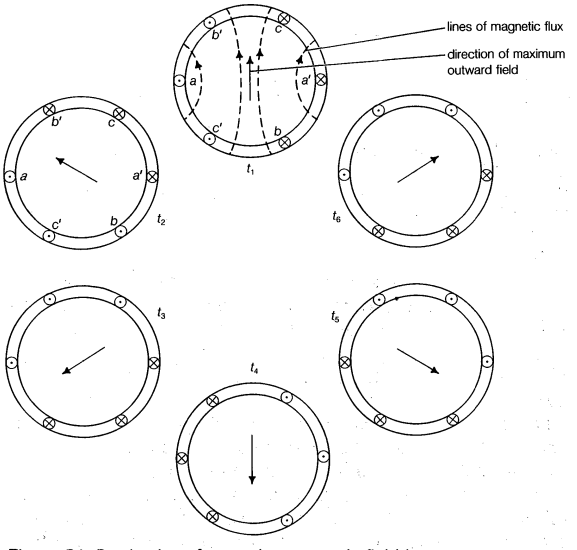

Figure 54: *Production of a rotating magnetic field by three-phase currents in three stator windings.* The symbol ⊙ indicates current flow toward observer; ⊗ denotes current flow away. The t represents the time instants in Figure 48.

The effect of the rotating field on the rotor

The rotational motion of the magnetic field with respect to the rotor conductors causes a voltage to be induced in each, proportional to the magnitude and the velocity of the field relative to the conductors. Since the rotor conductors are short-circuited together at each end, the effect will be to cause currents to flow in these conductors. In the simplest mode of operation, these currents will be about equal to the induced voltage divided by the conductor resistance. The pattern of rotor currents for the instant t_1 of Figure 54 is shown in Figure 55. The currents are seen to be sinusoidally distributed around the rotor periphery and to be located so as to produce a counterclockwise torque on the rotor (*i.e.*, a torque in the same direction as the field rotation). This torque acts to accelerate the rotor and to rotate the mechanical load. As the rotational speed of the rotor increases, its speed relative to that of the rotating field decreases. Thus, the induced voltage is reduced, leading to a proportional reduction in rotor conductor current and in torque. The rotor speed reaches a steady value when the torque produced by the rotor currents equals the torque required at that speed by the load with no excess torque available for accelerating the combined inertia of the load and the motor.

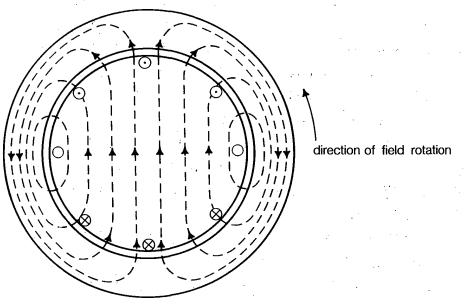

Figure 55: A rotating field and the currents that it produces in shorted rotor conductors.

The mechanical output power must be provided by an electrical input power. The original stator currents shown in Figure 54 are just sufficient to produce the rotating magnetic field. To maintain this rotating field in the presence of the rotor currents of Figure 55, it is necessary that the stator windings carry an additional component of sinusoidal current of such a magnitude and phase as to cancel the effect of the magnetic field that would otherwise be produced by the rotor currents in Figure 55. The total stator current in each phase winding is then the sum of a sinusoidal component to produce the magnetic field and another sinusoid, leading the first by one-quarter of a cycle, or 90°, to provide the required electrical power. The second, or power, component of the current is in phase with the voltage applied to the stator, while the first, or magnetizing, component lags the applied voltage by a quarter cycle, or 90°. At rated load, this magnetizing component is usually in the range of 0.4 to 0.6 of the magnitude of power component.

Power and magnetizing components of current

A majority of three-phase induction motors operate with their stator windings connected directly to a three-phase electric supply of constant voltage and constant frequency. Typical supply voltages range from 230 volts line-to-line for motors of relatively low power (*e.g.*, 0.5 to 50 kilowatts) to about 15 kilovolts line-to-line for high-power motors up to about 10 megawatts.

Except for a small voltage drop in the resistance of the stator winding, the supply voltage is matched by the time rate of change of the magnetic flux in the stator of the machine. Thus, with a constant-frequency, constant-voltage supply, the magnitude of the rotating magnetic field is held constant, and the torque is roughly proportional to the power component of the supply current.

With the induction motor shown in Figures 53, 54, and 55, the magnetic field rotates through one revolution for each cycle of the supply frequency. For a 60-hertz supply, the field speed is then 60 revolutions per second, or 3,600 per minute. The rotor speed is less than the speed of

the field by an amount that is just enough to induce the required voltage in the rotor conductors to produce the rotor current needed for the load torque. At full load, the speed is typically 0.5 to 5 percent lower than the field speed (often called synchronous speed), with the higher percentage applying to smaller motors. This difference in speed is frequently referred to as the slip.

Other synchronous speeds can be obtained with a constant frequency supply by building a machine with a larger number of pairs of magnetic poles, as opposed to the two-pole construction of Figure 53. The possible values of magnetic-field speed in revolutions per minute are $120f/p$, where f is the frequency in cycles per second and p is the number of poles (which must be an even number). A given iron frame can be wound for any one of several possible numbers of pole pairs by using coils that span an angle of approximately $(360/p)°$. The torque available from the machine frame will remain unchanged, since it is proportional to the product of the magnetic field and the allowable coil current. Thus, the power rating for the frame, being the product of torque and speed, will be roughly inversely proportional to the number of pole pairs. The most common synchronous speeds for 60-hertz motors are 1,800 and 1,200 revolutions per minute.

Construction of induction motors. The stator frame consists of laminations of silicon steel, usually with a thickness of about 0.5 millimetre. Lamination is necessary since a voltage is induced along the axial length of the steel as well as in the stator conductors. The laminations are insulated from each other by a varnish layer in most cases. This breaks up the conducting path in the steel and limits the losses (known as eddy current losses) in the steel.

The stator coils are normally made of copper; round conductors of many turns per coil are used for small motors, and rectangular bars of fewer turns are employed for larger machines. The coils are electrically insulated. It is common practice to bring only three leads out to a terminal block whether the winding is connected in wye or in delta.

The magnetic part of the rotor is also made of steel laminations, mainly to facilitate stamping conductor slots of the desired shape and size. In most induction motors, the rotor winding is of the squirrel-cage type where solid conductors in the slots are shorted together at each end of the rotor iron by conducting end rings. In such machines there is no need to insulate the conductors from the iron. For motors up to about 300 kilowatts, the squirrel cage often consists of an aluminum casting incorporating the conductors, the end rings, and a cooling fan. For larger motors, the squirrel cage is made of copper, aluminum, or brass bars welded or brazed to end rings of a similar material. In any case, the rotor is very rugged and is also economical to produce in contrast to rotors requiring an electrically insulated winding.

Squirrel-cage rotor winding

The rotor slots need not be rectangular. The shape of the slots can be designed to provide a variety of torque-speed characteristics.

Starting characteristics. When operated from a constant-frequency supply, the three-phase induction motor constitutes essentially a constant-speed drive, with the speed decreasing only 1 to 5 percent as load torque is increased from zero to rated value. In most installations, induction motors can be started and brought up to speed by connecting the stator terminals directly to the electric supply. This establishes the rotating field in the machine. At zero speed the velocity of this field, relative to that of the rotor, is high. If the rotor current were limited only by the resistance of the rotor bars, the rotor currents would be extremely high. The starting current is, however, limited by additional paths for the magnetic field around the stator and rotor conductors, known as flux leakage paths. Usually, the starting current is thus limited to about four to seven times rated current when started on full voltage. The torque at starting is usually in the range of 1.75 to 2.5 times rated value.

If the stator current on starting is larger than is permissible from the electric supply system, the motor may be started on a reduced voltage of about 70 to 80 percent using a step-down transformer. Alternatively, the stator windings can be connected in wye to start and can be switched to delta as the speed approaches rated value. Such measures reduce the starting torque substantially. A reduction in the starting voltage to 75 percent results in a reduction in the electric supply current to 56 percent but also results in only 56 percent of the starting torque that would be provided with full voltage.

Other motor starters insert a resistance or inductance in series with each stator phase during the starting period.

Protection. The heat generated by power losses in the conductors and iron parts of the machine, as well as the friction heat, must be removed by the cooling system to limit the temperature of the motor. The main purpose of protection apparatus is to prevent damage to the most vulnerable part of the motor, the insulation on the windings. For low-power motors, a temperature-sensitive device is often mounted inside the motor and used to switch off the electric supply if the temperature reaches its limiting value. With larger motors, temperature-sensitive detectors may be imbedded at one or more locations in the stator windings.

Wound-rotor induction motors. Some special induction motors are constructed with insulated coils in the rotor similar to those in the stator winding. The rotor windings are usually of a three-phase type with three connections made to insulated conducting rings (known as slip rings) mounted on an internal part of the rotor shaft. Carbon brushes provide for external electric connections.

Use of slip rings

A wound-rotor motor with three resistors connected to its slip rings can provide a high starting torque without excessive starting current. By varying the resistance, a degree of speed control can be provided for some types of mechanical load. The efficiency of such drives is, however, low unless the speed is reasonably close to the synchronous value because of the high losses in the rotor circuit resistances. As an alternative, an electronic rectifier-inverter system can be connected to the rotor slip rings to extract power and feed it back to the electric supply system. This arrangement, normally called a slip recovery system, provides speed control with acceptable efficiency.

Single-phase induction motors. The development of a rotating field in an induction machine requires a set of currents displaced in phase (as shown in Figure 48) flowing in a set of stator windings that are displaced around the stator periphery. While this is straightforward where a three-phase supply is available, most commercial and domestic supplies are only of a single phase, typically with a voltage of 120 or 240 volts. There are several ways in which the necessary revolving field can be produced from this single-phase supply.

Capacitor induction motor. This motor is similar to the three-phase motor except that it has only two windings on its stator displaced 90° from each other. One winding (a-a' in Figure 56) is connected directly to the single-phase supply. For starting, the other winding (commonly called the auxiliary winding) is connected through a capacitor (a device that stores electric charge) to the same supply. The effect of the capacitor is to make the current entering the winding b-b' lead the current in a-a' by approximately 90°, or one-quarter of a cycle, with the rotor at standstill. Thus, the rotating field and the starting torque are provided.

Means of providing a rotating field

As the motor speed approaches its rated value, it is no longer necessary to excite the auxiliary winding to maintain the rotating field. The currents produced in the rotor

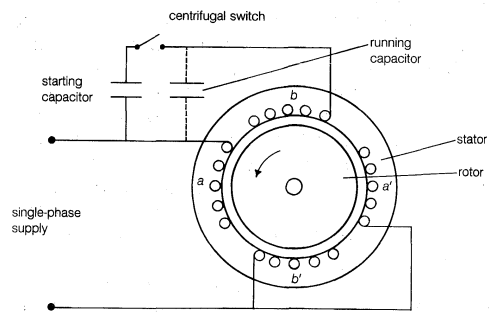

Figure 56: Capacitor induction motor.

squirrel-cage bars as they pass the winding *a-a′* are retained with negligible change as they rotate past the winding *b-b′*. The rotor can continue to generate the rotating field with only winding *a-a′* connected. The winding *b-b′* is usually disconnected by a centrifugal switch that opens when the speed is about 80 percent of rated value.

Power ratings for these capacitor-start induction motors are usually restricted to about two kilowatts for a 120-volt supply and 10 kilowatts for a 230-volt supply because of the limitations on the voltage drop in the supply lines, which would otherwise occur on starting. Typical values of synchronous speed on a 60-hertz supply are 1,800 or 1,200 revolutions per minute for four- and six-pole motors, respectively. Lower-speed motors can be constructed with more poles but are less common.

The efficiency of the motor can be somewhat increased and the line current decreased by the use of two capacitors, only one of which is taken out of the circuit (by means of a centrifugal switch) as the rated speed is approached. The remaining capacitor continues to provide a leading current to phase *b-b′*, approximating a two-phase supply. This arrangement, also shown in Figure 56, is known as a capacitor-start, capacitor-run motor.

Capacitor induction motors are widely used for heavy-duty applications requiring high starting torque. Examples are refrigerator compressors, pumps, and conveyors.

Use of two stator windings

Split-phase motors. An alternative means of providing a rotating field for starting is to use two stator windings, as in Figure 57, where the auxiliary winding *b-b′* is made of more turns of smaller conductors so that its resistance is much larger than that of winding *a-a′*. The effect of this is that the current in phase *b-b′* leads that of *a-a′*, but only by about 20–30 degrees at standstill. While the field is largely pulsating, it contains enough rotating component to provide a starting torque of 1.5 to 2.0 times rated value. To prevent overheating, the auxiliary winding is disconnected by a centrifugal switch when the speed reaches 75–80 percent of rated value.

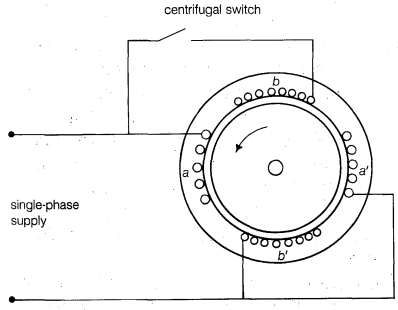

Figure 57: Split-phase induction motor.

These split-phase motors are inexpensive to produce and are installed in many domestic appliances. Where more than one steady speed is required, as in household laundry appliances, the motor may be wound for two alternative pole pairs, one for low speed and the other for high speed.

Shaded-pole motors. The shaded-pole motor is provided with a main winding connected to the single-phase electric supply. In addition, it has a permanently short-circuited winding located ahead of the main winding in the direction of rotation. This second winding is known as a shading coil and consists of one or more shorted turns. The shading coil delays the establishment of magnetic flux in the region that it encircles and thus produces a small component of rotating field at standstill.

The starting torque is small, typically only 30 to 50 percent of the rated torque. As a result, the motor is suitable only for mechanical loads, such as fans, for which the torque is low at low speed and increases with speed.

Shaded-pole motors are inefficient because of the losses in the permanently shorted winding. As a result, they are used only in small power ratings where efficiency is less important than initial cost. Typical efficiencies are up to 30 percent in larger units and less than 5 percent in very small ones. They are used mainly for fans and other small household appliances.

Servomotors. A servomotor is a small induction motor with two stator windings displaced 90° with respect to each other around its periphery. The rotor is usually of the squirrel-cage type but made with relatively high resistance conductors. The purpose of the motor is to provide a controlled torque in either direction of operation. To achieve this, one winding is connected to a single-phase, constant-frequency supply. The other winding is provided with a voltage of the same frequency, displaced 90° in phase. This voltage is normally provided by an electronic amplifier with a low power signal input. The motor torque is approximately proportional to the voltage on this second winding and thus to the signal input. The direction of the torque can be reversed by changing the input signal from 90° leading to 90° lagging.

On some servomotors the rotor consists of an aluminum cup fitted in the air gap between the stator and a stationary iron core. This rotor has low inertia and is capable of high acceleration. Servomotors are made only in small power ratings because of their high losses and low efficiency. They are used in position-control systems.

Linear induction motors. A linear induction motor provides linear force and motion rather than rotational torque. The shape and operation of a linear induction motor can be visualized as depicted in Figure 58 by making a radial cut in a rotating induction machine and flattening it out. The result is a flat "stator," or upper section, of iron laminations that carry a three-phase, multipole winding with conductors perpendicular to the direction of motion. The "rotor," or lower section, could consist of iron laminations and a squirrel-cage winding but more normally consists of a continuous copper or aluminum sheet placed over a solid or laminated iron backing.

Use of linear motors in rapid-transit vehicles

An emerging application of linear motors is in rapid-transit vehicles for public transportation. The stator (as described above) is carried on the underside of the vehicle, and the rotor is located between the rails on the track. An advantage of this type of propulsion is that high acceleration and braking can be obtained without dependence on adhesion of the steel wheels to the steel rails in the presence of rain, ice, or a steep slope.

Electrical power is supplied to such a rapid-transit vehicle through sliding connections to an energized rail or overhead wire. To provide speed control and braking, an electronic power-conditioning apparatus on board the vehicle produces a three-phase output of the desired voltage and frequency.

In an alternative arrangement for vehicle propulsion, the copper and iron sheets of Figure 58 can be placed on the underside of the vehicle and sections of stator can be placed at intervals along the track. This has the advantage that no electric power need be supplied to the vehicle itself.

Linear induction motors also are used to drive conveyors, sliding doors, textile shuttles, and machine tools. Their advantage is that no physical contact is required and thus wear and maintenance are minimized. In another form, linear motors are used as electromagnetic pumps where the rotor consists of a conducting fluid, such as a liquid metal (say, mercury of sodium-potassium alloy).

The efficiency of linear motors is somewhat less than

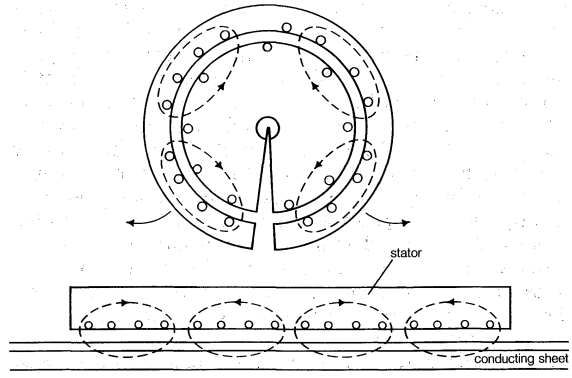

Figure 58: *Evolution of a linear induction motor.*
The four-pole induction motor is shown as (top) split open and (bottom) flattened (see text).

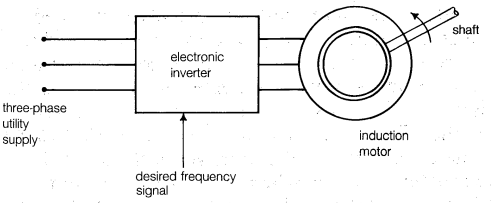

Figure 59: A variable-frequency, variable-speed induction-motor drive system.

that of rotating motors because of end effects. Its "rotor" must be magnetized as it comes under the "stator." This reduces the effectiveness of the first one or two pole spans. The input current is also relatively high because the air gap is usually larger than in rotating machines and more current is required to produce the magnetic field across it.

Induction motors for speed and position control. On a constant-frequency supply, an induction motor is essentially a near-constant speed drive. Induction motors, however, can be used to provide accurate speed and position control in either direction of rotation by furnishing a controllable-voltage, controllable-frequency three-phase supply. This is done by means of an electronic inverter, as shown in Figure 59. Using semiconductor switches (*e.g.*, transistors or thyristors), the utility supply is converted into a set of three near-sinusoidal inputs of controlled voltage and frequency to the stator winding. The speed of the motor will then approach the synchronous value of $120\,f/p$ revolutions per minute for a controlled frequency of f cycles per second. Reversal of the phase sequence from *abc* to *acb* reverses the direction of the torque. For accurate control of speed or of position, the speed of the shaft can be monitored by a tachometer or position sensor and compared with a signal representing the desired value. The difference is then used to control the inverter frequency. Generally, the voltage varies directly with the frequency to keep the magnitude of the magnetic field constant.

Synchronous motors. Such a motor is one in which the rotor normally rotates at the same speed as the revolving field in the machine. The stator is similar to that of an induction machine (as in Figure 53) consisting of a cylindrical iron frame with windings, usually three-phase, located in slots around the inner periphery. The difference is in the rotor, which normally contains an insulated winding connected through slip rings or other means to a source of direct current (see Figure 46).

The principle of operation of a synchronous motor can be understood by considering the stator windings to be connected to a three-phase alternating-current supply. The effect of the stator current is to establish a magnetic field rotating at $120\,f/p$ revolutions per minute for a frequency of f hertz and for p poles. A direct current in a p-pole field winding on the rotor will also produce a magnetic field rotating at rotor speed. These two magnetic fields will tend to align with each other. With no load torque, they may be assumed to be in alignment. As mechanical load is applied, the rotor slips back a number of degrees with respect to the rotating field of the stator, developing torque and continuing to be drawn around by this rotating field. The angle between the fields increases as load torque is increased. The maximum available torque is achieved for given magnitudes of stator and rotor currents when the angle by which the rotor field lags the stator field is 90°. Application of more load torque will stall the motor.

One advantage of the synchronous motor is that the magnetic field of the machine can be produced by the direct current in the field winding, so that the stator windings need to provide only a power component of current in phase with the applied stator voltage—*i.e.*, the motor can operate at unity power factor. This condition minimizes the losses and heating in the stator windings.

The power factor of the stator electrical input can be directly controlled by adjustment of the field current. If the field current is increased beyond the value required to provide the magnetic field, the stator current changes to include a component to compensate for this overmagnetization. The result will be a total stator current that leads the stator voltage in phase, thus providing to the power system reactive volt-amperes needed to magnetize other apparatuses, such as transformers and induction motors. Operation of a large synchronous motor at such a leading power factor may be an effective way of improving the overall power factor of the electrical loads in a manufacturing plant to avoid additional electric supply rates that may otherwise be charged for low power-factor loads.

Applications of three-phase synchronous motors

Three-phase synchronous motors find their major application in industrial situations where there is a large, reasonably steady mechanical load, usually in excess of 300 kilowatts, and where the ability to operate at leading power factor is of value. Below this power level, synchronous machines are generally more expensive than induction machines. In some instances, a synchronous machine is installed for the sole purpose of improving overall plant power factor. In this case, it is called a synchronous capacitor because it provides the same power factor correction as capacitors connected across the supply line.

The field current may be supplied from an externally controlled rectifier through slip rings, or, in larger motors, it may be provided by a shaft-mounted rectifier with a rotating transformer or generator.

A synchronous motor with only a field winding carrying a direct current would not be self-starting. At any speed other than synchronous speed, its rotor would experience an oscillating torque of zero average value as the rotating magnetic field repeatedly passes the slower moving rotor. Normally, a short-circuited winding similar to that of an induction machine is added to the rotor to provide starting torque, as shown in Figure 60. The motor is started, either with full or reduced stator voltage, and brought up to about 95 percent of synchronous speed, usually with the field winding short-circuited to protect it from excessive induced voltage. The field current is then applied and the rotor pulls into synchronism with the revolving field.

This additional rotor winding is usually referred to as a damper winding because of its additional property of damping out any oscillation that might be caused by sudden changes in the load on the rotor when in synchronism. Adjustment to load changes involves changes in the angle by which the rotor field lags the stator field and thus involves short-term changes in instantaneous speed. These cause currents to be induced in the damper windings, producing a torque that acts to oppose the speed change.

Protection for synchronous motors is similar to that employed with large induction motors. Temperature may be sensed in both the stator and field windings and used to switch off the electric supply. Considerable heating occurs in the rotor-damper winding during starting, and a timer is frequently installed to prevent repeated starts within a limited time interval.

Permanent-magnet motors. The magnetic field for a synchronous machine may be provided by using permanent magnets rather than a field winding. This eliminates the need for slip rings and an external source of field current and provides a simple rugged rotor. The motor does not, however, have a means of controlling the stator power factor.

Use in variable-speed drives

The rotor can be of the form shown in Figure 50 with radially directed magnets made of neodymium-boron-iron, samarium-cobalt, or ferrite. The machine in the figure does not contain a damper winding and thus cannot be started on a constant-frequency supply. The main application for a motor of this type is in variable-speed drives

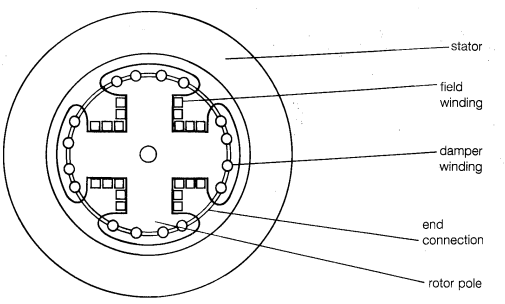

Figure 60: Cross section of rotor of a four-pole synchronous motor.

where the stator is supplied from a variable-frequency, variable-voltage source. Where starting capability is required, the magnets are imbedded in the rotor iron and a damper winding is placed in slots in the rotor surface (see Figure 60).

An alternative form of permanent-magnet motor is shown in Figure 61. Circumferentially directed magnets provide flux to iron poles, which in turn set up a radial field in the air gap. This form is particularly suitable for small motors using ferrite magnets.

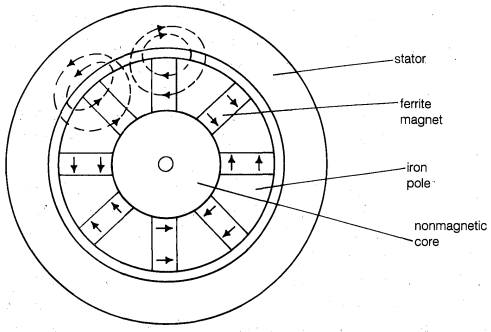

Figure 61: Cross section of an eight-pole synchronous motor with circumferentially directed permanent magnets.

Hysteresis motors. A distinctive feature of synchronous motors is that the speed is uniquely related to the supply frequency. As a result, several special types of synchronous motors have found wide application in devices such as clocks, tape recorders, and phonographs. One of the most extensively used is the hysteresis motor in which the rotor consists of a ring of a semi-permanent magnet material like a high-carbon steel. At full speed, the motor operates as a permanent-magnet machine. If the speed is reduced by pulling the rotor out of synchronism, the stator field causes the rotor material to be cyclically magnetized around its hysteresis loop, resulting in a rotor field that lags the stator field by a few degrees and continues to produce torque. These motors provide good starting torque and are very quiet. Their efficiency is low, and applications are restricted to small power ratings.

Reluctance motors. Machines of this kind operate on the principle that forces are established tending to minimize the volume of any air gap in an iron system carrying a magnetic field. One of the forms of a reluctance motor is shown in cross section in Figure 62. The rotor consists of four iron poles with no electrical windings. The stator has six poles each with a current-carrying coil. In the condition represented in the figure, current has just been passed through coils a and a', producing a torque on the rotor aligning two of its poles with those of the a-a' stator. The current is now switched off in coils a and a' and switched on to coils b and b'. This produces a counterclockwise torque on the rotor aligning two rotor poles with stator poles b and b'. This process is then repeated with stator coils c and c' and then with coils a and a'. The torque is dependent on the magnitude of the coil currents but is independent of its polarity. The direction of rotation can be changed by changing the order in which the coils are energized.

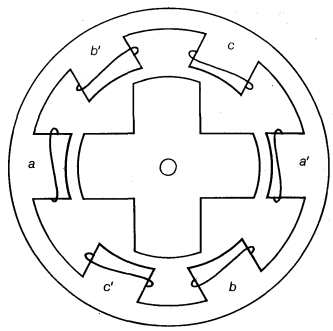

Figure 62: A reluctance motor in cross section.

The currents in the stator coils are usually controlled by semiconductor switches connecting the coils to a direct voltage source. A signal from a position sensor mounted on the motor shaft is used to activate the switches at the appropriate time instants. Frequently a magnetic sensor based on the Hall effect is employed. (The Hall effect involves the development of a transverse electric field in a semiconductor material when it carries a current and is placed in a magnetic field perpendicular to the current.) The overall system is known as a self-synchronous motor drive. It can operate over a wide and controlled speed range.

Self-synchronous motor drive

There are several other configurations for reluctance motors. In one form, the rotor consists of an iron ring with radial cuts or slots through it. A p-pole rotor has p sectors, or arcs. The magnetic flux travels circumferentially around the arc of this rotor ring, completing the path between adjacent stator poles.

In another form, the rotor has salient poles of the configuration shown in Figure 60 but without the field windings. The stator is cylindrical and contains a three-phase winding connected to a constant-frequency supply. A damper winding is fitted in the rotor surface so that the machine can start as an induction motor. After the rotor pulls into synchronism with the rotating field of the stator, it operates as a synchronous motor at constant speed.

Single-phase synchronous motors. A revolving field can be produced in synchronous motors from a single-phase source by use of the same method as for single-phase induction motors. With the main stator winding connected directly to the supply, an auxiliary winding may be connected through a capacitor, as in Figure 56. Alternatively, an auxiliary winding of a higher resistance can be employed, as in Figure 57. For small clock motors, the shaded-pole construction of the stator is widely used in combination with a hysteresis-type rotor (see above). The efficiency of these motors is very low, usually less than 2 percent, but the cost is low as well.

Direct-current commutator motors. A sketch of an elementary form of DC motor is provided in Figure 51. A stationary magnetic field is produced across the rotor by poles on the stator. These poles may be encircled by field coils carrying direct current, or they may contain permanent magnets. The rotor or armature consists of an iron core with a coil accommodated in slots. The ends of the coil are connected to the bars of a commutator switch mounted on the rotor shaft. Stationary graphite brushes lead to external terminals.

Components and characteristics

Suppose a direct-current supply is connected to the armature terminals such that a current enters at the positive terminal shown in Figure 51. This current interacts with the magnetic flux to produce a counterclockwise torque, which in turn accelerates the rotor. When the rotor has turned about 120° from the position shown in the figure, the connection from the supply to the armature coil is reversed by the commutator. The new direction of the current in the armature coil is such as to continue to produce counterclockwise torque. As the rotor rotates in a counterclockwise direction, a voltage proportional to the speed is generated in the armature coil (see *Direct-current generators* above). While this coil voltage is alternating, the commutator action produces a unidirectional voltage at the motor terminals with the polarity shown. The electrical input will be the product of this terminal voltage and the input current. The mechanical output power will be the product of the rotor torque and speed.

In a practical DC motor, the armature winding consists of a number of coils in slots, each spanning $1/p$ of the rotor periphery for p poles. In small motors the number of coils may be as low as six, while in large motors it may be as large as 300. The coils are all connected in series, and each junction is connected to a commutator bar, as indicated in Figure 63. If current enters at the positive brush, the coil currents have the directions shown. All coils under the poles contribute to torque production.

The motor in Figure 63 contains two poles made of ferrite permanent-magnet material. This structure is typical of small DC motors such as those used in automobile fans. When higher torque is required, as, for example, in

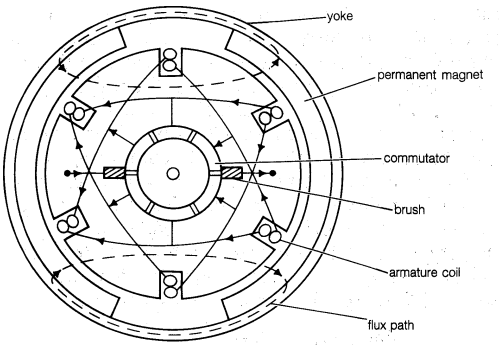

Figure 63: Direct-current commutator motor with a permanent-magnet field.

the starter motor of an automobile, stronger magnets such as neodymium-iron-boron may be employed. When the terminals of this motor are connected to a constant direct-voltage source, such as a battery, the initial current will be limited only by the resistance of the armature winding and the brushes. The torque produced by the interaction of this current with the field accelerates the rotor. A voltage is generated in the winding proportional to the speed. This voltage opposes that of the source, thus reducing the current and the torque. With no mechanical load, the generated voltage will rise to a value nearly equal to the source voltage, allowing just enough current to provide for friction torque. Application of a load torque slows down the rotor, decreasing the generated voltage, increasing the current, and producing torque to match the load torque.

With larger motors, the armature winding resistance is too low to limit the current on starting to a value that can be switched by the commutator. These motors are normally started with a resistance connected in series to the armature supply. This resistance is usually decreased in stages as the speed increases.

Speed-adjustment capability

The permanent-magnet commutator motor of Figure 63 has no provision for speed control when attached to a constant-voltage supply. If speed adjustment is desired, the permanent-magnet field can be replaced by iron poles with field coils. These coils can be provided with current from the same supply as for the armature or from a separate supply. A variable series resistor can be used to adjust the field current. With maximum field current and thus maximum magnetic flux, the generated voltage will equal the supply voltage at a minimum value of no-load speed. As load is added, the speed will reduce somewhat and the armature current will increase to produce the required torque. If the field current is reduced, the motor will have to rotate faster through the reduced flux to generate the same voltage. The no-load speed will be increased. For a given rated armature current, the available torque will be reduced because of the reduced flux. The motor, however, will be able to provide the same mechanical power at a higher speed and lower torque.

Shunt motors

Commutator motors with adjustable field current are known as shunt motors, or separately excited motors. Normally, the available speed range is less than 2 to 1, but special motors can provide a speed range of up to 10 to 1.

Another form of commutator motor is the series motor in which the field coils, with relatively few turns, carry the same current as does the armature. With a high value of current, the flux is high, making the torque high and the speed low. As the current is reduced, the torque is reduced and the speed increases. In the past, such motors were widely used in electric transportation vehicles, such as subway trains and fork-lift trucks.

Large DC motors usually have four or more poles to reduce the thickness of the required iron in the stator yoke and to reduce the length of the end connections on the armature coils. These motors may also have additional small poles, or interpoles, placed between the main poles and have coils carrying the supply current. These poles are placed so as to generate a small voltage in each armature coil as it is shorted out by the commutator. This assists the quick reversal of current in the coil and prevents commutator sparking.

DC commutator motors have been extensively used in steel mills, paper mills, robots, and machine tools where accurate control of speed or speed reversal, or both, are required. The field is supplied from a separate voltage source, usually with constant field current, or from permanent magnets. The armature is supplied from a source of controllable voltage. The speed is then approximately proportional to the source voltage. Reversal of the armature supply voltage at a controlled rate reverses the motor.

Alternating-current commutator motors. A specially designed series-commutator motor may be operated from a single-phase alternating voltage supply. When the supply current reverses, both the magnetic field and the armature current are reversed. Thus, the torque remains in the same direction. These motors are often called universal motors because they may be used with either a direct-voltage supply or with a 60-hertz alternating-voltage supply. They have wide application in such small domestic appliances as mixers, portable tools, and vacuum cleaners.

Universal motors

DEVELOPMENT OF ELECTRIC GENERATORS AND MOTORS

Within a year of Michael Faraday's discovery of electromagnetic induction (1831), a small hand generator was demonstrated in Paris, and by 1850 generators were being manufactured in several countries. These early generators were little more than assemblies of coils and permanent magnets that could be maintained in relative motion. Further developments of significance did not appear until the experimental work of William Sturgeon of England and of Joseph Henry and Thomas Davenport of the United States led to the manufacture of practical electromagnets. This technological advance contributed much to the development of practical electrical machines.

First electric motor of commercial significance

The French engineer and inventor Zénobe-Théophile Gramme built the first truly commercial electric motor, which he demonstrated in 1873. Using iron-cored electromagnets and an iron ring armature surrounded by a winding, Gramme produced a practical, efficient machine that could be used either as a motor or as a generator. His machine was of the DC commutator type. It provided the basis for early DC electric supply.

The first significant AC motor was patented by the Serbian-American inventor Nikola Tesla in 1888. Tesla's motor was able to utilize the two- and three-phase alternating-current supplies that were becoming readily available at the time. Its principle of operation provides the basis for the majority of electric motors produced today. (G.R.Sl.)

Direct energy-conversion devices

BATTERIES

General characteristics. A battery is a simple device that converts chemical energy directly to electrical energy. It consists of two or more galvanic, or electrochemical, cells that produce direct-current electricity. The term battery is also commonly applied to a single galvanic cell. Every battery (or cell) has a cathode, or positive electrode, and an anode, or negative electrode. These electrodes must be separated by and are often immersed in an electrolyte that permits the passage of ions between the electrodes (Figure 64). The electrode materials and electrolyte are chosen and arranged so that sufficient electromotive force (voltage) and electric current (amperes) can be developed between the terminals of a battery to operate lights, machines, or other devices. Since an electrode contains only a limited number of units of chemical energy convertible to electrical energy, it follows that a battery of a given size has a certain capacity to operate devices and will eventually become exhausted. The active parts of a battery are usually encased in a box (or jacket) and cover system that keeps air outside and the electrolyte solvent inside and that provides a structure for the assembly.

Factors that affect battery performance

Battery usefulness is limited not only by capacity but also by how fast current can be drawn from it. The salt ions chosen for the electrolyte solution must be able to move fast enough through the solvent to carry chemical matter between the electrodes equal to the rate of electrical demand. Battery performance is thus limited by the diffusion rates of internal chemicals as well as by capacity.

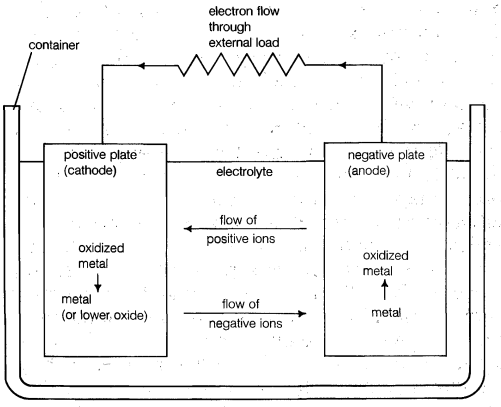

Figure 64: Basic components of an electrochemical cell.

The voltage of an individual cell and the diffusion rates inside it are both reduced if the temperature is lowered from a reference point, such as 21° C. If the temperature falls below the freezing point of the electrolyte, the cell will usually produce very little useful current and may actually change internal dimensions, resulting in internal damage and diminished performance even after it has warmed up again. If the temperature is raised deliberately, faster discharge can be sustained, but this is not generally advisable because the battery chemicals may evaporate or react spontaneously with one another, leading to early failure.

Beyond the technical factors so far discussed, it must be recognized that commercially available batteries are designed and built with market factors in mind. The quality of materials and the complexity of electrode and container design are reflected in the market price sought for any specific product. As new materials are discovered or the properties of traditional ones improved, however, the typical performance of even older battery systems sometimes increases by large percentages.

Batteries are divided into two general groups: (1) primary batteries and (2) secondary, or storage, batteries. Primary batteries are designed to be used until the voltage is too low to operate a given device and then discarded. Secondary batteries have many special design features, as well as particular materials for the electrodes, that permit them to be reconstituted (recycled). After partial or complete discharge, they can be recharged by DC voltage and current to their original state. While this original state is usually not restored completely, the loss per cycle in commercial batteries is only a small fraction of 1 percent even under varied conditions.

Principles of operation. The anode of an electrochemical cell (Figure 64) is usually a metal that is oxidized (gives up electrons) at a potential between 0.5 volt and about four volts above that of the cathode. The cathode generally consists of a metal oxide or sulfide that is converted to a less-oxidized state by accepting electrons, along with ions, into its structure. A conductive link via an external circuit (*e.g.*, a lamp or other device) must be provided to carry electrons from the anode to the negative battery contact. Sufficient electrolyte must be present as well. The electrolyte consists of a solvent (water, an organic liquid, or even a solid) and one or more chemicals that dissociate into ions in the solvent. These ions serve to deliver electrons and chemical matter through the cell interior to balance the flow of electric current outside the cell during cell operation.

Anode and cathode composition

The fundamental relationship of electrochemical cell operation put forth by Faraday in 1834 is that for every ampere that flows for a period of time a matching chemical reaction or other change must take place. The extent of these changes is dependent on the molecular and electronic structure of the elements comprising the battery electrodes and electrolyte. Secondary changes may also occur, but a primary pair of theoretically reversible reactions must take place at the electrodes for electricity to be produced. The actual DC power generated by a battery is measured by the number of amperes produced × the unit of time × the average voltage over that time. For a cell with electrodes of zinc and manganese dioxide (*e.g.*, the common flashlight dry cell), one finds that a chemical equivalent of zinc weighs 32.5 grams and that of manganese dioxide about 87 grams. The discharge of one equivalent weight of each of these electrodes will cause 32.5 grams of zinc to dissolve and 87 grams of manganese dioxide to change into a different oxide containing more hydrogen and zinc ions. Some of the electrolyte also will be consumed in the reaction. One chemical equivalent of each electrode produces one faraday, or 96,500 coulombs of current equal to 26.8 amperes per hour. If the cells operate at an average of 1.2 volts, this would yield 32.2 watt-hours of DC energy. Expressed another way,

$$\text{Energy (joules)} = nFV,$$

where n equals the number of chemical equivalents discharged, F is the Faraday constant (9.648×10^4 coulombs per mole), and V is the average (not necessarily constant) voltage of the cell for the period of the discharge.

There is a large number of elements and compounds from which to select potentially useful combinations for batteries. The commercial systems in common use represent the survivors of numerous tests where continued use depended on adequate voltage, high current-carrying capacity, low-cost materials, and tolerance for user neglect. Better sealing technology and plastics are making further development of all cell systems possible, but particularly those using very active lithium for the anode. This situation has yielded commercial cells with as much as 3.6 volts on load and very high current-carrying capability.

Primary batteries. *Zinc–manganese dioxide systems.* These cell systems are the most commonly used worldwide in flashlights, toys, radios, tape recorders, and flash cameras. There are three variations: the Leclanché cell, the zinc chloride cell, and the alkaline cell. All provide an initial voltage of 1.58 to 1.7 volts, which declines with use to an end point of about 0.8 volt. The Leclanché cell (Figure 65) is the least expensive, traditional general-purpose dry cell available nearly everywhere. Invented by the French engineer Georges Leclanché in 1866, it immediately became a commercial success in large sizes because of its readily available low-cost constituent materials. The anode of this primary cell is a zinc alloy sheet or "cup," the alloy containing small amounts of lead, cadmium, and mercury. The electrolyte consists of a saturated aqueous solution of ammonium chloride containing roughly 20 percent zinc chloride. The cathode is made of impure manganese dioxide (usually mined from selected deposits in Africa, Brazil, or Mexico). This compound is blended with carbon black and electrolyte to create a damp, active cathode mixture which is formed around a carbon collector rod, also called an electrode. All cells of this type are provided with an overwrap structure with metal covers for electrical contact.

Leclanché cell

While first patented in 1899, the zinc chloride cell is really a modern adaptation of the Leclanché cell. Its commercial success is attributable in part to the development of plastic seals that has made it possible to largely dispense with the use of ammonium chloride (Figure 66).

Zinc chloride cell

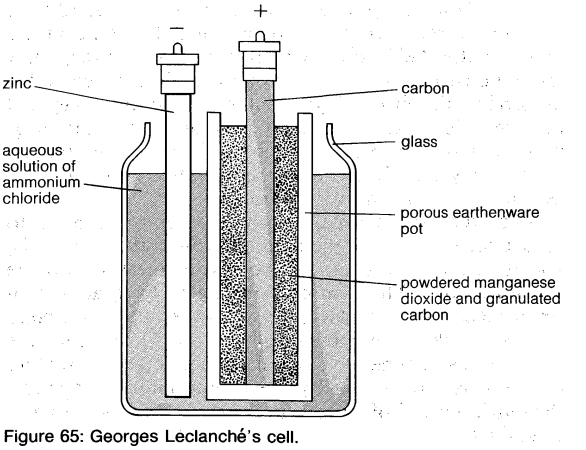

Figure 65: Georges Leclanché's cell.

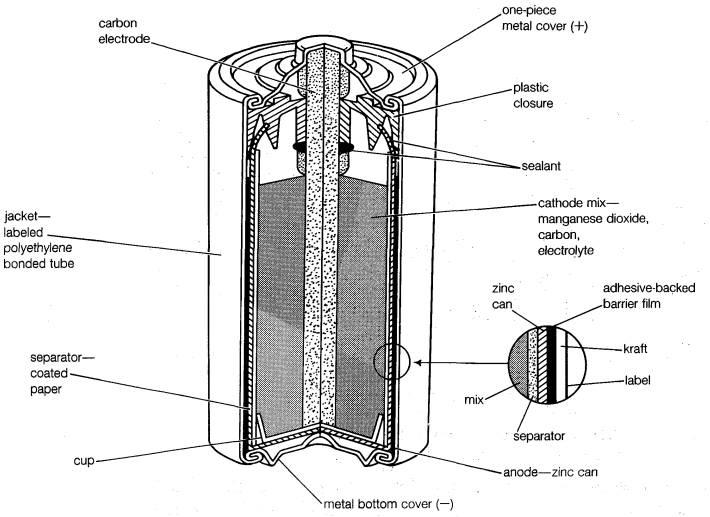

Figure 66: *Modern version of the Leclanché cell.* This heavy-duty carbon–zinc primary battery is a dry cell with an immobilized electrolyte.

By courtesy of Eveready Battery Co., Inc.

The manganese dioxide of the cathode is usually a blend of synthetic manganese dioxide of high purity with natural varieties. The zinc chloride cell is capable of greater continuous service than the Leclanché cell, particularly in motorized devices such as toys. Its use is also increasing because it can provide satisfactory performance without mercury in the zinc alloy.

Alkaline cell

The highest power density (watts per cubic centimetre) of the zinc–manganese dioxide cells is found in cells with an alkaline electrolyte, which permits a completely different type of construction, as illustrated in Figure 67. These cells became commercially available during the 1950s. A cathode of a very pure manganese dioxide–graphite mixture and an anode of a powdered zinc alloy are associated with a potassium hydroxide electrolyte and housed in a steel can. Whereas the zinc of alkaline cells formerly contained 6 to 8 percent mercury, that of present-day versions contains as little as 0.15 percent so as to reduce the environmental impact of disposal. These cells, moreover, provide higher capacity to operate flashlights, toys, cassette players, and radios than either of the other two zinc–manganese dioxide systems discussed above.

Magnesium–manganese dioxide cell. This system functions well for specialized applications. It is much like the zinc chloride cell but has 0.3 volt more per cell. Magnesium–manganese dioxide cells have a long shelf life, high energy density, and are lightweight, making them especially attractive for use as power packs for portable military radios. The one drawback of these cells is that they do not function nearly as well at below-freezing temperatures as at higher temperatures.

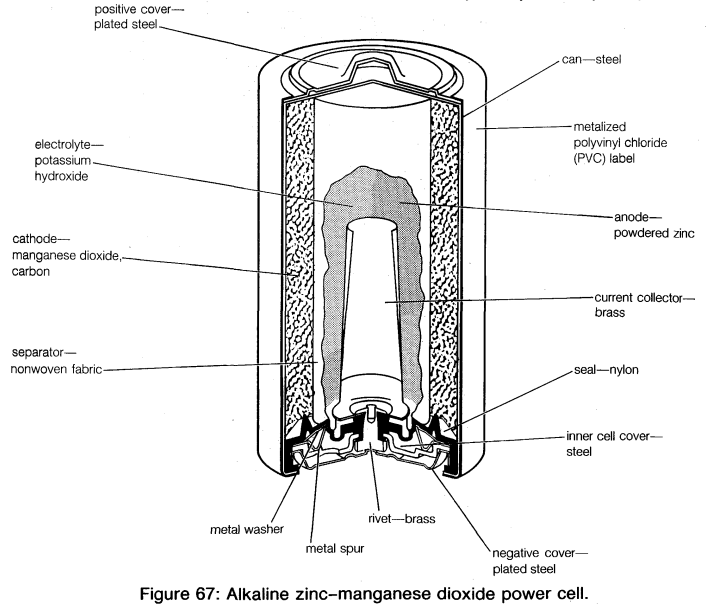

Figure 67: Alkaline zinc–manganese dioxide power cell.

Mercuric oxide–zinc cell. This is an alkaline-electrolyte battery system. It has long been used in the form of button-sized cells (Figure 68) for hearing aids and watches. Its energy density (watt-hours per cubic centimetre) is approximately four times greater than that of the alkaline zinc–manganese dioxide cell. Since the mercuric oxide–zinc cell provides an extremely reliable 1.35 volts, it serves as a standard reference cell.

Silver oxide–zinc cell. Another alkaline system, this cell features a silver oxide cathode and a powdered zinc anode. Because it will tolerate relatively heavy current load pulses and has a high, nearly constant, 1.5-volt operating voltage, the silver oxide–zinc cell is commonly used in watches, cameras, and hearing aids. In spite of its high cost, the outstanding current-carrying capability of this cell has resulted in its use as military torpedo batteries. Miniature cells can be obtained with either divalent silver oxide or monovalent silver oxide, the former usually having somewhat higher capacity.

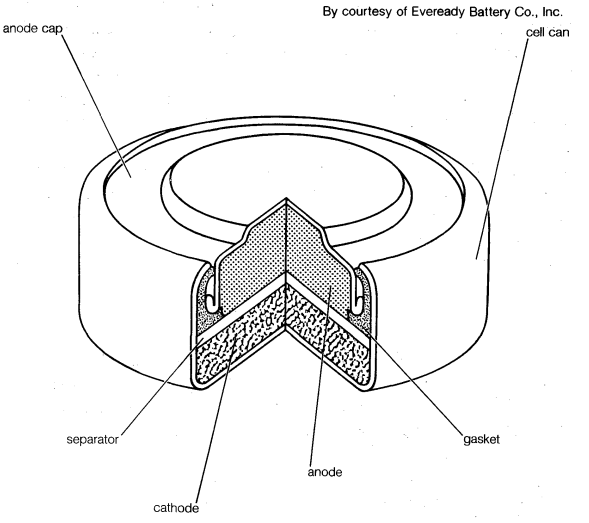

Figure 68: Typical construction of a miniature power cell, as, for example, a silver oxide–zinc or mercuric oxide–zinc system.

Lithium cells. The area of battery technology that has attracted the most research in recent years is a class of cells with a lithium anode. Because of the high chemical activity of lithium, nonaqueous (organic or inorganic) electrolytes have to be used. Such electrolytes include selected solid crystalline salts (see below). This whole new science has encouraged the commercial production of cells having no space between the anode and the liquid cathode, an unlikely condition for success in aqueous systems. A stable protective layer automatically forms on the lithium but breaks down on discharge to permit high-current operation at nearly constant voltages near 3.6 volts. By traditional measures, this allows very high power density and energy density. Lithium cells are especially attractive for use in certain aerospace applications, terrestrial portable military equipment, and such civilian applications as personal paging systems, heart pacers, and automated cameras.

Major types of lithium batteries

Lithium–iron sulfide cells in miniature sizes offer high capacity and low cost for light loads. In operations requiring 1.5 to 1.8 volts, they are a potential substitute for some silver oxide–zinc cells. In constructions where the electrodes consist of rolled up ("jelly roll") strips like those of small nickel–cadmium cells, higher power density is obtained while still retaining high capacity for premium general-purpose use. A typical electrolyte might be lithium tetrafluoborate salt in a solvent mixture of propylene carbonate, 2-methyl-2-oxazolidone, and dimethoxyethane.

Lithium–manganese dioxide cell systems have slowly gained increasingly wider application in small appliances.

Cells of this kind have an operating voltage of 2.8 volts each and offer high energy density and relatively low cost compared to some other lithium cell possibilities.

The lithium–carbon monofluoride system has been among the more successful early commercial lithium cells. It has been used extensively in cameras and smaller devices, providing about 3.2 volts per cell, high power density, and long shelf life. Good low-temperature performance and a flat voltage–time discharge relationship are provided as well. The cost of carbon monofluoride (CF_x) is high, however.

Lithium–thionyl chloride cells provide the highest energy density and power density commercially available. Thionyl chloride serves not only as the electrolyte solvent but also as the cathode material. A runaway reaction between the lithium anode and the adjacent liquid cathode material is prevented by the formation of a film of lithium chloride salt on the lithium. The electrical contact and reaction centre of the cathode are composed of porous pressed and bonded carbon powder. The performance of this type of cell system at room temperature is very impressive. Moreover, the cell can operate at −54° C, well below the point where aqueous systems function. Because of its high energy density, the lithium–thionyl chloride cell must be used with care and not be burned or disposed of casually. Such cells are useful for powering military equipment, providing backup power for aerospace systems, and operating personal pagers.

Lithium–sulfur dioxide cells have been used extensively for some emergency-aircraft power units and in military cold-weather applications (*e.g.*, radio operation). The cathode consists of a gas under pressure with another chemical as electrolyte salt; this is analogous to the thionyl chloride electrolyte and its liquid cathode. The system functions well but has been found to occasionally vent noxious sulfur dioxide, especially after cold discharge and subsequent warm-up. The release of corrosive or toxic gases by any type of cell in a closed space constitutes a significant design disadvantage.

Air-depolarized cells. A very practical way to obtain high energy density in a cell is to employ the oxygen in air for a "liquid" cathode material. If paired with an anode such as zinc, long cell life at low cost per watt-hour (for a dry cell) can be obtained because a given cell volume may be devoted more completely to anode and electrolyte material. The cell, however, must be constructed in such a way that the oxygen is prevented from reaching the anode, which it will attack.

Zinc–air cells

Zinc–air systems are commercially available in the form of very small cells and relatively large boxlike batteries. Their principle and design are simple, but the actual batteries are, from a technical standpoint, difficult to manufacture. The "air electrode" is extremely thin and usually has a waterproof polymer-bonded porous carbon layer with a metal mesh reinforcement. A catalyst and a booster oxide may be included with the carbon to render oxygen more effectively active. The sealing of the edges of the composite electrode film and electrolyte proofing of the pores have been achieved with fluorocarbons and plastics. Fundamental improvements in electrode assembly, cell seal, and vent designs continue to be sought in scientific and engineering studies.

Aluminum–air cells have not been a commercial success to date, but their light weight and potentially high energy density have attracted much government support in the United States. Research efforts have been concentrated on developing better aluminum alloys and techniques to resist corrosion during shelf storage while at the same time providing electricity at instant demand. Similarly, inhibitors for inclusion in the alkaline electrolyte are under study. Aluminum–air cells also are being considered for applications in which the metal anode, the electrolyte, and the reaction products are mechanically removed and replaced to create a kind of fuel cell (see *Fuel cells* below). If stability and cell design problems can be overcome, this system may very well prove attractive for many applications, including use in electric cars or trucks.

Other primary battery systems. Many other cell types are in use on a small scale. For example, cells that produce a very predictable standard voltage are the Clark cell (zinc–mercurous sulfate–mercury; 1.434 volts) and the Weston cell (cadmium–mercurous sulfate–mercury; 1.019 volts). For the construction of the latter, see Figure 69. Magnesium–silver chloride and magnesium–lead chloride batteries are commonly employed in undersea operations where the salt water becomes the electrolyte when the battery is submerged.

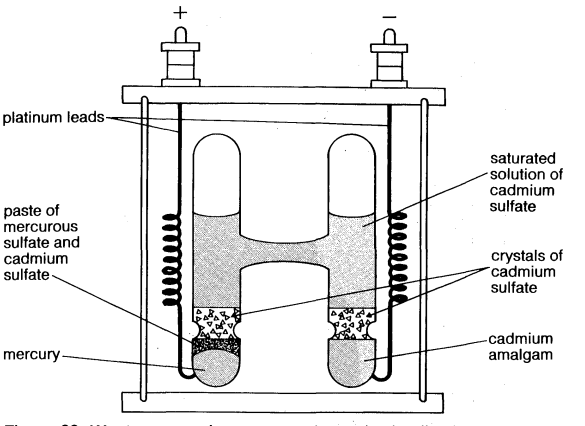

Figure 69: Weston normal or saturated standard cell.
From G. Vinal, *Storage Batteries* (© 1951), John Wiley & Sons, Inc.

An important new group of cells consists of systems with a solid electrolyte in which the mixture of compounds is such that cell ions can slowly move from site to site in the electrolyte crystal structure. Examples include silver–silver rubidium iodide–iodine cells and lithium–lithium iodide–lead iodide mixtures. Batteries with ion-containing polymers are being studied extensively. In such devices, electrode conductivity is achieved by special polymer structure and doping with charged ions either chemically or electrically.

Storage batteries. *Lead secondary cells.* The so-called lead-acid secondary battery has long been the most widely used rechargeable portable power source. Most such batteries are constructed of lead plates, or grids, where one of the grids, the positive electrode, is coated with lead dioxide in a particular crystalline form, along with additives such as calcium lignosulfate (Figure 70). The electrolyte, composed of sulfuric acid, participates in the electrode reactions where lead sulfate is formed and carries current in moving ions. Recent estimates show that in terms of

Components of lead-acid batteries

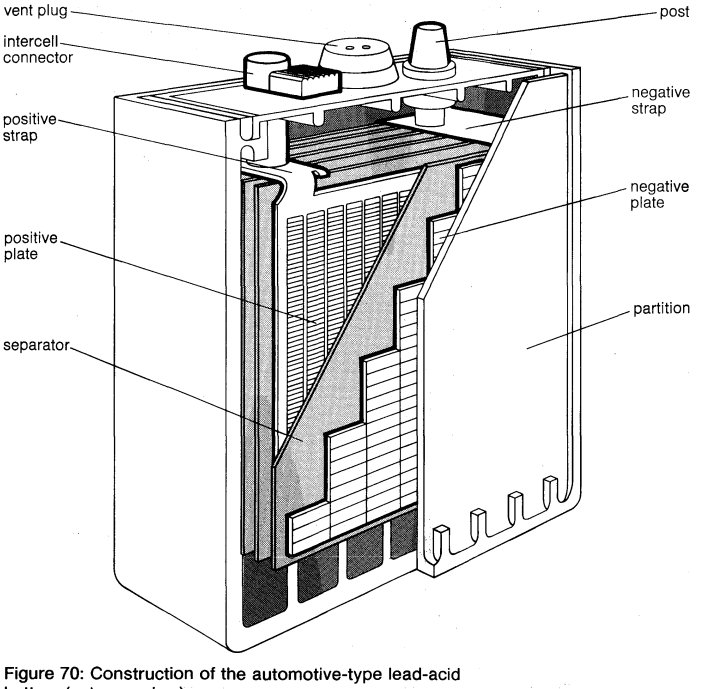

Figure 70: Construction of the automotive-type lead-acid battery (cutaway view).

capacity in use (watt-hours), the lead-acid battery has 20 times as much capacity as either the nickel–cadmium or nickel–iron alkaline rechargeable battery.

The lead-acid battery system has been as successful as it has because of the following features: wide capability range for high or low current demand over usual ambient temperatures; good cycle life with high reliability for hundreds of cycles, especially with good recharge control (a gram of positive active material may deliver as many as 100 ampere-hours during the service life of such a battery); relative low cost (lead is less expensive per kilogram or per ampere-hour than nickel, cadmium, or silver); comparatively good shelf life for a rechargeable system when stored; high cell voltage at 2.04 volts per cell; ease of fabricating lead components by casting, welding, or rolling; and a high degree of salvageability at low melting temperatures.

An area of continued interest for investigators working on lead-acid batteries is reduction of battery weight. Lead dioxide and lead have the lowest energy density of the major electrode materials in wide use, and they are rarely discharged in a highly efficient manner. At low rates of discharge, only about 60 percent of the active materials are cycled, and on short, 10-minute heavy loads utilization can fall to 10 percent.

Types of lead-acid batteries

Lead-acid batteries are generally classified into three groups: (1) starting–lighting–ignition (SLI) batteries, (2) traction batteries, and (3) stationary batteries. The automotive SLI battery is the best known portable rechargeable power source. High current can be obtained for hundreds of shallow-depth discharges over a period of several years. Traction batteries are employed in industrial lift trucks, delivery trucks, and other vehicles. While some are readily portable, others may weigh several tons. The great weight often serves to stabilize the vehicle during operation. Stationary batteries are now much more common than was once the case. These batteries have heavier grid structures and other features to give them long shelf life. They are used to power emergency lights and in uninterruptible power systems for hospitals, factories, and telephone exchanges.

In a lead-acid battery the active material of the positive electrode, lead dioxide, combines with the electrolyte, sulfuric acid, to produce lead sulfate and water during discharge. At the negative electrode the constituent lead combines with the sulfuric acid ions to produce lead sulfate and hydrogen ions, thereby replacing the hydrogen ions consumed at the positive electrode. The water formed and the loss of sulfate dilutes the electrolyte, lowering its density. Because of this, the state of charge of a lead-acid battery can be determined from the specific gravity of the electrolyte.

Alkaline storage batteries. In secondary batteries of this type, electric energy is derived from the chemical action in an alkaline solution. Such batteries feature a variety of electrode materials, some of the more notable of which are briefly discussed in this section.

Nickel–cadmium batteries

Nickel (hydroxide)–cadmium systems are the most common small rechargeable battery type for portable appliances. The sealed cells are equipped with "jelly roll" electrodes (see Figure 71), which allow high current to be delivered in an efficient way. These batteries are capable of delivering exceptionally high currents, can be rapidly recharged hundreds of times, and are tolerant of abuse such as overdischarging or overcharging. Nonetheless, compared to many primary batteries and even lead-acid batteries, nickel–cadmium cells are heavy and have comparatively limited energy density. They last longer and perform better if fully discharged each cycle before recharge. Otherwise, the cells may exhibit a so-called memory effect where they behave as if they had lower capacity than was built into the battery pack. Larger nickel–cadmium batteries are used for starting up aircraft engines and in emergency power systems. They also have found application in other backup power systems where very high currents, low temperature conditions, and reliability are special factors. In addition, they are used in tandem with a solar-powered current source to provide electric power at night.

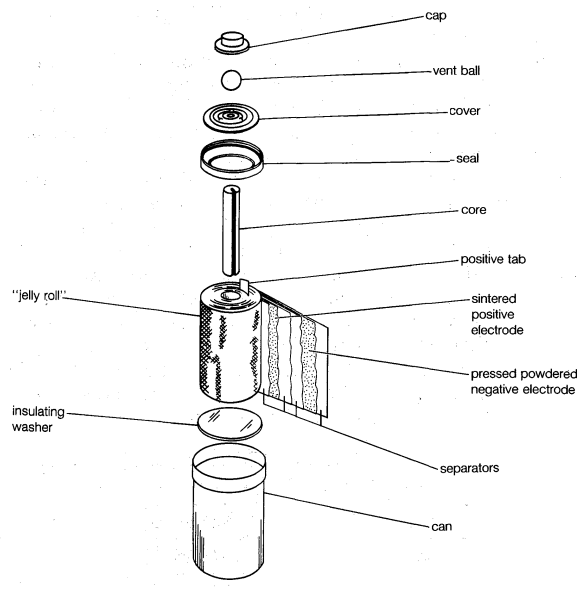

Figure 71: Nickel (hydroxide)–cadmium cell of "jelly roll" construction (see text).
By courtesy of Eveready Battery Co., Inc.

Nickel (hydroxide)–zinc cells are attractive from a development viewpoint. If their cycle life can be significantly improved, systems of this sort may become a viable substitute for nickel–cadmium cells or lead-acid traction batteries.

Nickel (hydroxide)–iron batteries can provide thousands of cycles but do not recharge with high efficiency, generating heat and consuming more electricity than is generally desirable. They have been used extensively in the European mining industry, however.

Nickel–hydrogen batteries

Nickel (hydroxide)–hydrogen cells were developed primarily for the U.S. space program. Research has shown that such alloys as lanthanum-nickel in certain proportions will reversibly dissolve or release hydrogen in proportion to changes in pressure and temperature. This hydrogen can serve as an active anode material. There is speculation that nickel–hydrogen batteries may replace nickel–cadmium batteries in many applications.

Alkaline zinc–manganese dioxide rechargeable cells have been developed as a substitute for other systems that provide moderate amounts of electricity for certain applications. Their high energy density and low cost encourage further engineering work and commercial introduction.

Silver (oxide)–zinc batteries are expensive but are employed where high power density, good energy-cycling efficiency, low weight, and low volume are critical. After years of use in torpedoes and mines, they have more recently become important in special vehicles for underwater tests and submarine exploration. They also are employed in portable radar units and communications equipment, as well as in aircraft and space vehicles.

Lithium secondary cells. These show considerable promise since their theoretical energy densities can range from 600 to 2,000 watt-hours per kilogram. Even after allowance is made for the inactive parts of such a cell, the net energy density is still competitive with aqueous systems. Systems of this type receiving developmental attention include lithium–titanium disulfide, lithium–manganese dioxide, and lithium–molybdenum disulfide. Much current research is devoted to developing better oxide and sulfide structures, better solvent combinations, and better and safer constructions.

Sodium–sulfur storage batteries. Much experimental work has been expended on this type of high-temperature system, which operates at 350° C. Many problems related to material stability have to be solved before a completely satisfactory system can be produced. This is particularly true given the need to tolerate cooling and heating the whole battery between uses. Yet, the ready availability of sodium and sulfur, low cost, and ability of each cell to deliver 2.3 volts make this system extremely attractive. It

could be used for electric vehicles or to help meet municipal peak power requirements.

Development of batteries. The Italian physicist Alessandro Volta is generally credited with having developed the first operable battery. Following up on the earlier work of his compatriot Luigi Galvani, Volta performed a series of experiments on electrochemical phenomena during the 1790s (see ELECTRICITY AND MAGNETISM). By about 1800 he had built his simple battery, which later came to be known as the "voltaic pile." This device consisted of alternating zinc and silver disks separated by layers of paper or cloth soaked in a solution of either sodium hydroxide or brine (Figure 72). Experiments performed with the voltaic pile eventually led Faraday to derive the quantitative laws of electrochemistry (about 1834). These laws, which established the exact relationship between the quantity of electrode material and the amount of electric power desired, formed the basis of modern battery technology.

The voltaic pile

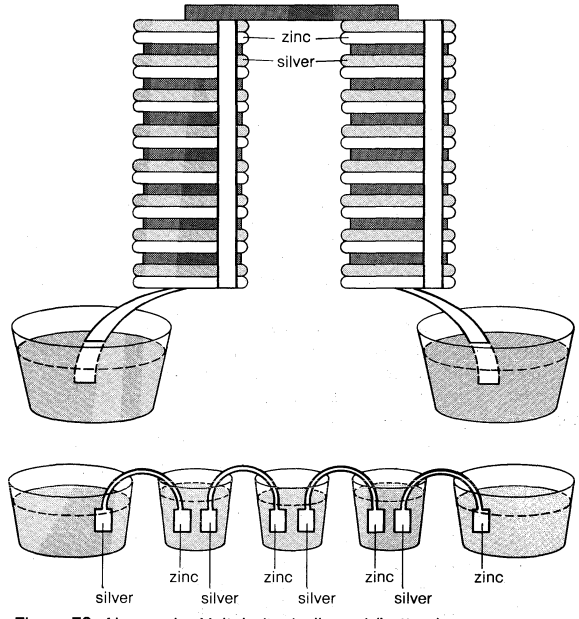

Figure 72: Alessandro Volta's (top) pile and (bottom) crown of cups.

Various commercially significant primary cells were produced on the heels of Faraday's theoretical contribution. In 1836 John Frederic Daniell, a British chemist, introduced an improved form of electric cell consisting of copper and zinc in sulfuric acid. The Daniell cell was able to deliver sustained currents during continuous operation far more efficiently than Volta's device.

Further advances were effected in 1839 by William Robert Grove with his two-fluid primary cell consisting of amalgamated zinc immersed in dilute sulfuric acid, with a porous pot separating the sulfuric acid from a strong nitric acid solution containing a platinum cathode. The nitric acid served as an oxidizing agent, which prevented voltage loss resulting from an accumulation of hydrogen at the cathode. The German chemist Robert Wilhelm Bunsen substituted inexpensive carbon for platinum in Grove's cell and thereby helped promote its wide acceptance.

In 1859 Gaston Planté of France invented a lead-acid cell, the first practical storage battery and the forerunner of the modern automobile battery. Planté's device was able to produce a remarkably large current, but it remained a laboratory curiosity for nearly two decades.

First practical storage battery

Georges Leclanché's prototype of the zinc–manganese dioxide system paved the way for the development of the modern primary cell. The original version of the Leclanché cell was "wet," as it had an electrolyte consisting of a solution of ammonium chloride. The idea of employing an immobilized electrolyte was finally introduced in the late 1880s and launched the dry-cell industry that continues to flourish today.

The invention of alkaline electrolyte batteries (specifically storage batteries of the nickel–cadmium and nickel–iron type) between 1895 and 1905 provided systems that could furnish much-improved cycle life for commercial application. The 1930s and '40s saw the development of the silver oxide–zinc and mercuric oxide–zinc alkaline cells, systems that provided the highest energy yet known per unit weight and volume. Since midcentury, advances in construction technology and the availability of new materials have given rise to smaller yet more powerful batteries suitable for use in a wide array of portable equipment. Perhaps most notable have been the entrance of lithium batteries into the commercial market and the development of nickel–hydrogen cells for use in spacecraft.

FUEL CELLS

General characteristics. A fuel cell is an electrochemical device that converts the chemical energy of a fuel directly and efficiently to direct-current electricity in a continuous manner. It resembles a battery in many respects, but it can supply electrical energy over a much longer period of time. This is because a fuel cell is continuously supplied with fuel and air (or oxygen) from an external source, while a battery contains only a limited amount of fuel material and oxidant, which are depleted with use.

External source of fuel and oxidizer

A fuel cell (actually a group of cells) has essentially the same kinds of components as a battery. As in the latter, each cell of a fuel-cell system has a matching pair of electrodes (Figure 73). These are the anode, which supplies electrons, and the cathode, which absorbs electrons. Both electrodes must be immersed in and separated by an electrolyte, which may be a liquid or a solid but which must in either case conduct ions between the electrodes in order to complete the chemistry of the system. A fuel, such as hydrogen, is supplied to the anode where it is oxidized, producing hydrogen ions and electrons. An oxidizer, such as oxygen, is supplied to the cathode where the hydrogen ions from the anode absorb electrons from the latter and react with the oxygen to produce water. The difference between the respective energy levels at the electrodes (electromotive force) is the voltage per unit cell. The amount of current available to the external circuit depends on the chemical activity and amount of the substances supplied as fuels. The current-producing process continues for as long as there is a supply of reactants, for, unlike in a regular battery, the electrodes and electrolyte of a fuel cell are designed to remain unchanged by chemical reaction.

A practical fuel cell is necessarily a complex system. It must have features to boost the activity of the fuel, pumps and blowers, fuel-storage containers, and a variety of sophisticated sensors and controls with which to monitor and adjust the operation of the system. The operating capability and lifetime of each of these system design features may limit the performance of the fuel cell.

As in the case of other electrochemical systems, fuel-cell operation is dependent on temperature. The chemical activity of the fuels and the value of the activity promoters, catalysts, are reduced by low temperatures (*e.g.*, 0° C). Very high temperatures, on the other hand, improve the

Temperature-dependent operation

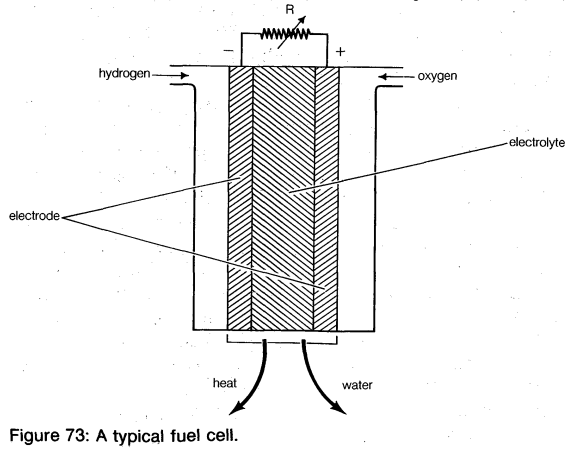

Figure 73: A typical fuel cell.

activity factors but may reduce the functioning lifetime of electrodes, blowers, construction materials, and sensors. Each type of fuel cell thus has an operating-temperature design range, and a significant departure from this range is likely to diminish both capacity and lifetime.

A fuel cell, like a battery, is inherently a high-efficiency device. Unlike internal-combustion machines, where a fuel is burned and gas is expanded to do work, the fuel cell converts chemical energy directly into electrical energy (Figure 74). Because of this fundamental characteristic, fuel cells may convert fuels to useful energy at an efficiency as high as 60 percent, whereas the internal-combustion engine is limited to efficiencies of near 40 percent or less. The high efficiency means that much less fuel and a smaller storage container are needed for a fixed energy requirement. For this reason, fuel cells are an attractive power supply for space missions of limited duration and for other situations where fuel is very expensive and difficult to supply. They also emit no noxious gases such as nitrogen dioxide and produce virtually no noise during operation, making them contenders for local municipal power generation stations.

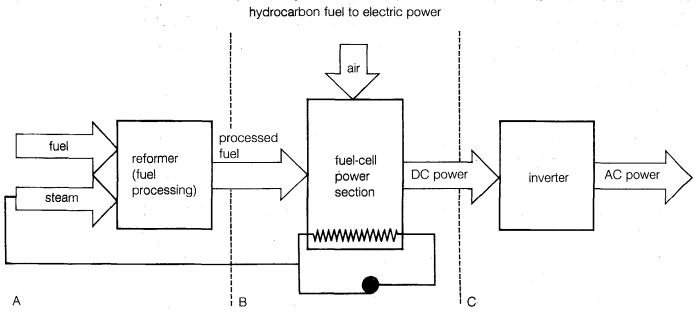

Figure 74: *Elements of a fuel-cell power plant.* (A) The reformer section processes hydrocarbon fuel for fuel-cell use. (B) The power section converts the processed fuel and air into DC power. (C) The inverter produces usable AC power to meet customer requirements.

Regenerative fuel cells

A fuel cell can be designed to operate reversibly. In other words, a hydrogen–oxygen cell that produces water as a product can be made to regenerate hydrogen and oxygen. Such a regenerative fuel cell entails not only a revision of electrode design but also the introduction of special means for separating the product gases. Eventually power modules comprised of this type of high-efficiency fuel cell, used in conjunction with large arrays of solar thermal collectors or other solar power systems, may be utilized to keep energy-cycle costs lower in longer-lived equipment.

Principles of operation. Because a fuel cell produces electricity continuously from fuel, it has many output characteristics similar to those of any other direct-current generator system. A DC generator system can be operated in either of two ways from a planning viewpoint: (1) Fuel may be burned in a heat engine to drive an electric generator, which makes power available and current flow. Or (2) fuel may be converted to a form suitable for a fuel cell, which then generates power directly.

Available fuels

A wide range of liquid and solid fuels may be used for a heat-engine system, while hydrogen, reformed natural gas (*i.e.,* methane that has been converted to hydrogen-rich gas), and methanol are the primary fuels available for current fuel cells. If fuels such as natural gas must be altered in composition for a fuel cell, the net efficiency of the fuel-cell system is reduced, and much of its efficiency advantage is lost. Such an "indirect" fuel-cell system would still display an efficiency advantage of as much as 20 percent. Nonetheless, to be competitive with modern thermal generating plants a fuel-cell system must attain a good design balance with low internal electrical losses, corrosion-resistant electrodes, electrolyte of constant composition, low catalyst costs, and ecologically acceptable fuels.

The first technical challenge that must be overcome in developing practical fuel cells is to design and assemble consistently an electrode that allows the gaseous or liquid fuel to contact a catalyst and an electrolyte at a group of solid sites that do not change very rapidly. Thus, a three-phase reaction situation is typical on an electrode that must also serve as an electrical conductor. As seen in Figure 75, such can be provided by thin sheets that have (1) a waterproof layer usually with Teflon (polytetrafluoroethylene), (2) an active layer of a catalyst (*e.g.,* platinum, gold, or a complex organometallic compound on a carbon base), and (3) a conducting layer to carry the current generated in or out of the electrode. If the electrode floods with electrolyte, the operation rate would become very slow at best. If the fuel breaks through to the electrolyte side of the electrode, the electrolyte compartment might become filled with gas or vapour, inviting an explosion should the oxidizing gas also reach the electrolyte compartment or the fuel gas enter the oxidizing gas compartment. In short, careful design, construction, and pressure control are essential in a working fuel cell to maintain stable operation. Since fuel cells have been used on Apollo lunar flights as well as on all other U.S. orbital manned space missions (*e.g.,* those of Gemini and the Space Shuttle), it is evident that all three requirements can be met reliably.

Providing a fuel-cell support system of pumps, blowers, sensors, and controls for maintaining fuel rates, electric current load, gas and liquid pressures, and fuel-cell temperature remains a major engineering design challenge. Significant improvements in the service life of these components under adverse conditions would contribute to the wider use of fuel cells.

Types of fuel cells. Various types of fuel cells have been developed. They are generally classified on the basis of the electrolyte used because the electrolyte determines the operating temperature of a system and in part the kind of fuel that can be employed.

Alkaline fuel cells. These are devices that, by definition, have an aqueous solution of sodium hydroxide or potassium hydroxide as the electrolyte. The fuel is almost always hydrogen gas, with oxygen or oxygen in air as the oxidizer. The cells generally operate at less than 100° C and are constructed of metal and certain plastics. Electrodes are made of carbon and a metal such as nickel. Product water must be removed from the system as a reaction product, usually by evaporation from the electrolyte either through the electrodes or in a separate evaporator. The operating support system presents a significant design problem. The strong, hot alkaline electrolyte attacks most polymers and tends to readily penetrate structural seams and joints. These problems have been overcome, however, and alkaline fuel cells are used on the U.S. Space Shuttle. Overall efficiencies range from 30 to 80 percent, depending on the fuel, oxidizer, and basis for the calculation.

Use on the U.S. Space Shuttle

Phosphoric acid fuel cells. Such cells have an orthophosphoric acid electrolyte that allows operation up to 200° C. They can use a hydrogen fuel contaminated with carbon dioxide and an oxidizer of air or oxygen. The electrodes consist of catalyzed carbon and are arranged in pairs set back-to-back to create a series generation circuit. The framing structure for this assembly of cells is made of graphite, which markedly raises the cost. The higher temperature and aggressive hot phosphate create struc-

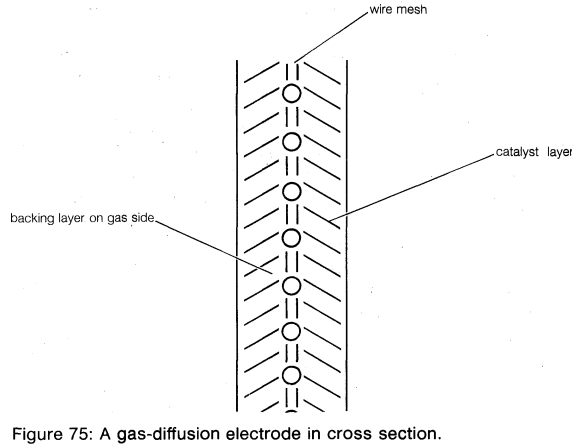

Figure 75: A gas-diffusion electrode in cross section.

tural design problems, particularly for joints, supporting pumps, and sensors. Phosphoric acid fuel cells have been proposed and tested on a limited scale for local municipal power stations and for remote-site generators.

Molten carbonate fuel cells. Fuel cells of this type operate quite differently from those so far discussed. The fuel consists of a mixture of hydrogen and carbon monoxide generated from water and a fossil fuel. The electrolyte is molten potassium lithium carbonate, which permits an operating temperature of about 650° C. In most cases, the electrodes are metallic-based, and the containment system is made of metals and special engineering plastics. (Surprisingly, such combinations of materials are anticipated to be relatively inexpensive, perhaps only three times that of the alkaline fuel cell and less than that of the phosphoric acid variety.) The cells combine the hydrogen and carbon monoxide first with the carbonate electrolyte and then with oxidizing oxygen to produce a reaction product of water vapour and carbon dioxide.

Molten carbonate fuel cells are expected to be useful in both local and larger power stations. Efficiencies of 45 percent may be attained where fossil fuels are already used. Operation at high temperatures creates a design problem for long-lived system parts and joints, especially if the cells must be heated and cooled frequently. The toxic fuel and high temperature together make power-plant safety an area of special concern in engineering design and testing as well as in commercial operation.

Solid oxide fuel cells. In some ways solid oxide fuel cells are similar to molten carbonate devices. Most of the cell materials, however, are special ceramics with some nickel. The electrolyte is an ion-conducting oxide such as zirconia treated with yttria. The fuel for these experimental cells is expected to be hydrogen combined with carbon monoxide, just as for molten carbonate cells. While internal reactions would be different in terms of path, the cell products would be water vapour and carbon dioxide. Because of the high operating temperature (800 to 1,000° C), the electrode reactions proceed very readily. As in the case of the molten carbonate fuel cell, there are many engineering challenges involved in creating a long-lived containment system for cells that operate at such a high-temperature range.

High operating temperature

Solid oxide fuel cells would be designed for use in central power-generation stations where temperature variation could be controlled efficiently and where fossil fuels would be available. The system would in most cases be associated with the so-called bottoming steam (turbine) cycle—*i.e.,* the hot gas product (at 1,000° C) of the fuel cell could be used to generate steam to run a turbine and extract more power from heat energy. Overall efficiencies of 50 to 55 percent might be possible.

Solid polymer electrolyte fuel cells. A cell of this sort is built around an ion-conducting membrane such as Nafion (trademark for a perfluorosulfonic acid membrane). The electrodes are catalyzed carbon, and several construction alignments are feasible. Solid polymer electrolyte cells function well (as attested to by their performance in Gemini spacecraft), but cost estimates are high for the total system compared to the types described above. Engineering or electrode design improvements could change this disadvantage.

Development of fuel cells. The general concept of a fuel battery, or fuel cell, dates back to the early days of electrochemistry. William Grove used hydrogen and oxygen as fuels catalyzed on platinum electrodes in 1839. During the late 1880s two English chemists, Ludwig Mond and Carl Langer, developed a fuel cell with a longer service life by employing a porous nonconductor to hold the electrolyte. It was subsequently found that a carbon base permitted the use of much less platinum, and the German chemist Wilhelm Ostwald proposed as a substitute for heat-engine generators electrochemical cells in which carbon would be oxidized to carbon dioxide by oxygen. During the early years of the 20th century Fritz Haber, Walther H. Nernst, and Edmond Bauer experimented with cells using a solid electrolyte. Limited success and high costs, however, suppressed interest in continuing developmental efforts.

From 1932 until well after World War II, Francis T. Bacon and his coworkers at Cambridge worked on creating practical hydrogen–oxygen fuel cells with an alkaline electrolyte. Research resulted in the invention of gas-diffusion electrodes in which the fuel gas on one side is effectively kept in controlled contact with an aqueous electrolyte on the other side. By mid-century O.K. Davtyan of the Soviet Union had published the results of experimental work on solid electrolytes for high-temperature fuel cells and for both high- and low-temperature alkaline electrolyte hydrogen–oxygen cells.

Invention of gas-diffusion electrodes

The need for high-efficiency stable power supplies for space satellites and manned spacecraft created exciting new opportunities for fuel-cell development during the 1950s and '60s. Molten carbonate cells with magnesium oxide pressed against the electrodes were demonstrated by J.A.A. Ketelaar and G.H.J. Broers of The Netherlands, while the very thin Teflon-bonded, carbon-metal screen catalyzed electrode was devised by other researchers. Many other technological advances, including the development of new materials, played a crucial role in the emergence of today's practical fuel cells. Further improvements in electrode materials and construction, combined with rising fuel costs, are expected to make fuel cells an increasingly attractive alternative power source, especially in Japan and other countries that have meagre nonrenewable energy resources. (B.S.)

SOLAR CELLS

General characteristics. A solar cell is an electronic device that directly converts the energy in light into electrical energy through the process of photovoltaics. Unlike batteries or fuel cells, solar cells do not utilize chemical reactions to produce electric power; and, unlike electric generators, they do not have any moving parts. Solar cells are also called solar batteries and, as the term solar implies, they are in most cases designed for converting sunlight into electrical energy.

Solar cells can be arranged into large groupings called arrays. These arrays, which may be composed of many thousands of individual cells, can function as central electric power stations in the same manner as nuclear power plants and coal- or oil-fired power plants. Such solar-cell power installations convert the energy in sunlight into electrical energy for distribution to industrial, commercial, and residential users. Solar cells in much smaller configurations, commonly referred to as solar-cell panels, are used to provide electric power in many remote terrestrial locations; they are well suited, for example, to run water pumps in desert areas and to power navigational aids at sea. Because they have no moving parts that could require service or fuels that would require replenishment, solar cells are ideal for providing power in space. As a consequence, most space satellites, including communications and weather satellites, are solar-cell powered. Since light is the basic source of the power generated by solar cells, space applications are generally limited to regions of the solar system that are close enough to the Sun to receive substantial amounts of radiant energy. Another growing application of solar cells is in consumer products, such as electronic toys, hand-held calculators, and portable radios. Solar cells used in devices of this kind may utilize indoor artificial light (*e.g.,* from incandescent and fluorescent lamps) as well as natural light from the Sun in converting radiant energy into electricity.

Arrays of solar cells

Structure and principles of operation. The basic structure of a typical solar cell, whether it is used in a central power station, a satellite, or a calculator, is shown in Figure 76. As many be seen, light enters the device through a layer of material called the antireflection layer. The function of this layer is to trap the light falling on the solar cell and to promote the transmission of this light into the energy-conversion layers below. Such materials as silicon oxides or titanium dioxide are employed as the antireflection layer in solar cells. The photovoltaic effect, which causes the cell to convert light directly into electrical energy, occurs in the three energy-conversion layers below the antireflection layer. The first of these three layers necessary for energy conversion in a solar cell is the top junction layer in Figure 76. The next layer in the structure

Energy-conversion layers

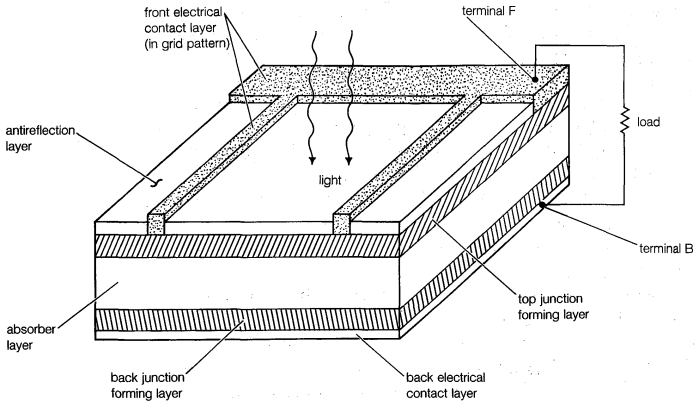

Figure 76: *A commonly used solar-cell structure.* In many such cells, the absorber layer and the back junction layer are both made of the same material.

is the core of the device; this is the absorber layer. The last of the energy-conversion layers is the back junction layer.

As may be seen from Figure 76, there are two additional layers that must be present in a solar cell. These are the electrical contact layers. There must obviously be two such layers to allow electric current to flow out of and into the cell. The electrical contact layer on the face of the cell where light enters is generally present in some grid pattern and is composed of a good conductor such as a metal. The grid pattern does not cover the entire face of the cell since grid materials, though good electrical conductors, are generally not transparent to light. Hence, the grid pattern must be widely spaced to allow light to enter the solar cell but not to the extent that the electrical contact layer will have difficulty collecting the current produced by the cell. The back electrical contact layer has no such diametrically opposed restrictions. It need simply function as an electrical contact and thus covers the entire back surface of the cell structure. Because the back layer must be a very good electrical conductor, it is always made of metal.

It is a fundamental fact of nature that, whenever different materials are placed in contact, an electric field exists at the interface, or junction, between these materials. The role of the junction layers in Figure 76 is to establish this electric field. The field created in the solar cell by the different junction-forming materials is termed the built-in electric field. An electric field is needed in a solar cell because it exerts a force on electrons. If electrons are not attached to specific atoms but are free to roam about in a material, they always will move in a direction dictated by the electric field. This movement constitutes an electric current.

Built-in electric field

The electric field set up by the junction-forming layers of the solar cell causes a current to flow when there are free electrons present in the top junction-forming layer, the absorber layer, and the back junction-forming layer. When light falls on the cell, free electrons occur as a result of the interaction of the light with the absorber layer. The special attribute of this cell layer is that it absorbs light by changing the energy and state (or condition) of some of the electrons in the material. When light is absorbed in the materials, the energy of an electron increases from the so-called ground state energy to an excited energy state. In the excited state, electrons are no longer associated with specific atoms in the absorber, but they are, instead, free to move.

In summary, the absorption of light in the absorber material of a solar cell results in energetic, free electrons that move in the direction forced on them by the built-in electric field. These energetic electrons of the induced current are then collected by the electrical contact layers for use in an external circuit where they can do useful work.

Since most of the energy in sunlight or indoor light is in visible light, a solar-cell absorber should be a strong absorber of electromagnetic radiation in that range of wavelengths. Materials that absorb the visible light of sunlight or of indoor light by producing excited free electrons belong to a class of substances known as semiconductor materials. Semiconductors can absorb all incident visible light in thicknesses of about one-hundredth of a centimetre or less; consequently, the thickness of a solar cell can be of this size. Examples of semiconductor materials employed in solar cells include silicon, gallium arsenide, indium phosphide, and copper indium selenide.

The materials in a solar cell used for the junction-forming layers need only be dissimilar, and, to carry the electric current, they must be conductors. The two junction-forming layers may be different semiconductors or they may be a metal and a semiconductor. Thus, the materials used to construct the various layers of solar cells are essentially the same materials used to produce the diodes and transistors of solid-state electronics and microelectronics (see also ELECTRONICS: *Optoelectronic devices*). Solar cells and microelectronic devices share the same basic technology. In solar-cell fabrication, however, one seeks to construct a large-area device because the power produced is proportional to the illuminated area. In microelectronics the goal is of course to construct devices of very small area to increase the number of circuit components on a single tiny semiconductor chip.

The photovoltaic effect that causes the direct energy conversion in a solar cell is summarized in the schematic of Figure 77. An analogy between an electron in the solar cell and a child at a slide is also presented in this figure. As shown, initially both the electron and the child are in their respective ground states. Next the electron is lifted up to its excited state by consuming energy in the incoming light, just as the child is lifted up to an excited state at the top of the slide by consuming chemical energy stored in his body. In both cases, there is now energy available in the excited state that can be expended. The excited electron is free and moves to the external circuit due to the built-in electric field. It is in this external circuit that the electron will dissipate its excess energy in some device, which in general can be termed a load. The external load is shown here as a simple resistor, but it can be any of a myriad of electrical or electronic devices ranging from motors to radios. Correspondingly, the child moves to the slide because of his desire for excitement. It is on the slide that the child dissipates his excess energy. Finally, when the excess energy is expended, both the electron and the child are back in the ground state where they can, of course, begin the whole process over again. As can be seen from the figure, the motion of the electron, like that of the child, is in one direction. In short, a solar cell produces a direct electric current—namely, one that flows constantly in only a single direction.

Photovoltaic effect

The photovoltaic process bears certain similarities to photosynthesis in plants by which the energy in light is converted into chemical energy. Since solar cells obviously cannot produce electric power in the dark, part of the energy they develop under light is stored, in many applications, for use when light is not available. One common means of storing this electrical energy is to charge chemical

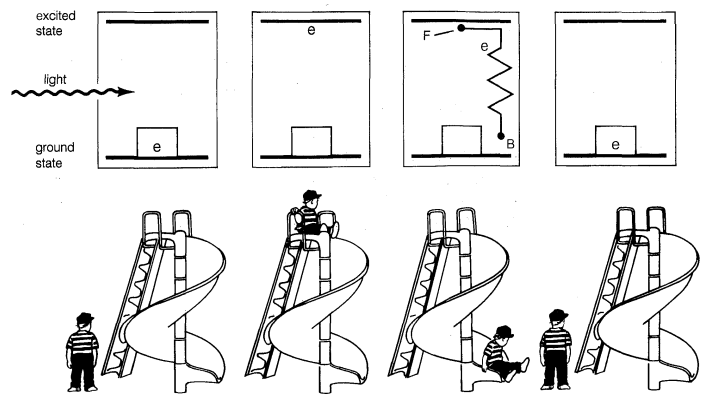

Figure 77: *Representation of an electron in a solar cell.* The electron is shown interacting with light and subsequently dissipating the excess energy it receives from the light by doing work in an external circuit. The electric current flows in and out of the cell through terminals B and F (as represented in Figure 76). The sequence of events involved is analogous to a child playing on a slide (see text).

storage batteries. This sequence of converting the energy in light into the energy of excited electrons and then into stored chemical energy is strikingly similar to the process of photosynthesis.

Development of solar cells. The development of solar-cell technology stems from the work of the French physicist Antoine-César Becquerel in 1839. Becquerel discovered the photovoltaic effect while experimenting with a solid electrode in an electrolyte solution; he observed that voltage developed when light fell upon the electrode. About 50 years later, Charles Fritts constructed the first true solar cells using junctions formed by coating the semiconductor selenium with an ultrathin, nearly transparent layer of gold. Fritts's devices were very inefficient converters of energy; they transformed less than 1 percent of the absorbed light energy into electrical energy. Though inefficient by today's standards, these early solar cells fostered among some a vision of abundant, clean power. In 1891 R. Appleyard wrote of "the blessed vision of the Sun, no longer pouring his energies unrequited into space, but by means of photo-electric cells . . . , these powers gathered into electrical storehouses to the total extinction of steam engines, and the utter repression of smoke."

By 1927 another metal–semiconductor-junction solar cell, in this case made of copper and the semiconductor copper oxide, had been demonstrated. By the 1930s both the selenium cell and the copper oxide cell were being employed in light-sensitive devices, such as photometers, for use in photography. These early solar cells, however, still had energy-conversion efficiencies of less than 1 percent. This impasse was finally overcome with the development of the silicon solar cell by Russell Ohl in 1941. Thirteen years later three other American researchers, G.L. Pearson, Daryl Chapin, and Calvin Fuller, demonstrated a silicon solar cell capable of a 6-percent energy-conversion efficiency when used in direct sunlight. By the late 1980s silicon cells, as well as those made of gallium arsenide, with efficiencies of more than 20 percent had been fabricated. In 1989 a concentrator solar cell, a type of device in which sunlight is concentrated onto the cell surface by means of lenses, achieved an efficiency of 37 percent due to the increased intensity of the collected energy. In general, solar cells of widely varying efficiencies and cost are now available. (S.J.F./R.T.F.)

First silicon solar cell

THERMOELECTRIC POWER GENERATORS

General characteristics. A unique aspect of thermoelectric energy conversion is that the conversion direction is reversible. This distinguishes thermoelectric energy converters from many other energy conversion systems. Electrical input power can be directly converted to pumped thermal power for the purpose of either refrigeration or heating. Conversely, thermal input power can be converted directly to electrical power for lighting, operating electrical equipment, and other work functions. Though any thermoelectric device can be applied in either mode of operation, the design of a particular device may not be optimal.

Capability for reversible energy conversion

All thermoelectric power generators are configured as shown in Figure 78. The heat source provides for the high temperature and the amount of heat flow through the thermoelectric converter to the heat sink. The heat sink is maintained at a temperature below that of the source. The temperature differential, $\Delta T = T_1 - T_0$, across the converter produces direct-current electrical power to a load R (ohms), having a terminal voltage V (volts), and provides a current I (amperes). There is no intermediate conversion process. For this reason, thermoelectric power generation is classified as direct power conversion. The amount of electrical power generated, W (watts), is I^2R_L or alternately VI.

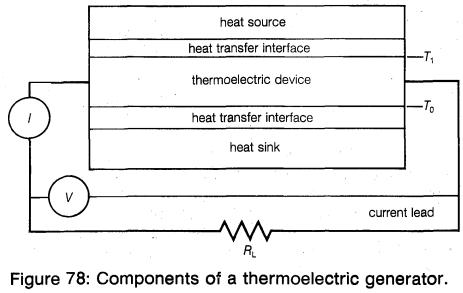

Figure 78: Components of a thermoelectric generator.

If the load resistor is removed and a DC power supply is substituted, the thermoelectric device of Figure 78 can be used to lower the temperature of the heat source, provided that the input thermal power is not increased. In this configuration, the reversed energy-conversion process of thermoelectric devices, using electrical power to pump heat, is invoked.

Principles of operation. An introduction to the phenomenon of thermoelectricity is necessary to understand the operating principles of thermoelectric devices.

In 1821 the German physicist Thomas Johann Seebeck discovered that when two strips of different conductors (metals, semimetals, or semiconductors—the distinction was not understood at that time) were joined together at their ends and separated along their length, a magnetic field developed around the two legs, provided however that a temperature difference existed between the two junctions. He published his observations the following year, and the phenomenon came to be known as the Seebeck effect. The significance of his discovery notwithstanding, Seebeck did not correctly identify the cause of the magnetic field. The magnetic field results from an equal but opposite electric current in the leg of each metal strip caused by a thermally generated electric potential difference between the junctions. If one junction is broken but the temperature differential is maintained, current no longer flows in the legs but a voltage can be measured. This generated voltage, V, is the Seebeck voltage and is related to the difference in temperature, ΔT, between the heated junction and opened junction by a proportionality factor, α, called the Seebeck coefficient, or $V = \alpha\Delta T$. The value for α is dependent on the types of material at the junction.

Seebeck effect

In 1834 the French physicist and watchmaker Jean-Charles-Athanase Peltier observed that if a current is passed through a single junction of the type described above, the amount of measured heat generated is not consistent with that which would be predicted from Joule heating (see below) alone. This observation is called the Peltier effect. As in Seebeck's case, Peltier failed to define the cause of the anomaly. He did not identify that heat was absorbed or evolved at the junction depending on the direction of current. He also did not recognize the reversible nature of this thermoelectric phenomenon and associate his discovery with Seebeck's.

Peltier effect

It was not until 1855 that William Thomson (later Lord Kelvin) drew the connection between the Seebeck and Peltier effects and made a significant contribution to the understanding of thermoelectric phenomena. The Peltier heat, Q_p, was shown to be proportional to the applied junction current, I, through the relationship $Q_p = \pi I$, where π is the Peltier coefficient. Thomson showed through thermodynamic analysis that $\pi = \alpha T$, where T is the absolute temperature of the junction. The Thomson effect, theoretically predicted by Thomson on the basis of thermodynamic considerations, showed that heat is absorbed or evolved, Q_τ, along the length of a material rod whose ends are at different temperatures. Q_τ was shown to be proportional to the flow of current, I, and the temperature gradient along the rod. The proportionality factor, τ, is known as the Thomson coefficient.

Thomson effect

All thermoelectric phenomena are described by these three effects. Analysis of a thermoelectric device is, however, adequately performed using only one of the thermoelectric parameters, the Seebeck coefficient, α. The reason is that the Thomson effect is small, and so it is generally neglected. The Peltier coefficient, on the other hand, is related to α through the operating condition of the junction temperature.

Two nonthermoelectric quantities must also be identified before a thermoelectric device can be appropriately described. They are Joule heating (the production of heat in a conductor when a current flows through it, as in the case of filaments of an electric kitchen range or toaster) and thermal conduction (the transfer of heat due to tem-

perature differences between adjacent parts of a body). Although a thermoelectric device is made up of many *p*-type and *n*-type semiconductor legs, its behaviour can be discussed using only one couple.

Figure 79 shows a *p*-type and *n*-type semiconductor leg coupled to a heat source, heat sink, and an electrical power consuming load. (Other couples can be connected electrically in series and thermally in parallel.) The leg geometry affects operation. The leg length is L, and the base area, a, is w^2. Under the condition that *p*- and *n*-type semiconductors are similar in their measured properties, average value parameters can be used to analytically describe the couple. The heat flow through the couple at T_1 is given by

$$H = 2aIT - I^2\rho\left(\frac{L}{a}\right) + 2\kappa\left(\frac{a}{L}\right)\Delta T,$$

where temperature is in kelvins, ρ is the electrical resistivity in ohms-centimetre, κ is the thermal conductivity in watts per centimetre kelvin, a is microvolts per kelvin, and L/a is in centimetres^{-1}. In this equation, the first term results from the reversible Peltier effect that generates heat at the top junction. The second term reflects loss due to irreversible Joule heating (one half of the total amount generated). The last term is the irreversible heat loss due to thermal conductivity in each leg.

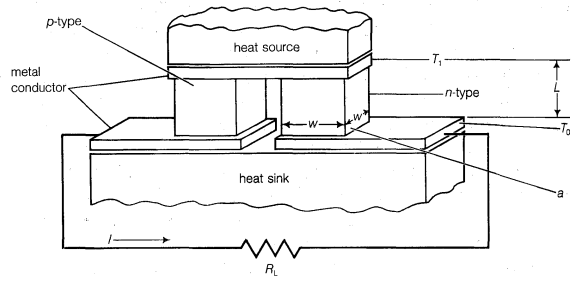

Figure 79: Single couple of a thermoelectric generator.

In a thermoelectric power generator, a temperature differential between the upper and lower surfaces of two legs of the device results in power being generated. If a power consuming load is not attached to the generator (open-circuited), the applied heat source (H) results in a temperature differential (ΔT) of some value dictated only by the thermal conductivity of the *p*- and *n*-type semiconductor legs. Since no current would flow in the thermoelectric device, no power would be generated. (The first and second terms of the above equation would be zero.) Because of the Seebeck effect, however, a voltage would be present at the output terminals, just like in an unconnected battery. When a load is attached, current will flow through the load. The Seebeck voltage $V_a = a\Delta T$ is divided between two terms: the internal device voltage drop IR_{int} due to internal resistance $R_{int} = 2\rho(L/a)$ (for the couple), and the external voltage drop IR_L. It is the Seebeck voltage and these two resistances that dictate the flow of current (and the generated output electrical power) given by

$$I = \frac{2a\Delta T}{(R_{int} + R_L)}.$$

This same current pumps heat within the thermoelectric device due to the Peltier effect, which in turn results in a lowering of the initial temperature differential when the current is zero. Part of the heat energy, H, through the Seebeck generated current, is converted to Joule heating within the legs of the thermoelectric device. The efficiency, η, for a power generator is the output power, I^2R_L, divided by H. It can be shown that

Thermal efficiency

$$\varepsilon \text{ max} = \left(\frac{T_1 - T_0}{T_1}\right)\left(\frac{\sqrt{1 + Z\overline{T}} - 1}{\sqrt{1 + Z\overline{T}} + \frac{T_0}{T_1}}\right),$$

where the first term is the Carnot efficiency (see *Transformation of energy* above). The second term contains $\overline{T}$, which is the average temperature of the leg. The Z is the figure of merit of the semiconductor legs; it represents a "quality factor" of the material to perform as thermoelectric device (it is 3×10^{-3} per kelvin at 300 K), given by

$$Z = \frac{a^2}{\kappa\rho}.$$

For material quality to improve (*i.e.*, larger Z), it is generally agreed that the thermal conductivity (κ) and electrical resistivity (ρ) of semiconductor materials must decrease. This has been the principal limiting factor toward higher conversion efficiency in thermoelectric power generation, which in turn has limited the use of thermoelectric devices. A new effort in materials research is required to obtain materials that can improve the overall efficiency of thermoelectric devices.

Major types of thermoelectric generators. Thermoelectric power generators vary in geometry, depending on the type of heat source and heat sink, power requirement, and intended use. In general, many units require a power conditioner to convert the generator output to a usable voltage value. Although the Soviet army used these devices to power portable communications transmitters during World War II, modern power generators are based on the substantial improvements made in semiconductor materials and electrical contacts between 1955 and 1965, as well as on engineering improvements achieved up to the present.

Fossil-fuel generators. Units have been constructed to use natural gas, propane, butane, kerosene, jet fuels, and wood, to name but a few heat sources. A 500-watt multifuel, maintenance-free tactical power generator for advance area application has been developed for the U.S. Army. Commercial units are in the 10- to 100-watt output power range for use in remote areas. Applications for these units include navigational aids, data collection systems and communications systems, and cathodic protection, which prevents electrolysis from corroding metallic pipelines and marine structures.

Solar-source generators. Early attempts to construct solar thermoelectric generators for orbiting spacecraft failed because of low efficiency and higher unit weight compared to silicon solar cells. They have, however, been used with some success to power small irrigation pumps in remote areas and underdeveloped regions of the world where fuel sources are unreliable. In addition, a group of U.S. researchers have described an experimental system capable of using warm surface ocean water as the heat source and cooler deep ocean water as the heat sink for large power generation. Economics favouring this system are based on it being so reliable that there is minimal maintenance cost. Still another system design features both heat pumping and power generation for thermal control of orbiting spacecraft. Utilizing solar heat from the Sun-oriented side of the spacecraft, thermoelectric devices generate electrical power. This power is used to supply current to other thermoelectric devices in dark areas of the spacecraft to reject heat from the vehicle. Operating in this mode, the use of thermoelectric devices, with their reversible function capability, decreases the amount of power required by the spacecraft to increase overall heat expulsion.

Nuclear-fueled generators. Thermoelectric generators that use radioisotopes as fuel derive a high-temperature heat source by the self-absorption of emitted decay products. Because thermoelectric devices are relatively immune to nuclear radiation and because the source can be made to last for a long period of time, such generators provide a unique source of power for many unattended and remote applications. For example, radioisotope thermoelectric generators provide electric power for nonorbiting as well as Earth-orbiting spacecraft, instrumentation for deep-ocean data collection and surface monitoring, warning and communications systems, isolated terrestrial weather monitoring stations, and certain medical applications. A low-power radioisotope thermoelectric generator was developed as early as 1970 and used to power cardiac pacemakers. The power range of radioisotope thermoelectric generators is between 10^{-6} and 10^2 watts.

Applications of radioisotope thermoelectric generators

Development of thermoelectric power generators. The

first application of a thermoelectric generator was in all likelihood Peltier's use of the Seebeck effect (see above) to generate a small amount of power required to pump heat in his junction experiments. An understanding of the principle involved in this phenomenon led to the use of dissimilar metal wires for measuring temperature—namely, the thermocouple. From this evolved the use of multiple but alternating dissimilar metallic wires in a thermopile with which to measure optical radiation.

As the need for electric power became increasingly more important between 1885 and 1910, investigators began studying thermoelectricity systematically. By 1910 E. Altenkirch, a German scientist, satisfactorily calculated the efficiency of thermoelectric generators and delineated the parameters of the materials needed to build practical devices. Unfortunately metallic conductors were the only materials available at the time, rendering it unfeasible to build thermoelectric generators with an efficiency of more than 0.6 percent.

During the late 1920s, Soviet researchers actively pursued theoretical and experimental work on thermoelectricity because of the need for electric power in remote yet habitable areas of their vast country. By 1940 a unit with a conversion efficiency of 4 percent had been developed using semiconductors. It was quickly realized that semiconductor materials were best suited for thermoelectric application. By the early 1950s, interest in thermoelectric power generation was on the rise in certain highly industrialized nations, most notably the United States. Scientific projects being undertaken by these countries in isolated, uninhabited areas necessitated power sources for data collection and communications systems. Yet, in spite of the increased research and developmental activity, gains in thermoelectric power-generating efficiency were relatively small. An efficiency capability of not much more than 10 percent had been attained as of the late 1980s. Better thermoelectric materials are required to go much beyond this performance level. Still, some varieties of thermoelectric generators have proved to be of considerable practical import. Those fueled by radioisotopes are the most versatile, reliable, and generally used power source for isolated or remote sites. (J.W.H.)

Adoption of semiconductors

THERMIONIC POWER CONVERTERS

General characteristics. A thermionic power converter—also variously called thermionic generator, thermionic power generator, or thermoelectric engine—is a device in which heat energy is directly converted into electrical energy. It has two electrodes. One of these is raised to a sufficiently high temperature to become a thermionic electron emitter and can be dubbed the "hot plate." The other electrode, called a collector because it receives the emitted electrons, is operated at a significantly lower temperature. The space between the electrodes is normally filled with a vapour or gas at low pressure (on the order of 1.333×10^2 pascals). The thermal energy may be supplied by chemical, solar, or nuclear sources.

Primary components

Principles of operation. The emission of electrons from the hot plate is analogous to the liberation of steam particles when water is heated. The flow of electrons may be completed by interconnecting the two electrodes by an external load, shown by a resistor R_L in Figure 80. Part of the thermal energy that is supplied to liberate the electrons ("boil them off") is converted directly into electrical energy.

A thermionic power converter can be viewed in several different ways. It can, for example, be examined in terms of thermodynamics as a heat engine that utilizes an electron-rich gas as its working fluid. A thermionic converter also may be thought of as a thermoelectric device—a thermocouple in which one of the conductors has been replaced by either a plasma or a vacuum (*i.e.*, an evacuated space). It can even be regarded in terms of electronics as a diode that converts heat to electrical energy via thermionic emission. No matter how thermionic converters are conceived of or labeled, however, they all work due to the discharge of electrons from heated conducting materials. The following discussion treats devices of this sort as heat engines.

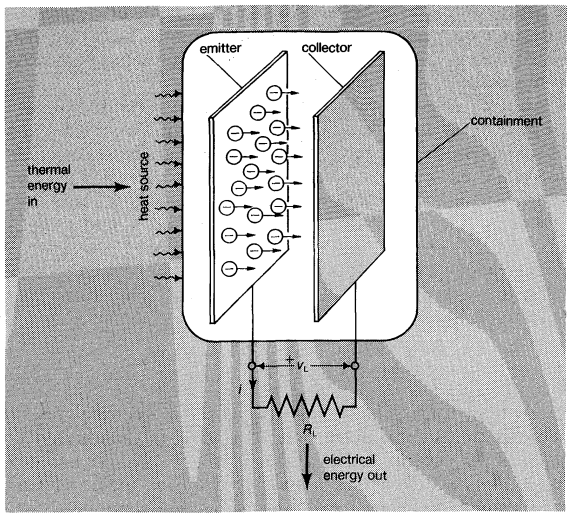

Figure 80: Schematic of a basic thermionic converter.

The major problem in developing large-scale thermionic power converters is the limit imposed on maximum current density due to the space-charge effect—*i.e.*, the negatively charged electrons that are emitted deter the movement of other electrons toward the collecting electrode. Two solutions to this problem have been pursued. One involves reducing the spacing between the electrodes to the order of micrometres, while the other entails the introduction of positive ions into the cloud of negatively charged electrons in front of the emitter. The latter method has proved to be the most feasible from many standpoints, especially manufacturing. It has resulted in the development of both the cesium and the auxiliary discharge thermionic power converters.

Minimizing space-charge effect

Thermionic emission. The emission of electrons is fundamental to thermionic power conversion. The mechanism for the escape of an electron is shown in Figure 81. The actual effect of a negatively charged electron (Figure 81A) may be represented equivalently by a positively charged electron located in a mirror-image arrangement (Figure 81B). This model permits the escape force to be determined from a fundamental law of physics, the inverse square law. That force is given by

$$\frac{e^2}{16\pi\varepsilon_0 x^2},$$

where e is electronic charge (coulombs) and ε_0 is permittivity of free space. The energy required to overcome this force—to cause the electron to escape—is called the work function φ. Each material has a unique value, as shown in Table 4, at common emitter temperatures above 2,000 K. (Collectors normally operate around 1,000 K.) The other parameter tabulated, R, is material-dependent, although the theoretical derivation of the governing equation fixes

its value as a universal constant $R = 1.2 \times 10^{-6}$ amperes per square metre kelvin squared (amp/m²-K²).

The rate at which electrons are liberated from the surface of the emitter is given by the Richardson–Dushman electron current density equation; *i.e.*,

Richardson–Dushman equation

$$J_0 = RT^2 \exp\left(-\frac{e\varphi}{kT}\right),$$

where T is absolute temperature (K) and k is Boltzmann's gas constant for one molecule (ergs per kelvin). This equation for emission current is named for Owen Willans Richardson and Saul Dushman, who did pioneering work on the phenomenon. The rate of emission increases rapidly with temperature and decreases exponentially with the work function. It is always desirable to operate a thermionic converter at a high temperature as well as to be selective in choosing its electrode material.

When electrons escape the emitter surface, they gain energy equal to the work function with some excess kinetic energy. Upon striking the collector, their kinetic energy is used to "absorb" the electrons into the surface. This absorbed energy must be rejected as heat from the collector or force the electrons through the external load, thereby giving the desired electrical energy conversion.

Table 4: Thermionic Emission Properties of Certain Materials

material	φ (volts)	R (amp/m²-K²) $\times 10^{-6}$
Cesium	1.89	0.5
Molybdenum	4.2	0.55
Nickel	4.61	0.3
Platinum	5.32	0.32
Tungsten	4.52	0.6
Tungsten + cesium	1.5	0.03
Tungsten + barium	1.6	0.015
Tungsten + thorium	2.7	0.04
Barium oxide	1.5	0.001
Strontium oxide	2.2	1.0

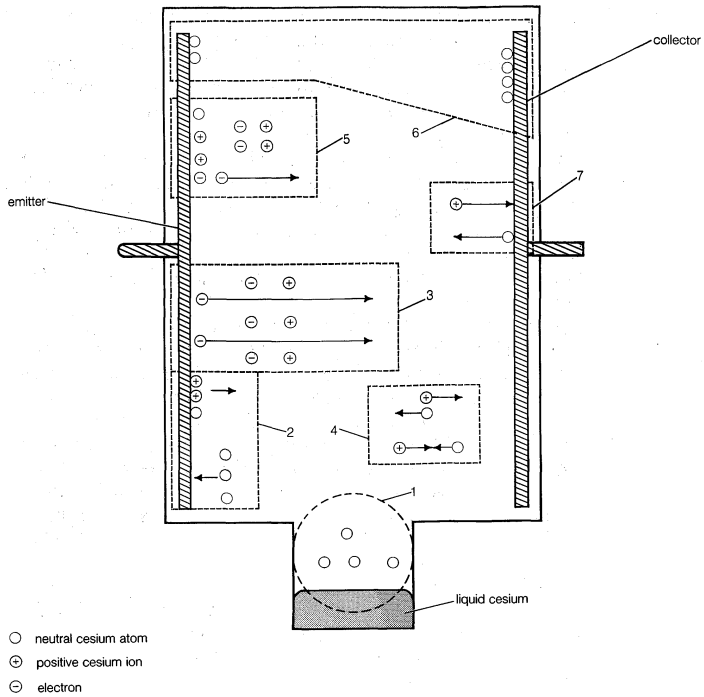

Figure 82: *The various processes in a gas-filled converter.* They occur in the following sequence: (1) evaporation of liquid cesium, (2) arrival of cesium atoms at emitter and departure as ions, (3) neutralization of space charge, (4) energy sharing of ions with atoms, (5) formation of an ion space-charge sheath, (6) reduction of work function due to cesium deposition, and (7) cesium ion recombination at the collector surface.

Major types of thermionic converters. *Vacuum converters.* This type of thermionic device has a vacuum gap between its electrodes. Because of the small spacing required between the emitter and collector to counteract the space charge, the vacuum converter has had only limited practical application; however, it has given rise to other configurations of greater utility. They are briefly described below.

Gas-filled converters. These devices are designed in such a way that positively charged ions are continuously generated and mixed with negatively charged electrons in front of the emitter to neutralize the electrostatic field. Because of this, a liberated electron has no electrostatic resistance in passing from the emitter to the collector. Figure 82 shows schematically the operation of a cesium-filled converter. Cesium is used in the most efficient converters because of its low ionization potential (3.87 electron volts). Potassium, rubidium, and various other metals produce similar results. The arrival rate of neutral cesium atoms is dependent on the gas pressure of cesium and its reservoir temperature. For efficient production of ions, the emitter temperature should be approximately 3.6 times the reservoir temperature.

Auxiliary discharge converters. Such thermionic generators operate at lower temperatures (say, 1,500 K), permitting the use of a fossil-fuel heat source. Ions are produced by applying voltage to a third electrode, shown schematically as auxiliary anodes in Figure 83. The gas between the electrodes in this system is inert (e.g., neon, argon, or xenon). The principal advantage of the auxiliary discharge converter—so called because of its spark plug-type configuration—is that conventional fossil fuels are adequate for the heat source. The disadvantage is the complexity of the discharge system.

Fossil fuels as heat source

Because thermionic converters are tolerant of high accelerations, have no moving parts, and exhibit a relatively high power-to-weight ratio, they are well suited for applications in spacecraft. Since they function best at high temperatures, they may be used as topping devices (*i.e.*, power boosters) on conventional power plants. Their efficiencies make them suitable power sources for remote or hostile environments (*e.g.*, under water) or for use in low-power radio transmitters.

Development of thermionic devices. As early as the mid-18th century, Charles François de Cisternay Du Fay, a French chemist, noted that electricity may be conducted in the gaseous matter—that is to say, plasma—adjacent to a red-hot body. In 1853 the French physicist Alexandre-Edmond Becquerel reported that only a few volts were required to drive electric current through air between high-temperature platinum electrodes. From 1882 to 1889 Julius Elster and Hans Geitel of Germany perfected a sealed device containing two electrodes, one of which could be heated while the other one was cooled. They discovered that, at fairly low temperatures, electric current flows with little resistance if the hot electrode is positively charged. At moderately higher temperatures, current flows readily in either direction. At even higher temperatures, however, electric charges from the negative electrode flow with the greatest ease.

In the 1880s the American inventor Thomas A. Edison applied for a patent pertaining to thermionic emission in a vacuum. In his patent request, he explained that a current

Edison effect

passes from a heated filament of an incandescent electric lamp to a conductor in the same glass globe. Though Edison was the first to disclose this phenomenon, which later came to be known as the Edison effect, he made no attempt to exploit it; his interest in perfecting the electric light system took precedence.

In 1899 the English physicist J.J. Thomson defined the nature of the negative charge carriers. He discovered that their ratio of charge to mass corresponded to the value he found for electrons, giving rise to an understanding of the fundamentals of thermionic emission. In 1915 W. Schlichter proposed that the phenomenon be used for generating electricity.

By the early 1930s the American chemist Irving Langmuir had developed sufficient understanding of thermionic emission to build basic devices, but little progress was made until 1956. That year another American scientist, George N. Hatsopoulos, described in detail two kinds of thermionic devices. His work led to rapid advances in thermionic power conversion. Recent research has been centred primarily on a converter capable of utilizing thermal energy from a nuclear reactor on board spacecraft.

(L.E.Si.)

MAGNETOHYDRODYNAMIC POWER GENERATORS

General characteristics. Magnetohydrodynamic (MHD) power generators produce electrical power through the interaction of a flowing, electrically conducting gas (or other fluid) and a magnetic field. Various countries, including the Soviet Union, Japan, China, Poland, and the United States, have undertaken active developmental programs, since MHD power plants offer the potential for large-scale electrical power generation at reasonable cost with comparatively little detrimental impact on the environment. Generators of the MHD type are also attractive for the production of large electrical power pulses, and their first practical application has been for this kind of service (see below).

The underlying principle of MHD power generation is elegantly simple. An electrically conducting fluid is driven by a primary energy source (*e.g.*, combustion of coal or a gas) through a magnetic field, resulting in the establishment of an electromotive force within the conductor in accordance with the principle established by Faraday (see above). Furthermore, if the conductor is an electrically conducting gas, it will expand, and so the MHD system constitutes a heat engine involving an expansion from high to low pressure in a manner similar to that of a gas turbine. The MHD system, however, involves a volume interaction between a gas and the magnetic field through which it is passing (see below), whereas the gas turbine operates through the gas interaction with the surfaces of a rotating blade system. It is, in effect, a system that depends on volume rather than surface interaction.

The MHD generator as an electromagnetic turbine

The MHD generator can properly be viewed as an electromagnetic turbine because its output is obtained from the conducting gas–magnetic field interaction directly in electrical form rather than in mechanical form, as in the case of a gas (or steam) turbine. This is illustrated in Figure 84, which compares a conventional turbogenerator with an MHD system. Other types of MHD turbines are possible and will be mentioned below. Here, attention is concentrated on the electrically conducting gas type, which has been the focus of most research and developmental work.

Electrical conduction in gases occurs when electrons are available to be organized into an electric current in response to an applied or induced electric field. The electrons may be either injected or generated internally, and, because of the electrostatic forces involved, they require the presence of corresponding positive charge from ions to maintain electrical neutrality. An electrically conducting gas consists in general of electrons, ions to balance the electric charge, and neutral atoms or molecules. Such a gas is termed a plasma.

In MHD generators, electrons for supporting the flow of current can be obtained in either of two ways: by heating the gas to a sufficiently high temperature to yield electrons through ionization or by the induction of a sufficiently strong electric field in a manner similar to that in gas-discharge devices. These methods are referred to as thermal ionization and nonequilibrium ionization, respectively. In either case, the mechanism of energy transfer from the flowing fluid to the electrical output can be thought of as a coupling of the electron-comprised gas to the ions through electromagnetic forces; the ions in turn are embedded in the background of atomic or molecular gas and lack mobility by virtue of their being coupled to the molecules or ions through collision processes described by kinetic behaviour.

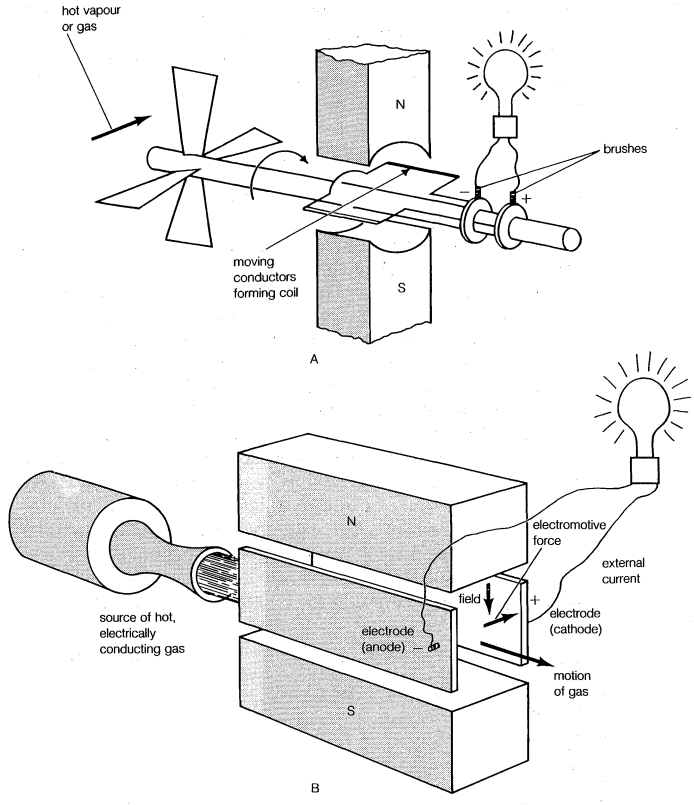

Figure 84: *Comparison of the operating principles of a turbogenerator and an MHD generator.*
(A) Turbogenerator and (B) MHD generator.

Interest in MHD-power generation was originally stimulated by the observation that the interaction of a plasma with a magnetic field could occur at much higher temperatures than were possible in a system consisting of a rotating mechanical system. The limiting performance from the point of view of efficiency in heat engines is established by the Carnot efficiency, obtained from the difference between the absolute hot source temperature, T_1, and the cold sink temperature, T_0, divided by T_1. For example, when the source temperature is 2,810 K and the sink temperature is that of the environment (say, 294 K), the Carnot efficiency is slightly less than 90 percent. Allowing for the inefficiencies introduced by finite heat transfer rates and component inefficiencies in real heat engines, a system employing an MHD generator offers the potential of an ultimate efficiency in the range 60 to 65 percent. This is to be compared with 35 to 36 percent achieved by a modern coal-fired, steam-turbine plant with scrubbers (devices that absorb sulfur dioxide from exhaust gases); 40 percent with a natural gas-fired, steam-turbine plant; and about 46 percent projected for gas-fired, combined gas–steam turbine installations. The implications of this efficiency improvement are an enhanced utilization of primary fuel resources due to higher thermodynamic efficiency and a lower emission of environmental pollutants. (The environmental advantages are discussed in *Major types of MHD systems* below.)

Comparatively high conversion efficiency of MHD generators

Principles of operation. As in the case of all electrical machines, the power output of MHD generators for every cubic metre of conductor depends directly on its conductivity, the square of the velocity at which the conductor

moves, and the square of the magnetic field through which it is passing. For MHD generators to operate competitively, the electrical conductivity of the plasma must be adequate to achieve good performance and reasonable physical dimensions in the temperature range of about 1,800 K and upward—*i.e.,* temperatures at which the turbine blades of a gas-turbine power system would no longer be able to operate. Analysis shows, and experience confirms, that adequate conductivity results if a small amount of additive, typically around 1 percent by mass, is injected into the working gas of the MHD system. This additive is in the form of readily ionizable material such as potassium carbonate and is referred to as the "seed." It is the principal source of electrons (and ions) that render the gas electrically conducting and thereby enable direct conversion to occur.

Addition of a seed material

The hot gas, at a pressure of several megapascals, has seed material added and is accelerated by a nozzle to a speed usually greater than that of sound (*i.e.,* to supersonic conditions). As shown in Figure 85, it then enters a containment structure known as the channel, or duct, across which a powerful magnetic field is applied. In accordance with the Faraday induction principle, an electromotive force acting in a direction perpendicular to the flow and field is set up and, to enable this to provide a current to an external circuit, the walls parallel to the magnetic field serve as electrodes. Because the electromagnetic force is induced in the gas, the positive electrode is the cathode, or electron emitter, and the negative electrode is the anode, or collector (Figure 85). The remaining two walls of the channel are insulators that confine the resultant voltage. Depending on the heat source and magnetic field strength, power densities of 10 to 500 megawatts per cubic centimetre in the duct can be obtained. A magnetic field in the range 4.5 to 6 teslas is required to achieve these values, and this is most readily obtained by using a superconducting magnet.

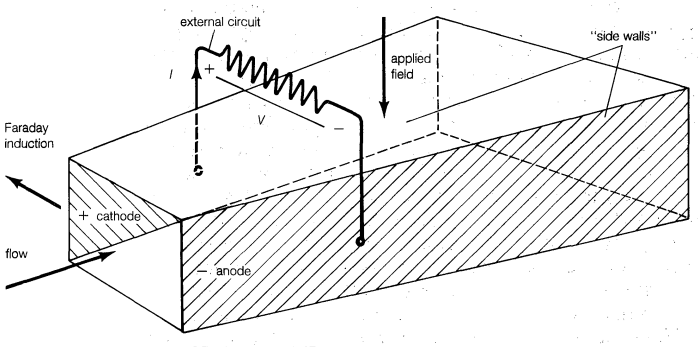

Figure 85: *Simple MHD generator.*
The load current is represented by *I* and the voltage by *V* (see text).

A complicating feature of a plasma MHD generator is the occurrence of a pronounced Hall effect, which results from the behaviour of electrons in the presence of both magnetic and electric fields. Electrons are accelerated in the direction of an electric field but follow a circular path around a magnetic field line (cyclotron behaviour). When these two actions are combined and the collision processes taken into account, the effect (named after its discoverer, the American physicist Edwin H. Hall) is for the electric current to flow at an angle with respect to the electric field, producing an additional field along the axis of the MHD duct. This field, called the Hall field, causes an axial current (Hall current) to flow if the electrodes are continuous, as in Figure 85. This in turn requires that either the electrode walls be constructed to support the Hall field or that the Hall field itself be used as the output to drive current through the electric circuit external to the MHD system.

A number of generator configurations can be used to achieve this objective. The principal ones are briefly described here. In the so-called Faraday generator (Figure 86A), the electrode walls are segmented to support the axial potential, and the power is taken out in a series of loads. The Hall generator (Figure 86B) maximizes the Hall output by short-circuiting the Faraday terminals and connecting a simple load between the ends of the duct. Consideration of the potentials at different points in the duct have led to the conclusion that an equipotential runs diagonally (across the insulator walls) and that, accordingly, electrodes may be connected along such a potential to achieve the diagonal configuration shown in Figure 86C. This diagonal generator may be thought of as a Faraday type in which the individual electrode pairs have been connected in series in a manner that does not violate the potential required for correct operation of the duct yet permits a single load to be used.

MHD generator configurations

An attractive alternative to the linear Hall generator in Figure 86B is the disk generator in which a radial output flow occurs and the short-circuited Faraday currents flow in closed circular paths (Figure 86D). The Hall output appears between the centre and the periphery of the disk. This disk generator is particularly attractive when nonequilibrium ionization is employed.

Major types of MHD systems. The type of ionization employed by an MHD power generator depends on the heat source selected and the method used to couple it to the working fluid. Several possibilities exist. A complete MHD system may include a solid- or liquid-fuel rocket motor (see *Rockets* above), seed injector, nozzle, duct, and magnet and may utilize thermal ionization in the combustion products that make up the working fluid. MHD generators currently in service are of this type. They are compact systems capable of providing very large amounts of power. Natural gas, oil, and coal also are excellent potential fuels for MHD systems and were in fact the first to be proposed and considered. With the addition of oxygen or compressed preheated air or both, these fossil fuels yield combustion products that readily reach the temperatures required for thermal ionization.

Possible fuel sources

Although conventional nuclear fission reactors of the light-water type operate at temperatures too low for MHD applications, nuclear heat sources represent still another option for MHD systems. If a nuclear heat source were employed, hydrogen or a noble gas such as argon or helium would be appropriate for the working fluid, and nonequilibrium ionization could be used. A possible candidate for this kind of heat source is the NERVA (nuclear energy for rocket vehicle application) high-temperature fission reactor, originally designed for space propulsion. While the ultimate form of fusion reactor has yet to be determined, it should be feasible to devise a scheme for coupling an MHD generator to a nuclear source of this type (see below). Solar concentrators also can in theory achieve the temperatures required for MHD operation, and there have been several proposals for exploiting solar radiation to provide the necessary thermal energy.

The use of fission and fusion reactors as heat sources for MHD generators is contingent upon the development of suitable high-temperature reactor systems. Similarly, in the case of solar-based MHD, high-temperature collectors for solar thermal systems are required. Since such systems have yet to be constructed, attention has so far been focused on fossil- and chemical-fueled systems, with the primary aim of using MHD technology for central station power generation.

As energy is extracted from an MHD generator, duct conditions become increasingly less favourable for maintenance of electrical conductivity and, in the case of thermal ionization, extraction is essentially completed when the temperature falls to about 2,500 K. A central station power system thus has to be based on a binary cycle, with an MHD generator topping a conventional steam plant. (Topping means that the gas generated by burning a fossil fuel is first passed through the MHD generator and then on to the turbogenerator of the ordinary power plant, which constitutes the bottoming portion of the binary cycle.) In effect, the exhaust gas from the MHD generator feeds the bottoming cycle so that the residual thermal energy in the gas can be used to furnish additional power output and also to preheat the oxidizer for further fuel combustion in the MHD generator. An MHD power plant employing such an arrangement is an open-cycle ("once-through") system.

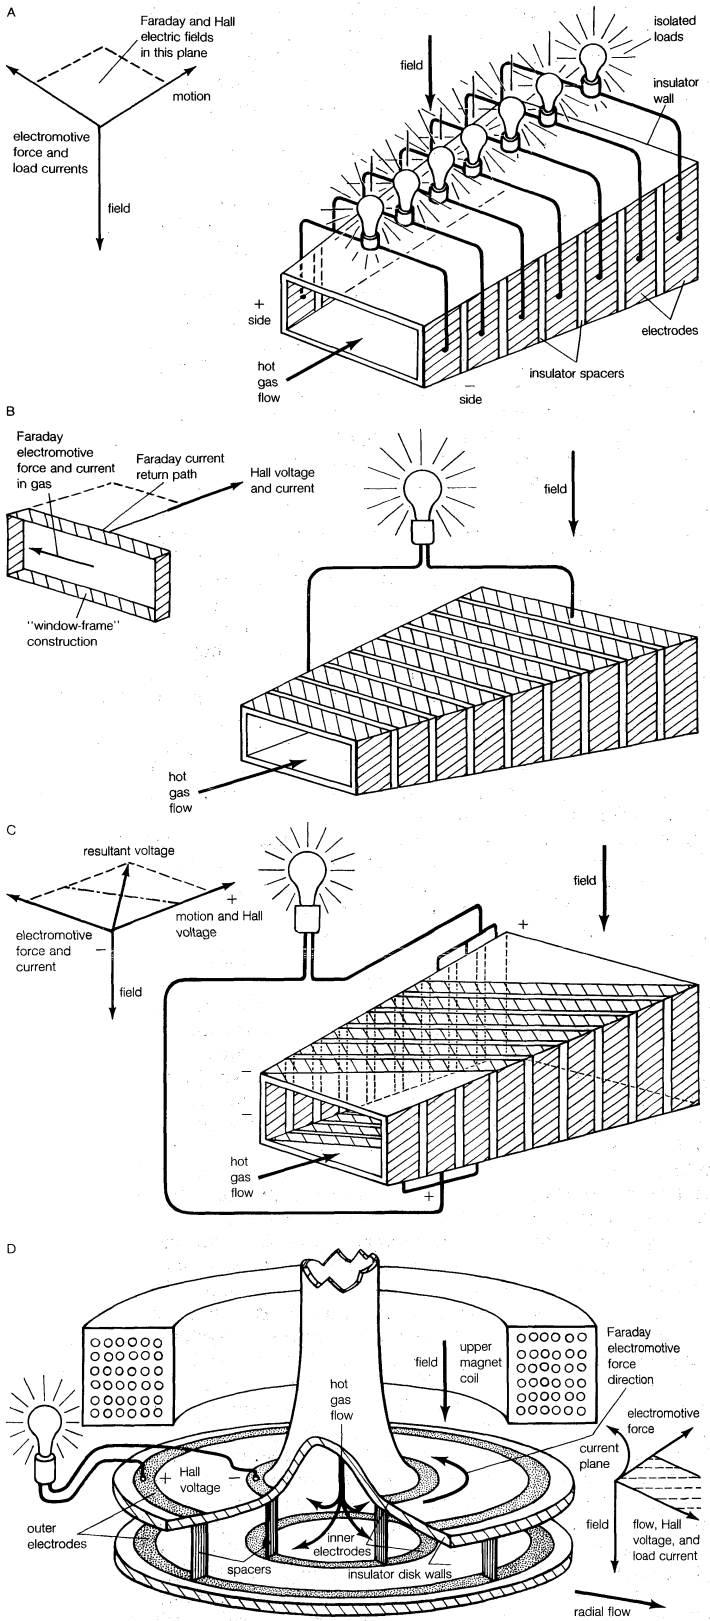

Figure 86: *MHD generator configurations.*
(A) Segmented Faraday generator, (B) Hall generator, (C) diagonal generator with "window-frame" construction, and (D) disk generator (see text).

The abundance of coal reserves in the United States has favoured the development of coal-fired MHD systems for domestic use. Coal combustion as a source of heat has several advantages. For example, it results in coal slag, which under magnetohydrodynamic conditions is molten and provides a layer that covers all of the insulator and electrode walls. The electrical conductivity of this layer is sufficient to provide conduction between the working gas and the electrode structure but not so high as to cause any significant leakage of electric currents and consequent loss. Indeed, the reduced thermal loss to the walls due to the slag layer more than compensates for any electrical losses arising from its presence.

Environmental benefits of coal-fired MHD power plants

The use of a seed material in conjunction with coal firing offers environmental benefits. When sulfur is present in the coal, the recombination chemistry that occurs in the duct of an MHD generator as the gas proceeds to lower temperatures favours the formation of potassium sulfate and so facilitates the removal of sulfur from high-sulfur coals. This in turn sharply reduces sulfur dioxide emissions. Moreover, the need to recover seed material ensures that a high level of particulate removal is built into an MHD coal-fired plant. Finally, by careful design of the boiler and control of combustion, very low levels of nitrogen oxides can be achieved. From an environmental viewpoint, MHD power systems offer effluent levels impressively lower than those currently established by the Environmental Protection Agency (EPA) in the United States.

Use in geophysical research

The need to provide large pulses of electrical power at remote sites has stimulated the development of pulsed MHD generators. For this application, the MHD system consists basically of a rocket motor, duct, magnet, and connections to electrical load. Similar generators are routinely operated in the Soviet Union as sources for pulse-power electromagnetic sounding apparatuses used in geophysical research; power levels up to 100 megawatts have been reported. In this application, the MHD generator provides a power pulse typically of a few seconds' duration to a magnetic or electric dipole located on the surface. The magnetic fields induced in the crust of the Earth are measured, and, through electrical conductivity, properties of the crust are determined.

An alternative MHD scheme involves a generator of the type shown in Figure 85, except that it employs a liquid metal as its electrically conducting medium. Liquid metal is an attractive option because of its high electrical conductivity, but it cannot serve directly as a thermodynamic working fluid. The liquid has to be combined with a driving gas or vapour to create a two-phase flow in the generator duct, or it has to be accelerated by a thermodynamic pump (often described as an ejector) and then separated from the driving gas or vapour before it passes through the duct. Depending on whether a condensable vapour or a gas is used, a number of cycles is possible, including condensing cycles essentially similar to that employed in a steam turbine. While the so-called liquid metal MHD systems offer attractive features from the viewpoint of electrical machine operation, they are limited in temperature by the properties of liquid metals to about 1,250 K. They thus have to compete with various existing energy-conversion systems and with other advanced systems capable of operating in the same temperature range.

The use of MHD generators to provide power for spacecraft for both burst and continuous operations has been considered. While both chemical and nuclear heat sources have been investigated, the latter is the preferred choice for applications such as supplying electric propulsion power for deep-space probes.

Development of MHD power generators. The first recorded MHD investigation was conducted in 1821 by the English chemist Humphry Davy when he showed that an arc could be deflected by a magnetic field. More than a decade later, Faraday sought to demonstrate motional electromagnetic induction in a conductor moving through the magnetic field of the Earth. To this end he set up in January 1832 a rudimentary open-circuit MHD generator, or flow meter, on the Waterloo Bridge across the River Thames. His experiment was unsuccessful, however, due to the electrodes being electrochemically polarized, an effect not understood at that time.

Faraday soon turned his attention to other aspects of electromagnetic induction, and MHD power generation received little attention until the 1920s and '30s, at which time B. Karlovitz, a Hungarian-born engineer, first pro-

posed a gaseous MHD system of the type described above. In 1938 he and D. Halász set up an experimental MHD facility at the Westinghouse research laboratories and by 1946 had shown that, through seeding the working gas, small amounts of electric power could be extracted. The project was abandoned, however, largely because of a lack of understanding of the conditions required to make the working gas an effective conductor.

First successful MHD power generator

Interest in magnetohydrodynamics grew rapidly during the late 1950s as a result of extensive studies of ionized gases for a number of applications. In 1959 the American engineer Richard J. Rosa operated the first truly successful MHD generator; this device produced about 10 kilowatts of electric power. By 1963 the Avco Research Laboratory, under the direction of the American physicist Arthur R. Kantrowitz, had constructed and operated a 33-megawatt MHD generator, and for many years this remained a record power output. The assumption in the late 1960s that nuclear power would dominate commercial power generation and the failure to find applications for space missions led to a sharp curtailment of MHD research. The energy crisis of the 1970s, however, brought about a revival, with the focus centred on coal-fueled systems in the United States and various other countries. By the late 1980s, development had reached the point where the construction of a complete demonstration system was feasible and, with the environmental advantages resulting from efficient conversion becoming increasingly apparent, the incentive to construct such a system within the next decade gained impetus. (W.D.J.)

FUSION REACTORS

Since the 1930s, scientists have known that the Sun and other stars generate their energy by nuclear fusion. They realized that if fusion energy generation could be replicated in a controlled manner on Earth, it might very well provide a safe, clean, and inexhaustible source of energy. The 1950s saw the beginning of a worldwide research effort to develop a fusion reactor. The substantial accomplishments and prospects of this continuing endeavour are described here.

General characteristics. The energy-producing mechanism in a fusion reactor is the joining together of two light atomic nuclei. When two nuclei fuse, a small amount of mass, m, is converted into a large amount of energy, E. Energy and mass are related through Einstein's relation, $E = mc^2$, by the large conversion factor c^2, where c is the speed of light. The inverse process, conversion of mass to energy by the splitting of a heavy nucleus, is the basis for the fission reactor (see *Nuclear fission reactors* above).

Energy-producing mechanism in fusion reactors

Fusion reactions are inhibited by the electrical repulsive force that acts between two positively charged nuclei. For fusion to occur, the two nuclei must approach each other at high speed to overcome the electrical repulsion and attain a sufficiently small separation (less than one-trillionth of a centimetre) that the short-range strong nuclear force dominates. For the production of useful amounts of energy, a large number of nuclei must undergo fusion; that is to say, a gas of fusing nuclei must be produced. In a gas at extremely high temperature, the average nucleus contains sufficient kinetic energy to undergo fusion. Such a medium can be produced by heating an ordinary gas of neutral atoms beyond the temperature at which electrons are knocked out of the atoms. The result is an ionized gas consisting of free negative electrons and positive nuclei. This gas constitutes a plasma. Most of the matter in the universe is in the plasma state.

The scientific problem of fusion is thus the problem of producing and confining a hot, dense plasma. The core of a fusion reactor would consist of burning plasma. Fusion would occur between the nuclei, with the electrons present only to maintain macroscopic charge neutrality.

Stars, including the Sun, consist of plasmas that generate energy by fusion reactions. In these "natural fusion reactors" the reacting, or burning, plasma is confined by its own gravity. It is not possible to assemble on Earth a plasma sufficiently massive to be gravitationally confined. The hydrogen bomb is an example of fusion reactions produced in an uncontrolled, unconfined manner in which the energy density is so high that the energy release is explosive. By contrast, the use of fusion for peaceful energy generation requires control and confinement of a plasma at high temperature and is often called controlled thermonuclear fusion.

In the development of fusion power technology, demonstration of "energy breakeven" is taken to signify the scientific feasibility of fusion. At breakeven, the fusion power produced by a plasma is equal to the power input to maintain the plasma. This requires a plasma that is hot, dense, and well confined. The temperature required, about 100 million kelvins, is several times that of the Sun. The product of the density and energy confinement time of the plasma (the time it takes the plasma to lose its energy if unreplaced) must exceed a critical value.

Principal approaches to controlled thermonuclear fusion

There are two main approaches to controlled fusion—namely, magnetic confinement and inertial confinement. In magnetic confinement, a low-density plasma is confined for a long period of time by a magnetic field. The plasma density is roughly 10^{15} particles per cubic centimetre, which is many thousands of times less than the density of air at room temperature. The energy confinement time must then be at least one second—*i.e.*, the energy in the plasma must be replaced every second. In inertial confinement, no attempt is made to confine the plasma beyond the time it takes the plasma to disassemble. The energy confinement time is simply the time it takes the fusing plasma to expand. Confined only by its own inertia, the plasma survives for only about one-billionth of a second (one nanosecond). Hence, breakeven in this scheme requires a very large density of particles, typically about 10^{24} particles per cubic centimetre, which is about 100 times the density of a liquid. The extremely high density is achieved by compressing a solid pellet of fuel by the pressure of incident laser or particle beams. These approaches are sometimes referred to as laser fusion or particle-beam fusion.

The fusion reaction least difficult to achieve combines a deuteron (the nucleus of the deuterium atom) with a triton (the nucleus of a tritium atom). Both nuclei are isotopes of the hydrogen nucleus and contain a single unit of positive electric charge. Deuterium–tritium (D–T) fusion thus requires the nuclei to have lower kinetic energy than is needed for the fusion of more highly charged, heavier nuclei. The two products of the reaction are an alpha particle (nucleus of the helium atom) at an energy of 3.5 million electron volts (MeV) and a neutron at an energy of 14.1 MeV. (One MeV is the energy equivalent of 10 billion kelvins.) The neutron, lacking electric charge, is not affected by electric or magnetic fields within the plasma and can escape the plasma to deposit its energy in a material, such as lithium, which can surround the plasma. The heat generated in the lithium blanket is then converted to electrical energy by conventional means, such as turbines. The electrically charged alpha particle collides with the deuterons and tritons (by their electrical interaction) and can be magnetically confined within the plasma. It thereby transfers its energy to the reacting nuclei. When this redeposition of the fusion energy into the plasma exceeds the power lost from the plasma (by electromagnetic radiation, conduction, and convection), the plasma will be self-sustaining, or "ignited."

Inexhaustible source of energy

With deuterium and tritium as the fuel, the fusion reactor would be an effectively inexhaustible source of energy. Deuterium is obtained from seawater. About one in every 3,000 water molecules contains a deuterium atom. There is enough deuterium in the oceans to provide for the world's energy needs for billions of years. One gram of fusion fuel can produce as much energy as 9,000 litres of oil. The amount of deuterium found naturally in one litre of water is the energy equivalent of 300 litres of gasoline. Tritium is bred in the fusion reactor. It is generated in the lithium blanket as a product of the reaction in which neutrons are captured by the lithium nuclei.

A fusion reactor would have several attractive safety features. First, it is not subject to a runaway, or "meltdown," accident as is a fission reactor. The fusion reaction is not a chain reaction. It requires a hot plasma. Accidental interruption of a plasma control system would extinguish

the plasma and terminate fusion. Second, fusion reaction does not produce long-term radioactive wastes. Neutron bombardment will, however, activate the walls of the containment vessel. Such activation can be greatly reduced by employing fusion reactions that do not produce neutrons. Such "advanced" fusion-fuel cycles, as, for example, the fusion of deuterons and helium-3 nuclei, require higher temperatures than D–T fusion. Nearly neutron-free fusion systems might make up a "second generation" of fusion reactors. Finally, a fusion reactor would not release the gaseous pollutants that accompany the combustion of fossil fuels.

Principles of magnetic confinement. *Confinement physics.* Magnetic confinement of plasmas is the most highly developed approach to controlled fusion. The hot plasma is contained by magnetic forces exerted on the charged particles. A large part of the problem of fusion has been the attainment of magnetic field configurations that effectively confine the plasma. A successful configuration must meet three criteria: (1) the plasma must be in a time-independent equilibrium state, (2) the equilibrium must be macroscopically stable, and (3) the leakage of plasma energy to the bounding wall must be small.

Basic requirements

A single charged particle tends to spiral about a magnetic line of force. It is necessary that the single particle trajectories do not intersect the wall. Moreover, the pressure force, arising from the thermal energy of all the particles, is in a direction to expand the plasma. For the plasma to be in equilibrium, the magnetic force acting on the electric current within the plasma must balance the pressure force at every point in the plasma.

The equilibrium thus obtained has to be stable. A plasma is stable if after a small perturbation it returns to its original state. A plasma is continually perturbed by random thermal "noise" fluctuations. If unstable, the plasma might depart from its equilibrium state and rapidly escape the confines of the magnetic field (perhaps in less than one-thousandth of a second).

A plasma in stable equilibrium can be maintained indefinitely if the leakage of energy from the plasma is balanced by energy input, much like a leaky bucket can maintain a constant water level if the amount of water flowing in equals that flowing out. If the plasma energy loss is too large, then ignition cannot be achieved. An unavoidable diffusion of energy across the magnetic field lines will occur from the collisions between the particles. A collision can give the particle a random kick across the field. The net effect is to transport energy from the hot core to the wall. This transport process, known as classical diffusion, is theoretically not strong in hot fusion plasmas and is easily compensated for by heat from the alpha particle fusion products. In experiments, however, energy is lost from plasma more rapidly than expected from classical diffusion.

The observed energy loss typically exceeds the classical value by a factor of 10–100. Reduction of this anomalous transport is important to the engineering feasibility of fusion. An understanding of anomalous transport in plasmas in terms of physics is not yet in hand. A viewpoint under investigation is that the anomalous loss is caused by fine-scale turbulence in the plasma. Turbulently fluctuating electric and magnetic fields can push particles across the confining magnetic field. Solution of the anomalous transport problem involves research into fundamental topics in plasma physics, such as plasma turbulence.

Types of magnetic configurations

Many different types of magnetic configurations for plasma confinement have been devised and tested over the years. This development has been an evolutionary process that has resulted in a family of related magnetic configurations, which may be grouped into two classes: closed, toroidal configurations; and open, linear configurations. Toroidal devices are the most highly developed. A simple straight magnetic field would not suffice, since the plasma would be free to stream out the ends. The ends, and the end loss, can be eliminated by forming the plasma and magnetic field in the closed shape of a doughnut, or torus. In the approach involving linear devices, also called mirror confinement, the end loss is reduced by "plugging" the ends of such a device magnetically and electrostatically.

Toroidal confinement. The most extensively investigated toroidal confinement concept is the tokamak (Figure 87). The tokamak (an acronym derived from the Russian words for toroidal magnetic confinement) was introduced in the mid-1960s by Soviet plasma physicists. The magnetic lines of force are helixes that spiral around the torus. The helical magnetic field is composed of two components: (1) a toroidal magnetic field component, which points the long way around the torus; and (2) a poloidal field, which is directed the short way around the machine. The toroidal field is produced by current-carrying coils that surround the toroidal vacuum chamber containing the plasma. (The plasma must be situated within an evacuated chamber to prevent it from being cooled by interactions with air molecules.) The poloidal magnetic field is generated by a toroidal electric current that is forced to flow within the conducting plasma. Both magnetic field components are necessary for the plasma to be in stable equilibrium. If the poloidal field were zero so that the field lines were simply circles wrapped about the torus, then the plasma would not be in equilibrium. The particles would not strictly follow the field lines but would drift to the walls. The addition of the poloidal field provides particle orbits that are contained within the device. If the toroidal field were zero so that the magnetic field lines were directed only the short way around the torus, the plasma would be in equilibrium, but it would be unstable. The plasma column would develop growing distortions, or kinks, which would carry the plasma into the wall.

The tokamak

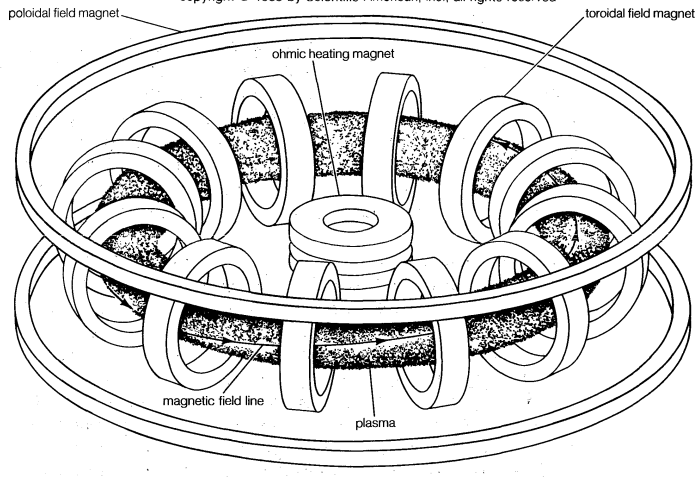

Figure 87: Tokamak magnetic confinement.

Several novel methods have been developed to drive the steady-state current that produces the poloidal magnetic field. A technique known as radio-frequency (RF) current drive employs electromagnetic waves to generate the current in a manner similar to the plasma-heating methods described below. Electromagnetic waves are injected into the plasma so that they propagate within the plasma in one direction around the torus. The speed of the waves is chosen to equal roughly the average speed of the electrons in the plasma. The wave electric field (which in a plasma has a component along its direction of travel) can then continuously accelerate the electrons as the wave and particles move together around the torus. In this way, the directed wave momentum is transferred to the electrons. The electrons develop a net motion, or current, in one direction. Although this technique is now well established, its efficiency is reduced at the density of a reacting plasma.

RF current drive

Another established current-drive technique is neutral-beam current drive. A beam of high-energy neutral atoms is injected into the plasma along the toroidal direction. The neutral beam will freely enter the plasma since it is unaffected by the magnetic field. Once inside the plasma, the neutral atoms of the beam become ionized by collisions with the electrons. The beam then consists of energetic positively charged nuclei (protons in the case of a hydrogen beam) that are confined within the plasma by the magnetic field. The high-speed ions travel toroidally

Neutral-beam current drive

along the magnetic field and collide with the electrons. The energy transfer from beam ion to electron will push the electrons in one direction and thereby produce a current. This technique is limited by the pace of the technological development of intense neutral-beam sources.

Faraday induction, or "ohmic current drive," can be used to initiate and build up the current. A magnetic flux that increases over time is produced through the hole in the torus. The plasma surrounds the flux. The time-varying flux induces a toroidal electric field that drives the plasma current. This technique efficiently drives a pulsed plasma current; however, it cannot be used for a steady-state current, which would require a magnetic flux increasing indefinitely over time. A pulsed reactor would suffer from engineering problems such as materials fatigue.

The plasma in a tokamak fusion reactor would have a major diameter in the range of 10 metres and a minor diameter in the range of roughly three metres. The plasma current would likely be tens of millions of amperes and the toroidal magnetic field would be several teslas. The coils that produce the strong toroidal magnetic field would probably be superconducting in order to minimize the power dissipation in the coils.

Other toroidal confinement concepts that offer potential advantages over the tokamak are under development, albeit at a smaller scale than tokamak research. Two such alternatives under investigation at various laboratories across the world are the reversed-field pinch (RFP) and stellarator concepts. Both configurations use helical magnetic fields similar to those of the tokamak. The reversed-field pinch operates with a low toroidal magnetic field. This results in a compact, high-power density reactor with ordinary (instead of superconducting) coils. The stellarator produces its magnetic field by external helical coils only. The plasma current is nearly zero, and plasma current drive is not required.

Reversed-field pinch and stellarator

Mirror confinement. An alternative approach to magnetic confinement is to employ a straight configuration in which the end loss is reduced by a combination of magnetic and electric plugging. In such a linear fusion reactor the magnetic field strength is increased at the ends. Charged particles that approach the end slow down, and many are reflected from this "magnetic mirror." The same magnetic reflection mechanism traps particles in the Earth's magnetosphere (specifically in the Van Allen belts). Unfortunately, particles with extremely high speed along the field are not stopped by the mirror. To inhibit this leakage out of the ends, electrostatic plugging is provided. An additional section of plasma is added at each end beyond the magnetic mirror. The plasma in these "end plugs" is of sufficient density and temperature to produce an electrostatic potential barrier to nuclei. The electric force on the nuclei would stop much of the leakage through the magnetic mirror. The final configuration is called a tandem mirror.

Plasma heating. A fusion reactor requires tens of megawatts of heating to reach ignition temperature. Two plasma-heating methods have been highly developed: electromagnetic wave heating and neutral-beam injection heating. In the former, electromagnetic waves are launched by antennas at the surface of the plasma. The waves penetrate the plasma and transfer their energy to the constituent particles. Ionized gases can support the propagation of a remarkably large variety of waves not found in other forms of matter. Effective wave-heating techniques employ frequencies from the radio-frequency range (tens of megahertz) to the microwave range (tens of gigahertz). Power sources are available over such frequencies. Power absorption often relies upon a resonant interaction between the wave and plasma. For example, if the frequency of the electromagnetic wave is equal to the frequency at which a nucleus gyrates about a magnetic field line, this resonant nucleus absorbs energy from the wave. This technique is called ion cyclotron resonance heating. Similarly, electron cyclotron resonance heating may be used to heat electrons. Such electron heating requires very high frequency (tens to hundreds of gigahertz). Recently developed free-electron lasers and gyrotron tubes are required at the highest frequencies.

Electromagnetic wave heating

In the second method, beams of neutral atoms at high energy (up to about one million electron volts) are injected into the plasma. The approach is quite similar to the neutral-beam current drive that was described above. When used for heating, however, the beams are injected in both directions around the torus, so that no net momentum is imparted to the plasma. The slowing down, or transfer of beam energy to the plasma, constitutes the heating mechanism.

Neutral beam injection heating

Principles of inertial confinement. In an inertial confinement fusion (ICF) reactor a tiny solid pellet of fuel (such as deuterium–tritium) would be compressed to tremendous density and temperature so that fusion power is produced in the very short time (tens of nanoseconds) before the pellet blows apart. The compression is accomplished by focusing an intense laser beam (or a charged particle beam) upon the small pellet (typically one to 10 millimetres in diameter). The surface of the pellet is ionized by the beam. The ablation of the ionized material generates a large inward force on the pellet (as in the rocket effect), which compresses the pellet to 1,000 to 10,000 times liquid density. During compression the temperature of the pellet increases to a value sufficient to produce fusion reactions (Figure 88). Ignition occurs, and the pellet, now a dense plasma, is burned up in a small micro-explosion. The process is repeated between one and 100 times per second.

Laser fusion

From F.F. Chen, *Introduction to Plasma Physics* (1974), Plenum Press

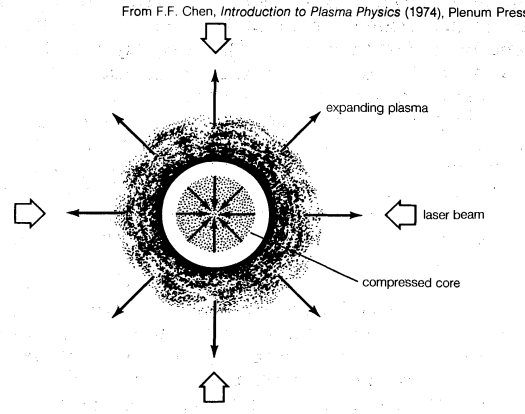

Figure 88: Laser fusion.

Inertial confinement fusion has been compared to the four-stage internal-combustion engine. In the fuel-injection stage, the pellet is injected into a blast chamber. In the compression stage, the pellet is compressed by the driver beams (laser or charged particle). In the ignition stage, the fusion reactions begin. In the final stage, the burn proceeds to completion and the fusion reaction products (neutrons, X rays, and charged particles) bombard and heat a blanket.

For efficient thermonuclear burn, the time to burn the pellet must be less than the disassembly time. This yields a criterion that in the compressed state the product of the pellet mass density and the pellet radius exceed about three grams per square centimetre. A high mass density will hasten the burn, and a large radius will slow the disassembly time. This criterion can be satisfied, for example, with a one-millimetre pellet and a fuel density of 30 grams per cubic centimetre. This density requires pellet compression to about 150 times its initial density (4.5×10^{22} particles per cubic centimetre).

The two key components of an ICF reactor are the driver beams and pellets. The power requirement of the driver beams is influenced by the efficiency of the driver (conversion of electrical power to beam power) and the efficiency at which the driver energy is absorbed by the pellet. At present, each of these efficiencies is between 1 and 10 percent for laser fusion. To overcome these losses requires an energy gain Q (fusion power/absorbed power) of about 1,000 to 10,000. An energy of one to five megajoules must be delivered to the pellet in one to 10 nanoseconds. Thus, the laser power is enormous, about one trillion watts. The laser irradiation must strike the pellet surface uniformly to compress the pellet effectively. Thus, many laser beams

irradiate the pellet with approximate spherical symmetry (see Figure 88).

Particle beam fusion

Charged particle driver beams can offer the advantage of more efficient production and absorption. Beams of electrons would "defocus" as a result of the small electron mass. Thus, light ion or heavy ion beams are employed. Beams of light ions (hydrogen through carbon) in the MeV energy range are produced by pulsed-power diode accelerators. In such accelerators, large voltage between a cathode and anode applies a strong electric force on the particles. The expected efficiency of light ion production is about 30 percent. Beams of heavy ions (xenon to uranium) are accelerated to energies of one billion electron volts (GeV) using accelerator technology from high-energy physics experiments. Such accelerators push particles by induction or with electromagnetic waves.

The pellets that are currently used are multilayered, consisting of several concentric spheres. This design has been chosen to optimize the symmetry, stability, and isentropy of the compression process (see below). The outermost layer is the ablation layer that absorbs the driver energy. It is converted to a plasma and blown away. In the plasma state, the high heat conduction symmetrizes the ablation process. The ablation layer surrounds a thick, heavy material of high atomic mass. The recoil from the ablation implodes the heavy layer, producing a shock wave that compresses and heats the next inner layer of deuterium–tritium fuel. The implosion speed is several hundred kilometres per second, produced by a force equivalent to some 10 billion atmospheres. The heavy layer inhibits the growth of instabilities (nonsymmetrical distortions) that would interfere with the compression. It also prevents the high-energy electrons and protons from the corona plasma from heating the deuterium–tritium layer. In this way, the compression is isentropic. The laser energy provides compression, not heat (entropy). The burn initiates in the D–T layer and spreads outward as the alpha particles collide with and heat the rest of the pellet to thermonuclear temperature.

Development of fusion reactor technology. *Magnetic confinement.* Several decades of fusion research have produced accomplishments of two types. First, the discipline of plasma physics has developed to the point that theoretical and experimental tools permit quantitative evaluation of many aspects of fusion reactor concepts. Second, and perhaps most revealing, the evolutionary improvement of plasma parameters has placed experiments at the threshold of energy breakeven.

Fusion research experiments are usually performed with hydrogen or deuterium plasmas. Radioactive tritium is not added since remote-handling requirements would unnecessarily complicate the experiments. A figure of merit with which to judge the plasma quality is the energy gain Q (= fusion power/heating power) that would occur if the plasma contained tritium. Over the past few decades Q has increased by more than one million, from 10^{-7} (less than one-millionth) in 1965 to about 0.5 in 1989. It is now a virtual certainty that the long-sought goal of energy breakeven $Q = 1$, is achievable. Current experiments confine plasmas with volumes of 100 cubic metres at temperatures in excess of 100 million kelvins (up to 20 kiloelectron volts) and with energy confinement times of a fraction of a second.

There is a wide variety of plasma experiments under way to investigate many aspects of the fusion problem. Parameters closest to the reactor level have been attained in the four large "flagship" experiments in the United States, western Europe, Japan, and the Soviet Union. These large tokamak facilities are the Tokamak Fusion Test Reactor (TFTR) at the Princeton Plasma Physics Laboratory in the United States; the Joint European Torus (JET), a multinational western European venture operated in Britain; JT-60 of the Japan Atomic Energy Research Institute; and T-15 at the I.V. Kurchatov Institute of Atomic Energy in Moscow.

A next major step in the development of fusion power is the construction of a facility to study the physics of a burning, ignited plasma (with Q being infinite). The presence of alpha particles can alter the behaviour of the plasma in ways not easily simulated in nonburning plasmas. A design effort is presently under consideration in the United States for an ignited-plasma facility called the Compact Ignition Tokamak (CIT). The experiment would employ extremely high magnetic fields (about 10 teslas) to enable the device to be relatively compact and thereby cost-effective. In recent years a consensus has emerged that the technical know-how exists to construct such an ignition device.

The next step after an ignition physics experiment would be a test reactor that would provide an integrated reactor facility, including materials and plasma engineering aspects. Under the auspices of the International Atomic Energy Agency, an international team is presently exploring a conceptual design of such a device, known as the International Thermonuclear Experimental Reactor (ITER). The expense of the device encourages collaboration between the United States, the countries of western Europe, the Soviet Union, and Japan. It is conceived that a device such as ITER would be followed by a demonstration fusion reactor power plant.

With the tremendous advances in scientific understanding and plasma quality, questions regarding the engineering and economic attractiveness of the tokamak concept have received greater attention. Materials development is required. For example, the wall exposed to the plasma must survive intense neutron bombardment. The optimal path to fusion-energy production involves some balance between further upscaling of the current tokamak concept toward reactor parameters and improvement of the magnetic confinement concept. Improvements can accrue from enhanced scientific understanding through research and by the development of alternative concepts, such as the stellarator and the reversed-field pinch.

Inertial confinement. ICF research has followed an evolutionary path similar to that of magnetic fusion. In the laser fusion approach, densities of 100 to 200 times liquid deuterium–tritium density have been achieved. For example, at the Lawrence Livermore National Laboratory in California, a product of density and energy-confinement time of 5×10^{14} seconds per cubic centimetre has been achieved using the world's largest and most powerful laser, the so-called Nova laser. (The Nova is a 10-beam neodymium–glass laser operated at an energy of 20,000 joules in a one-nanosecond pulse.) Although the value of this product is comparable to that representing breakeven for magnetic fusion, laser fusion requires a larger value to overcome the poor efficiency of existing lasers.

As a result of such progress, plans are being considered in the United States for a laboratory microfusion facility capable of demonstrating a fusion energy gain (fusion power/absorbed driver power) of 100 with a fusion energy release of nearly one billion joules. Light-ion beam experiments are also making headway. Scientists at the Particle Beam Fusion Accelerator (PBFA) at Sandia National Laboratories in New Mexico have demonstrated the ability to focus 72 beams to a spot diameter of less than six millimetres. One objective is to achieve an intensity of 10 terawatts per cubic centimetre (100 terawatts per cubic centimetre are required in a practical fusion reactor).

In both the magnetic and inertial confinement programs, the experimental steps become increasingly more expensive as the reactor regime is approached. At the same time, basic research and innovation are needed to enhance the attractiveness of the reactor concepts. Significant wisdom is required to balance these needs and to build effectively upon the impressive results to date so that nuclear fusion can indeed become a major factor in meeting the world's ever-growing energy needs. (S.C.P.)

GOLDSMID, *Applications of Thermoelectricity* (1960), a brief readable monograph covering thermoelectric effects, materials, devices, and applications; and ROBERT R. HEIKES and ROLAND W. URE, JR., *Thermoelectricity: Science and Engineering* (1961), a review of all aspects of thermoelectric devices. See also J.W.C. HARPSTER, P.R. SWINEHART, and F. BRAUN, "Solid State Thermal Control for Spacecraft," *Solid-State Electronics,* 18(6):551–555 (June 1975), an examination of the heat-pumping capabilities of thermoelectric devices in Earth-orbiting spacecraft. (J.W.H.)

(*Thermionic power converters*): Texts on thermodynamics in general include LEIGHTON E. SISSOM and DONALD R. PITTS, *Elements of Transport Phenomena* (1972); and FRANCIS F. HUANG, *Engineering Thermodynamics: Fundamentals and Applications,* 2nd ed. (1988). Discussions on thermionic converters in particular are G.N. HATSOPOULOS and E.P. GYFTOPOULOS, *Thermionic Energy Conversion,* 2 vol. (1973–79); and F.G. BAKSHT *et al., Thermionic Converters and Low-Temperature Plasma,* trans. from Russian (1978). (L.E.Si.)

(*Magnetohydrodynamic power generators*): RICHARD J. ROSA, *Magnetohydrodynamic Energy Conversion* (1968, reprinted 1987); GEORGE W. SUTTON and ARTHUR SHERMAN, *Engineering Magnetohydrodynamics* (1965); and V.A. KIRILLIN and A.E. SCHEINDLIN (eds.), *MHD Energy Conversion: Physiotechnical Problems* (1986; originally published in Russian, 1983), are general texts on MHD principles and applications. Useful journal articles include three from *Magnetohydrodynamics: An International Journal,* vol. 2, no. 1 (1989): L.H.TH. RIETJENS, "MHD for Large-Scale Electrical Power Generation in the 21st Century," pp. 17–25; E.P. VELIKHOV *et al.,* "Pulsed MHD Facilities: Geophysical Applications," pp. 27–33; and A.E. SCHEINDLIN and W.D. JACKSON, "Ninth International Conference on Magnetohydrodynamic Electrical Power Generation: Status Report Summary," pp. 11–16. Open-cycle MHD is treated in J.B. HEYWOOD and G.J. WOMACK (eds.), *Open-Cycle MHD Power Generation* (1969); and M. PETRICK and B. YA. SHUMYATSKY, *Open-Cycle Magnetohydrodynamic Electrical Power Generation* (1978), a joint U.S.–U.S.S.R. publication. Two conference proceedings are among important sources of current information: papers from meetings of the SYMPOSIUM ON THE ENGINEERING ASPECTS OF MAGNETOHYDRODYNAMICS, an American conference; and from the series of meetings of the INTERNATIONAL CONFERENCE ON MHD ELECTRICAL POWER GENERATION. (W.D.J.)

(*Fusion reactors*): Articles written for the lay reader include two from *Scientific American:* ROBERT W. CONN, "The Engineering of Magnetic Fusion Reactors," 249(4):60–71 (October 1983); and R. STEPHEN CRAXTON, ROBERT L. MCCRORY, and JOHN M. SOURES, "Progress in Laser Fusion," 255(2):68–79 (August 1986). The following books assume that the reader has a science background. Concepts of fusion in general are examined by THOMAS JAMES DOLAN, *Fusion Research: Principles, Experiments, and Technology* (1982). FRANCIS F. CHEN, *Introduction to Plasma Physics and Controlled Fusion,* vol. 1, *Plasma Physics,* 2nd ed. (1984); and WESTON M. STACEY, JR., *Fusion Plasma Analysis* (1981), provide introductions to plasma physics. Particular approaches to fusion are analyzed in JAMES J. DUDERSTADT and GREGORY A. MOSES, *Inertial Confinement Fusion* (1982); and WESTON M. STACEY, JR., *Fusion: An Introduction to the Physics and Technology of Magnetic Confinement Fusion* (1984). (S.C.P.)

Engineering

Engineering is the professional art of applying science to the optimum conversion of the resources of nature to the uses of humankind. Engineering has been defined by the Engineers Council for Professional Development, in the United States, as the creative application of "scientific principles to design or develop structures, machines, apparatus, or manufacturing processes, or works utilizing them singly or in combination; or to construct or operate the same with full cognizance of their design; or to forecast their behaviour under specific operating conditions; all as respects an intended function, economics of operation and safety to life and property." The term engineering is sometimes more loosely defined, especially in Great Britain, as the manufacture or assembly of engines, machine tools, and machine parts.

The words engine and ingenious are derived from the same Latin root, *ingenerare,* which means "to create." The early English verb *engine* meant "to contrive." Thus the engines of war were devices such as catapults, floating bridges, and assault towers; their designer was the "engine-er," or military engineer. The counterpart of the military engineer was the civil engineer, who applied essentially the same knowledge and skills to designing buildings, streets, water supplies, sewage systems, and other projects.

Associated with engineering is a great body of special knowledge; preparation for professional practice involves extensive training in the application of that knowledge. Standards of engineering practice are maintained through the efforts of professional societies, usually organized on a national or regional basis, with each member acknowledging a responsibility to the public over and above responsibilities to his employer or to other members of his society.

The function of the scientist is to know, while that of the engineer is to do. The scientist adds to the store of verified, systematized knowledge of the physical world; the engineer brings this knowledge to bear on practical problems. Engineering is based principally on physics, chemistry, and mathematics and their extensions into materials science, solid and fluid mechanics, thermodynamics, transfer and rate processes, and systems analysis.

Unlike the scientist, the engineer is not free to select the problem that interests him; he must solve problems as they arise; his solution must satisfy conflicting requirements. Usually efficiency costs money; safety adds to complexity; improved performance increases weight. The engineering solution is the optimum solution, the end result that, taking many factors into account, is most desirable. It may be the most reliable within a given weight limit, the simplest that will satisfy certain safety requirements, or the most efficient for a given cost. In many engineering problems the social costs are significant.

Engineers employ two types of natural resources—materials and energy. Materials are useful because of their properties: their strength, ease of fabrication, lightness, or durability; their ability to insulate or conduct; their chemical, electrical, or acoustical properties. Important sources of energy include fossil fuels (coal, petroleum, gas), wind, sunlight, falling water, and nuclear fission. Since most resources are limited, the engineer must concern himself with the continual development of new resources as well as the efficient utilization of existing ones.

For the history and functions of industrial engineering, see INDUSTRIAL ENGINEERING AND PRODUCT MANAGEMENT.

The article is divided into the following sections:

Engineering as a profession

HISTORY OF ENGINEERING

The first engineer known by name and achievement is Imhotep, builder of the Step Pyramid at Ṣaqqārah, Egypt, probably in about 2550 BC. Imhotep's successors—Egyptian, Persian, Greek, and Roman—carried civil engineering to remarkable heights on the basis of empirical methods aided by arithmetic, geometry, and a smattering of physical science. The Pharos (lighthouse) of Alexandria, Solomon's Temple in Jerusalem, the Colosseum in Rome, the Persian and Roman road systems, the Pont du Gard aqueduct in France, and many other large structures, some of which endure to this day, testify to their skill, imagination, and daring. Of many treatises written by them, one in particular survives to provide a picture of engineering education and practice in classical times: Vitruvius' *De architectura,* published in Rome in the 1st century AD, a 10-volume work covering building materials, construction methods, hydraulics, measurement, and town planning.

In construction medieval European engineers carried technique, in the form of the Gothic arch and flying buttress, to a height unknown to the Romans. The sketchbook of the 13th-century French engineer Villard de Honnecourt reveals a wide knowledge of mathematics, geometry, natural and physical science, and draftsmanship.

In Asia, engineering had a separate but very similar development, with more and more sophisticated techniques of construction, hydraulics, and metallurgy helping to create advanced civilizations such as the Mongol empire, whose large, beautiful cities impressed Marco Polo in the 13th century.

Civil engineering emerged as a separate discipline in the 18th century, when the first professional societies and

Civil and mechanical engineering

schools of engineering were founded. Civil engineers of the 19th century built structures of all kinds, designed water-supply and sanitation systems, laid out railroad and highway networks, and planned cities. England and Scotland were the birthplace of mechanical engineering, as a derivation of the inventions of the Scottish engineer James Watt and the textile machinists of the Industrial Revolution. The development of the British machine-tool industry gave tremendous impetus to the study of mechanical engineering both in Britain and abroad.

The growth of knowledge of electricity—from Alessandro Volta's original electric cell of 1800 through the experiments of Michael Faraday and others, culminating in 1872 in the Gramme dynamo and electric motor (named after the Belgian Z.T. Gramme)—led to the development of electrical and electronics engineering. The electronics aspect became prominent through the work of such scientists as James Clerk Maxwell of Britain and Heinrich Hertz of Germany in the late 19th century. Major advances came with the development of the vacuum tube by Lee De Forest of the United States in the early 20th century and the invention of the transistor in the mid-20th century. In the late 20th century electrical and electronics engineers outnumbered all others in the world.

Chemical engineering

Chemical engineering grew out of the 19th-century proliferation of industrial processes involving chemical reactions in metallurgy, food, textiles, and many other areas. By 1880 the use of chemicals in manufacturing had created an industry whose function was the mass production of chemicals. The design and operation of the plants of this industry became a function of the chemical engineer.

ENGINEERING FUNCTIONS

Problem solving is common to all engineering work. The problem may involve quantitative or qualitative factors; it may be physical or economic; it may require abstract mathematics or common sense. Of great importance is the process of creative synthesis or design, putting ideas together to create a new and optimum solution.

Although engineering problems vary in scope and complexity, the same general approach is applicable. First comes an analysis of the situation and a preliminary decision on a plan of attack. In line with this plan, the problem is reduced to a more categorical question that can be clearly stated. The stated question is then answered by deductive reasoning from known principles or by creative synthesis, as in a new design. The answer or design is always checked for accuracy and adequacy. Finally, the results for the simplified problem are interpreted in terms of the original problem and reported in an appropriate form.

In order of decreasing emphasis on science, the major functions of all engineering branches are the following:

Research. Using mathematical and scientific concepts, experimental techniques, and inductive reasoning, the research engineer seeks new principles and processes.

Development. Development engineers apply the results of research to useful purposes. Creative application of new knowledge may result in a working model of a new electrical circuit, a chemical process, or an industrial machine.

Design. In designing a structure or a product, the engineer selects methods, specifies materials, and determines shapes to satisfy technical requirements and to meet performance specifications.

Construction. The construction engineer is responsible for preparing the site, determining procedures that will economically and safely yield the desired quality, directing the placement of materials, and organizing the personnel and equipment.

Production. Plant layout and equipment selection are the responsibility of the production engineer, who chooses processes and tools, integrates the flow of materials and components, and provides for testing and inspection.

Operation. The operating engineer controls machines, plants, and organizations providing power, transportation, and communication; determines procedures; and supervises personnel to obtain reliable and economic operation of complex equipment.

Management and other functions. In some countries and industries, engineers analyze customers' requirements, recommend units to satisfy needs economically, and resolve related problems. (R.J.Sm./Ed.)

Major fields of engineering

MILITARY ENGINEERING

In its earliest uses the term engineering referred particularly to the construction of engines of war and the execution of works intended to serve military purposes. Military engineers were long the only ones to whom the title engineer was applied.

The role of the military engineer in modern war is to apply engineering knowledge and resources to the furtherance of the commander's plans. The basic requirement is a sound general engineering knowledge directed to the technical aspects of those tasks likely to be encountered in war. Engineering work is influenced by topographical considerations and in battle also by tactical limitations. At times engineering factors will actually govern the choice of the military plan adopted; a military engineer must, therefore, possess a sound military education so that the best technical advice will be given to the commander.

History. In the prehistoric period every man was a fighter and every fighter was to some extent an engineer. Primitive efforts were restricted to the provision of artificial protection for the person and machines for hurling destruction at the enemy. In the earliest war annals it is difficult to distinguish the military from the civil engineer. Julius Caesar referred to his *praefectus fabrum,* an official who controlled the labour gangs employed on road making and also parties of artisans. The Domesday survey of AD 1086 included one "Waldivus Ingeniator," who held nine manors direct from the crown and was probably William the Conqueror's chief engineer in England. Throughout the Middle Ages, ecclesiastics were frequently employed as military engineers, not only for purposes of planning and building but also for fighting. One of the best known is Gundulph, bishop of Rochester, who built the White Tower of the Tower of London and Rochester Castle.

Thus, in ancient and medieval times the military engineer became a specialist who made and used engines of war such as catapults, ballistas, battering rams, ramps, towers, scaling ladders, and other devices in attacking or defending castles, fortresses, and fortified camps. In peacetime the military engineer built fortifications for the defense of the country or city. Because such engineers frequently dug trenches or tunnels as means of approaching or undermining enemy positions, they came to be called sappers or miners. With the invention of gunpowder and the countless other inventions that came in later centuries, the military engineer was required to have far more technical knowledge. He nevertheless remained a soldier and fought side by side with the infantry in many wars.

The French corps of engineers

Before the late 17th century the engineers of French armies were selected infantry officers given brevets as engineers; they performed both civil and military duties for the king's service. In 1673 Sébastien Le Prestre de Vauban was appointed director general of the royal fortifications, and it was largely owing to this great designer of fortified places that in 1690 an officer corps of engineers was established. Sapper and miner companies were formed later, although these units were generally attached to the artillery. In 1801 the officer corps of engineers was integrated with the sapper and miner units, and the amalgamated corps served with great distinction throughout Napoleon's campaigns. In 1868 military telegraphists were added to the corps. The first engineer railway battalion was formed in 1876, and a battalion of aeronauts raised in 1904 was the forerunner of the French air force.

The first military engineering school was established at Mézières in 1748, and Lazare Carnot, a former graduate of Mézières, moved the school to Metz in 1795, where it was renamed the École Polytechnique ("Polytechnic School").

Military engineering functions. The functions of modern military engineers vary among the armies of the world, but as a rule they include the following activities: (1) construction and maintenance of roads, bridges, airfields, landing strips, and zones for the airdrop of personnel and supplies, (2) interference with the enemy's mobility

by means of demolitions, floods, destruction of matériel, mine fields, and obstacles and fortifications of many types, (3) mapping and aiding the artillery to survey gun positions, rocket-launching sites, and target areas, (4) supplying water and engineering equipment, and (5) disposal of unexploded bombs or warheads. In the British army the Royal Engineers also operate the army postal service.

The U.S. Army Corps of Engineers is both a combatant arm and a technical service. Alone among the arms and services, it engages in civil as well as military activities. During the 20th century its civil works activities have centred upon the planning, construction, and maintenance of improvements to rivers, harbours, and other waterways and upon flood control. The principal military service performed by the Corps of Engineers in the United States and abroad is the construction and maintenance of buildings and utilities. In theatres of operation in wartime, such construction is carried out by engineer troops. In the United States in peace and war and overseas in peacetime, such construction is usually accomplished by private industry under contract to the Corps of Engineers. (Ed.)

CIVIL ENGINEERING

The term civil engineering was first used in the 18th century to distinguish the newly recognized profession from military engineering, until then preeminent. From earliest times, however, engineers have engaged in peaceful activities, and many of the civil engineering works of ancient and medieval times—such as the Roman public baths, roads, bridges, and aqueducts; the Flemish canals; the Dutch sea defenses; the French Gothic cathedrals; and many other monuments—reveal a history of inventive genius and persistent experimentation.

History. The beginnings of civil engineering as a separate discipline may be seen in the foundation in France in 1716 of the Bridge and Highway Corps, out of which in 1747 grew the École Nationale des Ponts et Chaussées ("National School of Bridges and Highways"). Its teachers wrote books that became standard works on the mechanics of materials, machines, and hydraulics, and leading British engineers learned French to read them. As design and calculation replaced rule of thumb and empirical formulas, and as expert knowledge was codified and formulated, the nonmilitary engineer moved to the front of the stage. Talented, if often self-taught, craftsmen, stonemasons, millwrights, toolmakers, and instrument makers became civil engineers. In Britain, James Brindley began as a millwright and became the foremost canal builder of the century; John Rennie was a millwright's apprentice who eventually built the new London Bridge; Thomas Telford, a stonemason, became Britain's leading road builder.

Smeaton's work

John Smeaton, the first man to call himself a civil engineer, began as an instrument maker. His design of Eddystone Lighthouse (1756–59), with its interlocking masonry, was based on a craftsman's experience. Smeaton's work was backed by thorough research, and his services were much in demand. In 1771 he founded the Society of Civil Engineers (now known as the Smeatonian Society). Its object was to bring together experienced engineers, entrepreneurs, and lawyers to promote the building of large public works, such as canals (and later railways), and to secure the parliamentary powers necessary to execute their schemes. Their meetings were held during parliamentary sessions; the society follows this custom to this day.

The École Polytechnique was founded in Paris in 1794, and the Bauakademie was started in Berlin in 1799, but no such schools existed in Great Britain for another two decades. It was this lack of opportunity for scientific study and for the exchange of experiences that led a group of young men in 1818 to found the Institution of Civil Engineers. The founders were keen to learn from one another and from their elders, and in 1820 they invited Thomas Telford, by then the dean of British civil engineers, to be their first president. There were similar developments elsewhere. By the mid-19th century there were civil engineering societies in many European countries and the United States, and the following century produced similar institutions in almost every country in the world.

Engineering education

Formal education in engineering science became widely available as other countries followed the lead of France and Germany. In Great Britain the universities, traditionally seats of classical learning, were reluctant to embrace the new disciplines. University College, London, founded in 1826, provided a broad range of academic studies and offered a course in mechanical philosophy. King's College, London, first taught civil engineering in 1838, and in 1840 Queen Victoria founded the first chair of civil engineering and mechanics at the University of Glasgow, Scot. Rensselaer Polytechnic Institute, founded in 1824, offered the first courses in civil engineering in the United States. The number of universities throughout the world with engineering faculties, including civil engineering, increased rapidly in the 19th and early 20th centuries. Civil engineering today is taught in universities on every continent.

Civil engineering functions. The functions of the civil engineer can be divided into three categories: those performed before construction (feasibility studies, site investigations, and design), those performed during construction (dealing with clients, consulting engineers, and contractors), and those performed after construction (maintenance and research).

Feasibility studies. No major project today is started without an extensive study of the objective and without preliminary studies of possible plans leading to a recommended scheme, perhaps with alternatives. Feasibility studies may cover alternative methods—*e.g.,* bridge versus tunnel, in the case of a water crossing—or, once the method is decided, the choice of route. Both economic and engineering problems must be considered.

Site investigations. A preliminary site investigation is part of the feasibility study, but once a plan has been adopted a more extensive investigation is usually imperative. Money spent in a rigorous study of ground and substructure may save large sums later in remedial works or in changes made necessary in constructional methods.

Soil mechanics

Since the load-bearing qualities and stability of the ground are such important factors in any large-scale construction, it is surprising that a serious study of soil mechanics did not develop until the mid-1930s. Karl von Terzaghi, the chief founder of the science, gives the date of its birth as 1936, when the First International Conference on Soil Mechanics and Foundation Engineering was held at Harvard University and an international society was formed. Today there are specialist societies and journals in many countries, and most universities that have a civil engineering faculty have courses in soil mechanics.

Design. The design of engineering works may require the application of design theory from many fields—*e.g.,* hydraulics, thermodynamics, or nuclear physics. Research in structural analysis and the technology of materials has opened the way for more rational designs, new design concepts, and greater economy of materials. The theory of structures and the study of materials have advanced together as more and more refined stress analysis of structures and systematic testing has been done. Modern designers not only have advanced theories and readily available design data, but structural designs can now be rigorously analyzed by computers.

Construction. The promotion of civil engineering works may be initiated by a private client, but most work is undertaken for large corporations, government authorities, and public boards and authorities. Many of these have their own engineering staffs, but for large specialized projects it is usual to employ consulting engineers.

The role of the consulting engineer

The consulting engineer may be required first to undertake feasibility studies, then to recommend a scheme and quote an approximate cost. The engineer is responsible for the design of the works, supplying specifications, drawings, and legal documents in sufficient detail to seek competitive tender prices. The engineer must compare quotations and recommend acceptance of one of them. Although he is not a party to the contract, the engineer's duties are defined in it; the staff must supervise the construction and the engineer must certify completion of the work. Actions must be consistent with duty to the client; the professional organizations exercise disciplinary control over professional conduct. The consulting engineer's senior representative on the site is the resident engineer.

A phenomenon of recent years has been the turnkey or package contract, in which the contractor undertakes to finance, design, specify, construct, and commission a project in its entirety. In this case, the consulting engineer is engaged by the contractor rather than by the client.

The contractor is usually an incorporated company, which secures the contract on the basis of the consulting engineer's specification and general drawings. The consulting engineer must agree to any variations introduced and must approve the detailed drawings.

Maintenance. The contractor maintains the works to the satisfaction of the consulting engineer. Responsibility for maintenance extends to ancillary and temporary works where these form part of the overall construction. After construction a period of maintenance is undertaken by the contractor, and the payment of the final installment of the contract price is held back until released by the consulting engineer. Central and local government engineering and public works departments are concerned primarily with maintenance, for which they employ direct labour.

Research. Research in the civil engineering field is undertaken by government agencies, industrial foundations, the universities, and other institutions. Most countries have government-controlled agencies, such as the United States Bureau of Standards and the National Physical Laboratory of Great Britain, involved in a broad spectrum of research, and establishments in building research, roads and highways, hydraulic research, water pollution, and other areas. Many are government-aided but depend partly on income from research work promoted by industry.

Branches of civil engineering. In 1828 Thomas Tredgold of England wrote:

> The most important object of Civil Engineering is to improve the means of production and of traffic in states, both for external and internal trade. It is applied in the construction and management of roads, bridges, railroads, aqueducts, canals, river navigation, docks and storehouses, for the convenience of internal intercourse and exchange; and in the construction of ports, harbours, moles, breakwaters and lighthouses; and in the navigation by artificial power for the purposes of commerce.
>
> It is applied to the protection of property where natural powers are the sources of injury, as by embankments for the defence of tracts of country from the encroachments of the sea, or the overflowing of rivers; it also directs the means of applying streams and rivers to use, either as powers to work machines, or as supplies for the use of cities and towns, or for irrigation; as well as the means of removing noxious accumulations, as by the drainage of towns and districts to . . . secure the public health.

Aspects of civil engineering

A modern description would include the production and distribution of energy, the development of aircraft and airports, the construction of chemical process plants and nuclear power stations, and water desalination. These aspects of civil engineering may be considered under the following headings: construction, transportation, maritime and hydraulic engineering, power, and public health.

Construction. Almost all civil engineering contracts include some element of construction work. The development of steel and concrete as building materials had the effect of placing design more in the hands of the civil engineer than the architect. The engineer's analysis of a building problem, based on function and economics, determines the building's structural design.

Transportation. Roman roads and bridges were products of military engineering, but the pavements of McAdam and the bridges of Perronet were the work of the civil engineer. So were the canals of the 18th century and the railways of the 19th, which, by providing bulk transport with speed and economy, lent a powerful impetus to the Industrial Revolution. The civil engineer today is concerned with an even larger transportation field—*e.g.,* traffic studies, design of systems for road, rail, and air, and construction including pavements, embankments, bridges, and tunnels.

Maritime and hydraulic engineering. Harbour construction and shipbuilding are ancient arts. For many developing countries today the establishment of a large, efficient harbour is an early imperative, to serve as the inlet for industrial plant and needed raw materials and the outlet for finished goods. In developed countries the expansion of world trade, the use of larger ships, and the increase in total tonnage call for more rapid and efficient handling. Deeper berths and alongside-handling equipment (for example, for ore) and navigation improvements are the responsibility of the civil engineer.

The development of water supplies was a feature of the earliest civilizations, and the demand for water continues to rise today. In developed countries the demand is for industrial and domestic consumption, but in many parts of the world—*e.g.,* the Indus basin—vast schemes are under construction, mainly for irrigation to help satisfy the food demand, and are often combined with hydroelectric power generation to promote industrial development.

Dam engineering

Dams today are among the largest construction works, and design development is promoted by bodies like the International Commission on Large Dams. The design of large impounding dams in places with population centres close by requires the utmost in safety engineering, with emphasis on soil mechanics and stress analysis. Most governments exercise statutory control of engineers qualified to design and inspect dams.

Power. Civil engineers have always played an important part in mining for coal and metals; the driving of tunnels is a task common to many branches of civil engineering. In the 20th century the design and construction of power stations has advanced with the rapid rise in demand for electric power, and nuclear power stations have added a whole new field of design and construction, involving prestressed concrete pressure vessels for the reactor.

The exploitation of oil fields and the discoveries of natural gas in significant quantities have initiated a radical change in gas production. Shipment in liquid form from the Sahara and piping from the bed of the North Sea have been among the novel developments.

Public health. Drainage and liquid-waste disposal are closely associated with antipollution measures and the reuse of water. The urban development of parts of water catchment areas can alter the nature of runoff, and the training and regulation of rivers produce changes in the pattern of events, resulting in floods and the need for flood prevention and control.

Modern civilization has created problems of solid-waste disposal, from the manufacture of durable goods, such as automobiles and refrigerators, produced in large numbers with a limited life, to the small package, previously disposable, now often indestructible. The civil engineer plays an important role in the preservation of the environment, principally through design of works to enhance rather than to damage or pollute. (J.G.W./Ed.)

MECHANICAL ENGINEERING

Mechanical engineering is the branch of engineering that deals with machines and the production of power. It is particularly concerned with forces and motion.

Steam engine

History. The invention of the steam engine in the latter part of the 18th century, providing a key source of power for the Industrial Revolution, gave an enormous impetus to the development of machinery of all types. As a result, a new major classification of engineering dealing with tools and machines developed, receiving formal recognition in 1847 in the founding of the Institution of Mechanical Engineers in Birmingham, Eng.

Mechanical engineering has evolved from the practice by the mechanic of an art based largely on trial and error to the application by the professional engineer of the scientific method in research, design, and production. The demand for increased efficiency is continually raising the quality of work expected from a mechanical engineer and requiring a higher degree of education and training.

Mechanical engineering functions. Four functions of the mechanical engineer, common to all branches of mechanical engineering, can be cited. The first is the understanding of and dealing with the bases of mechanical science. These include dynamics, concerning the relation between forces and motion, such as in vibration; automatic control; thermodynamics, dealing with the relations among the various forms of heat, energy, and power; fluid flow; heat transfer; lubrication; and properties of materials.

Second is the sequence of research, design, and development. This function attempts to bring about the changes necessary to meet present and future needs. Such work requires a clear understanding of mechanical science, an ability to analyze a complex system into its basic factors, and the originality to synthesize and invent.

Third is production of products and power, which embraces planning, operation, and maintenance. The goal is to produce the maximum value with the minimum investment and cost while maintaining or enhancing longer term viability and reputation of the enterprise or the institution.

Fourth is the coordinating function of the mechanical engineer, including management, consulting, and, in some cases, marketing.

In these functions there is a long continuing trend toward the use of scientific instead of traditional or intuitive methods. Operations research, value engineering, and PABLA (problem analysis by logical approach) are typical titles of such rationalized approaches. Creativity, however, cannot be rationalized. The ability to take the important and unexpected step that opens up new solutions remains in mechanical engineering, as elsewhere, largely a personal and spontaneous characteristic.

Branches of mechanical engineering. *Development of machines for the production of goods.* The high standard of living in the developed countries owes much to mechanical engineering. The mechanical engineer invents machines to produce goods and develops machine tools of increasing accuracy and complexity to build the machines.

The principal lines of development of machinery have been an increase in the speed of operation to obtain high rates of production, improvement in accuracy to obtain quality and economy in the product, and minimization of operating costs. These three requirements have led to the evolution of complex control systems.

The most successful production machinery is that in which the mechanical design of the machine is closely integrated with the control system. A modern transfer (conveyor) line for the manufacture of automobile engines is a good example of the mechanization of a complex series of manufacturing processes. Developments are in hand to automate production machinery further, using computers to store and process the vast amount of data required for manufacturing a variety of components with a small number of versatile machine tools.

Development of machines for the production of power. The steam engine provided the first practical means of generating power from heat to augment the old sources of power from muscle, wind, and water. One of the first challenges to the new profession of mechanical engineering was to increase thermal efficiencies and power; this was done principally by the development of the steam turbine and associated large steam boilers. The 20th century has witnessed a continued rapid growth in the power output of turbines for driving electric generators, together with a steady increase in thermal efficiency and reduction in capital cost per kilowatt of large power stations. Finally, mechanical engineers acquired the resource of nuclear energy, whose application has demanded an exceptional standard of reliability and safety involving the solution of entirely new problems (see *Nuclear engineering* below).

Complex control systems

The mechanical engineer is also responsible for the much smaller internal combustion engines, both reciprocating (gasoline and diesel) and rotary (gas-turbine and Wankel) engines, with their widespread transport applications. In the transportation field generally, in air and space as well as on land and sea, the mechanical engineer has created the equipment and the power plant, collaborating increasingly with the electrical engineer, especially in the development of suitable control systems.

Development of military weapons. The skills applied to war by the mechanical engineer are similar to those required in civilian applications, though the purpose is to enhance destructive power rather than to raise creative efficiency. The demands of war have channeled huge resources into technical fields, however, and led to developments that have profound benefits in peace. Jet aircraft and nuclear reactors are notable examples.

Environmental control. The earliest efforts of mechanical engineers were aimed at controlling the human environment by draining and irrigating land and by ventilating mines. Refrigeration and air conditioning are examples of the use of modern mechanical devices to control the environment.

Many of the products of mechanical engineering, together with technological developments in other fields, give rise to noise, the pollution of water and air, and the dereliction of land and scenery. The rate of production, both of goods and power, is rising so rapidly that regeneration by natural forces can no longer keep pace. A rapidly growing field for mechanical engineers and others is environmental control, comprising the development of machines and processes that will produce fewer pollutants and of new equipment and techniques that can reduce or remove the pollution already generated. (J.F.Br./P.McG.R./Ed.)

Side effects of development

CHEMICAL ENGINEERING

Chemical engineering is the development of processes and the design and operation of plants in which materials undergo changes in physical or chemical state on a technical scale. Applied throughout the process industries, it is founded on the principles of chemistry, physics, and mathematics. The laws of physical chemistry and physics govern the practicability and efficiency of chemical engineering operations. Energy changes, deriving from thermodynamic considerations, are particularly important. Mathematics is a basic tool in optimization and modeling. Optimization means arranging materials, facilities, and energy to yield as productive and economical an operation as possible. Modeling is the construction of theoretical mathematical prototypes of complex process systems, commonly with the aid of computers.

History. Chemical engineering is as old as the process industries. Its heritage dates from the fermentation and evaporation processes operated by early civilizations. Modern chemical engineering emerged with the development of large-scale, chemical-manufacturing operations in the second half of the 19th century. Throughout its development as an independent discipline, chemical engineering has been directed toward solving problems of designing and operating large plants for continuous production.

Manufacture of chemicals in the mid-19th century consisted of modest craft operations. Increase in demand, public concern at the emission of noxious effluents, and competition between rival processes provided the incentives for greater efficiency. This led to the emergence of combines with resources for larger operations and caused the transition from a craft to a science-based industry. The result was a demand for chemists with knowledge of manufacturing processes, known as industrial chemists or chemical technologists. The term chemical engineer was in general use by about 1900. Despite its emergence in traditional chemicals manufacturing, it was through its role in the development of the petroleum industry that chemical engineering became firmly established as a unique discipline. The demand for plants capable of operating physical separation processes continuously at high levels of efficiency was a challenge that could not be met by the traditional chemist or mechanical engineer.

A landmark in the development of chemical engineering was the publication in 1901 of the first textbook on the subject, by George E. Davis, a British chemical consultant. This concentrated on the design of plant items for specific operations. The notion of a processing plant encompassing a number of operations, such as mixing, evaporation, and filtration, and of these operations being essentially similar, whatever the product, led to the concept of unit operations. This was first enunciated by the American chemical engineer Arthur D. Little in 1915 and formed the basis for a classification of chemical engineering that dominated the subject for the next 40 years. The number of unit operations—the building blocks of a chemical plant—is not large. The complexity arises from the variety of conditions under which the unit operations are conducted.

First chemical engineering textbook

In the same way that a complex plant can be divided into basic unit operations, so chemical reactions involved in the process industries can be classified into certain groups, or unit processes (*e.g.*, polymerizations, esterifications, and

nitrations), having common characteristics. This classification into unit processes brought rationalization to the study of process engineering.

The unit approach suffered from the disadvantage inherent in such classifications: a restricted outlook based on existing practice. Since World War II, closer examination of the fundamental phenomena involved in the various unit operations has shown these to depend on the basic laws of mass transfer, heat transfer, and fluid flow. This has given unity to the diverse unit operations and has led to the development of chemical engineering science in its own right; as a result, many applications have been found in fields outside the traditional chemical industry.

Study of the fundamental phenomena upon which chemical engineering is based has necessitated their description in mathematical form and has led to more sophisticated mathematical techniques. The advent of digital computers has allowed laborious design calculations to be performed rapidly, opening the way to accurate optimization of industrial processes. Variations due to different parameters, such as energy source used, plant layout, and environmental factors, can be predicted accurately and quickly so that the best combination can be chosen.

Chemical engineering functions. Chemical engineers are employed in the design and development of both processes and plant items. In each case, data and predictions often have to be obtained or confirmed with pilot experiments. Plant operation and control is increasingly the sphere of the chemical engineer rather than the chemist. Chemical engineering provides an ideal background for the economic evaluation of new projects and, in the plant construction sector, for marketing.

Branches of chemical engineering. The fundamental principles of chemical engineering underlie the operation of processes extending well beyond the boundaries of the chemical industry, and chemical engineers are employed in a range of operations outside traditional areas. Plastics, polymers, and synthetic fibres involve chemical-reaction engineering problems in their manufacture, with fluid flow and heat transfer considerations dominating their fabrication. The dyeing of a fibre is a mass-transfer problem. Pulp and paper manufacture involve considerations of fluid flow and heat transfer. While the scale and materials are different, these again are found in modern continuous production of foodstuffs. The pharmaceuticals industry presents chemical engineering problems, the solutions of which have been essential to the availability of modern drugs. The nuclear industry makes similar demands on the chemical engineer, particularly for fuel manufacture and reprocessing. Chemical engineers are involved in many sectors of the metals processing industry, which extends from steel manufacture to separation of rare metals.

Non-traditional employment

Further applications of chemical engineering are found in the fuel industries. In the second half of the 20th century, considerable numbers of chemical engineers have been involved in space exploration, from the design of fuel cells to the manufacture of propellants. Looking to the future, it is probable that chemical engineering will provide the solution to at least two of the world's major problems: supply of adequate fresh water in all regions through desalination of seawater and environmental control through prevention of pollution. (C.Ha./Ed.)

ELECTRICAL AND ELECTRONICS ENGINEERING

Electrical engineering deals with the practical applications of electricity in all its forms, including those of the field of electronics. Electronics engineering is that branch of electrical engineering concerned with the uses of the electromagnetic spectrum and with the application of such electronic devices as integrated circuits, transistors, and vacuum tubes. In engineering practice, the distinction between electrical engineering and electronics is based on the comparative strength of the electric currents used. In this sense, electrical engineering is the branch dealing with "heavy current"—that is, electric light and power systems and apparatuses—whereas electronics engineering deals with such "light current" applications as wire and radio communication, the stored-program electronic computer, radar, and automatic control systems.

The distinction between the fields has become less sharp with recent technical progress. For example, in the high-voltage transmission of electric power, large arrays of electronic devices are used to convert transmission-line current at power levels in the tens of megawatts. Moreover, in the regulation and control of interconnected power systems, electronic computers are used to compute requirements much more rapidly and accurately than is possible by manual methods. (D.G.F.)

History. Electrical phenomena attracted the attention of European thinkers as early as the 17th century. Beginning as a mathematically oriented science, the field has remained primarily in that form; mathematical predication often precedes laboratory demonstration. The most noteworthy pioneers include Ludwig Wilhelm Gilbert and Georg Simon Ohm of Germany, Hans Christian Ørsted of Denmark, André-Marie Ampère of France, Alessandro Volta of Italy, Joseph Henry of the United States, and Michael Faraday of England. Electrical engineering may be said to have emerged as a discipline in 1864 when the Scottish physicist James Clerk Maxwell summarized the basic laws of electricity in mathematical form and predicted that radiation of electromagnetic energy would occur in a form that later became known as radio waves. In 1887 the German physicist Heinrich Hertz experimentally demonstrated the existence of radio waves.

Early theorists

The first practical application of electricity was the telegraph, invented by Samuel F.B. Morse in 1837. The need for electrical engineers was not felt until some 40 years later, upon the invention of the telephone (1876) by Alexander Graham Bell and of the incandescent lamp (1878) by Thomas A. Edison. These devices and Edison's first central generating plant in New York City (1882) created a large demand for men trained to work with electricity.

First practical application

The discovery of the "Edison effect," a flow of current through the vacuum of one of his lamps, was the first observation of current in space. Hendrick Antoon Lorentz of The Netherlands predicted the electron theory of electrical charge in 1895, and in 1897 J.J. Thomson of England showed that the Edison effect current was indeed caused by negatively charged particles (electrons). This led to the work of Guglielmo Marconi of Italy, Lee De Forest of the United States, and many others, which laid the foundations of radio engineering. In 1930 the term electronics was introduced to embrace radio and the industrial applications of electron tubes. Since 1947, when the transistor was invented by John Bardeen, William H. Brattain, and William B. Shockley, electronics engineering has been dominated by the applications of such solid-state electronic devices as the transistor, the semiconductor diode, and the integrated circuit. (J.D.R./D.G.F./Ed.)

Electrical and electronics engineering functions. *Research.* The functions performed by electrical and electronics engineers include (1) basic research in physics, other sciences, and applied mathematics in order to extend knowledge applicable to the field of electronics, (2) applied research based on the findings of basic research and directed at discovering new applications and principles of operation, (3) development of new materials, devices, assemblies, and systems suitable for existing or proposed product lines, (4) design of devices, equipment, and systems for manufacture, (5) field-testing of equipment and systems, (6) establishment of quality control standards to be observed in manufacture, (7) supervision of manufacture and production testing, (8) postproduction assessment of performance, maintenance, and repair, and (9) engineering management, or the direction of research, development, engineering, manufacture, and marketing and sales.

Consulting. The rapid proliferation of new discoveries, products, and markets in the electrical and electronics industries has made it difficult for workers in the field to maintain the range of skills required to manage their activities. Consulting engineers, specializing in new fields, are employed to study and recommend courses of action.

The educational background required for these functions tends to be highest in basic and applied research. In most major laboratories a doctorate in science or engineering is

required to fill leadership roles. Most positions in design, product development, and supervision of manufacture and quality control require a master's degree. In the high-technology industries typical of modern electronics, an engineering background at not less than the bachelor's level is required to assess competitive factors in sales engineering to guide marketing strategy.

Branches of electrical and electronics engineering. The largest of the specialized branches of electrical engineering, the branch concerned with the electronic computer, was introduced during World War II. The field of computer science and engineering has attracted members of several disciplines outside electronics, notably logicians, linguists, and applied mathematicians.

Another very large field is that concerned with electric light and power and their applications. Specialities within the field include the design, manufacture, and use of turbines, generators, transmission lines, transformers, motors, lighting systems, and appliances.

A third major field is that of communications, which comprises not only telegraphy and telephony but also satellite communications and the transmission of voice and data by laser signals through optical-fibre networks. The communication of digital data among computers connected by wire, microwave, and satellite circuits is now a major enterprise that has built a strong bond between computer and communications specialists.

Applications for other fields

The applications of electricity and electronics to other fields of science have expanded since World War II. Among the sciences represented are medicine, biology, oceanography, geoscience, nuclear science, laser physics, sonics and ultrasonics, and acoustics. Theoretical specialties within electronics include circuit theory, information theory, radio-wave propagation, and microwave theory.

Another important speciality concerns improvements in materials and components used in electrical and electronics engineering, such as conductive, magnetic, and insulating materials and the semiconductors used in solid-state devices. One of the most active areas is the development of new electronic devices, particularly the integrated circuits used in computers and other digital systems.

The development of electronic systems—equipment for consumers, such as radios, television sets, stereo equipment, video games, and home computers—occupies a large number of engineers. Another field is the application of computers and radio systems to automobiles, ships, and other vehicles. The field of aerospace electronic systems includes navigation aids for aircraft, automatic pilots, altimeters, and radar for traffic control, blind landing, and collision prevention. Many of these devices are also widely used in the marine services. (D.G.F./Ed.)

PETROLEUM ENGINEERING

Petroleum engineering is a specialized engineering discipline whose origins lie in both mining engineering and geology. The petroleum engineer, whose aim is to extract gaseous and liquid hydrocarbon products from the earth, is concerned with drilling, producing, processing, and transporting these products and handling all the related economic and regulatory considerations.

History. The foundations of petroleum engineering were established during the 1890s in California. There geologists were employed to correlate oil-producing zones and water zones from well to well to prevent extraneous water from entering oil-producing zones. From this came the recognition of the potential for applying technology to oil-field development. The American Institute of Mining and Metallurgical Engineers (AIME) established a Technical Committee on Petroleum in 1914. In 1957 the name of the AIME was changed to the American Institute of Mining, Metallurgical, and Petroleum Engineers.

Introduction of petroleum technology courses

Petroleum technology courses were introduced at the University of Pittsburgh, Pa., in 1910 and included courses in oil and gas law and industry practices; in 1915 the university granted the first degree in petroleum engineering. Also in 1910 the University of California at Berkeley offered its first courses in petroleum engineering and in 1915 established a four-year curriculum in petroleum engineering. After these pioneering efforts, professional programs spread throughout the United States and other countries.

From 1900 to 1920 petroleum engineering focused on drilling problems, such as establishing casing points for water shutoff, designing casing strings, and improving the mechanical operations in drilling and well pumping. In the 1920s petroleum engineers sought means to improve drilling practices and to improve well design by use of proper tubing sizes, chokes, and packers. They designed new forms of artificial lift, primarily rod pumping and gas lift, and studied the ways in which methods of production affected gas–oil ratios and rates of production. The technology of drilling fluids was advanced, and directional drilling became a common practice.

The economic crisis that resulted from abundant discoveries in about 1930, notably in the giant East Texas Field, caused petroleum engineering to focus on the entire oil–water–gas reservoir system rather than on the individual well. Studying the optimum spacing of wells in an entire field led to the concept of reservoir engineering. During this period the mechanics of drilling and production were not neglected. Drilling penetration rates increased approximately 100 percent from 1932 to 1937.

Petrophysics (determination of fluid and rock characteristics) was introduced late in the 1930s. By 1940 electric logging had developed to the state that estimates could be made of oil and water saturations in the reservoir rocks.

After World War II, petroleum engineers continued to refine the techniques of reservoir analysis and petrophysics. The outstanding event of the 1950s was development of the offshore oil industry and a whole new technology. At first little was known of such matters as wave heights and wave forces. The oceanographer and marine engineer thus joined with the petroleum engineer to initiate design standards. Shallow-water drilling barges evolved into mobile platforms, then into jack-up barges, and finally into semi-submersible and floating drilling ships.

Specialization

Branches of petroleum engineering. During the evolution of petroleum engineering, the areas of specialization developed: drilling engineering, production engineering, reservoir engineering, and petrophysical engineering. In each specialization engineers from other disciplines (mechanical, civil, electrical, geological, chemical) freely entered, and their contributions were significant; however, it remained the unique role of the petroleum engineer to integrate all the specializations into an efficient system of oil and gas drilling, production, and processing.

Drilling engineering was among the first applications of technology to oil-field practices. The drilling engineer is responsible for the design of the earth-penetration techniques, the selection of casing and safety equipment, and, often, the direction of the operations. These functions involve understanding the nature of the rocks to be penetrated, the stresses in these rocks, and the techniques available to drill into and control the underground reservoirs. Because modern drilling involves organizing a vast array of machinery and materials, investing huge funds, and acknowledging the safety and welfare of the general public, the engineer must develop the skills of supervision, management, and negotiation.

The production engineer's work begins upon completion of the well—directing the selection of producing intervals and making arrangements for various accessories, controls, and equipment. Later his work involves controlling and measuring the produced fluids (oil, gas, and water), designing and installing gathering and storage systems, and delivering the raw products (gas and oil) to pipeline companies and other transportation agents. He is also involved in such matters as corrosion prevention, well performance, and formation treatments to stimulate production. As in all branches of petroleum engineering, the production engineer cannot view the in-hole or surface processing problems in isolation but must fit solutions into the complete reservoir, well, and surface system.

Reservoir engineers are concerned with the physics of oil and gas distribution and their flow through porous rocks—the various hydrodynamic, thermodynamic, gravitational, and other forces involved in the rock–fluid system. They are responsible for analyzing the rock–fluid system, establishing efficient well-drainage patterns, forecasting the

performance of the oil or gas reservoir, and introducing methods for maximum efficient production.

To understand the reservoir rock–fluid system, the drilling, production, and reservoir engineers draw assistance from the petrophysical, or formation-evaluation, engineer, who provides tools and analytical techniques for determining rock and fluid characteristics. The petrophysical engineer measures the acoustic, radioactive, and electrical properties of the rock–fluid system and takes samples of the rocks and well fluids to determine porosity, permeability, and fluid content in the reservoir.

(B.D.H./Ed.)

AEROSPACE ENGINEERING

Aerospace engineering is the study of the design, development, and operation of vehicles operating in the Earth's atmosphere or in outer space. In 1958 the first definition of aerospace engineering appeared, considering the Earth's atmosphere and the space above it as a single realm for development of flight vehicles. Today the more encompassing aerospace definition has commonly replaced the terms aeronautical engineering and astronautical engineering.

The design of a flight vehicle demands a knowledge of many engineering disciplines. It is rare that one person takes on the entire task; instead, most companies have design teams specialized in the sciences of aerodynamics, propulsion systems, structural design, materials, avionics, and stability and control systems. No single design can optimize all of these sciences, but rather there exist compromised designs that incorporate the vehicle specifications, available technology, and economic feasibility.

History. *Aeronautical engineering.* The roots of aeronautical engineering can be traced to the early days of mechanical engineering, to inventors' concepts, and to the initial studies of aerodynamics, a branch of theoretical physics. The earliest sketches of flight vehicles were drawn by Leonardo da Vinci, who suggested two ideas for sustentation. The first was an ornithopter, a flying machine using flapping wings to imitate the flight of birds. The second idea was an aerial screw, the predecessor of the helicopter. Manned flight was first achieved in 1783, in a hot-air balloon designed by the French brothers Joseph-Michel and Jacques-Étienne Montgolfier. Aerodynamics became a factor in balloon flight when a propulsion system was considered for forward movement. Benjamin Franklin was one of the first to propose such an idea, which led to the development of the dirigible. The power-driven balloon was invented by Henri Gifford, a Frenchman, in 1852. The invention of lighter-than-air vehicles occurred independently of the development of aircraft. The breakthrough in aircraft development came in 1799 when Sir George Cayley, an English baron, drew an airplane incorporating a fixed wing for lift, an empennage (consisting of horizontal and vertical tail surfaces for stability and control), and a separate propulsion system. Because engine development was virtually nonexistent, Cayley turned to gliders, building the first successful one in 1849. Gliding flights established a data base for aerodynamics and aircraft design. Otto Lilienthal, a German scientist, recorded more than 2,000 glides in a five-year period, beginning in 1891. Lilienthal's work was followed by the American aeronaut Octave Chanute, a friend of the American brothers Orville and Wilbur Wright, the fathers of modern manned flight.

The first manned flight

Following the first sustained flight of a heavier-than-air vehicle in 1903, the Wright brothers refined their design, eventually selling airplanes to the U.S. Army. The first major impetus to aircraft development occurred during World War I, when aircraft were designed and constructed for specific military missions, including fighter attack, bombing, and reconnaissance. The end of the war marked the decline of military high-technology aircraft and the rise of civil air transportation. Many advances in the civil sector were due to technologies gained in developing military and racing aircraft. A successful military design that found many civil applications was the U.S. Navy Curtiss NC-4 flying boat, powered by four 400-horsepower V-12 Liberty engines. It was the British, however, who paved the way in civil aviation in 1920 with a 12-passenger Handley-Page transport. Aviation boomed after Charles A. Lindbergh's solo flight across the Atlantic Ocean in 1927. Advances in metallurgy led to improved strength-to-weight ratios and, coupled with a monocoque design, enabled aircraft to fly farther and faster. Hugo Junkers, a German, built the first all-metal monoplane in 1910, but the design was not accepted until 1933, when the Boeing 247-D entered service. The twin-engine design of the latter established the foundation of modern air transport.

The advent of the turbine-powered airplane dramatically changed the air transportation industry. Germany and Britain were concurrently developing the jet engine, but it was a German Heinkel He 178 that made the first jet flight on Aug. 27, 1939. Even though World War II accelerated the growth of the airplane, the jet aircraft was not introduced into service until 1944, when the British Gloster Meteor became operational, shortly followed by the German Me 262. The first practical American jet was the Lockheed F-80, which entered service in 1945.

Commercial aircraft after World War II continued to use the more economical propeller method of propulsion. The efficiency of the jet engine was increased, and in 1949 the British de Havilland Comet inaugurated commercial jet transport flight. The Comet, however, experienced structural failures that curtailed the service, and it was not until 1958 that the highly successful Boeing 707 jet transport began nonstop transatlantic flights. While civil aircraft designs utilize most new technological advancements, the transport and general aviation configurations have changed only slightly since 1960. Because of escalating fuel and hardware prices, the development of civil aircraft has been dominated by the need for economical operation.

Technological improvements in propulsion, materials, avionics, and stability and controls have enabled aircraft to grow in size, carrying more cargo faster and over longer distances. While aircraft are becoming safer and more efficient, they are also now very complex. Today's commercial aircraft are among the most sophisticated engineering achievements of the day.

Growing complexity of aircraft

Smaller, more fuel-efficient airliners are being developed. The use of turbine engines in light general aviation and commuter aircraft is being explored, along with more efficient propulsion systems, such as the propfan concept. Using satellite communication signals, onboard microcomputers can provide more accurate vehicle navigation and collision-avoidance systems. Digital electronics coupled with servo mechanisms can increase efficiency by providing active stability augmentation of control systems. New composite materials providing greater weight reduction; inexpensive one-man, lightweight, noncertified aircraft, referred to as ultralights; and alternate fuels such as ethanol, methanol, synthetic fuel from shale deposits and coal, and liquid hydrogen are all being explored. Aircraft designed for vertical and short takeoff and landing, which can land on runways one-tenth the normal length, are being developed. Hybrid vehicles such as the Bell XV-15 tilt-rotor already combine the vertical and hover capabilities of the helicopter with the speed and efficiency of the airplane. Although environmental restrictions and high operating costs have limited the success of the supersonic civil transport, the appeal of reduced traveling time justifies the examination of a second generation of supersonic aircraft.

Aerospace engineering. The use of rocket engines for aircraft propulsion opened a new realm of flight to the aeronautical engineer. Robert H. Goddard, an American, developed, built, and flew the first successful liquid-propellant rocket on March 16, 1926. Goddard proved that flight was possible at speeds greater than the speed of sound and that rockets can work in a vacuum. The major impetus in rocket development came in 1938 when the American James Hart Wyld designed, built, and tested the first U.S. regeneratively cooled liquid rocket engine. In 1947 Wyld's rocket engine powered the first supersonic research aircraft, the Bell X-1, flown by the U.S. Air Force captain Charles E. Yeager. Supersonic flight offered the aeronautical engineer new challenges in propulsion, structures and materials, high-speed aeroelasticity, and transonic, supersonic, and hypersonic aerodynamics. The

experience gained in the X-1 tests led to the development of the X-15 research rocket plane, which flew more than 700 flights over a 22-year period. The X-15 established an extensive data base in transonic and supersonic flight (up to five times the speed of sound) and revealed vital information concerning the upper atmosphere.

The space exploration race

The late 1950s and '60s marked a period of intense growth for astronautical engineering. In 1957 the U.S.S.R. orbited Sputnik I, the world's first artificial satellite, which triggered a space exploration race with the United States. In 1961 the U.S. president John F. Kennedy recommended to Congress to undertake the challenge of "landing a man on the moon and returning him safely to the earth" by the end of the 1960s. This commitment was fulfilled on July 20, 1969, when astronauts Neil A. Armstrong and Edwin E. Aldrin, Jr., landed on the Moon.

The 1970s began the decline of the U.S. manned spaceflights. The exploration of the Moon was replaced by unmanned voyages to Jupiter, Saturn, and other planets. Eventually the exploitation of space was redirected from conquering distant planets to providing a better understanding of the human environment. Artificial satellites provide statistical data pertaining to geographic formations, oceanic and atmospheric movements, radiation mapping, and worldwide communications. The frequency of U.S. spaceflights in the 1960s and '70s led to the development of a reusable, low-orbital-altitude space shuttle. With several successful flights in the 1980s, the shuttle inaugurated a new age of commercially viable space vehicles.

Aerospace engineering functions. In most countries, governments are the aerospace industry's largest customers, and most engineers work on the design of military vehicles. The largest demand for aerospace engineers comes from the transport and fighter aircraft, missile, spacecraft, and general aviation industries. The typical aerospace engineer holds a bachelor's degree, but there are many engineers holding master's or doctorate degrees (or their equivalents) in various disciplines associated with aerospace-vehicle design, development, and testing.

The U.S. National Aeronautics and Space Administration (NASA) and the European Space Agency (ESA) are governmental organizations that employ many engineers for research, development, testing, and procurement of military vehicles. Government agencies award and monitor industrial contracts ranging from engineering problem studies to design and fabrication of hardware. Universities receive limited funding, primarily for analytical research. Some of the larger institutions, however, are developing or expanding flight-research facilities and increasing faculty members in an effort to increase productivity in both research and testing.

The design of a flight vehicle is a complex and time-consuming procedure requiring the integration of many engineering technologies. Supporting teams are formed to provide expertise in these technologies, resulting in a completed design that is the best compromise of all the engineering disciplines. Usually the support teams are supervised by a project engineer or chief designer for technical guidance and by a program manager responsible for program budgets and schedules. Because of the ever-increasing requirement for advanced technology and the high cost and high risk associated with complex flight vehicles, many research and development programs are canceled before completion.

The phases of the design process

The design process can be dissected into five phases and is the same for most aerospace products. Phase one is a marketing analysis to determine customer specifications or requirements. Aerospace engineers are employed to examine technical, operational, or financial problems. The customer's requirements are established and then passed on to the conceptual design team for the second phase.

The conceptual design team generally consists of aerospace engineers, who make the first sketch attempt to determine the vehicle's size and configuration. Preliminary estimates of the vehicle's performance, weight, and propulsion systems are made. Performance parameters include range, speed, drag, power required, payload, and takeoff and landing distances. Parametric trade studies are conducted to optimize the design, but configuration details usually change. This phase may take from a few months to years for major projects.

Phase three is the preliminary design phase. The optimized vehicle design from phase two is used as the starting point. Aerospace engineers perform computer analyses on the configuration; then wind-tunnel models are built and tested. Flight control engineers study dynamic stability and control problems. Propulsion groups supply data necessary for engine selection. Interactions between the engine inlet and vehicle frame are studied. Civil, mechanical, and aerospace engineers analyze the bending loads, stresses, and deflections on the wing, airframe, and other components. Material science engineers aid in selecting low-weight, high-strength materials and may conduct aeroelastic and fatigue tests. Weight engineers make detailed estimates of individual component weights. As certain parameters drive the vehicle design, the preliminary designers are often in close contact with both the conceptual designers and the marketing analysts. The time involved in the preliminary design phase depends on the complexity of the problem but usually takes from six to 24 months.

Phase four, the detailed design phase, involves construction of a prototype. Mechanical engineers, technicians, and draftsmen help lay out the drawings necessary to construct each component. Full-scale mock-ups are built of cardboard, wood, or other inexpensive materials to aid in the subsystem layout. Subsystem components are built and bench-tested, and additional wind-tunnel testing is performed. This phase takes from one to three years.

The final phase concerns flight-testing the prototype. Engineers and test pilots work together to assure that the vehicle is safe and performs as expected. If the prototype is a commercial transport aircraft, the vehicle must meet the requirements specified by government organizations such as the Federal Aviation Administration in the United States and the Civil Aviation Authority in the United Kingdom. Prototype testing is usually completed in one year but can take much longer because of unforeseen contingencies. The time required from the perception of a customer's needs to delivery of the product can be as long as 10 to 15 years depending on the complexity of the design, the political climate, and the availability of funding.

High-speed computers have now enabled complex aerospace engineering problems to be analyzed rapidly. More extensive computer programs, many written by aerospace engineers, are being formulated to aid the engineer in designing new configurations.

Branches of aerospace engineering. The aerospace engineer is armed with an extensive background suitable for employment in most positions traditionally occupied by mechanical engineers as well as limited positions in the other various engineering disciplines. The transportation, construction, communication, and energy industries provide the most opportunities for non-aerospace applications.

Non-aerospace applications

Because land and sea vehicles are designed for optimum speed and efficiency, the aerospace engineer has become a prominent member of the design teams. Because up to half of the power required to propel a vehicle is due to the resistance of the air, the configuration design of low-drag automobiles, trains, and boats offers better speed and fuel economy. The presence of the aerospace engineer in the automobile industry is evident from the streamlined shapes of cars and trucks that evolved during the late 20th century, at a time when gasoline prices were escalating and the aerospace industry was in a lull. Airline companies employ engineers as performance analysts, crash investigators, and consultants. The Federal Aviation Administration and other governmental organizations use the technical expertise of the aerospace engineer in various capacities.

The construction of large towers, buildings, and bridges requires predictions of aerodynamic forces and the creation of an optimum design to minimize these forces. The consideration of aerodynamic forces of flat surfaces such as the side of a building or superstructure is not new. In 1910 Alexandre-Gustave Eiffel achieved remarkable experimental results measuring the wind resistance of a flat plate, using the Eiffel Tower as a test platform.

Many companies benefit not from the advanced hard-

ware developments of aerospace technology but by the understanding and application of aerospace methodology. Companies engaged in satellite communications require an understanding of orbital mechanics, trajectories, acceleration forces, and aerodynamic heating and an overall knowledge of the spacecraft industry. Advanced aerodynamic design of airfoils and rotor systems is applied in an effort to improve the efficiency of propellers, windmills, and turbine engines. The impact of aerospace technology has trickled down to many companies engaged in the research and development of flight simulation, automatic controls, materials, dynamics, robotics, medicine, and other high-technology fields. (K.A.St./Ed.)

BIOENGINEERING

Bioengineering is the application of engineering knowledge to the fields of medicine and biology. The bioengineer must be well grounded in biology and have engineering knowledge that is broad, drawing upon electrical, chemical, mechanical, and other engineering disciplines. The bioengineer may work in any of a large range of areas. One of these is the provision of artificial means to assist defective body functions—such as hearing aids, artificial limbs, and supportive or substitute organs. In another direction, the bioengineer may use engineering methods to achieve biosynthesis of animal or plant products—such as for fermentation processes.

History. Before World War II the field of bioengineering was essentially unknown, and little communication or interaction existed between the engineer and the life scientist. A few exceptions, however, should be noted. The agricultural engineer and the chemical engineer, involved in fermentation processes, have always been bioengineers in the broadest sense of the definition since they deal with biological systems and work with biologists. The civil engineer, specializing in sanitation, has applied biological principles in the work. Mechanical engineers have worked with the medical profession for many years in the development of artificial limbs. Another area of mechanical engineering that falls in the field of bioengineering is the air-conditioning field. In the early 1920s engineers and physiologists were employed by the American Society of Heating and Ventilating Engineers to study the effects of temperature and humidity on humans and to provide design criteria for heating and air-conditioning systems.

Today there are many more examples of interaction between biology and engineering, particularly in the medical and life-support fields. In addition to an increased awareness of the need for communication between the engineer and the associate in the life sciences, there is an increasing recognition of the role the engineer can play in several of the biological fields, including human medicine, and, likewise, an awareness of the contributions biological science can make toward the solution of engineering problems.

Much of the increase in bioengineering activity can be credited to electrical engineers. In the 1950s bioengineering meetings were dominated by sessions devoted to medical electronics. Medical instrumentation and medical electronics continue to be major areas of interest, but biological modeling, blood-flow dynamics, prosthetics, biomechanics (dynamics of body motion and strength of materials), biological heat transfer, biomaterials, and other areas are now included in conference programs.

The merging of medical and engineering needs

Bioengineering developed out of specific desires or needs: the desire of surgeons to bypass the heart, the need for replacement organs, the requirement for life support in space, and many more. In most cases the early interaction and education were a result of personal contacts between physician, or physiologist, and engineer. Communication between the engineer and the life scientist was immediately recognized as a problem. Most engineers who wandered into the field in its early days probably had an exposure to biology through a high-school course and no further work. To overcome this problem, engineers began to study not only the subject matter but also the methods and techniques of their counterparts in medicine, physiology, psychology, and biology. Much of the information was self-taught or obtained through personal association and discussions. Finally, recognizing a need to assist in overcoming the communication barrier as well as to prepare engineers for the future, engineering schools developed courses and curricula in bioengineering.

Branches of bioengineering. *Medical engineering.* Medical engineering concerns the application of engineering principles to medical problems, including the replacement of damaged organs, instrumentation, and the systems of health care, including diagnostic applications of computers.

Agricultural engineering. This includes the application of engineering principles to the problems of biological production and to the external operations and environment that influence this production.

Bionics. Bionics is the study of living systems so that the knowledge gained can be applied to the design of physical systems.

Biochemical engineering. Biochemical engineering includes fermentation engineering, application of engineering principles to microscopic biological systems that are used to create new products by synthesis, including the production of protein from suitable raw materials.

Human-factors engineering. This concerns the application of engineering, physiology, and psychology to the optimization of the human–machine relationship.

Environmental health engineering. Also called bioenvironmental engineering, this field concerns the application of engineering principles to the control of the environment for the health, comfort, and safety of human beings. It includes the field of life-support systems for the exploration of outer space and the ocean. (Ed.)

NUCLEAR ENGINEERING

Nuclear engineering is concerned with the control and use of energy and radiation released from nuclear reactions. It encompasses the development, design, and construction of power reactors, naval-propulsion reactors, nuclear fuel-cycle facilities, and radioactive-waste disposal facilities; the development and production of nuclear weapons; and the production and application of radioisotopes.

History. Nuclear engineering began with the first major demonstrations of the utilization of nuclear energy: the development of nuclear weapons and nuclear reactors.

The Manhattan Project

The World War II Manhattan Project, under which the U.S. government built, in a relatively short period, such facilities as production reactors, chemical-reprocessing plants, test and research reactors, and weapons production facilities, stands out as a monumental engineering feat. Engineers in early programs had to learn about a host of nuclear-related subjects, ranging from reactor theory and reactor control to radioactivity and the behaviour of material under irradiation. They were educated on the job by nuclear scientists and physicists, first through personal discussions and later through seminars and classes. Many of those who entered the field had been educated in other engineering disciplines—mechanical, electrical, chemical, and so on. Nuclear engineering continues today to be a strongly interdisciplinary activity.

Early schools. In the late 1940s, as the many potential peaceful uses of nuclear energy became evident, two schools of reactor technology were established, one in Tennessee at Oak Ridge National Laboratory and another in Illinois at Argonne National Laboratory.

In 1946 Clinch College was established at Oak Ridge. In its first year 35 American participants from universities, industry, the U.S. Navy, and government agencies took courses in nuclear technology. They attended lectures, conducted laboratory experiments, and gained hands-on experience in operating nuclear reactors.

In 1950 Clinch College was succeeded by the Oak Ridge School of Reactor Technology (ORSORT). The participants were again selected from academic, government, and industry sectors. In addition to lectures and laboratory work, the students were assigned to teams working on the development of new concepts. Several concepts developed by these teams later grew into major research and development programs, including the high-flux isotope reactor, the molten-salt reactor, and several nuclear propulsion schemes. ORSORT was disbanded in 1965 because nuclear engineering programs had by that time become widely available at universities and colleges.

The International School of Nuclear Science and Engineering was established at Argonne National Laboratory in 1955. The school was created to meet the international need for trained scientists and engineers, and its program was conducted jointly by Argonne National Laboratory, North Carolina State College, and Pennsylvania State University. Basic course work was presented at the universities in a 17-week program combining lecture with laboratory experience. More advanced work, including lectures and participation in design and laboratory projects, was given in a second 17-week program at the International School at Argonne. In 1960 the basic course work was discontinued, and the program was redirected to serve more advanced and experienced students from abroad. In recognition of the worldwide growth of programs and facilities to provide basic nuclear training at universities and laboratories, the program at Argonne was discontinued in 1964.

University programs. In 1950 the first full-fledged nuclear engineering curriculum offered for college credit was established at North Carolina State College. By 1952 several schools had graduate programs in nuclear engineering. Most of these programs consisted of two or three courses, providing a background on reactor physics, reactor control, heat transfer, radiation effects, and shielding.

With the support of the U.S. Atomic Energy Commission's Division of Nuclear Education and Training, the curricula and the number of schools in the United States continued to increase. By 1965, 61 schools were offering nuclear engineering programs. The programs had grown in diverse directions, however, and it became apparent that it was desirable to develop a consensus among educators about nuclear engineering education. To meet this need, a joint committee of the American Nuclear Society and the American Society of Engineering Education developed basic educational criteria. The committee members came from industry, national laboratories, and universities with nuclear engineering programs. The committee's "Report on Objective Criteria in Nuclear Engineering Education" had a major influence in shaping nuclear engineering curricula around the world and did much to establish nuclear engineering as a distinct discipline.

Education criteria established

Nuclear engineering functions. *Research and development.* Research and development entails the conception and development of new materials, processes, components, and systems for nuclear facilities and the development of analytical methods and experimental procedures for use in the development, analysis, design, and control of fission and fusion systems.

Design. Another area of emphasis is the engineering design of such items as fuel elements, reactor-core supports, reflectors, thermal shields, biological shields, instrumentation and control systems, and safety systems.

Fuel management. Fuel management involves specifying, procuring, and managing fuel throughout its reactor lifetime and beyond.

Safety analysis. Normal and anticipated abnormal operating conditions must be considered in the analysis of the safety of a reactor or other facility using radioactive material. Hypothetical reactor accidents are analyzed to assess possible consequences and to devise means to prevent or mitigate these consequences.

Operation and test. This function of nuclear engineering is concerned with the supervision and operation of nuclear power reactors and ancillary nuclear facilities.

Affected industries

Nuclear engineers perform these functions for various kinds of employers: (1) architectural engineering firms, in which they handle design, safety analysis, project coordination, construction supervision, quality assurance, quality control, and related matters, (2) reactor vendors and other manufacturing organizations, in which they pursue research, development, design, manufacture, and installation of various components of nuclear systems, (3) electric utility companies, in which they handle planning, construction supervision, reactor-safety analysis, in-core nuclear fuel management, power-reactor economic analysis, environmental-impact assessment, personnel training, plant management, operation-shift supervision, radiation protection, spent-fuel storage, and radioactive-waste management, (4) regulatory agencies, in which they undertake licensing, rule making, safety research, risk analysis, on-site inspection, and research administration, (5) defense programs, in which they are employed in naval and nuclear weapons programs, (6) universities, in which they hold various faculty positions, and (7) national laboratories and industrial research laboratories, in which they carry out advanced research and development on a variety of nuclear programs in nuclear energy areas. Most of the advanced research and development on nuclear-related programs is conducted at national laboratories.

Branches of nuclear engineering. *Nuclear power.* The greatest growth in the nuclear industry has been in the development of nuclear power plants. It is estimated that by the year 2000 one-third of all electric power generated worldwide will come from nuclear power plants.

Nearly all commercial nuclear reactors in operation or under construction are thermal reactors. They are called thermal reactors because their fuel is fissioned by neutrons that have been slowed down by a moderator until they are in thermal equilibrium with the moderator. The boiling water reactor (BWR) and the pressurized water reactor (PWR) are the two predominant types of power reactors in use throughout the world. Both types are called light-water reactors (LWR). The water is used in these reactors as both moderator and coolant. In the BWR, steam is generated by direct boiling of water in the reactor core. In the PWR, steam is produced in an external steam generator rather than in the core, where the coolant under pressure is not allowed to boil. Other types of power reactors include graphite-moderated gas-cooled reactors in use in Great Britain and pressurized heavy-water reactors in Canada.

A major advance in nuclear power is expected with the further development of the liquid-metal fast-breeder reactor (LMFBR). Programs are in progress in several countries to develop and deploy the LMFBR. (The reactor is cooled by a liquid metal, sodium, and fission is caused by fast neutrons. The reactor is called a breeder because it produces more nuclear fuel than it consumes.) Fuel in the breeder is utilized 60 times more effectively than that in light-water reactors. It is estimated that without the breeder the world supply of fissionable material for nuclear power plants could be consumed in a few decades. With the improved fuel utilization provided by the breeder, nuclear power plants would be able to supply the world's electric energy requirement for centuries.

Fusion. Fusion is a potential energy resource with a wide range of applications. The fusion process of combining two light atoms to form a heavier atom, with less mass than the two original atoms, is the basic energy process in the universe (*i.e.,* fusion is the process that takes place in all stars). If fusion can be harnessed for terrestrial applications, the energy can be released in a variety of forms, including charged particles, electromagnetic radiation, and neutrons. Possible applications include electricity production, synthetic fuel production, process-heat applications, and fissile fuel production for fission reactors.

Plasma physics

Fusion research since about 1950 has concentrated on the issues of plasma physics, specifically the production of high-temperature plasmas (100,000,000° C [180,000,000° F] or greater) that can be confined at sufficiently high densities for sufficiently long times to produce net energy. Energy break-even conditions are expected to be demonstrated in several fusion devices in the late 20th century. Fusion physics research has made steady progress, and research efforts have begun to address the important engineering issues of fusion. Among the more important of these issues are those related to extracting useful energy from a plasma and developing complete fuel systems for fusion reactors. These areas are expected to receive increased research and development support in the future.

Naval nuclear propulsion. The use of nuclear reactors to propel naval vessels has revolutionized naval operations throughout the world. The navies of Great Britain, France, the U.S.S.R., China, and the United States are equipped with nuclear-powered ships, which are considered to be of the highest importance to the defense of their countries. Nuclear warships are capable of nearly unlimited high-speed operation without the need of fuel-oil support. In the 25 years following the maiden voyage of the *Nautilus* in

1954, the nuclear navy of the United States steamed more than 80,000,000 kilometres (50,000,000 miles) throughout the oceans of the world, accumulating 25 centuries of reactor-plant operation without any accidents involving a nuclear reactor. By the mid-1980s, more than 40 percent of U.S. combat warships were nuclear-powered.

Nuclear weapons. Fission weapons (atomic bombs), fusion weapons (hydrogen bombs), and combination fission-fusion weapons are part of the world's nuclear arsenal. Nuclear engineers are employed on weapons programs in such diverse activities as research, development, design, fabrication, production, testing, maintenance, and surveillance of a large array of nuclear weapons systems.

Efforts are in progress in the United States to develop, upgrade, and integrate weapons into warhead programs and to explore advanced concepts for future weapons systems. A concept of particular interest is inertial-confinement fusion. This program is directed at determining the feasibility of burning very small pellets of thermonuclear fuel using laser or particle-beam drivers. The program is of interest not only for applications to weapons physics but also for possible energy applications.

Radioisotopes. More than 500 radioisotopes are produced in nuclear reactors. The production, packaging, and application of these isotopes has become a large industry. They are used in heart pacemakers, medical research, sterilization of medical instruments, industrial tracers, X-ray equipment, curing of plastics, preservation of food, and as an energy source in electric generators. Perhaps the most important use of radioisotopes is in the field of medicine. They are used in procedures for half of all patients admitted to hospitals in the United States.

Nuclear-waste management. Nuclear wastes can be classified in two groups, low-level and high-level. Low-level wastes come from nuclear power facilities, hospitals, and research institutions and include such items as contaminated clothing, wiping rags, tools, test tubes, needles, and other medical research materials. In the disposal of low-level wastes, the wastes are reduced in volume, then packaged in leak-proof containers, which are placed in an earth-covered trench in a low-level-waste disposal site. Such sites should be continuously monitored to detect any migration of radioactive material. High-level wastes are highly radioactive and derive from the chemical reprocessing of spent fuel elements and from the weapons program.

By the late 20th century many countries were evaluating potential nuclear-waste disposal sites and developing terminal waste-storage technology. All these countries were preparing to handle high-level wastes. All had identified geologic formations that appeared to be technically feasible for repositories. In 1982 the U.S. Congress passed legislation establishing schedules for the selection, development, licensing, and construction of repositories for the safe, permanent storage of high-level waste. (I.Bo./Ed.)

BIBLIOGRAPHY. Works on the history of the engineering profession include A.P.M. FLEMING and H.J.S. BROCKLEHURST, *A History of Engineering* (1925); R.S. KIRBY *et al., Engineering in History* (1956); and J.K. FINCH, *The Story of Engineering* (1960). Contemporary descriptions may be found in R.J. SMITH, *Engineering as a Career,* 3rd ed. (1969); and T.J. HOOVER and J.C.L. FISH, *The Engineering Profession,* 2nd ed. (1950).

HAWKINS, *Applied Petroleum Reservoir Engineering* (1959); EDWARD J. LYNCH, *Formation Evaluation* (1962), on oil-well logging; T.E.W. NIND, *Principles of Oil Well Production* (1964); SYLVAIN J. PIRSON, *Geologic Well Log Analysis* (1983); and LESTER C. UREN, *Petroleum Production Engineering,* 3 vol. (1950–56), on petroleum production economics, oil-field exploitation, and oil-field development. See also ARTHUR W. MCCRAY and FRANK W. COLE, *Oil Well Drilling Technology* (1959); and NATIONAL PETROLEUM COUNCIL, *Impact of New Technology on the U.S. Petroleum Industry: 1946–1965* (1967). *Oil and Gas Journal,* vol. 57, no. 5 (Jan. 28, 1959), is a special issue surveying the first 100 years of the petroleum industry; see also vol. 75, no. 35 (August 1977).

Aerospace engineering: See *Engineering and Technology Enrollments* and *Engineering and Technology Degrees,* two annual publications that supply information on engineering schools and technical education in the United States, both of which are issued by the Engineering Manpower Commission of the American Association of Engineering Societies. FRANK W. ANDERSON, *Orders of Magnitude,* 2nd ed. (1981), a book in the NASA history series, covers the period from 1915 to 1980; JOHN D. ANDERSON, *Introduction to Flight: Its Engineering and History* (1978), deals with theoretical questions of aerodynamics and describes the design and construction of airplanes; and CHARLES H. GIBBS-SMITH, *Flight Through the Ages* (1974), is a survey of aeronautics from its early period to the age of space exploration. TOM D. CROUCH, *A Dream of Wings* (1981), traces the history of aeronautics in the United States; JEROME LEDERER, "Highlights in the Development of Civilian Aircraft," *Automotive Engineering* 88(12):33–43 (December 1980), is a review that dwells on the prominent technical concepts and development of civil air transportation; BARNES W. MCCORMICK, *Aerodynamics, Aeronautics, and Flight Mechanics* (1979), is an illustrated monograph; LELAND M. NICOLAI, *Fundamentals of Aircraft Design* (1975), is an illustrated source, with bibliographies; and RICHARD S. SHEVELL, *Fundamentals of Flight* (1983), is a monograph, with bibliography.

Nuclear engineering: HENRY DEWOLF SMYTH, *Atomic Energy for Military Purposes: The Official Report on the Development of the Atomic Bomb Under the Auspices of the United States Government, 1940–1945* (1945, reprinted 1978), commonly known as the Smyth report, issued by the Manhattan District of the U.S. Corps of Engineers; SAMUEL GLASSTONE and MILTON C. EDLUND, *The Elements of Nuclear Reactor Theory* (1952), a discussion of general principles of reactor technology; HAROLD ETHERINGTON, *Nuclear Engineering Handbook* (1958), a standard reference work that covers all phases of nuclear engineering; SAMUEL GLASSTONE and RALPH H. LOVBERG, *Controlled Thermonuclear Reactions* (1960, reprinted 1975), an introduction to nuclear fusion; SAMUEL GLASSTONE and ALEXANDER SESONSKE, *Nuclear Reactor Engineering,* 3rd ed. (1981), a basic work for nuclear engineering education; GLENN THEODORE SEABORG and WILLIAM R. CORLISS, *Man and Atom* (1971), a work that explores peaceful applications of nuclear energy; RICHARD G. HEWLETT and FRANCIS DUNCAN, *Nuclear Navy, 1946–1962* (1974), a historical and analytical study; RAYMOND LEROY MURRAY, *Nuclear Energy,* 2nd ed. (1980), an introduction to basic nuclear processes; and MANSON BENEDICT, THOMAS H. PIGFORD, and HANS WOLFGANG LEVI, *Nuclear Chemical Engineering,* 2nd ed. (1981), a comprehensive work that emphasizes nuclear processing and includes useful information on metallurgy.

English Literature

Although for the purposes of this article English literature is treated as being confined to writings in English by natives or inhabitants of the British Isles (including Ireland), it is to a certain extent the case that literature—and this is particularly true of the literature written in English—knows no frontiers. Thus, English literature can be regarded as a cultural whole of which the mainstream literatures of the United States, Australia, New Zealand, and Canada and important elements in the literatures of other Commonwealth or ex-Commonwealth countries are parts (see AMERICAN LITERATURE; AUSTRALIA AND NEW ZEALAND, LITERATURES OF; and CANADIAN LITERATURE).

English literature has sometimes been stigmatized as insular. It can be argued that no single English novel attains the universality of the Russian writer Leo Tolstoy's *War and Peace* or the French writer Gustave Flaubert's *Madame Bovary*. Yet in the Middle Ages the Old English literature of the subjugated Saxons was leavened by the Latin and Anglo-Norman French writings, eminently foreign in origin, in which the churchmen and the Norman conquerors expressed themselves. From this combination emerged a flexible and subtle linguistic instrument exploited by Geoffrey Chaucer and brought to supreme application by William Shakespeare. During the Renaissance the renewed interest in classical learning and values had an important effect on English literature, as on all of the arts; and ideas of Augustan literary propriety in the 18th century and reverence in the 19th century for a less specific, though still selectively viewed, classical antiquity continued to shape the literature. All three of these impulses derived from a foreign source, namely the Mediterranean basin. The Decadents of the late 19th century and modernists of the early 20th looked to continental European individuals and movements for inspiration. Nor was attraction toward European intellectualism dead in the late 20th century, for by the mid-1980s the approach known as structuralism, a phenomenon predominantly French and German in origin, infused the very study of English literature itself in a host of published critical studies and university departments.

Further, Britain's past imperial glories around the globe, particularly those that were connected with the Indian subcontinent, continued to inspire literature—in some cases wistful, in other cases hostile. Finally, English literature has enjoyed a certain diffusion abroad, not only in predominantly English-speaking countries but also in all those others where English is the first choice of study as a second language.

English literature is therefore not so much insular as detached from the continental European tradition across the Channel. It is strong in all the conventional categories of the bookseller's list: in Shakespeare it has a dramatist of world renown; in poetry, a genre notoriously resistant to adequate translation and therefore difficult to compare with the poetry of other literatures, it is so peculiarly rich as to merit inclusion in the front rank; English literature's humour has been found as hard to convey to foreigners as poetry, if not more so—a fact at any rate permitting bestowal of the label "idiosyncratic"; English literature's remarkable body of travel writings constitutes another counterthrust to the charge of insularity; in autobiography, biography, and historical writing English literature compares with the best of any culture; and children's literature, fantasy, essays, and journals, which tend to be considered minor genres, are all fields of exceptional achievement as regards English literature. Even in philosophical writings, popularly thought of as hard to combine with literary value, thinkers such as Thomas Hobbes, John Locke, David Hume, John Stuart Mill, and Bertrand Russell stand comparison for lucidity and grace with the best of the French philosophers and the masters of classical antiquity.

Some of English literature's most distinguished practitioners in the 20th century—from Henry James and Joseph Conrad at its beginning to V.S. Naipaul and Tom Stoppard more recently—were of foreign origin. What is more, none of the aforementioned had as much in common with his adoptive country as did, for instance, Doris Lessing and Peter Porter (two other distinguished writer-immigrants to Britain) by virtue both of having been born into a British family and of having been brought up on British Commonwealth soil.

On the other hand, during the same period in the 20th century, many notable practitioners of English literature left Britain to live abroad: James Joyce, D.H. Lawrence, Aldous Huxley, Christopher Isherwood, Robert Graves, Graham Greene, Muriel Spark, Anthony Burgess, and Sir Angus Wilson. In one case, that of Samuel Beckett, this process was carried to the extent of writing works first in French and then translating them into English.

Even English literature considered purely as a product of the British Isles is extraordinarily heterogeneous, however. Literature actually written in those Celtic tongues once prevalent in Cornwall, Ireland, Scotland, and Wales—called the "Celtic Fringe"—is treated separately (see CELTIC LITERATURE). Yet Irish, Scots, and Welsh writers have contributed enormously to English literature even when they have written in dialect, as the 18th-century poet Robert Burns and the 20th-century Scots writer Alasdair Gray have done. In the latter half of the 20th century interest began also to focus on writings in English or English dialect by recent settlers in Britain, such as Afro-Caribbeans and people from Africa proper, the Indian subcontinent, and East Asia.

Even within England, culturally and historically the dominant partner in the union of territories comprising Britain, literature has been as enriched by strongly provincial writers as by metropolitan ones. Another contrast more fruitful than not for English letters has been that between social milieus, however much observers of Britain in their own writings may have deplored the survival of class distinctions. As far back as medieval times a courtly tradition in literature cross-fertilized with an earthier demotic one. Shakespeare's frequent juxtaposition of royalty in one scene with plebeians in the next reflects a very British way of looking at society. This awareness of differences between high life and low, a state of affairs fertile in creative tensions, is observable throughout the history of English literature.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, Part Six, Division II, Section 621. (Ed.)

This article is divided into the following sections:

The Old English period

POETRY

The Angles, Saxons, and Jutes who invaded Britain in the 5th and 6th centuries brought with them the common Germanic metre; but of their earliest oral poetry, probably used for panegyric, magic, and short narrative, little or none survives. For nearly a century after the conversion of King Aethelberht I of Kent to Christianity in 597, there is no evidence that the English wrote poetry in their own language. But St. Bede the Venerable, in his *Historia ecclesiastica gentis Anglorum* ("Ecclesiastical History of the English People"), wrote that in the late 7th century Caedmon, an illiterate Northumbrian cowherd, was inspired in a dream to compose a short hymn in praise of the creation. Caedmon later composed verses based on Scripture, which was expounded for him by monks at Streaneshalch (Whitby), but only the "Hymn of Creation" survives. Caedmon legitimized the native verse form by adapting it to Christian themes. Others, following his example, gave England a body of vernacular poetry unparalleled in Europe before the end of the 1st millennium.

Bede's account of Caedmon

Alliterative verse. Virtually all Old English poetry is written in a single metre, a four-stress line with a syntactical break, or caesura, between the second and third stresses, and with alliteration linking the two halves of the line; this pattern is occasionally varied by six-stress lines. The poetry is formulaic, drawing on a common set of stock phrases and phrase patterns, applying standard epithets to various classes of characters, and depicting scenery with such recurring images as the eagle and wolf, which wait during battles to feast on carrion, and the ice and snow, which appear in the landscape to signal sorrow. In the best poems such formulas, far from being tedious, give a strong impression of the richness of the cultural fund from which poets could draw. Other standard devices of this poetry are the kenning, a metaphorical name for a thing, usually expressed in a compound noun (*e.g.,* "swan-road" used to name the sea); and variation, the repeating of a single idea in different words, with each repetition adding a new level of meaning. That these verse techniques changed little during 400 years of literary production suggests the extreme conservatism of Anglo-Saxon culture.

The major manuscripts. Most Old English poetry is preserved in four manuscripts of the late 10th and early 11th centuries. The Beowulf manuscript (British Library) contains *Beowulf, Judith,* and three prose tracts; the Exeter Book (Exeter cathedral) is a miscellaneous gathering of lyrics, riddles, didactic poems, and religious narratives; the Junius manuscript (Bodleian Library, Oxford) contains biblical paraphrases; and the Vercelli Book (cathedral library, Vercelli, Italy) contains saints' lives, several short religious poems, and prose homilies. In addition to the poems in these books are historical poems in the *Anglo-Saxon Chronicle;* poetic renderings of Psalms 51–150; the 31 "Metres" included in King Alfred the Great's translation of Boethius' *Consolation of Philosophy;* magical, didactic, elegiac, and heroic poems; and others, miscellaneously interspersed with prose, jotted in margins and even worked in stone or metal.

Problems of dating. Few poems can be dated as closely as Caedmon's "Hymn." King Alfred's compositions fall into the late 9th century, and Bede composed his "Death Song" within 50 days of his death on May 25, 735. His-

torical poems like "The Battle of Brunanburh" (after 937) and "The Battle of Maldon" (after 991) are fixed by the dates of the events they commemorate. A translation of one of Aldhelm's riddles is found not only in the Exeter Book but also in an early 9th-century manuscript at Leiden; it can be no later than the Leiden manuscript. And at least a part of "The Dream of the Rood" can be dated by an excerpt carved on the 8th-century Ruthwell Cross (in Dumfriesshire, Scotland). But in the absence of such indications, Old English poems are hard to date, and the scholarly consensus that most were composed in the Midlands and the North in the 8th and 9th centuries has crumbled in recent years. Many now hold that "The Wanderer," *Beowulf,* and other poems once assumed to be early are of the 9th or 10th century. For most poems, little more than that they were written between the 8th and the 11th centuries can be said with certainty.

Religious verse. If few poems can be dated accurately, still fewer can be attributed to particular poets. The most important author from whom a considerable body of work survives is Cynewulf, who wove his runic signature into the epilogues of four poems. Aside from his name, little is known of him; he probably lived in the 9th century in Mercia. His works include *The Fates of the Apostles,* a short martyrology; *The Ascension* (also called *Christ II*), a homily and biblical narrative; *Juliana,* a saint's passion set in the reign of Maximian (late 3rd century AD); and *Elene,* perhaps the best of his poems, which describes the mission of St. Helena, mother of the emperor Constantine, to recover Christ's cross. Cynewulf's work is lucid and technically elegant; his theme is the continuing evangelical mission from the time of Christ to the triumph of Christianity under Constantine. Several poems not by Cynewulf are associated with him because of their subject matter. These include two lives of St. Guthlac and *Andreas,* the story of St. Andrew among the Mermedonians, which has stylistic affinities with *Beowulf.* Also in the "Cynewulf group" are several poems with Christ as their subject, of which the most important is "The Dream of the Rood," in which the cross speaks of itself as Christ's loyal thane and yet the instrument of his death. This tragic paradox echoes a recurring theme of secular poetry and at the same time movingly expresses the religious paradoxes of Christ's triumph in death and mankind's redemption from sin.

Cynewulf's poems

The Old Testament narratives (*Genesis, Exodus,* and *Daniel*) of the Junius manuscript were once attributed to Caedmon but now are thought to be of anonymous authorship. Of these *Exodus* is remarkable for its intricate diction and bold imagery. The fragmentary *Judith* of the Beowulf manuscript stirringly embellishes the story from the apocrypha of the heroine who led the Jews to victory over the Assyrians.

Elegiac and heroic verse. The term elegy is used of Old English poems that lament the loss of worldly goods, glory, or human companionship. "The Wanderer" is narrated by a man, deprived of lord and kinsmen, whose journeys lead him to the realization that there is stability only in heaven. "The Seafarer" is similar, but its journey motif more explicitly symbolizes the speaker's spiritual yearnings. Several others have similar themes, and three elegies, "The Husband's Message," "The Wife's Lament," and "Wulf and Eadwacer," describe what appears to be a conventional situation: the separation of husband and wife by the husband's exile.

"Deor" bridges the gap between the elegy and the heroic poem, for in it a poet laments the loss of his position at court by alluding to sorrowful stories from Germanic legend. *Beowulf* itself narrates the battles of Beowulf, a prince of the Geats (a tribe in what is now southern Sweden), against the monstrous Grendel, Grendel's mother, and a fire-breathing dragon. The account contains some of the best elegiac verse in the language; and by setting marvelous tales against a historical background in which victory is always temporary and strife is always renewed, the poet gives the whole an elegiac cast. *Beowulf* also is one of the best religious poems, not only because of its explicitly Christian passages but also because Beowulf's monstrous foes are depicted as God's enemies and Beowulf himself as God's champion. Other heroic narratives are fragmentary.

Beowulf

Of "The Battle of Finnsburh" and "Waldere" only enough remains to indicate that when whole they must have been fast paced and stirring.

Of several poems dealing with English history and preserved in the *Anglo-Saxon Chronicle,* the most notable is "The Battle of Brunanburh," a panegyric on the occasion of King Athelstan's victory over a coalition of Norsemen and Scots in the year 937. But the best historical poem is not from the *Chronicle.* "The Battle of Maldon," which describes the defeat of Aldorman Byrhtnoth at the hands of Viking invaders in 991, states eloquently the heroic ideal, contrasting the determination of some of Byrhtnoth's thanes to avenge his death or die in the attempt with the cowardice of others who left the field. Minor poetic genres include catalogs (two sets of "Maxims" and "Widsith," a list of rulers, tribes, and notables in the heroic age), dialogues, metrical prefaces and epilogues to prose works of the Alfredian period, and liturgical poems associated with the Benedictine Office.

PROSE

The earliest English prose work, the law code of King Aethelberht I of Kent, was written within a few years of St. Augustine of Canterbury's arrival in England (597). Other 7th- and 8th-century prose, similarly practical in character, includes more laws, wills, and charters. According to Cuthbert, who was a monk at Jarrow, Bede had just finished a translation of the Gospel of St. John at the time of his death, though this does not survive; and two medical tracts, a *Herbarium* and *Medicina de quadrupedibus,* very likely date from the 8th century.

Early translations into English. But the earliest literary prose dates from the late 9th century, when King Alfred, eager to improve the state of English learning, led a vigorous program to translate into English "certain books that are necessary for all men to know." Alfred himself translated St. Gregory I the Great's *Pastoral Care,* Boethius' *Consolation of Philosophy,* St. Augustine of Hippo's *Soliloquies* and the first 50 psalms. His *Pastoral Care* is a fairly literal translation, but his Boethius is extensively restructured and revised to make explicit the Christian message that medieval commentators saw in that work. He revised the *Soliloquies* even more radically, departing from his source to draw from St. Jerome, Gregory, and other works by Augustine. Alfred's prefaces to these works are of great historical interest.

At Alfred's urging Bishop Werferth of Worcester translated the *Dialogues* of Gregory; probably Alfred also inspired anonymous scholars to translate Bede's *Historia ecclesiastica* and Paulus Orosius' *Historiarum adversum paganos libri vii* ("History Opposing the Pagans, In Seven Books"). Both of these works are much abridged; the Bede translation follows its source slavishly, but the translator of Orosius added many details of northern European geography and also accounts of the voyages of Ohthere the Norwegian and Wulfstan the Dane. These accounts, in addition to their geographical interest, show that friendly commerce between England and Scandinavia was possible even during the Danish wars. The *Anglo-Saxon Chronicle* probably originated in Alfred's reign. Its earliest annals (from 60 BC) are laconic, except the entry for 755, which records in detail a feud between the West Saxon king Cynewulf and the would-be usurper Cyneheard. The entries covering the Danish wars of the late 9th century are much fuller, and those running from the reign of Aethelred I to the Norman Conquest in 1066 (when the *Chronicle* exists in several versions) contain many passages of excellent writing. The early 10th century is not notable for literary production, but some of the homilies in the Vercelli Book and the Blickling manuscript (Scheide Library, Princeton University) may belong to that period.

The *Anglo-Saxon Chronicle*

Late 10th- and 11th-century prose. The Benedictine reform of the mid-10th century brought about a period of lively literary activity. Aethelwold, bishop of Winchester and one of the leaders of the reform, translated the Rule of St. Benedict. But the greatest and most prolific writer of this period was his pupil Aelfric, abbot of Eynsham, whose works include three cycles of 40 homilies each (*Catholic Homilies,* 2 vol., and the *Lives of the Saints*), as well as

homilies not in these cycles; a Latin grammar; a treatise on science; pastoral letters; and several translations. His Latin *Colloquy,* supplied with an Old English version by an anonymous glossarist, gives a charming picture of everyday life in Anglo-Saxon England. Aelfric wrote with lucidity and astonishing beauty, using the rhetorical devices of Latin literature frequently but without ostentation; his later alliterative prose, which loosely imitates the rhythms of Old English poetry, influenced writers long after the Norman Conquest. Wulfstan, archbishop of York, wrote legal codes, both civil and ecclesiastical, and a number of homilies, including *Sermo Lupi ad Anglos* ("Wulf's Address to the English"), a ferocious denunciation of the morals of his time. To judge from the number of extant manuscripts, these two writers were enormously popular. Byrhtferth of Ramsey wrote several Latin works and the *Enchiridion,* a textbook on the calendar, notable for its ornate style. Numerous anonymous works, some of very high quality, were produced in this period, including homilies, saints' lives, dialogues, and translations of such works as the Gospels, several Old Testament books, liturgical texts, monastic rules, penitential handbooks, and the romance *Apollonius of Tyre* (translated from Latin but probably derived from a Greek original). The works of the monastic reform were written during a few remarkable decades around the turn of the millennium. Little original work can be securely dated to the period after Wulfstan's death (1023), but the continued vigour of the *Anglo-Saxon Chronicle* shows that good Old English prose was written right up to the Norman Conquest. By the end of this period English had been established as a literary language with a polish and versatility unequaled among European vernaculars.

The Early Middle English period

POETRY

The Norman Conquest worked no immediate transformation on either the language or literature of the English. Older poetry continued to be copied during the last half of the 11th century; two poems of the early 12th century—"Durham," which praises that city's cathedral and its relics, and "Instructions for Christians," a didactic piece—show that correct alliterative verse could be composed well after 1066. But even before the Conquest rhyme had begun to supplant rather than supplement alliteration in some poems, which continued to use the older four-stress line but the rhythms of which varied from the set types used in classical Old English verse. A post-Conquest example is "The Grave," which contains several rhyming lines; a poem from the *Anglo-Saxon Chronicle* on the death of William the Conqueror, lamenting his cruelty and greed, has more rhyme than alliteration.

Influence of French poetry. By the end of the 12th century English poetry had been so heavily influenced by French models that such a work as the long epic *Brut* (*c.* 1200) by Lawamon, a Worcestershire priest, seems archaic for mixing alliterative lines with rhyming couplets while generally eschewing French vocabulary. The *Brut* mainly draws upon Wace's Anglo-Norman *Roman de Brut* (1155; based in turn upon Geoffrey of Monmouth's *Historia regum Britanniae,* or *History of the Kings of Britain*), but in Lawamon's hands the Arthurian story takes on a Germanic and heroic flavour largely missing in Wace. The *Brut* exists in two manuscripts, one written shortly after 1200 and the other some 50 years later. That the later version has been extensively modernized and somewhat abridged suggests the speed with which English language and literary tastes were changing in this period. *The Proverbs of Alfred* also were written in the late 12th century; these deliver conventional wisdom in a mixture of rhymed couplets and alliterative lines, and it is hardly likely that any of the material they contain actually originated with the king whose wisdom they celebrate. The early 13th-century *Bestiary* mixes alliterative lines, three- and four-stress couplets, and septenary lines, but the logic behind this mix is more obvious than in the *Brut* and the *Proverbs,* for the poet was imitating the varied metres of his Latin source. More regular in form than these poems is the anonymous *Poema morale* in septenary couplets, in which an old man delivers a dose of moral advice to his presumably younger audience.

Lawamon's *Brut*

By far the most brilliant poem of this period is *The Owl and the Nightingale* (written after 1189), an example of the popular debate genre. The two birds argue topics ranging from their hygienic habits, looks, and songs to marriage, prognostication, and the proper modes of worship. The nightingale stands for the joyous aspects of life, the owl for the sombre; there is no clear winner, but the debate ends as the birds go off to state their cases to one Nicholas of Guildford, a wise man. The poem is learned in the clerical tradition but wears its learning lightly as the disputants speak in colloquial and sometimes earthy language. Like the *Poema morale, The Owl and the Nightingale* is metrically regular (octosyllabic couplets), but it uses the French metre with an assurance that is astonishing in so early a poem.

Didactic poetry. The 13th century saw a rise in the popularity of long didactic poems presenting biblical narrative, saints' lives, or moral instruction for those untutored in Latin or French. The most idiosyncratic of these is the *Ormulum* by Orm, an Augustinian canon in the north of England. Written in some 20,000 lines arranged in unrhymed but metrically rigid couplets, the work is interesting mainly in that the manuscript that preserves it is Orm's autograph and shows his somewhat fussy (and ineffectual) efforts to reform and regularize English spelling. Other biblical paraphrases are *Genesis and Exodus, Jacob and Joseph,* and the vast *Cursor mundi,* whose subject, as its title suggests, is the whole history of the world. An especially popular work was the *South English Legendary,* which began as a miscellaneous collection of saints' lives but was expanded by later redactors and rearranged in the order of the church calendar. The didactic tradition continued into the 14th century with Robert Mannyng's *Handlyng Synne,* a confessional manual the expected dryness of which is relieved by the insertion of lively narratives, and the *Pricke of Conscience,* a summary of theology sometimes attributed to Richard Rolle.

Verse romance. The earliest examples of verse romance, a genre that would remain popular through the Middle Ages, appeared in the 13th century. *King Horn* and *Floris and Blauncheflour* both are preserved in a manuscript of around 1250. *King Horn,* oddly written in short two- and three-stress lines, is a vigorous tale of a kingdom lost and regained, with a subplot concerning Horn's love for Princess Rymenhild. *Floris and Blauncheflour* is more exotic, being the tale of a pair of royal lovers who become separated and, after various adventures in eastern lands, reunited. Not much later than these is *The Lay of Havelok the Dane,* a tale of princely love and adventure similar to *King Horn* but more competently executed. Many more such romances were produced in the 14th century. Popular subgenres were "the matter of Britain" (Arthurian romances such as *Of Arthour and of Merlin* and *Ywain and Gawain*); "the matter of Troy" (tales of antiquity such as *The Seege of Troye* and *Kyng Alisaunder*); and the English Breton lays, stories of otherworldly magic, such as *Lai le Freine* and *Sir Orfeo,* modeled after those of professional Breton storytellers. These relatively unsophisticated works were no doubt written for a bourgeois audience, and the manuscripts that preserve them are early examples of commercial book production. The humorous beast epic makes its first appearance in the 13th century in *The Fox and the Wolf,* taken indirectly from the Old French *Roman de Renart.* In the same manuscript with this work is *Dame Sirith,* the earliest English fabliau. Another sort of humour is found in *The Land of Cockaygne,* which depicts a utopia better than heaven, where rivers run with oil, milk, honey, and wine, geese fly about already roasted, and monks hunt with hawks and dance with nuns.

Floris and Blauncheflour

The lyric. The lyric was virtually unknown to Old English poets: poems like "Deor" and "Wulf and Eadwacer," which have been called lyrics, are thematically different from those that began to circulate orally in the 12th century and to be written down in great numbers in the 13th; and these Old English poems have a stronger narrative component than the later productions. The most frequent

topics in the Middle English secular lyric are springtime and romantic love; many rework such themes tediously, but some, such as "Foweles in the frith" (13th century) and "Ich am of Irlaunde" (14th century), convey strong emotions in a few lines. Two lyrics of the early 13th century, "Mirie it is while sumer ilast" and "Sumer is icumen in," are preserved with musical settings, and probably most of the others were meant to be sung. The dominant mood of the religious lyrics is passionate: the poets sorrow for Christ on the Cross and for Mary, celebrate the "five joys" of Mary, and import language from love poetry to express religious devotion. Excellent early examples are "Nou goth sonne under wod" and "Stond wel, moder, ounder rode." Many of the lyrics are preserved in manuscript anthologies, of which the best is British Library manuscript Harley 2253 from the early 14th century. The love poems in this collection, such as "Alysoun" and "Blow, Northerne Wynd," take after the poems of the Provençal troubadours but are less formal and abstract and therefore more lively. The religious lyrics also are of high quality; but the most remarkable of the Harley Lyrics, "The Man in the Moon," far from being about love or religion, imagines the man in the Moon as a simple peasant, sympathizes with his hard life, and offers him some useful advice on how to best the village hayward.

A poem such as "The Man in the Moon" serves as a reminder that, although the poetry of the early Middle English period is increasingly influenced by the Anglo-Norman literature produced for the courts, it is seldom "courtly." Most English poets, whether writing about kings or peasants, looked at life from a middle-class perspective. If their work sometimes lacks sophistication, it nevertheless has a vitality that comes from preoccupation with daily affairs; its practicality, as much as its language, gives it a distinctly English flavour.

PROSE

Old English prose texts were copied for more than a century after the Norman Conquest; the homilies of Aelfric were especially popular, and King Alfred's translations of Boethius and Augustine survive only in 12th-century manuscripts. In the early 13th century an anonymous worker at Worcester supplied glosses to certain words in a number of Old English manuscripts, demonstrating that by this time the older language was beginning to pose difficulties for readers.

The composition of English prose also continued without interruption. Two manuscripts of the *Anglo-Saxon Chronicle* exhibit very strong prose for years after the Conquest, and one of these, *The Peterborough Chronicle,* continues to the year 1154. Two manuscripts of around 1200 contain 12th-century sermons, and another has a workmanlike compilation on the "Vices and Virtues," composed around 1200. But the English language faced stiff competition from both Anglo-Norman (the insular dialect of French being used increasingly in the monasteries) and Latin, a language intelligible to speakers of both English and French. It was inevitable, then, that the production of English prose should decline in quantity, if not in quality. The great prose works of this period were composed mainly for those who could read only English—women especially. In the West Midlands the Old English alliterative prose tradition remained very much alive into the 13th century, when the several texts known collectively as the Katherine Group were written. "St. Katherine," "St. Margaret," and "St. Juliana," found together in a single manuscript, have rhythms strongly reminiscent of those of Aelfric and Wulfstan. So, to a lesser extent, do "Hali Meithhad" ("Holy Maidenhood") and "Sawles Warde" ("The Guardianship of the Soul") from the same book, but newer influences can be seen in these works as well: as the title of another devotional piece, "The Wohunge of Ure Lauerd" ("The Wooing of Our Lord"), suggests, the prose of this time often has a rapturous, even sensual flavour, and, like the poetry, it frequently employs the language of love to express religious fervour.

Composition in English, Anglo-Norman, and Latin

Further removed from the Old English prose tradition, though often associated with the Katherine Group, is the *Ancrene Wisse* ("Guide for Anchoresses," also known as the *Ancrene Riwle,* or "Rule for Anchoresses"), a manual for the guidance of women recluses outside the regular orders. This anonymous work, which was translated into French and Latin and remained popular until the 16th century, is notable for its humanity, practicality, and insight into human nature but even more for its brilliant style. Like the other prose of its time, it uses alliteration as ornament, but it is more indebted to new fashions in preaching, which had originated in the universities, than to native traditions. With its richly figurative language, rhetorically crafted sentences, and carefully logical divisions and subdivisions, it manages to achieve in English the effects that such contemporary writers as John of Salisbury and Walter Map were striving for in Latin.

Little noteworthy prose was written in the late 13th century. In the early 14th century Dan Michel produced in Kentish the *Ayenbite of Inwit* ("Prick of Conscience"), a translation from French. But the best prose of this time is by the mystic Richard Rolle, the hermit of Hampole, whose English tracts include *The Commandment, Meditations on the Passion,* and *The Form of Perfect Living,* among others. His intense and stylized prose was among the most popular of the 14th century and inspired such later works as Walter Hilton's *Scale of Perfection,* Julian of Norwich's *Sixteen Revelations of Divine Love,* and the anonymous *Cloud of Unknowing.* (P.S.Ba.)

The later Middle English and early Renaissance periods

One of the most important factors in the nature and development of English literature between about 1350 and 1550 was the peculiar linguistic situation in England at the beginning of the period. Among the small minority of the population that could be regarded as literate, bilingualism and even trilingualism were common. Insofar as it was considered a serious literary medium at all, English was obliged to compete on uneven terms with Latin and with the Anglo-Norman dialect of French widely used in England at the time. Moreover, extreme dialectal diversity within English itself made it difficult for vernacular writings, irrespective of their literary pretensions, to circulate very far outside their immediate areas of composition, a disadvantage not suffered by writings in Anglo-Norman and Latin. Literary culture managed to survive and in fact to flourish in the face of such potentially crushing factors as the catastrophic mortality of the Black Death (1347–51), chronic external and internal military conflicts in the form of the Hundred Years' War and the Wars of the Roses, and serious social, political, and religious unrest, as evinced in the Peasants' Revolt (1381) and the rise of Lollardism (centred on the religious teachings of John Wycliffe). All the more remarkable then was the literary and linguistic revolution that took place in England between about 1350 and 1400 and that was slowly and soberly consolidated over the subsequent 150 years.

LATER MIDDLE ENGLISH POETRY

The revival of alliterative poetry. The most puzzling episode in the development of later Middle English literature was the apparently sudden reappearance of unrhymed alliterative poetry in the mid-14th century. Debate continues as to whether the group of long, serious, and sometimes learned poems written between about 1350 and the first decade of the 15th century should be regarded as an "alliterative revival" or rather as the late flowering of a largely lost native tradition stretching back to the Old English period. The earliest examples of the phenomenon, *William of Palerne* and *Winner and Waster,* are both datable to the 1350s, but neither poem exhibits to the full all the characteristics of the slightly later poems central to the movement. *William of Palerne,* condescendingly commissioned by a nobleman for the benefit of "them that know no French," is a homely paraphrase of a courtly continental romance, the only poem in the group to take love as its central theme. The poet's technical competence in handling the difficult syntax and diction of the alliterative style is not, however, to be compared with that of *Winner and Waster*'s author, who exhibits full mastery of the

form, particularly in brilliant descriptions of setting and spectacle. This poem's topical concern with social satire links it primarily with another, less formal body of alliterative verse, of which William Langland's *Piers Plowman* was the principal representative and exemplar. Indeed, *Winner and Waster,* with its sense of social commitment and occasional apocalyptic gesture, may well have served as a source of inspiration for Langland himself.

The expression alliterative revival should not be taken to imply a return to the principles of classical Old English versification. The authors of the later 14th-century alliterative poems either inherited or developed their own conventions, which resemble those of the Old English tradition in only the most general way. The syntax and particularly the diction of later Middle English alliterative verse were also distinctive, and the search for alliterating phrases and constructions led to the extensive use of archaic, technical, and dialectal words. Hunts, feasts, battles, storms, and landscapes were described with a brilliant concretion of detail rarely paralleled since, while the abler poets also contrived subtle modulations of the staple verse-paragraph to accommodate dialogue, discourse, and argument. Among the poems central to the movement were three pieces dealing with the life and legends of Alexander, the massive *Destruction of Troy,* and the *Siege of Jerusalem.* The fact that all of these derived from various Latin sources suggests that the anonymous poets were likely to have been clerics with a strong, if bookish, historical sense of their romance "matters." The "matter of Britain" was represented by an outstanding composition, the alliterative *Morte Arthure,* an epic portrayal of King Arthur's conquests in Europe and his eventual fall, combining a strong narrative thrust with considerable density and subtlety of diction. A gathering sense of inevitable transitoriness gradually tempers the virile realization of heroic idealism, and it is not surprising to find that the poem was later used by Sir Thomas Malory as a source for his prose account, *Le Morte Darthur* (completed *c.* 1470).

The alliterative movement would today be regarded as a curious but inconsiderable episode, were it not for four other poems now generally attributed to a single anonymous author: the chivalric romance *Sir Gawayne and the Grene Knight,* two homiletic poems called *Patience* and *Purity* (or *Cleanness*), and an elegiac dream vision known as *Pearl,* all miraculously preserved in a single manuscript dated *c.* 1400. The poet of *Sir Gawayne* far exceeded the other alliterative writers in his mastery of form and style, and though he wrote ultimately as a moralist, human warmth and sympathy (often taking comic form) were also close to the heart of his work. *Patience* relates the biblical story of Jonah as a human comedy of petulance and irascibility set off against God's benign forbearance. *Purity* imaginatively re-creates several monitory narratives of man's impurity and its consequences in a spectacular display of poetic skill: the Flood, the destruction of Sodom, and Belshazzar's Feast. The poet's principal achievement, however, was *Sir Gawayne,* in which he used the conventional apparatus of chivalric romance to engage in a serious exploration of man's moral conduct in the face of the unknown. The hero, a questing knight of Arthur's court, embodies a combination of the noblest chivalric and spiritual aspirations of the age, but instead of triumphing in the conventional way, he fails when tested (albeit rather unfairly) by mysterious supernatural powers. No paraphrase can hope to recapture the brilliant imaginative resources displayed in the telling of the story and the structuring of the poem as a work of art. The *Pearl* stands somewhat aside from the alliterative movement proper. In common with a number of other poems of the period, it was composed in stanzaic form, with alliteration used for ornamental effect. Technically it is one of the most complex poems in the language, an attempt to work in words an analogy to the jeweler's art. The jeweler-poet is vouchsafed a heavenly vision in which he sees his pearl, the discreet symbol used in the poem for a lost infant daughter who has died to become a bride of Christ. She offers theological consolation for his grief, expounding the way of salvation and the place of human life in a transcendental and extra-temporal view of things.

Sir Gawayne and the Grene Knight

The alliterative movement was primarily confined to poets writing in northern and northwestern England, who showed little regard for courtly, London-based literary developments. It is likely that alliterative poetry, under aristocratic patronage, filled a gap in the literary life of the provinces caused by the decline of Anglo-Norman in the latter half of the 14th century. Alliterative poetry was not unknown in London and the southeast, but it penetrated those areas in a modified form and in poems that dealt with different subject matter.

Piers Plowman

William Langland's long alliterative poem *Piers Plowman* begins with a vision of the world seen from the Malvern Hills in Worcestershire, where, tradition has it, the poet was born and brought up, and where he would have been open to the influence of the alliterative movement. If what he tells about himself in the poem is true (and there is no other source of information), he later lived obscurely in London as an unbeneficed cleric. Langland wrote in the unrhymed alliterative mode, but he modified it in such a way as to make it more accessible to a wider audience by treating the metre more loosely and avoiding the arcane diction of the provincial poets. His poem exists in three versions: A, *Piers Plowman* in its short, early form, dating from the 1360s; B, a major revision and extension of A made in the late 1370s; and C (1380s), a less "literary" version of B, apparently intended to bring its doctrinal issues into clearer focus. The poem takes the form of a series of dream visions dealing with the social and spiritual predicament of later 14th-century England against a sombre apocalyptic backdrop. Realistic and allegorical elements are mingled in a phantasmagoric way, and both the poetic medium and the structure are frequently subverted by the writer's spiritual and didactic impulses. Passages of involuted theological reasoning mingle with scatological satire, and moments of sublime religious feeling appear alongside forthright political comment. This makes it a work of the utmost difficulty, defiant of categorization, but at the same time Langland never fails to convince the reader of the passionate integrity of his writing. His bitter attacks on political and ecclesiastical corruption (especially among the friars) quickly struck chords with his contemporaries. Among minor poems in the same vein were *Mum and the Sothsegger* (*c.* 1399–1406) and a Lollard piece called *Pierce the Ploughman's Creed* (*c.* 1395). In the 16th century *Piers Plowman* was issued as a printed book and was used for apologetic purposes by the early Protestants.

Courtly poetry. Apart from a few late and minor reappearances in Scotland and the northwest of England, the alliterative movement was over before the first quarter of the 15th century had passed. The other major strand in the development of English poetry from about 1350 proved much more durable. The cultivation and refinement of human sentiment with respect to love, already present in earlier 14th-century writings such as the Harley Lyrics, took firm root in English court culture during the reign of Richard II (1377–99). English began to displace Anglo-Norman French as the language spoken at court and in aristocratic circles, and signs of royal and noble patronage for English vernacular writers became evident. These processes undoubtedly created some of the conditions in which a writer of Chaucer's interests and temperament might flourish, but they were encouraged and given direction by his genius in establishing English as a literary language.

Chaucer and Gower. Geoffrey Chaucer, a Londoner of bourgeois origins, was at various times a courtier, diplomat, and civil servant. His poetry frequently (but not always unironically) reflects the views and values associated with the term "courtly." It is in some ways not easy to account for his decision to write in English, and it is not surprising that his earliest substantial poems, the *Book of the Duchess* (*c.* 1370) and the *House of Fame* (*c.* 1380), were heavily indebted to the fashionable French love-vision poetry of the time. Also of French origin was the octosyllabic couplet used in these poems. Chaucer's abandonment of this engaging but ultimately jejune metre in favour of a 10-syllable or iambic pentameter line was a portentous moment for English poetry. His mastery of it

was first revealed in stanzaic form, notably the seven-line stanza (rhyme royal) of the *Parlement of Foules* (*c.* 1382) and *Troilus and Criseyde* (*c.* 1385), and later was extended in the decasyllabic couplets of the prologue to the *Legend of Good Women* and large parts of *The Canterbury Tales.*

Though Chaucer wrote a number of moral and amatory lyrics, which were imitated by his 15th-century followers, his major achievements were in the field of narrative poetry. The early influence of French courtly love poetry (notably the *Roman de la Rose,* which he translated) gave way to an interest in Italian literature. Chaucer was acquainted with Dante's writings and took a story from Petrarch for the substance of his "Clerk's Tale." Two of his major poems, *Troilus and Criseyde* and "The Knight's Tale," were based, respectively, on the *Filostrato* and the *Teseida* of Boccaccio. The *Troilus,* Chaucer's single most ambitious poem, is a moving story of love gained and betrayed set against the background of the Trojan War. As well as being a poem of profound human sympathy and insight, it also has a marked philosophical dimension derived from Chaucer's reading of Boethius' *De consolatione philosophiae,* a work that he also translated in prose.

Chaucer's *Canterbury Tales*

His consummate skill in narrative art, however, was most fully displayed in *The Canterbury Tales* (*c.* 1387–1400), an unfinished series of stories purporting to be told by a group of pilgrims journeying from London to the shrine of St. Thomas Becket and back. The illusion that the individual pilgrims (rather than Chaucer himself) tell their tales gave him an unprecedented freedom of authorial stance, which enabled him to explore the rich fictive potentialities of a number of genres: pious legend (in "The Man of Law's Tale" and "The Prioress's Tale"), fabliaux ("The Shipman's Tale," "The Miller's Tale," and "The Reeve's Tale"), chivalric romance ("The Knight's Tale"), popular romance (parodied in Chaucer's "own" "Tale of Sir Thopas"), beast fable ("The Nun's Priest's Tale" and "The Manciple's Tale") and more—what Dryden later summed up as "God's plenty."

A recurrent concern in Chaucer's writings was the refined and sophisticated cultivation of love, commonly described by the modern expression "courtly love." A contemporary French term, *fine amour,* gives a more authentic description of the phenomenon; Chaucer's friend John Gower translated it as "fine loving" in his long poem *Confessio amantis* (begun *c.* 1386). The *Confessio* runs to some 33,000 lines in octosyllabic couplets and takes the form of a collection of exemplary tales placed within the framework of a lover's confession to a priest of Venus. Gower provides an interesting and sometimes refreshing contrast to Chaucer, in that the sober and earnest moral intent behind his writing is always clear, whereas Chaucer can be irritatingly noncommital and evasive. On the other hand, though Gower's verse is generally fluent and pleasing to read, it has a thin homogeneity of texture that cannot compare with the colour and range to be found in the language of his great contemporary. Gower was undoubtedly extremely learned by lay standards, and many classical myths (especially those deriving from Ovid's *Metamorphoses*) make the first of their numerous appearances in English literature in the *Confessio.* He was also deeply concerned with the moral and social condition of contemporary society, and he dealt with it in two weighty compositions in French and Latin, respectively: the *Mirour de l'omme* (*c.* 1374–78; "The Mirror of Man") and *Vox clamantis* (*c.* 1385).

Gower's *Confessio amantis*

Poetry after Chaucer and Gower. *Courtly poetry.* The numerous 15th-century followers of Chaucer continued to treat the conventional range of courtly and moralizing topics, but only rarely with the intelligence and stylistic accomplishment of their distinguished predecessors. The canon of Chaucer's works began to accumulate delightful but apocryphal trifles such as "The Flower and the Leaf" and "The Assembly of Ladies" (both *c.* 1475), the former, like a surprising quantity of 15th-century verse of this type, purportedly written by a woman. The stock figures of the ardent but endlessly frustrated lover and the irresistible but disdainful lady were cultivated as part of the "game of love" depicted in numerous courtly lyrics. Vernacular literacy spread rapidly among both lay men and women, the influence of French courtly love poetry remaining strong. Aristocratic and knightly versifiers such as Charles, duc d'Orléans (captured at Agincourt in 1415), his "jailer" William de la Pole, duke of Suffolk, and Sir Richard Ros (translator of Alain Chartier's influential *La Belle Dame sans merci*) were widely read and imitated among the gentry and in bourgeois circles well into the 16th century.

Both Chaucer and Gower had to some extent enjoyed royal and aristocratic patronage, and the active seeking of patronage became a pervasive feature of the 15th-century literary scene. Thomas Hoccleve, a minor civil servant who probably knew Chaucer and claimed to be his disciple, dedicated his *Regiment of Princes* (*c.* 1412), culled from an earlier work of the same name, to the future Henry V. Most of Hoccleve's compositions seem to have been written with an eye to patronage, and though they occasionally yield interesting and unexpected glimpses of his daily and private lives, they have little to recommend them as poetry. Hoccleve's aspiration to be Chaucer's successor was rapidly overshadowed, in sheer bulk if not necessarily in literary merit, by the formidable oeuvre of John Lydgate, a monk at the abbey of Bury St. Edmunds. Lydgate, too, was greatly stimulated at the prospects opened up by distinguished patronage, producing as a result a number of very long pieces that were greatly admired in their day. A staunch Lancastrian, Lydgate dedicated his *Troy Book* and *Life of Our Lady* to Henry V and his *Fall of Princes* (based ultimately on Boccaccio's *De casibus virorum illustrium*) to Humphrey Plantagenet, duke of Gloucester. He also essayed courtly verse in Chaucer's manner (*The Complaint of the Black Knight* and *The Temple of Glas*), but his imitation of the master's style was rarely successful. Both Lydgate and Hoccleve admired above all Chaucer's "eloquence," by which they meant mainly the Latinate elements in his diction. Their own painfully polysyllabic or "aureate" style unfortunately came to be widely imitated for more than a century. In sum, the major 15th-century English poets were generally undistinguished as successors of Chaucer, and for a significant but independent extension of his achievement one must look to the Scots *makaris* ("makers"), among whom were King James I of Scotland, Robert Henryson, and William Dunbar.

John Lydgate

Lydgate's following at court gave him a central place in 15th-century literary life, but the typical concerns shown by his verse do not distinguish it from a great body of religious, moral, historical, and didactic writing, much of it anonymous. A few identifiable provincial writers turn out to have had their own local patrons, often among the country gentry. East Anglia may be said to have produced a minor school in the works of John Capgrave, Osbern Bokenam, and John Metham, among others also active around the middle of the century. Some of the most moving and accomplished verse of the time is to be found in the anonymous lyrics and carols (songs with a refrain) on conventional subjects such as the transience of life, the coming of death, the sufferings of Christ, and other penitential themes. The author of some distinctive poems in this mode was John Audelay of Shropshire, whose style was heavily influenced by the alliterative movement. Literary devotion to the Virgin Mary was particularly prominent and at its best could produce masterpieces of artful simplicity, such as the justly famous "I sing of a maiden that is makeless."

Provincial writers

Popular and secular verse. The art that conceals art was also characteristic of the best popular and secular verse of the period, outside the courtly mode. Some of the shorter verse romances, usually in a form called tail rhyme, were far from negligible: *Ywain and Gawain* from the *Yvain* of Chrétien de Troyes; *Sir Launfal,* after Marie de France's *Lanval;* and *Sir Degrevant.* Humorous and lewd songs, versified tales, folk songs, ballads, and others form a lively but essentially subliterary body of compositions. Oral transmission was probably common, and the survival of much of what is extant is fortuitous. The Percy Folio manuscript, a 17th-century antiquarian collection of such material, may be a fair sampling of the repertoire of the late medieval itinerant entertainer. In addition to a number of more or less execrable popular romances of the

type satirized long before by Chaucer in "Sir Thopas," the Percy manuscript also contains a number of impressive ballads very much like those collected from oral sources in the 18th and 19th centuries. The extent of medieval origin of the poems collected in Francis J. Child's *English and Scottish Popular Ballads* (1882–98) is debatable. Several of the Robin Hood ballads undoubtedly were known in the 15th century, and the characteristic laconically repetitious and incremental style of the ballads is also to be seen in the enigmatic *Corpus Christi Carol,* preserved in an early 16th-century London grocer's commonplace book. In the same manuscript, but in a rather different vein, is *The Nut-Brown Maid,* an enchanting and expertly managed dialogue-poem on female constancy.

Political verse. A genre that does not fit easily into the categories already mentioned is political verse, of which a good deal was written in the 15th century. Much of it was avowedly and often crudely propagandist, especially during the Wars of the Roses, though a piece like the *Agincourt Carol* shows that it was already possible to strike the characteristically English note of insular patriotism soon after 1415. Of particular interest is the *Libel of English Policy* (*c.* 1436) on another typically English theme of a related kind: "Cherish merchandise, keep the admiralty,/ That we be masters of the narrow sea."

LATER MIDDLE ENGLISH PROSE

The continuity of a tradition in English prose writing, linking the later with the early Middle English period, is somewhat clearer than that to be detected in verse. The *Ancrene Wisse,* for example, continued to be copied and adapted to suit changing tastes and circumstances. But sudden and brilliant imaginative phenomena like the writings of Chaucer, Langland, and the author of *Sir Gawayne* are not to be found. Instead, there is a steady growth in the composition of religious prose of various kinds and the first appearance of secular prose in any quantity.

Religious prose. Of the first importance was the development of a sober, analytical, but nonetheless impressive kind of contemplative or mystical prose, represented by Walter Hilton's *Scale of Perfection* and the anonymous *Cloud of Unknowing.* The authors of these pieces certainly knew the more rugged and fervent writings of their earlier 14th-century predecessor Richard Rolle, and to some extent they reacted against what they saw as excesses in the style and content of his work. It is of particular interest to note that the mystical tradition was continued into the 15th century, though in very different ways, by two women writers, Julian of Norwich and Margery Kempe of King's Lynn. Julian, often regarded as the first English woman of letters, underwent a series of mystical experiences in 1373 about which she went on to write in her *Revelations of Divine Love,* one of the foremost works of English spirituality by the standards of any age. Rather different religious experiences went into the making of *The Book of Margery Kempe* (*c.* 1438), the extraordinary autobiographical record of a highly emotional bourgeoise, apparently dictated to a priest. The nature and status of its spiritual content remain controversial, but its often engaging colloquial style and vivid realization of the medieval scene are of abiding interest.

Mystical writings

Another important branch of the contemplative movement in prose involved the translation of continental Latin texts. A major example, and one of the best loved of all medieval English books in its time, was *The Mirror of the Blessed Life of Jesus Christ* (*c.* 1410), Nicholas Love's translation of the *Meditationes vitae Christi,* attributed to St. Bonaventure. Love's work was particularly valued by the church as an orthodox counterbalance to the heretical tendencies of the Lollards, who espoused the teachings of John Wycliffe and his circle. The Lollard movement generated a good deal of interesting and stylistically distinctive prose writing, though as the Lollards soon came under threat of death by burning, nearly all of it remains anonymous. A number of English works have been attributed to Wycliffe himself, and the first English translation of the Bible to Wycliffe's disciple John Purvey, but there are no firm grounds for these attributions. The Lollard Bible, which exists in a crude early form and in a more impressive later version (supposedly Purvey's work), was widely read in spite of being under doctrinal suspicion. It later influenced William Tyndale's translation of the New Testament, completed in 1525, and, through Tyndale, the Authorized Version (1611).

Secular prose. Secular compositions and translations in prose also came into prominence in the last quarter of the 14th century, though their stylistic accomplishment does not always match that of the religious tradition. Chaucer's "Tale of Melibeus" and his two astronomical translations, the *Treatise on the Astrolabe* and the *Equatorie of the Planetis,* were relatively modest endeavours beside the massive efforts of John of Trevisa, who translated from Latin both Ranulph Higden's universal history, *Polychronicon* (*c.* 1385–87), and Bartholomaeus Anglicus' encyclopaedia *De proprietatibus rerum* (1398). Judging by the number of surviving manuscripts, however, the most widely read secular prose work of the period is likely to have been *The Travels of Sir John Mandeville,* the supposed adventures of Sir John Mandeville, knight of St. Albans, on his journeys through Asia to the Orient. Though the work now is believed to be purely fictional, the exotic allure of the *Travels* and the occasionally arch style of their author were popular with the English reading public down to the 18th century.

Mandeville's *Travels*

The 15th century saw the consolidation of English prose as a respectable medium for serious writings of various kinds. The anonymous *Brut* chronicle survives in more manuscripts than any other medieval English work and was instrumental in fostering a new sense of national identity. John Capgrave's *Chronicle of England* (*c.* 1462) and Sir John Fortescue's *On the Governance of England* (*c.* 1470) were part of the same trend. At its best, the style of such works could be vigorous and straightforward, close to the language of everyday speech, like that found in the chance survivals of private letters of the period. Best known and most numerous among letters are those of the Paston family of Norfolk, but significant collections were also left by the Celys of London and the Stonors of Oxfordshire. More eccentric prose stylists of the period were the religious controversialist Reginald Pecock and John Skelton, whose "aureate" translation of the *Bibliotheca historica* of Diodorus Siculus stands in marked contrast to the demotic exuberance of his verse.

The crowning achievement of later Middle English prose writing was Sir Thomas Malory's cycle of Arthurian legends, which was given the title *Le Morte Darthur* by William Caxton when he printed his edition in 1485. There is still uncertainty as to the identity of Malory, who described himself as a "knight-prisoner." The characteristic mixture of chivalric nostalgia and tragic feeling with which he imbued his book gave fresh inspiration to the tradition of writing on Arthurian themes. The nature of Malory's artistry eludes easy definition, and the degree to which the effects he achieved were a matter of conscious contrivance on his part is debatable. Much of the *Morte Darthur* was translated from prolix French prose romances, and Malory evidently selected and condensed his material with instinctive mastery as he went along. At the same time he cast narrative and dialogue in the cadences of a virile and natural English prose that admirably matched the nobility of both the characters and the theme.

Malory's Arthurian cycle

MIDDLE ENGLISH DRAMA

Because the manuscripts of medieval English plays were usually ephemeral performance scripts rather than reading matter, very few examples have survived from what once must have been a very large dramatic literature. What little survives from before the 15th century includes some bilingual fragments, indicating that the same play might have been given in English or Anglo-Norman, according to the composition of the audience. From the late 14th century onward two main dramatic genres are discernible, the mystery or Corpus Christi cycles and the morality plays. The mystery plays were long cyclic dramas of the Creation, Fall, and Redemption of mankind, based mostly on biblical narratives. They usually included a selection of Old Testament episodes (such as the stories of Cain and Abel and Abraham and Isaac) but concentrated mainly on

Mystery and morality plays

the life and Passion of Jesus Christ. They always ended with the Last Judgment. The cycles were generally financed and performed by the craft guilds and staged on wagons in the streets and squares of the towns. Texts of the cycles staged at York, Chester, Wakefield, and at an unstated location in East Anglia have survived, together with fragments from Coventry, Newcastle, and Norwich. Their literary quality is uneven, but the York cycle (probably the oldest) has a most impressively realized version of Christ's Passion by a dramatist influenced by the alliterative style in verse. Wakefield has several particularly brilliant plays, attributed to the anonymous Wakefield Master, and his *Second Shepherds' Play* is one of the masterpieces of medieval English literature. The morality plays were allegorical dramas depicting the progress of a single character, representing the whole of mankind, from the cradle to the grave and sometimes beyond. The other dramatis personae might include God and the Devil but usually consisted of personified abstractions, such as the Vices and Virtues, Death, Penance, Mercy, and so forth. An interesting and varied collection of the moralities is known as the Macro Plays (*The Castle of Perseverance, Wisdom, Mankind*), but the single most impressive piece is undoubtedly *Everyman,* a superb English rendering of a Dutch play on the subject of the coming of death. Both the mystery and morality plays have been frequently revived and performed in the 20th century.

THE TRANSITION FROM MEDIEVAL TO RENAISSANCE

Transition from medieval to Renaissance

The 15th century was a major period of growth in lay literacy, a process powerfully expedited by the introduction into England of printing by William Caxton in 1476. Caxton's Malory (1485) was published in the same year that Henry Tudor acceded to the throne as Henry VII, and the period from this time to the mid-16th century has been called the transition from medieval to Renaissance in English literature. A typical figure was the translator Alexander Barclay. His *Eclogues* (*c.* 1515), drawn from 15th-century Italian humanist sources, was an early essay in the fashionable Renaissance genre of pastoral, while his rendering of Sebastian Brant's *Narrenschiff* as *The Ship of Fools* (1509) is a thoroughly medieval satire on contemporary folly and corruption. *The Passetyme of Pleasure* (1506) by Stephen Hawes, ostensibly an allegorical romance in Lydgate's manner, unexpectedly adumbrates the great Tudor theme of academic cultivation as a necessary accomplishment of the courtly knight or gentleman.

The themes of education and good government predominate in the new humanist writing of the 16th century, both in discursive prose (such as Sir Thomas Elyot's *Boke Named the Governour* and Roger Ascham's *Toxophilus* and *Scholemaster*) and in the drama (the plays of Henry Medwall and Richard Rastall). The preeminent work of English humanism, Sir Thomas More's *Utopia* (1516), was composed in Latin and appeared in an English translation in 1551. Undoubtedly the most distinctive voice in the poetry of the time was that of John Skelton, tutor to Henry VII's sons and author of an extraordinary range of writing, often in an equally extraordinary style. His works include a long play, *Magnyfycence,* like his *Bowge of Courte* an allegorical satire on court intrigue; intemperate satirical invectives, such as *Collyn Clout* and *Why Come Ye Nat to Courte?* (both 1522); and unusual reflexive essays on the role of the poet and poetry, in *Speke, Parrot* (written 1521) and *The Garland of Laurel* (1523). The first half of the 16th century was also a notable period for courtly lyric verse in the stricter sense of poems with musical settings, such as those found in the Devonshire manuscript. This is very much the literary milieu of the "courtly makers" Sir Thomas Wyatt and Henry Howard, earl of Surrey, but though the courtly context of much of their writing is of medieval origin, their most distinctive achievements look to the future. Poems like Wyatt's "They flee from me" and "Whoso list to hunt" vibrate with personal feeling at odds with the medieval convention of anonymity, while Surrey's translations from the *Aeneid* introduce blank verse (unrhymed iambic pentameter) into English for the first time, providing an essential foundation for the achievements of Shakespeare and Milton. (Ri.B.)

The Renaissance period: 1550–1660

LITERATURE AND THE AGE

In a tradition of literature remarkable for its exacting and brilliant achievements, the Elizabethan and early Stuart periods have been said to represent the most brilliant century of all. (The reign of Elizabeth I began in 1558 and ended with her death in 1603; she was succeeded by the Stuart king James VI of Scotland, who took the title James I of England as well. English literature of his reign as James I, from 1603 to 1625, is properly called Jacobean.) These years produced a gallery of authors of genius, some of whom have never been surpassed, and conferred on scores of lesser talents the enviable ability to write with fluency, imagination, and verve. From one point of view, this sudden renaissance looks radiant, confident, heroic—and belated, but all the more dazzling for its belatedness. Yet from another point of view, this was a time of unusually traumatic strain, in which English society underwent massive disruptions that transformed it on every front and decisively affected the life of every individual. In the brief, intense moment in which England assimilated the European Renaissance, the circumstances that made the assimilation possible were already disintegrating and calling into question the newly won certainties, as well as the older truths that they were dislodging. This doubleness, of new possibilities and new doubts simultaneously apprehended, gives the literature its unrivaled intensity.

Social conditions. In this period England's population doubled; prices rocketed, rents followed, old social loyalties dissolved, and new industrial, agricultural, and commercial veins were first tapped. Real wages hit an all-time low in the 1620s, and social relations were plunged into a state of unprecedented fluidity from which the merchant and ambitious lesser gentleman profited at the expense of the aristocrat and labourer, as satires and comedies current from the 1590s complain. Behind the Elizabethan vogue for pastoral poetry lies the fact of the prosperity of the enclosing sheep farmer, who aggressively sought to increase pasture at the expense of the peasantry. Tudor platitudes about order and degree could neither combat nor survive the challenge posed to rank by these arrivistes. The position of the crown, politically dominant yet financially insecure, had always been potentially unstable, and when Charles I lost the confidence of his greater subjects in the 1640s his authority crumbled. Meanwhile, the huge body of poor fell ever further behind the rich; the pamphlets of Thomas Harman (1566) and Robert Greene (1591–92), and Shakespeare's *King Lear* (1605), provide glimpses of a horrific world of vagabondage and crime, the Elizabethans' biggest, unsolvable social problem.

Intellectual and religious revolution. The barely disguised social ferment was accompanied by an intellectual revolution, as the medieval synthesis collapsed before the new science, new religion, and new humanism. While modern mechanical technologies were pressed into service by the Stuarts to create the scenic wonders of the court masque, the discoveries of astronomers and explorers were redrawing the cosmos in a way that was profoundly disturbing:

> And freely men confess that this world's spent,
> When in the planets, and the firmament
> They seek so many new . . .
>
> (John Donne, *The First Anniversary,* 1611)

The majority of people were more immediately affected by the religious revolutions of the 16th century. The man in early adulthood at the accession of Elizabeth in 1558 would, by her death in 1603, have been vouchsafed an unusually disillusioning insight into the duty owed by private conscience to the needs of the state. The Tudor church was an instrument of social and political coercion, yet the mid-century controversies over the faith had already wrecked any easy confidence in the authority of doctrines and forms and had taught men to question carefully the rationale of their own beliefs (as Donne does in his third *Satire, c.* 1596). The Elizabethan ecclesiastical compromise was the object of continual criticism, both from radicals within (who desired progressive reforms, such as the abolition of bishops) and from papists without (who

desired the return of England to the Roman Catholic fold), but the incipient liberalism of individuals like John Milton and William Chillingworth was held in check by the majority's unwillingness to tolerate a plurality of religions in a supposedly unitary state. Nor was the Calvinist orthodoxy that cradled most English writers comforting, for it told them that they were corrupt, unfree, unable to earn their own salvations, and subject to heavenly judgments that were arbitrary and absolute. It deeply informs the world of the Jacobean tragedies, whose heroes are not masters of their fates but victims of divine purposes that are terrifying yet inscrutable.

The race for cultural development. The third complicating factor was the race to catch up with continental developments in arts and philosophy. The Tudors badly needed to create a class of educated diplomats, statesmen, and officials and to dignify their court by making it a fount of cultural as well as political patronage. The new learning, widely disseminated through the Erasmian educational programs of such men as John Colet and Sir Thomas Elyot, proposed to use a systematic schooling in Latin authors and some Greek to encourage in the social elites a flexibility of mind and civilized serviceableness by which enlightened princely government could walk hand in hand with responsible scholarship. Humanism fostered an intimate familiarity with the classics that was a powerful incentive for the creation of an English literature of answerable dignity. It fostered as well a practical, secular piety that left its impress everywhere on Elizabethan writing. Humanism's effect, however, was modified by the simultaneous impact of the flourishing continental cultures, particularly the Italian. Repeatedly, crucial innovations in English letters developed resources originating from Italy, such as the sonnet of Petrarch, the epic of Ariosto, the pastoral of Sannazzaro, the canzone, and blank verse, and values imported with these forms were in competition with the humanists' ethical preoccupations. Social ideals of wit, many-sidedness, and *sprezzatura* (accomplishment mixed with unaffectedness) were imbibed from Baldassare Castiglione's *Il cortegiano,* translated as *The Courtyer* by Sir Thomas Hoby in 1561, and Elizabethan court poetry is steeped in Castiglione's aristocratic Neoplatonism, his notions of universal proportion, and the love of beauty as the path to virtue. Equally significant was the welcome afforded to Niccolò Machiavelli, whose lessons were vilified publicly and absorbed in private. *The Prince,* written in 1513, was unavailable in English until 1640, but as early as the 1580s Gabriel Harvey, a friend of the poet Edmund Spenser, can be found enthusiastically hailing its author as the apostle of modern pragmatism. "We are much beholden to Machiavel and others," said Bacon, "that write what men do, and not what they ought to do."

The mark of humanism

So the literary revival occurred in a society deeply torn and rife with tensions, uncertainties, and competing versions of order and authority, religion and status, sex and the self. The Elizabethan compromise was exactly that; the Tudor pretense that all the nation thought the same disguised the actual fragmentation of the old consensus under the strain of change. The new scientific knowledge proved both man's littleness and his power to command nature; against the Calvinist idea of man's helplessness pulled the humanist faith in his dignity, especially that conviction, derived from the reading of Seneca and so characteristic of the period, of man's constancy and fortitude, his heroic and almost divine capacity for self-determination. It was still possible for Elizabeth to hold these divergent tendencies together in a single, heterogeneous culture, but under her successors they would eventually fly apart. The philosophers speaking for the new century would be Francis Bacon, who argued for the gradual advancement of science through patient accumulation of experiments, and the skeptic Michel de Montaigne (his *Essais* translated from the French by John Florio, 1603), who denied that it was possible to formulate any general principles of knowledge.

Cutting across all of these was the persistence of popular habits of thought and expression. Both humanism and puritanism set themselves against vulgar ignorance and folk tradition, but, fortunately, neither could remain aloof for long from the robustness of popular taste. Sir Philip Sidney, in England's first neoclassical literary treatise, *The Defence of Poesie* (written *c.* 1578–1583, published 1595), candidly admitted that "the old song of Percy and Douglas" would move his heart "more than with a trumpet," and his *Arcadia* is a representative instance of the continual, fruitful cross-fertilization of genres in this period—the contamination of aristocratic pastoral with popular tale, the lyric with the ballad, comedy with romance, tragedy with satire, and poetry with prose. The language, too, was undergoing a rapid expansion that all classes contributed to and benefited from, sophisticated literature borrowing without shame the idioms of colloquial speech. Macbeth's allusion to heaven peeping "through the blanket of the dark" only became a problem in an age when tragic dignity implied politeness, when it was below the dignity of a tragic hero to mention so lowly an object as a blanket. The Elizabethans' ability to address themselves to several audiences simultaneously and to bring into relation opposed experiences, emphases, and worldviews invested their writing with complexity and power.

Influence of popular taste

ELIZABETHAN POETRY AND PROSE

English poetry and prose burst into sudden glory in the late 1570s. A decisive shift of taste toward a fluent artistry self-consciously displaying its own grace and sophistication was announced in the works of Spenser and Sidney. It was accompanied by an upsurge in literary production that came to fruition in the 1590s and 1600s, two decades of astonishing productivity by writers of every persuasion and calibre.

The groundwork was laid in the 30 years from 1550, a period of slowly increasing confidence in the literary competence of the language and tremendous advances in education, which for the first time produced a substantial English readership, keen for literature and possessing cultivated tastes. This development was underpinned by the technological maturity and accelerating output (mainly in pious or technical subjects) of Elizabethan printing. The Stationers' Company, which controlled the publication of books, was incorporated in 1557, and Richard Tottel's *Miscellany* (1557) revolutionized the relationship of poet and audience by making publicly available lyric poetry, which hitherto had circulated only among a courtly coterie. Edmund Spenser was the first considerable English poet deliberately to use print for the advertisement of his talents.

Tottel's *Miscellany*

Development of the English language. The prevailing opinion of the language's inadequacy, its lack of "terms" and innate inferiority to the eloquent classical tongues, was combated in the work of the humanists Thomas Wilson, Roger Ascham, and Sir John Cheke, whose treatises on rhetoric, education, and even archery argued in favour of an unaffected vernacular prose and a judicious attitude toward linguistic borrowings. Their stylistic ideals are attractively embodied in Ascham's educational tract *The Scholemaster* (1570), and their tonic effect on that particularly Elizabethan art, translation, can be felt in the earliest important examples, Sir Thomas Hoby's Castiglione (1561) and Sir Thomas North's Plutarch (1579). A further stimulus was the religious upheaval that took place in the middle of the century. The desire of Reformers to address as comprehensive an audience as possible—the bishop and the boy who follows the plough, as Tyndale put it—produced the first true classics of English prose: the reformed Anglican Book of Common Prayer (1549, 1552, 1559); John Foxe's *Actes and Monuments* (1563), which celebrates the martyrs, great and small, of English Protestantism; and the various English versions of Scripture, from William Tyndale's (1525), Miles Coverdale's (1535), and the Geneva Bible (1560) to the syncretic Authorized Version (1611). The latter's combination of grandeur and plainness is justly celebrated, even if it represents an idiom never spoken in heaven or on earth. Nationalism inspired by the Reformation motivated the historical chronicles of the capable and stylish Edward Hall (1548), who bequeathed to Shakespeare the tendentious Tudor interpretation of the 15th century, and of the rather less capable Raphael Holinshed (1577). John

Ponet's remarkable *Short Treatise of Politic Power* (1556) is a vigorous polemic against Mary Tudor, whom he saw as a papist tyrant.

In verse, Tottel's much reprinted *Miscellany* generated a series of imitations and, by popularizing the lyrics of Wyatt and Surrey, carried into the 1570s the tastes of the early Tudor court. The newer poets collected by Tottel and other anthologists include Nicholas Grimald, Richard Edwardes, George Turberville, Barnabe Googe, George Gascoigne, Sir John Harington, and many others, of whom Gascoigne is the most considerable. The modern preference for the ornamental manner of the next generation has eclipsed these poets, who continued the tradition of plain, weighty verse, addressing themselves to ethical and didactic themes and favouring the meditative lyric, satire, and epigram. But their taste for economy, restraint, and aphoristic density was, in the verse of Ben Jonson and Donne, to outlive the cult of elegance. The period's major project was *A Mirror for Magistrates* (1559; enlarged editions 1563, 1578, 1587), a collection of verse laments, by several hands, purporting to be spoken by participants in the Wars of the Roses and preaching the Tudor doctrine of obedience. The quality is uneven, but Thomas Sackville's "Induction" and Thomas Churchyard's *Legend of Shore's Wife* are distinguished, and the intermingling of history, tragedy, and political morality was to be influential on the drama.

Sidney and Spenser. With the work of Sidney and Spenser, Tottel's contributors suddenly began to look old-fashioned. Sir Philip Sidney epitomized the new Renaissance "universal man": a courtier, diplomat, soldier, and poet whose *Defence of Poesie* included the first considered account of the state of English letters. Sidney's treatise defends literature on the ground of its unique power to teach, but his real emphasis is on its delight, its ability to depict the world not as it is but as it ought to be. This quality of "forcefulness or *energia*" he himself demonstrated in his sonnet sequence of unrequited desire, *Astrophel and Stella* (written *c.* 1582, published 1591). His *Arcadia,* in its first version (written *c.* 1577–80), is a pastoral romance in which courtiers disguised as Amazons and shepherds make love and sing delicate experimental verses. The revised version (written *c.* 1580–84, published 1590), vastly expanded but abandoned in mid-sentence, added sprawling plots of heroism in love and war, philosophical and political discourses, and set pieces of aristocratic etiquette. Sidney was a dazzling and assured innovator whose pioneering of new forms and stylistic melody was seminal for his generation. His public fame was as an aristocratic champion of an aggressively Protestant foreign policy, but Elizabeth had no time for idealistic warmongering, and thus his fictions abound with situations of inhibition and withheld satisfactions—unresolved conflicts of desire against restraint, heroism against patience, rebellion against submission—that mirror his own position as an unsuccessful courtier.

Sidney's *Defence of Poesie*

Protestantism also loomed large in the life of Edmund Spenser. He enjoyed the patronage of the Earl of Leicester, who sought to advance militant Protestantism at court, and his poetic manifesto, *The Shepheardes Calender* (1579), covertly praised Archbishop Edmund Grindal, who had been suspended by Elizabeth for his Puritan sympathies. Spenser's masterpiece, *The Faerie Queene* (1590–1609), is an epic of Protestant nationalism in which the villains are infidels or papists, the hero is King Arthur, and the central value is married chastity.

Spenser's *Faerie Queene*

Spenser was one of the humanistically trained breed of public servants, and the *Calender,* an expertly crafted collection of pastoral eclogues, both advertised his talents and announced his epic ambitions, the exquisite lyric gift that it reveals being voiced again in the marriage poems *Epithalamion* (1595) and *Prothalamion* (1596). With *The Faerie Queene* he achieved the central poem of the Elizabethan period. Its form fuses the medieval allegory with the Italian romantic epic; its purpose was "to fashion a gentleman or noble person in virtuous and gentle discipline." The plan was for 12 books (six were completed), focusing on 12 virtues exemplified in the quests of 12 knights from the court of Gloriana, the Faerie Queene, a symbol for Elizabeth herself. Arthur, in quest of Gloriana's love, would appear in each book and come to exemplify Magnificence, the complete man. Spenser took the decorative chivalry of the Elizabethan court festivals and reworked it through a constantly shifting veil of allegory, so that the knight's adventures and loves build into a complex, multileveled portrayal of the moral life. The verse, a spacious and slow-moving nine-lined stanza, and archaic language frequently rise to an unrivaled sensuousness.

The Faerie Queene was a public poem, addressed to the Queen, and politically it echoed the hopes of the Leicester circle for government motivated by godliness and militancy. Spenser's increasing disillusion with the court and with the active life, a disillusion noticeable in the later books and in his bitter satire *Colin Clouts Come Home Againe* of 1591, voiced the fading of these expectations in the last decade of Elizabeth's reign, the beginning of that remarkable failure of political and cultural confidence in the monarchy. In the "Mutabilitie Cantos," melancholy fragments of a projected seventh book, Spenser turned away from the public world altogether, toward the ambiguous consolations of eternity.

The lessons taught by Sidney and Spenser in the cultivation of melodic smoothness and graceful refinement appear to good effect in the subsequent virtuoso outpouring of lyrics and sonnets. These are among the most engaging achievements of the age, though the outpouring was itself partly a product of frustration, as a generation trained to expect office or preferment but faced with courtly parsimony channeled its energies in new directions in search of patronage. For Sidney's fellow courtiers, pastoral and love lyric were also a means of obliquely expressing one's relationship with the Queen, of advancing a proposal or an appeal.

Elizabethan lyric. Virtually every Elizabethan poet tried his hand at the lyric; few, if any, failed to write one that is not still anthologized today. The fashion for interspersing prose fiction with lyric interludes, begun in the *Arcadia,* was continued by Robert Greene and Thomas Lodge (notably in the latter's *Rosalynde,* 1590, the source for Shakespeare's *As You Like It*), and in the theatres plays of every kind were diversified by songs both popular and courtly. Fine examples are in the plays of John Lyly, George Peele, Thomas Nashe, Ben Jonson, and Thomas Dekker (though all, of course, are outshone by Shakespeare's). The most important influence, though, was the outstanding richness of late Tudor music, in both the native tradition of expressive lute song, represented by John Dowland, and the complex Italianate madrigal newly imported by William Byrd and Thomas Morley. The foremost talent among lyricists, Thomas Campion, was composer as well as poet; his songs (four *Bookes of Ayres,* 1601–17) are unsurpassed for their clarity, harmoniousness, and rhythmic subtlety. Even the work of a lesser talent, however, such as Nicholas Breton, is remarkable for the suggestion of depth and poise in the slightest performances; the smoothness and apparent spontaneity of Elizabethan lyric conceals a consciously ordered and laboured artifice, attentive to decorum and rhetorical fitness. These are not personal but public pieces, intended for singing and governed by a Neoplatonic aesthetic in which delight is a means of addressing the moral sense, harmonizing the auditor's mind and attuning it to the discipline of reason and virtue. This necessitates a deliberate narrowing of scope—to the readily comprehensible situations of pastoral or Petrarchan hope and despair—and makes for a certain uniformity of effect, albeit an agreeable one. The lesser talents are well displayed in the miscellanies *The Phoenix Nest* (1593), *Englands Helicon* (1600), and *A Poetical Rhapsody* (1602).

Campion's songs

The sonnet sequence. The publication of Sidney's *Astrophel and Stella* in 1591 generated an equally extraordinary vogue for the sonnet sequence, Sidney's principal imitators being Samuel Daniel, Michael Drayton, Fulke Greville, Spenser, and Shakespeare, and his lesser, Henry Constable, Barnabe Barnes, Giles Fletcher, Thomas Lodge, Richard Barnfield, and many more. *Astrophel* had re-created the Petrarchan world of proud beauty and despairing lover in a single, brilliant stroke, though in English hands the preferred division of the sonnet into three quatrains and a

couplet gave Petrarch's contemplative form a more forensic turn, investing it with an argumentative terseness and epigrammatic sting. Within the common ground shared by the sequences there is much diversity. Only Sidney's endeavours to tell a story, the others being more loosely organized as variations focusing on a central (usually fictional) relationship. Daniel's *Delia* (1592) is eloquent and elegant, dignified and high-minded; Drayton's *Ideas Mirrour* (1594; much revised by 1619) rises to a strongly imagined, passionate intensity; Spenser's *Amoretti* (1595) celebrates, eccentrically, fulfilled sexual love achieved within marriage. Shakespeare's sonnets (published 1609) present a different world altogether, the conventions upside down, the lady no beauty but dark and treacherous, the loved one genuinely beyond considerations of sexual possession because he is a boy. The sonnet tended to gravitate toward correctness or politeness, and for most readers its chief pleasure must have been rhetorical, in its forceful pleading and consciously exhibited artifice, but under the pressure of Shakespeare's urgent metaphysical concerns, dramatic toughness, and shifting and highly charged ironies, the form's conventional limits were exploded.

Other poetic styles. Sonnet and lyric represent one tradition of verse within the period, that most conventionally delineated as Elizabethan, but the picture is complicated by the coexistence of other poetic styles in which ornament was distrusted or turned to different purposes; the sonnet was even parodied by Sir John Davies in his *Gulling Sonnets* (*c.* 1594) and by the Jesuit poet Robert Southwell. A particular stimulus to experiment was the variety of new possibilities made available by verse translation, from Richard Stanyhurst's extraordinary *Aeneid* (1582), in quantitative hexameter and littered with obscure or invented diction, and Sir John Harington's version of Ariosto's *Orlando furioso* (1591), with its Byronic ease and narrative fluency, to Christopher Marlowe's blank verse rendering of *Lucan's First Book* (published 1600), probably the finest Elizabethan translation.

Epyllion

The genre to benefit most from translation was the epyllion, or little epic. This short narrative in verse was usually on a mythological subject, taking most of its material from Ovid, either his *Metamorphoses* (English version by Arthur Golding, 1565–67) or his *Heroides* (English version by Turberville, 1567). This form flourished from Thomas Lodge's *Scillaes Metamorphosis* (1589) to Francis Beaumont's *Salmacis and Hermaphroditus* (1602) and is best represented by Marlowe's *Hero and Leander* (published 1598) and Shakespeare's *Venus and Adonis* (1593). Ovid's reputation as an esoteric philosopher left its mark on George Chapman's *Ovid's Banquet of Sense* (1595) and Drayton's *Endimion and Phoebe* (1595), in which the love of mortal for goddess becomes a parable of wisdom. But his real attraction was as an authority on the erotic, and most epyllia treat physical love with sophistication and sympathy, unrelieved by the gloss of allegory—a tendency culminating in John Marston's *The Metamorphosis of Pigmalion's Image* (1598), a poem that has shocked tender sensibilities. Inevitably, the shift of attitude had an effect on style: for Marlowe the experience of translating (inaccurately) Ovid's *Amores* meant a gain for *Hero and Leander* in terms of urbanity and, more important, wit.

With the epyllion comes a hint of the tastes of the following reign, and a similar shift of taste can be felt among those poets of the 1590s who began to modify the ornamental style in the direction of native plainness or classical restraint. An astute courtier like Sir John Davies might, in his *Orchestra* (1596) and *Hymns of Astraea* (1599), write confident panegyrics to the aging Elizabeth, but in Sir Walter Raleigh's "Eleventh Book of the Ocean to Cynthia," a kind of broken pastoral eclogue, praise of the Queen is undermined by an obscure but eloquent sense of hopelessness and disillusionment. For Raleigh the complimental manner seems to be disintegrating under the weight of disgrace and isolation at court; his scattered lyrics, notably that contemptuous dismissal of the court, "The Lie," often draw their resonance from the resources of the plain style. Another courtier whose writing suggests similar pressures is Fulke Greville, Lord Brooke. Greville's *Caelica* (published 1633) begins as a conventional sonnet sequence but gradually abandons Neoplatonism for pessimistic reflections on religion and politics. Other works in his sinewy and demanding verse include philosophical treatises and unperformed melodramas (*Alaham* and *Mustapha*) that have a sombre Calvinist tone, presenting man as a vulnerable creature inhabiting a world of unresolved contradictions:

> Oh wearisome condition of humanity!
> Born under one law, to another bound;
> Vainly begot, and yet forbidden vanity,
> Created sick, commanded to be sound.
>
> (*Mustapha,* chorus)

Greville was a friend of the Earl of Essex, whose revolt against Elizabeth ended in 1601 on the scaffold, and other poets on the edge of the Essex circle fueled the taste for aristocratic heroism and individualist ethics. George Chapman's masterpiece, his translation of Homer (1598), is dedicated to Essex, and his original poems are intellectual and recondite, often deliberately cultivating obscurities; his abstruseness is a means of restricting his audience to a worthy, understanding elite. Samuel Daniel, in his verse *Epistles* (1603) written to various noblemen, strikes a mean between plainness and compliment; his *Musophilus* (1599), dedicated to Greville, defends the worth of poetry but says there are too many frivolous wits writing. The cast of Daniel's mind is stoical, and his language is classically precise. His major project was a verse history of *The Civil Wars between the Two Houses of Lancaster and York* (1595–1609), and versified history is also strongly represented in the *Legends* (1593–1607), *Barons' Wars* (1596, 1603), and *Englands Heroicall Epistles* (1597) of Michael Drayton.

Satire

The form really to set its face against Elizabethan politeness was the satire. Satire was related to the complaint, of which there were notable examples by Daniel (*The Complaint of Rosamond,* 1592) and Shakespeare (*The Rape of Lucrece,* 1594), and these are dignified and tragic laments in supple verse, but the Elizabethans mistakenly held the term satire to derive from the Greek *satyros,* a satyr, and so set out to match their manner to their matter and make their verses snarl. In the works of the principal satirists, John Donne (five satires, 1593–98), Joseph Hall (*Virgidemiarum,* 1597–98), and John Marston (*Certaine Satyres* and *The Scourge of Villainy,* 1598), the denunciation of vice and folly repeatedly tips into invective, raillery, and sheer abuse. The versification of Donne's satires is frequently so rough as barely to be verse at all; Hall apologized for not being harsh enough, and Marston was himself pilloried in Ben Jonson's play *Poetaster* (1601) for using ridiculously difficult language. "Vex all the world," wrote Marston to himself, "so that thyself be pleased." The satirists popularized a new persona, that of the malcontent who denounces his society not from above but from within, and their continuing attraction resides in their self-contradictory delight in the world they profess to abhor and their evident fascination with the minutiae of life in court and city. They were enthusiastically followed by Everard Guilpin, Samuel Rowlands, Thomas Middleton, and Cyril Tourneur, and so scandalous was the flood of satires that in 1599 their printing was banned. Thereafter the form survived in Jonson's classically balanced epigrams and poems of the good life, but its more immediate impact was on the drama, in helping to create the vigorously skeptical voices that people *The Revenger's Tragedy* and *Hamlet.*

Prose styles. Description of the development of Elizabethan prose begins with the 1570s. Prose was easily the principal medium in the Elizabethan period, and, despite the mid-century uncertainties over the language's weaknesses and strengths—whether coined and imported words should be admitted; whether the structural modeling of English prose on Latin writing was beneficial or, as Bacon would complain, a pursuit of "choiceness of phrase" at the expense of "soundness of argument"—the general attainment of prose writing was uniformly high, as is often manifested in contexts not conventionally imaginative or "literary," such as tracts, pamphlets, and treatises. The obvious instance of such casual success is Richard Hakluyt's *Principall Navigations, Voiages, and*

Discoveries of the English Nation (1589; expanded 1598–1600), a massive collection of travelers' tales, of which some are highly accomplished narratives. William Harrison's gossipy, entertaining *Description of England* (1577), Philip Stubbes's excitable and humane social critique *The Anatomy of Abuses* (1583), Reginald Scot's anecdotal *Discovery of Witchcraft* (1584), and John Stow's invaluable *Survey of London* (1598) also deserve passing mention. William Kempe's account of his morris dance from London to Norwich, *Kempe's Nine Days' Wonder* (1600), has great charm.

Early prose fiction

The writers listed above all use an unpretentious style, enlivened with a vivid vocabulary; the early prose fiction, on the other hand, delights in ingenious formal embellishment at the expense of narrative economy. This runs up against preferences ingrained in the modern reader by the novel, but Elizabethan fiction is not at all novelistic and finds room for debate, song, and the conscious elaboration of style. The unique exception is George Gascoigne's "Adventures of Master F. J." (1573), a tale of thwarted love set in an English great house, which is the first success in English imaginative prose. Gascoigne's story has a surprising authenticity and almost psychological realism (it may be autobiographical), but even so it is heavily imbued with the influence of Castiglione.

The existence of an audience for polite fiction was signaled in the collections of stories imported from France and Italy by William Painter (1566), Geoffrey Fenton (1577), and George Pettie (1576). Pettie, who claimed not to care "to displease twenty men to please one woman," believed his readership was substantially female. There were later collections by Barnaby Rich (1581) and George Whetstone (1583); historically, their importance was as sources of plots for many Elizabethan plays. The direction fiction was to take was established by John Lyly's *Euphues: The Anatomy of Wit* (1578), which, with its sequel *Euphues and His England* (1580), set a fashion for an extreme rhetorical mannerism that came to be known as "euphuism." The priggish plot of *Euphues*—a rake's fall from virtue and his recovery—is but an excuse for a series of debates, letters, and speechifyings, thick with assonance, antithesis, parallelism, and balance and displaying a pseudoscientific learning. Lyly's style was to be successful on the stage, but in fiction its density and monotony are wearying. The other major prose work of the 1570s, Sidney's *Arcadia,* is no less rhetorical (Abraham Fraunce illustrated his handbook of style *The Arcadian Rhetoric,* 1588, almost entirely with examples from the *Arcadia*), but with Sidney rhetoric is in the service of psychological insight and an exciting plot. Dozens of imitations of *Arcadia* and *Euphues* followed from the pens of Robert Greene, Thomas Lodge, Anthony Munday, Emanuel Forde, and others; none has much distinction.

Prose was to be decisively transformed through its involvement in the bitter and learned controversies of the 1570s and '80s over the reform of the English Church and the problems the controversies raised in matters of authority, obedience, and conscience. The fragile ecclesiastical compromise threatened to collapse under the demands made by Elizabeth's more godly subjects for further reformation, and its defense culminated in Richard Hooker's *Of the Laws of Ecclesiastical Polity* (eight books, 1593–1662), the first English classic of serious prose. Hooker's

Writings on religious issues

is a monumental work, structured in massive and complex paragraphs brilliantly recreating the orotund style of Cicero. His air of maturity and detachment has recommended him to modern tastes, but no more than his opponents was he above the cut and thrust of controversy. On the contrary, his magisterial rhetoric was designed all the more effectively to fix blame onto his enemies, and even his account (in books VI–VIII) of the relationship of church and state was deemed too sensitive for publication in the 1590s.

More decisive for English fiction was the appearance of the "Martin Marprelate" tracts of 1588–90. These seven pamphlets argued the Puritan case but with an unpuritanical scurrility and created great scandal by hurling invective and abuse at Elizabeth's bishops with comical gusto. The bishops employed Lyly and Thomas Nashe to reply to Marprelate, and the consequence may be read in Nashe's prose satires of the following decade, especially *Piers Penniless His Supplication to the Devil* (1592), *The Unfortunate Traveller* (1594), and *Lenten Stuffe* (1599), the latter a mock encomium on red herring. Nashe's "extemporal vein" makes fullest use of the flexibility of colloquial speech and delights in nonsense, redundancy, and disconcerting shifts of tone, which demand an answering agility from the reader. His language is probably the most profusely inventive of all Elizabethan writers', and he even makes the low-life pamphlets of Robert Greene (1591–92), with their sensational tales from the underworld, look conventional. His only rival is Thomas Deloney, whose *Jack of Newbury* (1597), *The Gentle Craft* (1597–98), and *Thomas of Reading* (1600) are enduringly attractive for their depiction of the lives of ordinary citizens, interspersed with elements of romance, jest book, and folktale. Deloney's entirely convincing dialogue indicates how important for the development of a flexible prose must have been the example of a flourishing theatre in Elizabethan London. In this respect, as in so many others, the role of the drama was crucial.

ELIZABETHAN AND EARLY STUART DRAMA

Theatre and society. In the Elizabethan and early Stuart period the theatre was the focal point of the age. Public life was shot through with theatricality—monarchs ruled with ostentatious pageantry, rank and status were defined in a rigid code of dress—while on the stages the tensions and contradictions working to change the nation were embodied and played out. More than any other form, the drama addressed itself to the total experience of its society. Playgoing was inexpensive, and the playhouse yards were thronged with apprentices, fishwives, labourers, and the like, but the same play that was performed to citizen spectators in the afternoon would often be restaged at court by night. The drama's power to activate complex, multiple perspectives on a single issue or event resides in its sensitivity to the competing prejudices and sympathies of this diversely minded audience.

Moreover, the theatre was fully responsive to the developing technical sophistication of nondramatic literature. In the hands of Shakespeare the blank verse employed for translation by the Earl of Surrey became a medium infinitely mobile between extremes of formality and intimacy, while prose encompassed both the control of Hooker and the immediacy of Nashe. This was above all a spoken drama, glorying in the theatrical energies of language. And the stage was able to attract the most technically accomplished writers of its day because it offered, uniquely, a literary career with some realistic prospect of financial return. The decisive event was the opening of the first purpose-built London playhouse in 1576, and during the next 70 years some 20 theatres more are known to have operated. The quantity and diversity of plays they commissioned is little short of astonishing.

Humanism and popular taste in the theatre

Theatres in London and the provinces. So the London theatres were a meeting ground of humanism and popular taste. They inherited, on the one hand, a tradition of humanistic drama current at court, the universities, and the Inns of Court (collegiate institutions responsible for legal education). This tradition involved the revival of classical plays and attempts to adapt Latin conventions to English, particularly to reproduce the type of tragedy, with its choruses, ghosts, and sententiously formal verse, associated with Seneca (10 tragedies by Seneca in English translation appeared in 1581). A fine example of the type is *Gorboduc* (1561), by Thomas Sackville and Thomas Norton, a tragedy based on British chronicle history that draws for Elizabeth's benefit a grave political moral about irresponsible government. It is also the first English play in blank verse. On the other hand, all the professional companies performing in London continued also to tour in the provinces, and the stage was never allowed to lose contact with its roots in country show, pastime, and festival. The simple moral scheme that pitted virtues against vices in the mid-Tudor interlude was never entirely submerged in more sophisticated drama, and the "Vice," the tricksy villain of the morality play, survives,

in infinitely more amusing and terrifying form, in Shakespeare's *Richard III*. Another survival was the clown or fool, apt at any moment to step beyond the play's illusion and share jokes directly with the spectators. The intermingling of traditions is clear in two farces, Nicholas Udall's *Ralph Roister Doister* (1553) and the anonymous *Gammer Gurton's Needle* (1559), in which academic pastiche is overlaid with country game; and what the popular tradition did for tragedy is indicated in Thomas Preston's *Cambises, King of Persia* (*c.* 1560), a blood and thunder tyrant play with plenty of energetic spectacle and comedy. A third tradition was that of revelry and masques, practiced at the princely courts across Europe and preserved in England in the witty and impudent productions of the schoolboy troupes of choristers who sometimes played in London alongside the professionals. An early play related to this kind is the first English prose comedy, Gascoigne's *Supposes* (1566), translated from a reveling play in Italian. Courtly revel reached its apogee in England in the ruinously expensive court masques staged for James I and Charles I, magnificent displays of song, dance, and changing scenery performed before a tiny aristocratic audience and glorifying the king. The principal masque writer was Ben Jonson, the scene designer Inigo Jones.

Professional playwrights. The first generation of professional playwrights in England was known collectively as the "university wits." Their nickname identifies their social pretensions, but their drama was primarily middle class, patriotic, and romantic. Their preferred subjects were historical or pseudo-historical, mixed with clowning, music, and love interest. At times plot virtually evaporated; George Peele's *Old Wives' Tale* (*c.* 1595) and Nashe's *Summer's Last Will and Testament* (1600) are simply popular shows, charming medleys of comic turns, spectacle, and song. Peele was a civic poet, and his serious plays are bold and pageant-like; *The Arraignment of Paris* (1584) is a pastoral entertainment, designed to compliment Elizabeth. Robert Greene's speciality was comical histories, interweaving a serious plot set among kings with comic action involving clowns. In his *Friar Bacon and Friar Bungay* (1594) and *James IV* (1598) the antics of vulgar characters complement but also criticize the follies of their betters. Only John Lyly, writing for the choristers, endeavoured to achieve a courtly refinement. His *Gallathea* (1584) and *Endimion* (1591) are fantastic comedies in which courtiers, nymphs, and goddesses make rarefied love in intricate, artificial patterns, the very stuff of courtly dreaming.

The university wits

Christopher Marlowe. Outshining all these is Christopher Marlowe, who alone realized the tragic potential inherent in the popular style, with its bombast and extravagance. His heroes are men of towering ambition who speak blank verse of unprecedented (and occasionally monotonous) elevation, their "high astounding terms" embodying the challenge that they pose to the orthodox norms and limitations of the societies they disrupt. In *Tamburlaine the Great* (two parts, published 1590) and *Edward II* (*c.* 1591; published 1594) traditional political orders are overwhelmed by conquerors and politicians who ignore the boasted legitimacy of weak kings; *The Jew of Malta* (*c.* 1589; published 1633) studies the man of business whose financial acumen and trickery give him unrestrained power; *The Tragical History of Dr. Faustus* (*c.* 1593; published 1604) shows the overthrow of a man whose learning and atheism threaten even God. The main focus of all these plays is on the uselessness of society's moral and religious sanctions against pragmatic, amoral will. They patently address themselves to the anxieties of an age being transformed by new forces in politics, commerce, and science; indeed, the sinister, ironic prologue to *The Jew of Malta* is spoken by Machiavelli. In his own time Marlowe was damned as atheist, homosexual, and libertine, and his plays remain disturbing because his verse makes theatrical presence into the expression of power, enlisting the spectators' sympathies on the side of his gigantic villain-heroes. His plays thus present the spectator with dilemmas that can be neither resolved nor ignored, and they articulate exactly the divided consciousness of their time. There is a similar effect in *The Spanish Tragedy* (*c.* 1591), by Marlowe's friend Thomas Kyd, an early "revenge tragedy" in which the hero seeks justice for the loss of his son but, in an unjust world, can achieve it only by taking the law into his own hands. Kyd's use of Senecan conventions (notably a ghost impatient for revenge) in a Christian setting expresses a genuine conflict of values, making the hero's success at once triumphant and horrifying.

Shakespeare's works. Above all other dramatists stands William Shakespeare, a supreme genius whom it is impossible to characterize briefly. Shakespeare is unequaled as poet and intellect, but he remains elusive. His capacity for assimilation—what Keats called his "negative capability"—means that his work is comprehensively accommodating; every attitude or ideology finds its resemblance there, yet also finds itself subject to criticism and interrogation. In part, Shakespeare achieved this by the total inclusiveness of his aesthetic, by putting clowns in his tragedies and kings in his comedies, juxtaposing public and private, and mingling the artful with the spontaneous; his plays imitate the counterchange of values occurring at large in his society. The sureness and profound popularity of his taste enabled him to lead the English Renaissance without privileging or prejudicing any one of its divergent aspects, while as actor, dramatist, and shareholder in the Lord Chamberlain's players he was involved in the Elizabethan theatre at every level. His career (dated from 1589 to 1613) was exactly coterminous with the period of greatest literary flourishing, and only in his work are the total possibilities of the Renaissance fully realized.

The early histories. Shakespeare's early plays were principally histories and comedies. About a fifth of all Elizabethan plays were histories, but this was the genre that Shakespeare particularly made his own, dramatizing the whole sweep of English history from Richard II to Henry VII in two four-play sequences, an astonishing project carried off with triumphant success. The first sequence, comprising the three *Henry VI* plays and *Richard III* (1589–92), begins as a patriotic celebration of English valour against the French. But this is soon superseded by a mature, disillusioned understanding of the world of politics, culminating in the devastating portrayal of Richard III—probably the first "character," in the modern sense, on the English stage—who boasts in *Henry VI,* Part 3, that he can "set the murtherous Machevil to school." Ostensibly *Richard III* monumentalizes the glorious accession of the dynasty of Tudor, but its realistic depiction of the workings of state power insidiously undercuts such platitudes, and the appeal of Richard's quick-witted individuality is deeply unsettling, short-circuiting any easy moral judgments. The second sequence, *Richard II* (1595), *Henry IV* (two parts, 1596–98), and *Henry V* (1599), begins with the deposing of a bad but legitimate king and follows its consequences through two generations, probing relentlessly at the difficult questions of authority, obedience, and order that it raises. (The Earl of Essex' faction paid for a performance of *Richard II* on the eve of their ill-fated rebellion against Elizabeth.) In the *Henry IV* plays, which are dominated by the massive character of Falstaff and his roguish exploits in Eastcheap, Shakespeare intercuts scenes among the rulers with scenes among those who are ruled to create a multifaceted composite picture of national life at a particular historical moment. The tone of these plays, though, is increasingly pessimistic, and in *Henry V* a patriotic fantasy of English greatness is hedged around with hesitations and qualifications about the validity of the myth of glorious nationhood offered by the Agincourt story. Through all these plays runs a concern for the individual and his subjection to historical and political necessity, a concern that is essentially tragic and anticipates greater plays yet to come. Shakespeare's other history plays, *King John* (*c.* 1591) and *Henry VIII* (1613) approach similar questions through material drawn from John Foxe's *Actes and Monuments.*

History sequences

The early comedies. The early comedies share the popular and romantic forms used by the university wits but overlay them with elements of elegant courtly revel and a sophisticated consciousness of comedy's fragility and artifice. These are festive comedies, giving access to a

Festivity, sportiveness, and the role of nature

society vigorously and imaginatively at play. One group, *The Comedy of Errors* (*c.* 1589–94), *The Taming of the Shrew* (*c.* 1590–94), *The Merry Wives of Windsor* (*c.* 1597–1601), and *Twelfth Night* (1601), are comedies of intrigue, fast moving, often farcical, and placing a high premium on wit. A second group, *The Two Gentlemen of Verona* (*c.* 1592–93), *Love's Labour's Lost* (*c.* 1595), *A Midsummer Night's Dream* (*c.* 1595–96), and *As You Like It* (1599), have as a common denominator a journey to a natural environment, such as a wood or park, in which the restraints governing everyday life are released and the characters are free to remake themselves untrammeled by society's forms, sportiveness providing a space in which the fragmented individual may recover wholeness. All the comedies share a belief in the positive, health-giving powers of play, but none is completely innocent of doubts about the limits that encroach upon the comic space, and in the four plays that approach tragicomedy, *The Merchant of Venice* (*c.* 1596–97), *Much Ado About Nothing* (1598–99), *All's Well That Ends Well* (1602–03), and *Measure for Measure* (1604), festivity is in direct collision with the constraints of normality, with time, business, law, human indifference, treachery, and selfishness. These plays give greater weight to the less optimistic perspectives on society current in the 1590s, and their comic resolutions are openly acknowledged to be only provisional, brought about by manipulation, compromise, or the exclusion of one or more major characters. The unique play *Troilus and Cressida* (*c.* 1601–03) presents a kind of theatrical no-man's-land between comedy and tragedy, between satire and savage farce. Shakespeare's reworking of the Trojan War pits heroism against its parody in a way that voices fully the fin-de-siècle sense of man's confused and divided individuality.

The tragedies. The confusions and contradictions of Shakespeare's age find their highest expression in his tragedies. In these extraordinary achievements, all values, hierarchies, and forms are tested and found wanting, and all society's latent conflicts are activated. Shakespeare sets husband against wife, father against child, the individual against society; he uncrowns kings, levels the nobleman with the beggar, and interrogates the gods. Already in the early experimental tragedies *Titus Andronicus* (*c.* 1592–94), with its spectacular violence, and *Romeo and Juliet* (*c.* 1595), with its comedy and romantic tale of adolescent love, Shakespeare had broken away from the conventional Elizabethan understanding of tragedy as a twist of fortune to an infinitely more complex investigation of character and motive, and in *Julius Caesar* (1599) he begins to turn the political interests of the history plays into secular and corporate tragedy, as men fall victim to the unstoppable train of public events set in motion by their private misjudgments. In the major tragedies that follow, Shakespeare's practice cannot be confined to a single general statement that covers all cases, for each tragedy belongs to a separate category: revenge tragedy in *Hamlet* (1600), domestic tragedy in *Othello* (*c.* 1603–04), social tragedy in *King Lear* (1605), political tragedy in *Macbeth* (1606), and heroic tragedy in *Antony and Cleopatra* (1607). In each category Shakespeare's play is exemplary and defines its type; the range and brilliance of this achievement is staggering. The worlds of Shakespeare's heroes are collapsing around them, and their desperate attempts to cope with the collapse uncover the inadequacy of the systems by which they rationalize and justify their existence. The ultimate insight is Lear's irremediable grief over his dead daughter: "Why should a dog, a horse, a rat, have life,/And thou no breath at all?" Before the overwhelming suffering of these great and noble spirits, all consolations are void and all versions of order stand revealed as adventitious. The humanism of the Renaissance is punctured in the very moment of its greatest single product.

Investigation of character and motive

Shakespeare's later works. In his last period, Shakespeare's astonishingly fertile invention returned to experimentation. In *Coriolanus* (1608) he completed his political tragedies, drawing a dispassionate analysis of the dynamics of the secular state; in the scene of the Roman food riot (not unsympathetically depicted) that opens the play is echoed the Warwickshire enclosure riots of 1607. *Timon of Athens* (1607–08) is an unfinished spin-off, a kind of tragical satire. The last group of plays comprises the four romances, *Pericles* (*c.* 1607–08), *Cymbeline* (*c.* 1609–10), *The Winter's Tale* (*c.* 1610–11), and *The Tempest* (1611), which develop a long, philosophical perspective on fortune and suffering. (A final work, *The Two Noble Kinsmen,* 1613, was written in collaboration with John Fletcher.) In these plays Shakespeare's imagination returns to the popular romances of his youth and dwells on mythical themes—wanderings, shipwrecks, the reunion of sundered families, and the resurrection of people long thought dead. There is consolation here, of a sort, beautiful and poetic, but still the romances do not turn aside from the actuality of suffering, chance loss, and unkindness, and Shakespeare's subsidiary theme is a sustained examination of the nature of his own art, which alone makes these consolations possible. Even in this unearthly context a subtle interchange is maintained between the artist's delight in his illusion and his mature awareness of his own disillusionment.

Playwrights after Shakespeare. Shakespeare's perception of a crisis in public norms and private belief became the overriding concern of the drama until the closing of the theatres in 1642. The prevailing manner of the playwrights who succeeded him was realistic, satirical, and antiromantic, and their comedies and tragedies focused predominantly on those two symbolic locations, the city and the court, with their typical activities, the pursuit of wealth and power. "Riches and glory," wrote Sir Walter Raleigh, "Machiavel's two marks to shoot at," had become the universal aims, and this situation was addressed by both "city comedy" and "tragedy of state." Increasingly, it was on the stages that the rethinking of early Stuart assumptions took place.

Theme of the pursuit of wealth and power

On the one hand, in the works of Thomas Heywood, Thomas Dekker, John Day, Samuel Rowley, and others, the old tradition of festive comedy was reoriented toward the celebration of confidence in the dynamically expanding commercial metropolis. Heywood claimed to have been involved in some 200 plays, and they include fantastic adventures starring citizen heroes, spirited, patriotic, and inclined to a leveling attitude in social matters. His masterpiece, *A Woman Kilde with Kindnesse* (1603), is a middle-class tragedy. Dekker was a kindred spirit, best seen in his *Shoemakers' Holiday* (1599), a celebration of citizen brotherliness and Dick Whittington-like success, which nevertheless faces squarely up to the hardships of work, thrift, and the contempt of the great. On the other hand, the very industriousness that the likes of Heywood viewed with civic pride became in the hands of Ben Jonson, George Chapman, John Marston, and Thomas Middleton a sign of aggression, avarice, and anarchy, symptomatic of the sicknesses in society at large.

Ben Jonson. The crucial innovations in satiric comedy were made by Ben Jonson, Shakespeare's friend and nearest rival, who stands at the fountainhead of what has subsequently been the dominant modern comic tradition. His early plays, particularly *Every Man in His Humour* (1598) and *Every Man Out of His Humour* (1599), with their galleries of grotesques, scornful detachment, and rather academic effect, were patently indebted to the verse satires of the 1590s; they introduced to the English stage a vigorous and direct anatomizing of "the time's deformities," the language, habits, and humours of the London scene. Jonson began as a self-appointed social legislator, aristocratic, conservative, and authoritarian, outraged by a society given over to inordinate appetite and egotism and ambitious through his mammoth learning to establish himself as the privileged artist, the fearless and faithful mentor and companion to kings; but he was ill at ease with a court inclined in its masques to prefer flattery to judicious advice. Consequently the greater satires that followed are marked by their gradual accommodations with popular comedy and by their unwillingness to make their implied moral judgments explicit: in *Volpone* (1606) the theatrical brilliance of the villain easily eclipses the sordid legacy hunters whom he deceives; *Epicoene* (1609) is a noisy farce of metropolitan fashion and frivolity; *The Alchemist* (1610) exhibits the conjurings and deceptions

The London scene in Jonson's plays

of clever London rogues; and *Bartholomew Fair* (1614) draws a rich portrait of city life parading through the annual fair at Smithfield, a vast panorama of a complete society. In these plays, fools and rogues are indulged to the very height of their daring, forcing upon the audience both criticism and admiration; the strategy leaves the audience to draw its own conclusions while liberating Jonson's wealth of exuberant comic invention, virtuoso skill with plot construction, and mastery of a language tumbling with detailed observation of London's multifarious ephemera. After 1616 Jonson abandoned the stage for the court, but, finding himself increasingly disregarded, he made a hard-won return to the theatres. The most notable of his late plays are popular in style: *The New Inn* (1629), which has affinities with the Shakespearean romance, and *A Tale of a Tub* (1633), which resurrects the Elizabethan country farce.

Marston and Middleton. Of Jonson's successors in city comedy, Francis Beaumont, in *The Knight of the Burning Pestle* (1607), amusingly insults the citizenry while ridiculing their taste for romantic plays. John Marston adopts so sharp a satirical tone that his plays in this genre frequently border on tragedy. All values are mocked by Marston's bitter and universal skepticism; his city comedy *The Dutch Courtezan* (1604), set in London, quotes a defense of libertinism from Montaigne. His tragicomedy *The Malcontent* (1604) is remarkable for its wild language and sexual and political disgust; Marston cuts the audience adrift from the moorings of reason by a dizzying interplay of parody and seriousness. Only in the city comedies of Thomas Middleton was Jonson's moral concern with greed and self-ignorance bypassed, for Middleton accepts the pursuit of money as, inevitably, the sole human absolute and presents buying and selling, usury, law, and the wooing of rich widows as the dominant modes of social interaction. His unprejudiced satire touches the actions of citizen and gentleman with equal irony and detachment; the only operative distinction is between fool and knave, and the sympathies of the audience are typically engaged on the side of wit, with the resourceful prodigal and dexterous whore. His characteristic form, used in *Michaelmas Terme* (1605) and *A Tricke to Catch the Old-One* (1606), was intrigue comedy, which enabled him to portray his society dynamically, as a mechanism in which each sex and class pursues its own selfish interests. He was thus concerned less to characterize the individual in depth than to examine the inequalities and injustices of the world that cause him to behave as he does. *The Roaring Girle* (*c.* 1608) and *A Chaste Maid in Cheapside* (1613) are the only Jacobean comedies to rival the comprehensiveness of *Bartholomew Fair,* but their social attitudes are opposed to Jonson's; the misbehaviour that Jonson condemned morally as "humours" or affectation Middleton understands as the product of circumstance.

Social concerns in Middleton's tragedies

Middleton's social concerns are also powerfully operative in his great tragedies, *Women Beware Women* (*c.* 1621) and *The Changeling* (1622), in which the moral complacency of men of rank is shattered by the dreadful violence they themselves have casually set in train, proving the answerability of all men for their actions despite the exemptions claimed for privilege and status. The hand of heaven is even more explicitly at work in the overthrow of the aristocratic libertine D'Amville in Cyril Tourneur's *Atheist's Tragedie* (*c.* 1611). Here the breakdown of old codes of deference before a progressive middle-class morality is strongly in evidence, and in *The Revenger's Tragedy* (1607), now generally attributed to Middleton, a scathing attack on courtly dissipation is reinforced by complaints about inflation and penury in the countryside at large. For more traditionally minded playwrights, new anxieties lay in the corrupt and sprawling bureaucracy of the modern court and in the political eclipse of the nobility before incipient royal absolutism. In Jonson's *Sejanus* (1603) Machiavellian statesmen abound, while George Chapman's *Bussy d'Ambois* (1604) and *Conspiracy of Charles, Duke of Byron* (1608) drew on recent French history to chart the collision of the magnificent but redundant heroism of the old-style aristocrat, whose code of honour had outlived its social function, with pragmatic arbitrary monarchy; Chapman doubtless had the career and fate of Essex in mind. The classic tragedies of state are John Webster's, with their dark Italian courts, intrigue and treachery, spies, malcontents, and informers. His *White Divel* (1612), a divided, ambivalent play, elicits sympathy even for a vicious heroine, since she is at the mercy of her deeply corrupt society; and the heroine in *The Duchess of Malfi* (1623) is the one decent and spirited inhabitant of her world, yet her noble death cannot avert the fearfully futile and haphazard carnage that ensues. As so often on the Jacobean stage, the challenge to the male-dominated world of power was mounted through the experience of its women.

Early Stuart drama. In the early Stuart period signs of a more polite drama, such as would prevail after 1660, were already beginning to appear in the comedies of fashionable manners written by John Fletcher and James Shirley, but even these playwrights lampooned courtiers and their overbearing ways. The traditions of a socially and politically critical theatre were carried down to the Civil War in the tragedies of John Ford (*'Tis Pitty Shee's a Whore,* 1633) and Philip Massinger (*Believe as You List,* 1631) and in comedies by Massinger (*A New Way to Pay Old Debts,* 1624; *The City Madam,* 1632) and Richard Brome (*The Antipodes,* 1638), which continued to probe at the tensions that were soon completely to undermine the basis of Stuart government. The outbreak of fighting in 1642 brought about the closing of the playhouses, but this was not because of any hostility by dramatists to politics or to change; rather, the crisis in which they were embroiled was one that had been the drama's continuing preoccupation for three generations.

EARLY STUART POETRY AND PROSE

In the early Stuart period the failure of consensus was dramatically announced in the political collapse of the 1640s and in the growing sociocultural divergences of the immediately preceding years. While it was still possible for the theatres to address the nation very much as a single audience, the court, with the baroque, absolutist style it encouraged in painting, masque, and panegyric, was becoming increasingly remote from the country at large and was regarded with justifiable distrust. In fact, a growing separation between polite and vulgar literature was to dispel many of the characteristic strengths of Elizabethan writing. Simultaneously, long-term intellectual changes were beginning to impinge on the status of poetry and prose. Sidney's defense of poetry, which maintained that poetry depicted what was ideally rather than actually true, was rendered redundant by the loss of agreement over transcendent absolutes; the scientist, the Puritan with his inner light, and the skeptic differed equally over the criteria by which truth or meaning was to be established. From the circle of Lord Falkland at Great Tew, which included poets such as Edmund Waller, Thomas Carew, and Sidney Godolphin, William Chillingworth argued that it was unreasonable for any individual to force his opinions onto any other, while Thomas Hobbes reached the opposite conclusion (in his *Leviathan,* 1651), that all must be as the state pleases. In this context, the old idea of poetry as a persuader to virtue fell obsolete, and the century as a whole witnessed a massive transfer of energy into new literary forms, particularly into the rationally balanced couplet, the autobiography, and the novel. At the same time, these influences were neither uniform nor consistent; Hobbes might repudiate the use of metaphor as senseless and ambiguous, yet his own prose is frequently enlivened by half-submerged metaphors.

Emergence of new literary forms

The Metaphysical poets. Writers responded to these conditions in different ways, and in poetry three types of practice may broadly be distinguished, which have been coupled with the names of Spenser, Jonson, and Donne. John Donne heads the tradition that Samuel Johnson typified for all time as the Metaphysicals; what unites them as a group is less the violent yoking of unlike ideas to which Johnson objected than that they were all poets of personal and individual feeling, responding to their time's pressures privately or introspectively (this very privateness, of course, was new; the period in general experienced a

massive trend toward contemplative or devotional verse).

Donne. Donne has been taken to be the apex of the 16th-century tradition of plain poetry, and certainly the love lyrics of his that parade their cynicism, indifference, and libertinism pointedly invert and parody the conventions of Petrarchan lyric, though no less than the Petrarchans he courts admiration for his poetic virtuosity. A "great haunter of plays" in his youth, he is always dramatic; his verse cultivates "strong lines," dissonance, and colloquiality. Thomas Carew praised him for exiling from poetry the "train of gods and goddesses"; what fills it instead is a dazzling battery of language and argument drawn from science, law and trade, court and city. Donne is the first London poet: his early satires and elegies are packed with the busy metropolitan milieu, and the songs and sonnets, which include his best writing, with their kaleidoscope of contradictory attitudes, ironies, and contingencies, are authentic to the modern phenomenon of urban living. Donne treats experience as relative, a matter of individual point of view; the personality is multiple, quizzical, and inconsistent, eluding definition. His love poetry is that of the frustrated careerist. By inverting normal perspectives and making the mistress "all states, and all princes, I, nothing else is," he belittles the public world, defiantly asserting the superior validity of his private experience, and frequently he erodes the traditional dichotomy of body and soul, outrageously praising the mistress in language reserved for platonic or religious contexts. The defiance is complicated, however, by a recurrent conviction of personal unworthiness that culminates in the *Anniversaries* (1611–12), two long commemorative poems written on the death of a patron's daughter. These expand into the classic statement of Jacobean melancholy, an intense meditation on the vanity of the world and the collapse of traditional certainties. Donne would, reluctantly, find respectability in a church career, but even his religious poems are torn between the same tense self-assertion and self-abasement that mark his secular poetry.

Donne's influence. Donne's influence was vast; the taste for wit and conceits reemerged in dozens of minor lyricists, among them courtiers such as Aurelian Townshend, William Habington, and William Cartwright and religious poets such as Francis Quarles and Henry King. The only true Metaphysical, in the sense of a poet with genuinely philosophical pretensions, was Edward Herbert (Lord Herbert of Cherbury), important as an early proponent of religion formulated by the light of reason. Donne's most interesting imitators were the three major religious poets—George Herbert, with his practical piety and richly domestic world, who substituted for Donne's tortured selfhood a humane, meditative assurance; the Roman Catholic Richard Crashaw, whose hymns introduced the sensuous ecstasies and effusions of the continental baroque; and Henry Vaughan, with his hermetic naturalism and mystical raptures.

In the context of the Civil War, however, Vaughan's and Crashaw's introspection begins to look like retreat, and when the satires of John Cleveland and the lyrics of Abraham Cowley take the Donne manner to extremes of paradox and vehemence, it suggests a loss of control in the face of political and social traumas. The one poet for whom metaphysical wit became a strategy for enforcing accommodations between conflicting allegiances was Donne's

Marvell

outstanding heir, Andrew Marvell. Marvell's finest writing is taut, extraordinarily dense and precise, uniquely combining a cavalier lyric grace with puritanical economy of statement. It seems to have been done at the time of greatest strain, in about 1650–53, and under the patronage of Sir Thomas Fairfax, parliamentarian general but opponent of the King's execution, whose retirement from politics to his country estate Marvell accorded qualified praise in "Upon Appleton House." His lyrics are poems of the divided mind, sensitive to all the major conflicts of their society—body against soul, action against retirement, experience against innocence, Oliver Cromwell against the King—but Marvell sustains the conflict of irreconcilables through paradox and wit rather than attempting to decide or transcend it. In this situation, irresolution has become a strength; in a poem like "An Horatian Ode upon Cromwell's Return from Ireland," which weighs the claims of King Charles and Cromwell, the poet's reserve was the only effective way of confronting the unprecedented demise of traditional structures of politics and morality.

Jonson and the Cavalier poets. By contrast, the Jonsonian tradition was, broadly, that of social verse, written with a classical clarity and weight and deeply informed by ideals of civilized reasonableness, ceremonious respect, and inner self-sufficiency derived from Seneca; it is a poetry of publicly shared values and norms. Jonson's own verse was occasional; it addresses other individuals, distributes praise and blame, and promulgates sober and judicious ethical attitudes. His favoured forms were the ode, elegy, satire, epistle, and epigram, and they are always crafted as exactly articulated objects, achieving a classical symmetry and monumentality. For Jonson the plain style meant not colloquiality but labour, restraint, and control; a good poet had first to be a good man, and his verses lead his society toward an aristocratic ethic of gracious but responsible living. With the Cavalier poets who succeeded him, the element of urbanity and conviviality tended to loom larger; Robert Herrick was perhaps England's first poet to express impatience with the tediousness of country life. However, Herrick's "The Country Life" and "The Hock Cart" rival Jonson's "To Penshurst" as panegyrics to the Horatian ideal of the "good life," calm and retired, but Herrick's poems gain poignancy by their implied contrast with the disruptions of the Civil War. The courtiers Thomas Carew, Sir John Suckling, and Richard Lovelace developed a manner of ease and naturalness suitable to the world of gentlemanly pleasure in which they moved; Suckling's *A Session of the Poets* lists more than 20 wits then in town. The Cavalier poets were writing England's first vers de société, lyrics of compliments and casual liaisons, often cynical, occasionally obscene; this was a line to be picked up again after 1660, as was the heroic verse and attitudinizing drama of Jonson's successor as poet laureate, Sir William Davenant. A different contribution was the elegance and smoothness that came to be associated with Sir John Denham and Edmund Waller, whom Dryden named as the first exponents of "good writing." Waller's polite lyrics now seem rather insipid, but Denham's topographical poem "Cooper's Hill" (1641), a considerable work in its own right, is plainly an important precursor of the balanced Augustan couplet (as is the otherwise slight oeuvre of Lucius Cary, Viscount Falkland). The growth of Augustan gentility was further encouraged by work done on translations in mid-century, particularly by Sir Richard Fanshawe (*Il Pastor Fido,* 1647) and Thomas Stanley.

Continued influence of Spenser. Donne had shattered Spenser's leisurely ornamentation, and Jonson censured his archaic language, but the continuing regard for Spenser at this time was significant. Variants of the Spenserian stanza were used by the brothers Giles and Phineas Fletcher, the former in his long religious poem *Christs Victorie* (1610), which is also indebted to Josuah Sylvester's highly popular translations from the French Calvinist poet Guillaume du Bartas, the *Divine Weeks and Works* (1605). Similarly, Spenserian pastorals still flowed from the pens of William Browne (*Britannia's Pastorals,* 1613–16), George Wither (*The Shepherd's Hunting,* 1614), and Michael Drayton, who at the end of his life returned nostalgically to portraying an idealized Elizabethan golden age (*The Muses Elizium,* 1630). Nostalgia was a dangerous quality under the progressive and absolutist Stuarts; the taste for Spenser involved a respect for values—traditional, patriotic, and Protestant—that were popularly, if erroneously, linked with the Elizabethan past but thought to be disregarded by the new regime. These poets believed they had a spokesman at court in the heroic and promising Prince Henry, but his death in 1612 disappointed many expectations, intellectual, political, and religious, and this group in particular was forced further toward the puritanical position. Increasingly their pastorals and fervently Protestant poetry aligned them in opposition to a court of Cavalier wits and of suspiciously pro-Spanish and pro-Catholic sympathies in foreign affairs; so sharp became Wither's satires that he earned imprisonment and was lampooned by Ben Jonson in a court masque. The failure

Literary opposition at court

of the Stuarts to conciliate attitudes such as these was to be crucial to their inability to maintain the cohesion of the Elizabethan compromise in the next generation. The nearest affinities, both in style and substance, of John Milton's early poetry would be with the Spenserians; in *Areopagitica* (1644) Milton praised "our sage and serious poet Spenser" as "a better teacher than Scotus or Aquinas."

Effect of religion and science on early Stuart prose. Puritanism also had a powerful effect on early Stuart prose. The best-sellers of the period were godly manuals that ran to scores of editions, like Arthur Dent's *Plain Man's Pathway to Heaven* (25 editions by 1640) and Lewis Bayly's *Practice of Piety* (1611; some 50 editions followed), the two of which formed the meagre dowry of John Bunyan's first wife. Puritans preferred sermons in the plain style too, eschewing rhetoric for an austerely profitable treatment of doctrine, though equally some famous godly preachers, such as Henry Smith and Thomas Adams, believed it their duty to make the Word of God eloquent. The other shaping factor was the desire among scientists for a utilitarian prose that would accurately and concretely represent the relationship between words and things, without figurative luxuriance. This hope, repeatedly voiced in the 1640s and '50s, eventually bore fruit in the practice of the Royal Society (incorporated 1662), which decisively affected prose after the Restoration. Its impact on earlier prose, though, was limited; most early Stuart science was written in the baroque style.

Sir Francis Bacon

The impetus toward a scientific prose derived ultimately from Sir Francis Bacon, the towering intellect of the century, who charted a philosophical system well in advance of his generation and beyond his own powers to complete. In the *Advancement of Learning* (1605) and the *Novum Organum* (1620) Bacon visualized a great synthesis of knowledge, rationally and comprehensively ordered so that each discipline might benefit from the discoveries of the others. The two radical novelties of his scheme were his insight that there could be progress in learning, that the limits of knowledge were not fixed but could be pushed forward, and his inductive method, by which scientific principles were to be established by experimentation, beginning at particulars and working toward generalities, instead of working backward from preconceived systems. Bacon democratized knowledge at a stroke, removing the tyranny of authority and lifting scientific inquiry free of religion and ethics and into the domain of mechanically operating second causes (though he held that the perfection of the machine itself testified to God's glory). The implications for prose are contained in his statement in the *Advancement* that the preoccupation with words instead of matter was the first "distemper" of learning; his own prose, however, was far from plain. The level exposition of idea in the *Advancement* is underpinned by a tactful but firmly persuasive rhetoric; and the famous *Essayes* (1597; enlarged 1612, 1625) are shifting and elusive, teasing the reader toward unresolved contradictions and half-apprehended complications.

The *Essayes* are masterworks in the new Stuart genre of the prose of leisure, the reflectively aphoristic prose piece in imitation of the *Essais* of Montaigne. Lesser collections were published by Sir William Cornwallis (1600–01), Owen Felltham (1623), and Ben Jonson (his posthumous *Timber; or, Discoveries*). A related genre was the "character," a brief, witty description of a social or moral type, imitated from Theophrastus, and practiced first by Joseph Hall (*Characters of Vertues and Vices,* 1608) and later by Sir Thomas Overbury, John Webster, and Thomas Dekker. The best characters are John Earle's (*Microcosmographie,* 1628). Character-writing led naturally into the writing of biography; the chief practitioners of this genre were Thomas Fuller, who included brief sketches in *The Holy State* (1642; includes *The Profane State*), and Izaak Walton, the biographer of Donne, George Herbert, and Richard Hooker. Walton's hagiographies are entertaining, but he manipulated the facts shamelessly; his biographies seem lightweight when placed beside Fulke Greville's tragical and valedictory *Life of the Renowned Sir Philip Sidney* (*c.* 1610; published 1652). The major historical work of the period was Sir Walter Raleigh's unfinished *History of the World* (1614), with its rolling periods and sombre skepticism, written from the Tower during his disgrace. Raleigh's providential framework would recommend his *History* to Cromwell and Milton; King James found it "too saucy in censuring princes." Bacon's *History of the Raigne of King Henry the Seventh* (1622) belongs to a more secular, Machiavellian tradition, which valued history for its lessons in pragmatism.

Prose styles. The essayists and character writers initiated a reaction against the orotund flow of serious Elizabethan prose that has been variously described as metaphysical, anti-Ciceronian, or Senecan, but these terms are used vaguely to denote both the cultivation of a clipped, aphoristic prose style, curt to the point of obscurity, and a fashion for looseness, asymmetry, and open-endedness. The age's professional stylists were the preachers, and in the sermons of Lancelot Andrewes and John Donne the clipped style is used to crumble the preacher's exegesis into tiny, hopping fragments or to suggest a nervous, agitated restlessness. An extreme example of the loose style is Robert Burton's *Anatomy of Melancholy* (1621), a massive encyclopaedia of learning, pseudoscience, and anecdote strung around an investigation into human psychopathology. Burton's compendiousness, his fascination with excess, necessitated a style that was infinitely extensible; his successor was Sir Thomas Urquhart, whose translation of *Gargantua and Pantagruel* (1653) outdoes even Rabelais. In the *Religio Medici* (1635), *The Garden of Cyrus,* and *Hydriotaphia, Urne-buriall, or A discourse of the Sepulchrall Urnes Lately Found in Norfolk* (1658) of Sir Thomas Browne the loose style serves a mind delighting in paradox and unanswerable speculation, content with uncertainty because of its intuitive faith in ultimate assurance. Browne's majestic prose invests his confession of his belief and his antiquarian and scientific tracts alike with an almost Byzantine richness and melancholy.

These were all learned styles, Latinate and sophisticated, but the appearance in the 1620s of the first *corantos,* or courants (news books), generated by interest in the Thirty Years' War, heralded the great 17th-century shift from an elite to a mass readership, a change effected by the explosion of popular journalism that accompanied the political confusion of the 1640s. The search for new kinds of political order and authority generated an answering chaos of styles, as voices were heard that had hitherto been denied access to print. The radical ideas of educated political theorists like Thomas Hobbes and the republican James Harrington were advanced within the traditional decencies of polite (if ruthless) debate, but they spoke in competition with vulgar writers who deliberately breached the literary canons of good taste—Levellers, such as John Lilburne and Richard Overton, with their vigorously dramatic manner; Diggers, like Gerrard Winstanley with his call for a general *Law of Freedom* (1652); and Ranters, whose language and syntax were as disruptive as the libertinism they professed. The outstanding examples were Milton's tracts against the bishops (1641–42), which revealed an unexpected talent for scurrilous abuse and withering sarcasm. Milton's later pamphlets, on divorce, education, and free speech (*Areopagitica,* 1644) and in defense of tyrannicide (*The Tenure of Kings and Magistrates,* 1649), adopt a loosely Ciceronian sonorousness, but their language is plain and always intensely imaginative and absorbing.

Rise of popular journalism

Milton's view of the poet's role. Milton had a concept of the public role of the poet even more elevated, if possible, than Jonson's; he early declared his hope to do for his native tongue what "the greatest and choicest wits of Athens, Rome, or modern Italy" had done for theirs. But where Jonson's humanism had led him toward a classical absolutism, Milton's was crossed by a respect for the conscience acting in pursuance of those things that it, individually, knew were right; he wished to "contribute to the progress of real and substantial liberty; which is to be sought for not from without, but within." His early verse aligned him, poetically and politically, with the Spenserians: religious and pastoral odes; "Lycidas" (1637), a pastoral elegy that incidentally bewails the state of the church; and *Comus* (1634), a masque against "masquing," performed privately in the country and opposing a private

heroism in chastity and virtue to the courtly round of revelry and pleasure.

During the interregnum, between the execution of Charles I and the restoration of Charles II, Milton saw his role as the intellectual serving the state in a glorious cause; he devoted his energies to pamphleteering, and he became Oliver Cromwell's Latin secretary. But the republic of virtue failed to materialize; Milton's courageous voice was the last before the Restoration to propose *The Ready and Easy Way to Establish a Free Commonwealth* (1660), a desperate program for a permanent oligarchy of the puritan elect, intended to avert the return to royal slavery. His greatest achievements, *Paradise Lost, Paradise Regained,* and *Samson Agonistes,* did not appear until several years after the Restoration, but their roots are deep in the radical experience of the 1640s and '50s and in the ensuing transformations in politics and society. For Milton and his contemporaries, 1660 was a watershed that was to necessitate a complete rethinking of expectations and ideas and a corresponding reassessment of the literary language, traditions, and forms appropriate to the new age. (M.H.B.)

The Restoration

LITERARY REACTIONS TO THE POLITICAL CLIMATE

The restoration of Charles II in 1660 led many to a painful revaluation of the political hopes and millenarian expectations bred during two decades of civil war and republican government. With the return of an efficient censorship, ambitiously heterodox ideas in theology and politics that had found their way freely into print during the 1640s and '50s were once again denied publication. The experience of defeat needed time to be absorbed, and fresh strategies had to be devised to encounter the challenge of hostile times. Much caustic and libelous political satire was written during the reigns of Charles II and James II and (because printing was subject to repressive legal constrictions) circulated anonymously and widely in manuscript. Andrew Marvell, sitting as member of Parliament for Hull in three successive parliaments from 1659 to 1678, experimented energetically with this mode, and his *Last Instructions to a Painter* (written in 1667) achieves a control of a broad canvas and an alertness to apt detail and to the movement of masses of people that make it a significant forerunner of Alexander Pope's *Dunciad* (however divergent the two poets' political visions may be). Marvell also proved himself to be a dexterous, abrasive prose controversialist, comprehensively deriding the anti-Dissenter arguments of Samuel Parker (later bishop of Oxford) in *The Rehearsal Transpros'd* (1672, with a sequel in 1673) and providing so vivid an exposition of Whig suspicions of the restored monarchy's attraction to absolutism in *An Account of the Growth of Popery, and Arbitrary Government in England* (1677) that a reward of £100 was offered for revealing its author's identity.

Return of censorship

The defeated republicans. The greatest prose controversialist of the pre-1660 years, John Milton, did not return to that mode but, in his enforced retirement from the public scene, devoted himself to his great poems of religious struggle and conviction, *Paradise Lost* (1667) and *Paradise Regained* and *Samson Agonistes* (both 1671). Each, in its probing of the intricate ways in which God's design reveals itself in human history, can justly be read (in one of its dimensions) as a chastened but resolute response to the failure of a revolution in which Milton himself had placed great trust and hope.

Others of the defeated republicans set out to record their own or others' experiences in the service of what they called the "good old cause." Lucy Hutchinson, for example, composed, probably in the mid-1660s, her remarkable memoirs of the life of her husband, Colonel Hutchinson, the Parliamentarian commander of Nottingham during the Civil War. Edmund Ludlow, like Hutchinson one of the regicides, fled to Switzerland in 1660, where he compiled his own *Memoirs.* These were published only in 1698–99 after Ludlow's death, and the discovery in 1970 of part of Ludlow's own manuscript revealed that they were edited and rewritten by another hand before printing. Civil War testimony still had political applications in the last years of the century, but those who sponsored its publication judged that Ludlow's now old-fashioned, millenarian rhetoric should be suppressed in favour of a soberer commonwealthman's dialect. Some autobiographers themselves adjusted their testimony in the light of later developments. George Fox, the Quaker leader, for example, dictating his *Journal* to various amanuenses, dubiously claimed for himself an attachment to pacifist principles during the 1650s, whereas it was, in fact, only in 1661, in the aftermath of the revolution's defeat, that the peace principle became central to Quakerism. The *Journal* itself only reached print in 1694 (again, after its author's death) after revision by a group superintended by William Penn. Such caution suggests a lively awareness of the influence such a text could have in consolidating a sect's sense of its own identity and continuity.

Writings of the Nonconformists. John Bunyan's *Grace Abounding* (1666), written while he was imprisoned in Bedford jail for nonconformity with the Church of England, similarly relates the process of his own conversion for the encouragement of his local, dissenter congregation. It testifies graphically to the force, both terrifying and consolatory, with which the biblical word could work upon the consciousness of a scantily educated, but overwhelmingly responsive, 17th-century believer. The form of *Grace Abounding* has numerous precedents in spiritual autobiography of the period, but with *The Pilgrim's Progress* (the first part of which appeared in 1678) Bunyan found himself drawn into a much more novel experiment, developing an ambitious allegorical narrative when his intent had been to write a more conventionally ordered account of the processes of redemption. The resulting work (with its second part appearing in 1684) combines a careful exposition of the logical structure of the Calvinist scheme of salvation with a delicate responsiveness to the ways in which his experience of his own world (of the life of the road, of the arrogance of the rich, of the rhythms of contemporary speech) can be deployed to render with a new vividness the strenuous testing the Christian soul must undergo. His achievement owes scarcely anything to the literary culture of his time, but his masterpiece has gained for itself a readership greater than that achieved by any other English 17th-century work with the exception of the King James Bible. Two other of his works, though lesser in stature, are especially worth reading: *The Life and Death of Mr. Badman* (1680), which, with graphic local detail, remorselessly tracks the sinful temptations of everyday life, and *The Holy War* (1682), a grandiose attempt at religious mythmaking interlaced with contemporary political allusions.

John Bunyan

Richard Baxter, a Nonconformist cleric who, although enduring persecution after 1660, was by instinct and much of his practice a reconciler, published untiringly on religious issues. He wrote, soon after the death of his wife, the moving *Breviate* (1681), a striking combination of exemplary narrative and unaffectedly direct reporting of the nature of their domestic life. His finest work, however, is the *Reliquiae Baxterianae* (published, five years after his death, in 1696), an autobiography that is also an eloquent defense of the Puritan impulse in the 17th-century Christian tradition.

The voice of anti-Puritan reaction can be heard in Samuel Butler's extensive mock-heroic satire *Hudibras* (published in three installments between 1662 and 1678). This was a massively popular work, with an influence stretching well into the 18th century (when Samuel Johnson, for example, greatly admired it and William Hogarth illustrated some scenes from it). It reads partly as a consummately destructive act of revenge upon those who had usurped power in the previous two decades, but although it is easy to identify what *Hudibras* opposes, it is difficult to say what, if anything, it affirms. Although much admired by Royalist opinion, it shows no wish to celebrate the authority or person restored in 1660, and its brazenly undignified use of rhyming tetrameters mirrors, mocks, and lacerates rooted human follies far beyond the power of one political reversal to obliterate. A comparable sardonic disenchantment is apparent in Butler's shorter verse satires and in his incisive and densely argued collection of prose *Characters.*

Samuel Butler

Writings of the Royalists. Royalists also resorted to biography and autobiography to record their experiences of defeat and restoration. Three of the most intriguing are by women: Margaret, duchess of Newcastle's life of her husband (1667) and the memoirs of Ann, Lady Fanshawe, and of Anne, Lady Halkett (both written in the late 1670s but not published in a fairly complete form until, respectively, 1829 and 1875). But incomparably the richest account of those years is *The History of the Rebellion and Civil Wars in England* by Edward Hyde, earl of Clarendon. The work was begun in exile during the late 1640s and was revised and completed in renewed exile after Clarendon's fall from royal favour in 1667. Clarendon was a close adviser to two kings, and his intimacy with many of the key events is unrivaled. Though his narrative is inevitably partisan, the ambitious range of his analysis and his mastery of character portraiture make the *History* an extraordinary accomplishment. His autobiography, which he also wrote during his last exile, gravely chronicles the transformations of the gentry world between the 1630s and '60s.

Role of the Church of England

In 1660 feeling in the country ran strongly in favour of the Church of England, persecution having confirmed in many a deep affection for Anglican rites and ceremonies. The reestablished church, accepting for itself the role of staunch defender of kingly authority, tended to eschew the exploration of ambitious and controversial theological issues and devoted itself instead to expounding codes of sound moral conduct. It was an age of eminent preachers (including Robert South, Isaac Barrow, Edward Stillingfleet, and John Tillotson) and of keen interest in the art of preaching. In conscious reaction against the obscurantist dialects judged typical of the sects, a plain and direct style of sermon oratory was favoured. Thus, in his funeral sermon on Tillotson in 1694, Gilbert Burnet praised the Archbishop because he "said what was just necessary to give clear Ideas of things, and no more" and "laid aside all long and affected Periods."

MAJOR GENRES AND MAJOR AUTHORS OF THE PERIOD

A comparable preference for an unembellished and perspicuous use of language is apparent in much of the nontheological literature of the age. Thomas Sprat, in his propagandizing *History of the Royal Society of London* (1667), and with the needs of scientific discovery in mind, also advocated "a close, naked natural way of speaking, positive expressions, clear senses, a native easiness." Sprat's work and a series of books by Joseph Glanvill, beginning with *The Vanity of Dogmatizing* (1661), argued the case for an experimental approach to natural phenomena against both the old scholastic philosophy and general conservative prejudice. That a real struggle was involved can be seen from the invariably disparaging attitude of contemporary satires to the labours of the Royal Society's enthusiasts (see, for instance, Samuel Butler's "The Elephant in the Moon," probably written in 1670–71, and Thomas Shadwell's *The Virtuoso,* 1676)—a tradition to be sustained later by Swift and Pope. But evidence of substantial achievement for the new generation of explorers was being published throughout the period, in, for example, Robert Boyle's *Sceptical Chymist* (1661), Robert Hooke's *Micrographia* (1665), John Ray's *Historia Plantarum* (in three volumes, 1686–1704), and, above all, Isaac (later Sir Isaac) Newton's *Philosophiae Naturalis Principia Mathematica* (1687).

Chroniclers. The Restoration, in its turn, bred its own chroniclers. Anthony à Wood, the Oxford antiquarian, made in his *Athenae Oxonienses* (1691–92) the first serious attempt at an English biographical dictionary. His labours were aided by John Aubrey, whose own unsystematic but enticing manuscript notes on the famous have been published in modern times under the title *Brief Lives.* After 1688 secret histories of the reigns of Charles II and James II were popular, of which the outstanding instance, gossipy but often reliable, is the *Memoirs of the Count Grammont,* compiled in French by Anthony Hamilton and first translated into English in 1714. A soberer but still free-speaking two-volume *History of My Own Time* (published posthumously, 1724–34) was composed by the industrious Gilbert Burnet, bishop of Salisbury from 1689. In the last months of the life of the court poet John Wilmot, 2nd earl of Rochester, Burnet had been invited to attend him, and in *Some Passages of the Life and Death of John, Earl of Rochester* (1680) he offered a fascinating account of their conversations as the erstwhile rake edged toward a rapprochement with the faith he had spurned.

A sparer, more finely focused prose was written by George Savile, 1st marquess of Halifax, who, closely involved in the political fray for 35 years, but remaining distrustful of any simple party alignments, wrote toward the end of his life a series of thoughtful, wryly observant essays, including *The Character of a Trimmer* (circulated in manuscript in late 1684 or very early 1685), *A Letter to a Dissenter* (published clandestinely in 1687), and *A Character of King Charles the Second* (written after about 1688). He also composed for his own daughter *The Lady's New-Year's-Gift; or, Advice to a Daughter* (1688), in which he anatomizes, with a sombre but affectionate wit, the pitfalls awaiting a young gentlewoman in life, especially in marriage.

Diarists. Two great diarists are among the most significant witnesses to the development of the Restoration world. Both possessed formidably active and inquisitive intelligences. John Evelyn was a man of some moral rectitude and therefore often unenamoured of the conduct he observed in court circles; but his curiosity was insatiable, whether the topic in question happened to be Tudor architecture, contemporary horticulture, or the details of sermon rhetoric. Samuel Pepys, whose diary, unlike Evelyn's, covers only the first decade of the Restoration, was the more self-scrutinizing of the two, constantly mapping his own behaviour with an alert and quizzical eye. Though not without his own moral inhibitions and religious gravity, Pepys immersed himself more totally than Evelyn in the new world of the 1660s, and it is he who gives the more resonant and idiosyncratic images of the changing London of the time.

The court wits. Among the subjects for gossip in London the group known as the "court wits" held a special place. Their conduct of their lives provoked censure from many, but among them were poets of some distinction, who drew upon the example of gentlemen-authors of the preceding generation (especially Sir John Suckling, Abraham Cowley, and Edmund Waller, the last two of whom themselves survived into the Restoration and continued to write impressive verse). The court wits' best works are mostly light lyrics, for example, Sir Charles Sedley's "Not, Celia, that I juster am" or Charles Sackville, earl of Dorset's "Dorinda's sparkling wit, and eyes." One of their number, the previously mentioned John Wilmot, earl of Rochester, possessed, however, a wider range and richer talent. Though some of his surviving poetry is in the least ambitious sense occasional work, he also produced writing of great force and authority, including a group of lyrics (for example, "All my past life is mine no more" and "An age in her embraces past") that, in psychological grasp and limpid deftness of phrasing, are among the finest of the century. He also wrote the harsh and scornfully dismissive *Satire Against Reason and Mankind* (probably before 1676) and experimented ingeniously with various forms of verse satire on contemporary society. The most brilliant of these, *A Letter from Artemisia in the Town, to Chloë in the Country* (written about 1675), combines a shrewd ear for currently fashionable idioms with a Chinese box structure that masks the author's own thoughts. Rochester's determined use of strategies of indirection anticipates Swift's tactics as an ironist.

John Oldham, a young schoolmaster, received encouragement as a poet from Rochester. His career, like his patron's, was to be cut short by an early death (in 1683, at age 30); but of his promise there can be no doubt. His *Satires upon the Jesuits* (1679–81), written during the Popish Plot, makes too unrelenting use of a rancorous, hectoring tone, but his development of the possibilities (especially satiric) of the "imitation" form, already explored by Rochester in, for example, *An Allusion to Horace* (written 1675–76), earns him an honourable place in the history of a mode that Pope was to put to such dazzling use. His imitation of the ninth satire of Horace's first

book exemplifies the agility and tonal resource with which Oldham could adapt a classical original to, and bring its values to bear upon, Restoration experience.

A poet who found early popularity with Restoration readers is Charles Cotton, whose *Scarronides* (1664–65), travesties of books one and four of Virgil's *Aeneid,* set a fashion for poetical burlesque. He is valued today, however, for work that attracted less contemporary interest but was to be admired by Wordsworth, Coleridge, and Charles Lamb. The posthumous *Poems on Several Occasions* (1689) includes deft poetry of friendship and love written with the familiar, colloquial ease of the Cavalier tradition and carefully observed, idiosyncratically executed descriptions of nature. He also added a second part to his friend Izaak Walton's *Compleat Angler* in 1676. A writer whose finest work was unknown to his contemporaries, much of it having been published only during the 20th century, is the poet and mystic Thomas Traherne. Influenced by the Hermetic writings and the lengthy Platonic tradition, he wrote, with extreme transparency of style, out of a conviction of the original innocence and visionary illumination of infancy. His poetry, though uneven, contains some remarkable writing, but his richest achievements are perhaps to be found in the prose *Centuries of Meditations* (first published in 1908).

Dryden. A poetic accomplishment of quite another order is that of John Dryden. He was 29 years old when Charles II returned from exile, and little writing by him survives from before that date. But for the remaining 40 years of his life he was unwearyingly productive, responding to the challenges of an unstable world with great formal originality and a mastery of many poetic styles. He was profoundly a poet of the public domain, but the ways in which he addressed himself to the issues of the day varied greatly in the course of his career. Thus, his poem to celebrate the Restoration itself, *Astraea Redux* (1660), invokes Roman ideas of the return of a golden age under Augustus Caesar in order to encourage similar hopes for England's future; whereas in 1681 the Exclusion Crisis (the attempt to exclude Charles II's brother James, a Roman Catholic, from succeeding to the throne) drew from Dryden one of his masterpieces, *Absalom and Achitophel,* in which the Old Testament story of King David, through an ingenious mingling of heroic and satiric tones, is made to shadow and comment decisively upon the current political confrontation. Another of his finest inventions, *Mac Flecknoe* (written mid-1670s, published 1682), explores, through agile mock-heroic fantasy, the possibility of a world in which the profession of humane letters has been thoroughly debased through the unworthiness of its practitioners. The 1680s also saw the publication of two major religious poems: *Religio Laici or a Laymans Faith* (1682), in which he uses a plain style to handle calmly the basic issues of faith, and *The Hind and the Panther* (1687), in which an elaborate allegorical beast fable is deployed to trace the history of animosities between Anglicanism and Roman Catholicism. In the Revolution of 1688 Dryden stayed loyal to the Catholicism to which he had been converted a few years earlier and thus lost his public offices. Financial need spurred him into even more literary activity thereafter, and his last years produced immensely skilled translations of Juvenal, Persius, and Virgil and handsome versions of Boccaccio and Chaucer, as well as further fine original poetry.

Dryden's commentary on public life

Dryden was also, in Samuel Johnson's words, the father of English criticism. Throughout his career he wrote extensively on matters of critical precept and poetic practice. Such sustained effort for which there was no precedent presumed the possibility of an interested audience but also contributed substantially to the creation of one. His tone is consistently exploratory and undogmatic. He writes as a working author, with an eye to problems he has himself faced, and is skeptical of theoretical prescriptions that threaten to become straitjackets for the poet or the critic. His discussion of Ben Jonson's *Epicoene, or The Silent Woman* in *Of Dramatick Poesie, an Essay* (1668) is remarkable as the first extended analysis of an English play, and his *Discourse Concerning the Origin and Progress of Satire* (1693) and the preface to the *Fables Ancient and Modern* (1700) both contain detailed commentary of the highest order.

Dryden as critic

A contrary critical philosophy was espoused by Thomas Rymer, an adherent of the most rigid neoclassical notions of dramatic decorum, who surveyed the pre-1642 English drama in *Tragedies of the Last Age* (1678) and *A Short View of Tragedy* (1693) and found it wanting. His zealotry reads unattractively today, but Dryden was impressed by him, if disinclined to accept his judgments without protest. In due course the post-1660 playwrights were to find their own scourge in Jeremy Collier, whose *Short View of the Immorality and Profaneness of the English Stage* (1698) comprehensively indicted the Restoration stage tradition. The theoretical frame of Collier's tract is crude, but his strength lay in his dogged citation of evidence from published play texts, especially when the charge was blasphemy, a crime still liable to stiff penalties in the courts. Even so clever a man as William Congreve was left struggling when attempting to deny in print the freedoms he had allowed his wit.

Drama by Dryden and others. Characteristically, Dryden, as dramatist, experimented vigorously in all the popular stage modes of the day, exploring the possibilities of the rhymed heroic play in the 1660s and early 1670s and producing some distinguished tragic writing in *All for Love* (1677) and *Don Sebastian* (1689); but his greatest achievement, *Amphitryon* (1690), is a comedy. In this he was typical of his age. Though there were individual successes in tragedy (especially Thomas Otway's *Venice Preserved,* 1682, and Nathaniel Lee's *Lucius Junius Brutus,* 1680), the splendour of the Restoration theatre lies in its comic creativity. Several generations of dramatists contributed to that wealth. In the 1670s the most original work can be found in Sir George Etherege's *Man of Mode* (1676), William Wycherley's *Country-Wife* (1675) and *Plain-Dealer* (1676), and Aphra Behn's two-part *Rover* (1677, 1681). Commentary has often claimed to detect a disabling repetitiveness in even the best Restoration comic invention, but an attentive reading of *The Country-Wife* and *The Man of Mode* will reveal how firmly the two authors, close acquaintances, have devised dramatic worlds significantly dissimilar in atmosphere that set distinctive challenges for their players. The disturbed years of the Popish Plot produced comic writing of matching mood, especially in Otway's abrasive *Soldier's Fortune* (1680) and Lee's extraordinary variation on the Madame de La Fayette novella, *The Princess of Cleve* (1681–82). After the Revolution of 1688 a series of major comedies hinged on marital dissension and questions (not unrelated to contemporary political traumas) of contract, breach of promise, and the nature of authority. These include, in addition to *Amphitryon,* Thomas Southerne's *Wives Excuse* (1691), Sir John Vanbrugh's *Relapse* (1696) and *Provok'd Wife* (1697), and George Farquhar's *Beaux Stratagem* (1707). These years also saw the premieres of Congreve's four comedies and one tragedy, climaxing with his masterpiece, *The Way of the World* (1700), a brilliant combination of intricate plotting and incisively humane portraiture. The pressures brought upon society at home by continental wars against the French also began to make themselves felt, the key text here being Farquhar's *Recruiting Officer* (1706), in which the worlds of soldier and civilian are placed in suggestive proximity.

Creativity in comic Restoration theatre

After 1710 contemporary writing for the stage waned in vitality. The 18th century is a period of great acting and strong popular enthusiasm for the theatre, but only a few dramatists (Gay, Fielding, Goldsmith, and Sheridan) achieved writing of a quality to compete with their predecessors' best, and even a writer of Richard Brinsley Sheridan's undeniable resource produced in his best plays—*The Rivals* (1775), *The School for Scandal* (1777), and *The Critic* (1779)—work that seems more like a technically ingenious, but cautious, rearrangement of familiar materials than a truly innovative contribution to the corpus of English comic writing for the stage. A number of the Restoration masterpieces, however, continued to be performed well into the new century, and the influence of this comic tradition was also strongly apparent in satiric poetry and the novel in the decades that followed.

Locke. One other late 17th-century figure with a formidable influence in the 18th century demands consideration: the philosopher John Locke. His *Essay Concerning Human Understanding* (1690) rejects a belief in innate ideas and argues that the mind at birth is a tabula rasa. Experience of the world can only be accumulated through the senses, which are themselves prone to unreliability. The *Essay,* cautiously concerned to define the exact limits of what the mind can truly claim to know, threw exciting new light on the workings of human intelligence and stimulated further debate and exploration through the fertility of its suggestions—for example, about the way in which ideas come to be associated. Locke was equally influential on political thought. He came from Puritan stock and was closely linked during the Restoration with leading Whig figures, especially the most controversial of them all, the Earl of Shaftesbury. His *Two Treatises of Government* (published in 1690, but mainly written during the Exclusion Crisis 10 years earlier) asserts the right of resistance to unjust authority and, in the last resort, of revolution. To establish this he had to think radically about the origins of civil society, the mutual obligations of subjects and rulers, and the rights of property. The resulting work became the crucial reference point from which subsequent debate took its bearings.

The 18th century

PUBLICATION OF POLITICAL LITERATURE

The expiry of the Licensing Act in 1695 halted state censorship of the press. During the next 20 years there were to be 10 general elections. These two factors combined to produce an enormous growth in the publication of political literature. Senior politicians, especially Robert Harley, saw the potential importance of the pamphleteer in wooing the support of a wavering electorate, and numberless hack writers produced copy for the presses. Richer talents also played their part. Harley, for instance, instigated Daniel Defoe's industrious work on the *Review* (1704–13), which consisted, in essence, of a regular political essay defending, if often by indirection, current governmental policy. He also secured Jonathan Swift's polemical skills for contributions to *The Examiner* (1710–11). Swift's most ambitious intervention in the paper war, again overseen by Harley, was *The Conduct of the Allies* (1711), a devastatingly lucid argument against any further prolongation of the War of the Spanish Succession. Writers like Defoe and Swift did not confine themselves to straightforward discursive techniques in their pamphleteering but experimented deftly with mock forms and invented personae to carry the attack home. According to contemporary testimony, Defoe's *Shortest-Way with the Dissenters* (1702) so brilliantly sustained its impersonation of a High Church extremist, its alleged narrator, that it was at first mistaken for the real thing. This avalanche of political writing whetted the contemporary appetite for reading matter generally and, in the increasing sophistication of its ironic and fictional maneuvers, assisted in preparing the way for the astonishing growth in popularity of narrative fiction during the subsequent decades.

Contribution to political reviews

Political journalism. After Defoe's *Review* the great innovation in periodical journalism came with the achievements of Richard Steele and Joseph Addison in *The Tatler* (1709–11) and then *The Spectator* (1711–12). In a familiar, easily approachable style they tackled a great range of topics, from politics to fashion, from aesthetics to the development of commerce. They aligned themselves with those who wished to see a purification of manners after the laxity of the Restoration and wrote extensively, with descriptive and reformative intent, about social and family relations. Their political allegiances were Whig, and in their creation of Sir Roger de Coverley they painted a wry portrait of the landed Tory squire as likable, possessed of good qualities, but feckless and anachronistic. Contrariwise, they spoke admiringly of the positive and honourable virtues bred by a healthy, and expansionist, mercantile community. Addison, the more original of the two, was an adventurous literary critic who encouraged esteem for the ballad through his enthusiastic account of *Chevy-Chase,* wrote a thoughtful and probing examen of *Paradise Lost,* and hymned the pleasures of the imagination in a series of papers deeply influential on 18th-century thought. The success with which Addison and Steele established the periodical essay as a prestigious form can be judged by the fact that they were to have more than 300 imitators before the end of the century. The awareness of their society and curiosity about the way it was developing, which they encouraged in their eager and diverse readership, left its mark on much subsequent writing.

Major political writers. *Pope.* Alexander Pope contributed to *The Spectator* and moved for a time in Addisonian circles; but from about 1711 onward his more influential friendships were with Tory intellectuals. His early verse shows a dazzling precocity, his *Essay on Criticism* (1711) combining ambition of argument with great stylistic assurance and *Windsor-Forest* (1713) achieving an ingenious, late Stuart variation on the 17th-century mode of topographical poetry. The mock-heroic *Rape of the Lock* (final version published in 1714) is an astonishing feat, marrying a rich range of literary allusiveness and a delicately ironic commentary upon the contemporary social world with a potent sense of suppressed energies threatening to break through the civilized veneer. That he could also write successfully in a more plaintive mode is shown by "Eloisa to Abelard" (1717), which, modeled on Ovid's heroic epistles, enacts with moving force Eloisa's struggle to reconcile grace with nature, virtue with passion. But the prime focus of his labours between 1713 and 1720 was his energetically sustained and scrupulous translation of Homer's *Iliad* (to be followed by the *Odyssey* in the mid-1720s). From that decade onward his view of the transformations wrought in Robert Walpole's England by economic individualism and opportunism grew increasingly embittered and despairing. In this he was following a common Tory trend, epitomized most trenchantly by the writings of his friend, the politician Henry St. John, 1st Viscount Bolingbroke. Pope's *Essay on Man* (1733–34) was a grand systematic attempt to buttress the notion of a God-ordained, perfectly ordered, all-inclusive hierarchy of created things. But his most probing and startling writing of these years comes in the four *Moral Essays* (1731–35), the series of Horatian imitations, and the final four-book version of *The Dunciad* (1743), in which he turns to anatomize with outstanding imaginative resource the moral anarchy and perversion of once-hallowed ideals he sees as typical of the commercial society in which he must perforce live.

Pope's *Rape of the Lock*

Thomson, Prior, and Gay. James Thomson also sided with the opposition to Walpole, but his poetry sustained a much more optimistic vision. In *The Seasons* (first published as a complete entity in 1730 but then massively revised and expanded until 1746) Thomson meditated upon, and described with fascinated precision, the phenomena of nature. He brought to the task a vast array of erudition and a delighted absorption in the discoveries of post-civil war, especially Newtonian, science, from whose vocabulary he borrowed freely. The image he developed of man's relationship to, and cultivation of, nature provided a buoyant portrait of the achieved civilization and wealth that ultimately derive from them and that, in his judgment, contemporary England enjoyed. The diction of *The Seasons* has many Miltonian echoes. In *The Castle of Indolence* (1748) Thomson's model is Spenserian, and its wryly developed allegory lauds the virtues of industriousness and mercantile achievement.

A poet who, at his best, chose a less ambitious song to sing is Matthew Prior, a diplomat and politician of some distinction, who essayed graver themes in *Solomon on the Vanity of the World* (1718), a disquisition on the vanity of human knowledge, but who also wrote some of the most direct and coolly elegant love poetry of the period. Prior's principal competitor as a writer of light verse was John Gay, whose *Trivia: or, the Art of Walking the Streets of London* (1716) catalogues the dizzying diversity of urban life through a dexterous burlesque of Virgil's *Georgics.* His *Fables,* particularly those in the 1738 collection, contain sharp, subtle writing, and his work for the stage, especially in *The What D'Ye Call It* (1715), *Three Hours After Mar-*

riage (1717; written with John Arbuthnot and Pope), and *The Beggar's Opera* (1728), shows a sustained ability to breed original and vital effects from witty generic cross-fertilization.

Swift. Swift, who also wrote verse of high quality throughout his career, like Gay favoured octosyllabic couplets and a close mimicry of the movement of colloquial speech. His technical virtuosity allowed him to switch assuredly from poetry of great destructive force to the intricately textured humour of *Verses on the Death of Dr. Swift* (completed in 1732; published 1739) and to the delicate humanity of his poems to Stella. But his prime distinction is, of course, as the greatest prose satirist in the English language. His period as secretary to the distinguished man of letters, Sir William Temple, gave him the chance to extend and consolidate his reading, and his first major work, *A Tale of a Tub* (1704), deploys its author's learning to chart the anarchic lunacy of its supposed creator, a Grub Street hack, whose solipsistic "modern" consciousness possesses no respect for objectivity, coherence of argument, or inherited wisdom from Christian or classical tradition. Techniques of impersonation were central to Swift's art thereafter. The *Argument Against Abolishing Christianity* (1708), for instance, offers brilliant ironic annotations on the "Church in Danger" controversy through the carefully assumed voice of a "nominal" Christian. That similar techniques could be adapted to serve specific political goals is demonstrated by "The Drapier's Letters" (1724–25), part of a successful campaign to prevent the imposition of a new, and debased, coinage on Ireland. Swift had hoped for preferment in the English church, but his destiny lay in Ireland, and the ambivalent nature of his relationship to that country and its inhabitants provoked some of his most demanding and exhilarating writing—above all, *A Modest Proposal* (1729), in which the ironic use of an invented persona achieves perhaps its most extraordinary and mordant development. His most wide-ranging satiric work, however, is also his most famous, *Gulliver's Travels* (1726). Swift grouped himself with Pope and Gay in hostility to the Walpole regime and the Hanoverian court, and that preoccupation leaves its mark on this work. But *Gulliver's Travels* also hunts larger prey. At its heart is a radical critique of human nature in which subtle ironic techniques work to part the reader from any comfortable preconceptions and challenge him to rethink from first principles his notions of man.

Swift's major works

Shaftesbury and others. More consoling doctrine was available in the popular writings of Anthony Ashley Cooper, 3rd earl of Shaftesbury, which were gathered in his *Characteristicks of Men, Manners, Opinions, Times* (1711). Although Shaftesbury had been tutored by Locke, he dissented from the latter's rejection of innate ideas and posited that man is born with a moral sense that is closely associated with his sense of aesthetic form. The tone of Shaftesbury's essays is characteristically idealistic, benevolent, gently reasonable, and unmistakably aristocratic. His optimism was buffeted by Bernard de Mandeville, whose *Fable of the Bees* (1714–29), which includes "The Grumbling Hire" (1705), takes a closer look at early capitalist society than Shaftesbury was prepared to do. Mandeville stressed the indispensable role played by the ruthless pursuit of self-interest in securing society's prosperous functioning. He thus favoured an altogether harsher view of man's natural instincts than Shaftesbury did and used his formidable gifts as a controversialist to oppose the various contemporary hypocrisies, philosophical and theological, that sought to deny the truth as he saw it. He was, in his turn, the target of acerbic rebukes by, among others, William Law, John Dennis, and Francis Hutcheson. George Berkeley, who criticized both Mandeville and Shaftesbury, set himself against what he took to be the age's irreligious tendencies and the obscurantist defiance by some of his philosophical forbears of the truths of common sense. His *Treatise Concerning the Principles of Human Knowledge* (1710) and *Three Dialogues Between Hylas and Philonous* (1713) continued the 17th-century debates about the nature of human perception, to which Descartes and Locke had contributed. The extreme lucidity and elegance of his style contrast markedly with the more effortful, but intensely earnest, prose of Joseph Butler's *Analogy of Religion* (1736), which also seeks to confront contemporary skepticism and ponders scrupulously the bases of man's knowledge of his creator. In a series of works beginning with *A Treatise of Human Nature* (1739–40), David Hume identified himself as a key spokesman for ironic skepticism and probed uncompromisingly the human mind's propensity to work by sequences of association and juxtaposition rather than by reason. Edmund Burke's *Philosophical Enquiry into the Origin of Our Ideas of the Sublime and Beautiful* (1757) merged psychological and aesthetic questioning by hypothesizing that the spectator's or reader's delight in the sublime depended upon a sensation of pleasurable pain. An equally bold assumption about human psychology—in this case, that man is an ambitious, socially oriented, product-valuing creature—lies at the heart of Adam Smith's masterpiece of laissez-faire economic theory, *An Inquiry into the Nature and Causes of the Wealth of Nations* (1776).

THE NOVEL

The major novelists. *Defoe.* Such ambitious debates on society and human nature ran parallel with the explorations of a literary form finding new popularity with a large audience, the novel. Defoe, for example, fascinated by any intellectual wrangling, was always willing (amid a career of unwearying activity) to publish his own views on the matter currently in question, be it economic, metaphysical, educational, or legal. His lasting distinction, though earned in other fields of writing than the disputative, is constantly underpinned by the generous range of his curiosity. Only someone of his catholic interests could have sustained, for instance, the superb *Tour Thro' the Whole Island of Great Britain* (1724–27), a vivid, county-by-county review and celebration of the state of the nation. He brought the same diversity of enthusiasms into play in writing his novels. The first of these, *Robinson Crusoe* (1719), an immediate success at home and on the Continent, is a unique fictional blending of the traditions of Puritan spiritual autobiography with an insistent scrutiny of the nature of man as social creature and an extraordinary ability to invent a sustaining modern myth. *A Journal of the Plague Year* (1722) displays enticing powers of self-projection into a situation of which Defoe can only have had experience through the narrations of others, and both *Moll Flanders* (1722) and *Roxana* (1724) lure the reader into puzzling relationships with narrators the degree of whose own self-awareness is repeatedly and provocatively placed in doubt.

Defoe's major works

Richardson. The enthusiasm prompted by Defoe's best novels demonstrated the growing readership for innovative prose narrative. Samuel Richardson, a prosperous London printer, was the next major author to respond to the challenge. His *Pamela: or, Virtue Rewarded* (1740, with a less happy sequel in 1741), using (like all Richardson's novels) the epistolary form, tells a story of an employer's attempted seduction of a young servant woman, her subsequent victimization, and her eventual reward in virtuous marriage with the penitent exploiter. Its moral tone is self-consciously rigorous and proved highly controversial. Its main strength lies in the resourceful, sometimes comically vivid imagining of the moment-by-moment fluctuations of the heroine's consciousness as she faces her ordeal. Pamela herself is the sole letter writer, and the technical limitations are strongly felt, though Richardson's ingenuity works hard to mitigate them. But Pamela's frank speaking about the abuses of masculine and gentry power sounds the skeptical note more radically developed in Richardson's masterpiece, *Clarissa: or, the History of a Young Lady* (1747–48), which has a just claim to being considered the most reverberant and moving tragic fiction in the English novel tradition. *Clarissa* uses multiple narrators and develops a profoundly suggestive interplay of opposed voices. At its centre is the taxing soul debate and eventually mortal combat between the aggressive, brilliantly improvisatorial libertine Lovelace and the beleaguered Clarissa, maltreated and abandoned by her family but abiding sternly loyal to her own inner sense of probity. The tragic consummation that grows from this

involves an astonishingly ruthless testing of the psychological natures of the two leading characters. After such intensities, Richardson's final novel, *The History of Sir Charles Grandison* (1753–54), is perhaps inevitably a less ambitious, cooler work, but its blending of serious moral discussion and a comic ending ensured it an influence on his successors, especially Jane Austen.

Fielding. Henry Fielding turned to novel writing after a successful period as a dramatist, during which his most popular work had been in burlesque forms. His entry into prose fiction was also in that mode. *An Apology for the Life of Mrs. Shamela Andrews* (1741), a travesty of Richardson's *Pamela,* transforms the latter's heroine into a predatory fortune hunter who cold-bloodedly lures her booby master into matrimony. Fielding continued his quarrel with Richardson in *The History of the Adventures of Joseph Andrews* (1742), which also uses *Pamela* as a starting point but which, developing a momentum of its own, soon outgrows any narrow parodic intent. His hostility to Richardson's sexual ethic notwithstanding, Fielding was happy to build, with a calm and smiling sophistication, on the growing respect for the novel to which his antagonist had so substantially contributed. In *Joseph Andrews* and *The History of Tom Jones, a Foundling* (1749) Fielding openly brought to bear upon his chosen form a battery of devices from more traditionally reputable modes (including epic poetry, painting, and the drama). This is accompanied by a flamboyant development of authorial presence. Fielding the narrator buttonholes the reader repeatedly, airs critical and ethical questions for the reader's delectation, and urbanely discusses the artifice upon which his fiction depends. In the deeply original *Tom Jones* especially, this assists in developing a distinctive atmosphere of self-confident magnanimity and candid optimism. His fiction, however, can also cope with a darker range of experience. *The Life of Mr. Jonathan Wild the Great* (1743), for instance, uses a mock-heroic idiom to explore a derisive parallel between the criminal underworld and England's political elite, and *Amelia* (1751) probes with sombre precision images of captivity and situations of taxing moral paradox.

Authorial presence in Fielding's novels

Smollett. Tobias Smollett had no desire to rival Fielding as a formal innovator, and his novels consequently tend to be rather ragged assemblings of disparate incidents. But, although uneven in performance, all of them include extended passages of real force and idiosyncracy. His freest writing is expended on grotesque portraiture in which the human is reduced to fiercely energetic automatism. Smollett can also be a stunning reporter of the contemporary scene, whether the subject be a naval battle or the gathering of the decrepit at a spa. His touch is least happy when, complying too facilely with the gathering cult of sensibility, he indulges in rote-learned displays of emotionalism and good-heartedness. His most sustainedly invigorating work can perhaps be found in *The Adventures of Roderick Random* (1748), *The Adventures of Peregrine Pickle* (1751), and (an altogether more interesting encounter with the dialects of sensibility) *The Expedition of Humphry Clinker* (1771).

Sterne. An experiment of a radical and seminal kind is Laurence Sterne's *Tristram Shandy* (1759–67), which, drawing on a tradition of learned wit from Erasmus and Rabelais to Burton and Swift, provides a brilliant comic critique of the progress of the English novel to date. The focus of attention is shifted from the fortunes of the hero himself to the nature of his family, environment, and heredity, and dealings within that family offer repeated images of human unrelatedness and disconnection. Tristram, the narrator, is isolated in his own privacy and doubts how much, if anything, he can know certainly even about himself. Sterne is explicit about the influence of Lockean psychology on his writing, and the book, fascinated with the fictive energies of the imagination, is filled with characters reinventing or mythologizing the conditions of their own lives. It also draws zestful stimulus from a concern with the limitations of language, both verbal and visual, and teases an intricate drama out of Tristram's imagining of, and playing to, the reader's likely responses. Sterne's *Sentimental Journey Through France and Italy* (1768) similarly defies conventional expectations of what a travel book might be. An apparently random collection of scattered experiences, it mingles affecting vignettes with episodes in a heartier, comic mode, but coherence of imagination is secured by the delicate insistence with which Sterne ponders how the impulses of sentimental and erotic feeling are psychologically interdependent.

Minor novelists. The work of these five giants was accompanied by interesting experiments from a number of lesser novelists. Sarah Fielding, for instance, Henry's sister, wrote penetratingly and gravely about friendship in *The Adventures of David Simple* (1744, with a sequel in 1753). Charlotte Lennox in *The Female Quixote* (1752) and Richard Graves in *The Spiritual Quixote* (1773) responded inventively to the influence of Cervantes, also discernible in the writing of Fielding, Smollett, and Sterne. John Cleland's *Memoirs of a Woman of Pleasure* (known as *Fanny Hill;* 1748–49) chose a more contentious path; in his charting of a young girl's sexual initiation, he experiments with minutely detailed ways of describing the physiology of intercourse. In emphatic contrast, Henry Mackenzie's *Man of Feeling* (1771) offers an extremist, and rarefied, version of the sentimental hero, while Horace Walpole's *Castle of Otranto* (1765) somewhat laboriously initiated the vogue for Gothic fiction. William Beckford's *Vathek* (1786), Ann Radcliffe's *Mysteries of Udolpho* (1794), and Matthew Lewis' *Monk* (1796) are among the more distinctive of its successors. But the most engaging and thoughtful minor novelist of the period is Fanny Burney, who was also an evocative and self-revelatory diarist and letter writer. Her *Evelina* (1778) and *Camilla* (1796) in particular handle with independence of invention and emotional insight the theme of a young woman negotiating her first encounters with a dangerous social world.

POETS AND POETRY AFTER POPE

Eighteenth-century poetry after Pope produced nothing that can compete with achievements on the scale of *Clarissa* and *Tristram Shandy;* but much that was vital was accomplished. William Collins' *Odes on Several Descriptive and Allegoric Subjects* (1747), for instance, displays great technical ingenuity and a resonant insistence on the imagination and the passions as poetry's true realm. The odes also mine vigorously the potentiality of personification as a medium for poetic expression. In his *Elegy Written in a Country Churchyard* (1751), Thomas Gray revisited the terrain of such recent poems as Thomas Parnell's *Night-Piece on Death* (1722) and Robert Blair's poem *The Grave* (1743) and discovered a tensely humane eloquence far beyond his predecessors' powers. In later odes, particularly *The Progress of Poesy* (1757), Gray successfully sought close imitation of the original Pindaric form, even emulating Greek rhythms in English, while developing ambitious ideas about cultural continuity and renewal. Gray's fascination with the potency of primitive art (as evidenced in another great ode, *The Bard,* 1757) is part of a larger movement of taste, of which the contemporary enthusiasm for James Macpherson's alleged translations of Ossian (1760–63) is a further indicator.

Experimentation in poetic expression

Another eclectically learned and energetically experimental poet is Christopher Smart, whose renown rests largely on two poems. *Jubilate Agno* (written during confinement in various asylums between 1758/59 and 1763 but not published until 1939) is composed in free verse and experiments with applying the antiphonal principles of Hebrew poetry to English. *A Song to David* (1763) is a rhapsodic hymn of praise, blending enormous linguistic vitality with elaborate structural patterning. Both contain encyclopaedic gatherings of recondite and occult lore, numerous passages of which modern scholarship has yet to explicate satisfactorily, but the poetry is continually energized by minute alterations of tone, startling conjunctions of material, and a unique alertness to the mystery of the commonplace. Smart was also a superb writer of hymns, a talent in which his major contemporary rival was William Cowper in his *Olney Hymns* (1779). Both are worthy successors to the richly inventive work of Isaac Watts in the first half of the century. Elsewhere, Cowper can write with buoyant humour and satiric relaxation, as when, for instance, he

wryly observes from the safety of rural seclusion the evils of town life. But some of his most characterful poetry emerges from a painfully intense experience of withdrawal and isolation. His rooted Calvinism caused him periods of acute despair when he could see no hope of admission to salvation, a mood chronicled with grim precision in his masterly short poem *The Castaway* (written 1799). His most extended achievement is *The Task* (1785), an extraordinary fusion of disparate interests, working calmly toward religious praise and pious acceptance.

Burns. The 1780s brought publishing success to Robert Burns for his *Poems, Chiefly in the Scottish Dialect* (1786). Drawing on the precedents of Allan Ramsay and Robert Fergusson, Burns demonstrated how Scottish idioms and ballad modes could lend a new vitality to the language of poetry. Although born a poor tenant farmer's son, Burns had made himself well versed in English literary traditions, and his innovations were fully premeditated. His range is wide, from uninhibitedly passionate love songs to sardonic satires on moral and religious hypocrisy, of which the monologue *Holy Willie's Prayer* (written 1785) is an outstanding example. His work bears the imprint of the revolutionary decades in which he wrote, and recurrent in much of it are a joyful hymning of freedom, both individual and national, and an instinctive belief in the possibility of a new social order.

Goldsmith. Two other major poets, both of whom also achieved distinction in an impressive array of nondramatic modes, demand attention: Oliver Goldsmith and Samuel Johnson. Goldsmith's contemporary fame as a poet rested chiefly on *The Traveller* (1764), *The Deserted Village* (1770), and the incomplete *Retaliation* (1774). The last, published 15 days after his own death, is a dazzling series of character portraits in the form of mock epitaphs on a group of his closest acquaintances. *The Traveller,* a philosophical comparison of the differing national cultures of western Europe and the degrees of happiness their citizens enjoy, is narrated by a restless wanderer whose heart yet yearns after his own native land, where his brother still dwells. In *The Deserted Village* the experience is one of enforced exile, as an idealized village community is ruthlessly broken up in the interests of landed power. A comparable story of a rural idyll destroyed (though, this time, narrative artifice allows its eventual restoration) is at the centre of his greatly popular but tonally elusive novel, *The Vicar of Wakefield* (1766). He was also a deft and energetic practitioner of the periodical essay, contributing to at least eight journals between 1759 and 1773. His *Citizen of the World,* originally published in *The Public Ledger* in 1760–61, uses the device of a Chinese traveler whose letters home comment tolerantly but shrewdly on his English experiences. He also produced two stage comedies, one of which, *She Stoops to Conquer* (1773), is one of the few incontrovertible masterpieces of the theatre after the death of Farquhar in 1707.

Johnson's poetry and prose. Goldsmith belonged to the circle of a writer of still ampler range and outstanding intellect, Samuel Johnson. Pope recognized Johnson's poetical promise in *London* (1738), an invigorating reworking of Juvenal's third satire as a castigation of the decadence of contemporary Britain. His finest poem, *The Vanity of Human Wishes* (1749), also takes its cue from Juvenal, this time his 10th satire. It is a tragic meditation on the pitiful spectacle of human unfulfillment, which yet ends with an urgent prayer of Christian hope. But, great poet though he was, the lion's share of his formidable energies was expended on prose. From his early years in London he lived by his pen and gave himself unstintingly to satisfy the booksellers' demands. Yet he managed to sustain a remarkable coherence of ethical ambition and personal presence throughout his voluminous labours. His twice-weekly essays for *The Rambler* (1750–52), for instance, consistently show his powers at their fullest stretch, handling an impressive array of literary and moral topics with a scrupulous intellectual gravity and attentiveness. Many of the preoccupations of *The Vanity of Human Wishes* and the *Rambler* essays reappear in *Rasselas* (1759), which catalogues with profound resource the vulnerability of human philosophies of life to humiliation at the hands of life itself. His forensic brilliance can be seen in his relentless review of Soame Jenyns' *Free Inquiry into the Nature and Origin of Evil* (1757), which caustically dissects the latter's complacent attitude to human suffering, and his analytic capacities are evidenced at their height in the successful completion of two major projects, his innovative *Dictionary of the English Language* (1755) and the great edition of Shakespeare's plays (1765). His last years produced much political writing (including the humanely resonant *Thoughts on the Late Transactions Respecting Falkland's Islands,* 1771); the socially and historically alert *Journey to the Western Islands of Scotland,* 1775; and the consummate *Lives of the Poets,* 1779–81. The latter was the climax of 40 years' writing of poetical biographies, including the multifaceted *Account of the Life of Mr. Richard Savage* (1744). These last lives, covering the period from Cowley to the generation of Gray, show Johnson's mastery of the biographer's art of selection and emphasis and (together with the preface and notes to his Shakespeare edition) contain the most provocative critical writing of the century. Although his allegiances lay with neoclassical assumptions about poetic form and language, his capacity for improvisatory responsiveness to practice that lay outside the prevailing decorums should not be underrated. His final faith, however, in his own creative practice as in his criticism, was that the greatest art eschews unnecessary particulars and aims toward carefully pondered and ambitious generalization. The same creed was eloquently expounded by another member of the Johnson circle, Sir Joshua Reynolds, in his 15 *Discourses* (delivered to the Royal Academy between 1769 and 1790, but first published collectively in 1797).

Johnson as essayist, editor, and political writer

The other prime source of Johnson's fame, his reputation as a conversationalist of epic genius, rests on the detailed testimony of contemporary memorialists including Fanny Burney, Hester Lynch Piozzi, and Sir John Hawkins. But the key text is James Boswell's magisterial *Life of Samuel Johnson* (1791). This combines in unique measure a deep respect for its subject's ethical probity and resourceful intellect with a far from inevitably complimentary eye for the telling details of his personal habits and deportment. Boswell manifests rich dramatic talent and a precise ear for conversational rhythms in his re-creation, and orchestration, of the debates that lie at the heart of this great biography. Another dimension of Boswell's literary talent came to light in the 1920s and '30s when two separate hoards of unpublished manuscripts were discovered. In these he is his own subject of study. The 18th century had not previously produced much autobiographical writing of the first rank, though the actor and playwright Colley Cibber's flamboyant *Apology for the Life of Mr. Colley Cibber* (1740) and William Cowper's sombre *Memoir* (written about 1766, first published in 1816) are two notable exceptions. But the drama of Boswell's self-observations has a richer texture than either of these. In the *London Journal* especially (covering 1762–63, first published in 1950), he records the processes of his dealings with others and of his own self-imaginings with a sometimes unnerving frankness and a tough willingness to ask difficult questions of himself.

Boswell's *Life of Samuel Johnson*

Boswell narrated his experiences at the same time as, or shortly after, they occurred. Edward Gibbon, on the other hand, taking full advantage of hindsight, left in manuscript at his death six autobiographical fragments, all having much ground in common, but each telling a subtly different version of his life. Though he was in many ways invincibly more reticent than Boswell, Gibbon's successive explorations of his own history yet form a movingly resolute effort to see the truth clearly. These writings were undertaken after the completion of the great work of his life, *The History of the Decline and Fall of the Roman Empire* (1776–88). He brought to the latter an untiring dedication in the gathering and assimilation of knowledge, an especial alertness to evidence of human fallibility and failure, and a powerful ordering intelligence supported by a delicate sense of aesthetic coherence. His central theme—that the destruction of the Roman Empire was the joint triumph of barbarism and Christianity—is sustained with formidable ironic resource. (M.Co.)

The Romantic period

THE NATURE OF ROMANTICISM

As a term to cover the most distinctive writers who flourished in the last years of the 18th century and the first decades of the 19th, "Romantic" is indispensable but also a little misleading: there was no self-styled "Romantic movement" at the time, and the great writers of the period did not call themselves Romantics.

Many of the age's foremost writers thought that something new was happening in the world's affairs, nevertheless. Blake's affirmation in 1793 that "A new Heaven is begun . . . " was matched a generation later by Shelley's "The world's great age begins anew." "These, these shall give the world/Another heart, and other pulses" wrote Keats, referring to Rousseau and Wordsworth. Fresh ideals came to the fore: in particular the ideal of freedom, long cherished in England, was being extended to every range of human endeavour. As that ideal swept through Europe, it became natural to believe that the age of tyrants might soon end.

Role of individual feeling and thought

The feature most likely to strike a reader turning to the poets of the time after reading their immediate predecessors is the new role of individual feeling and thought. Where the main trend of 18th-century poetics had been to praise the general, to see the poet as a spokesman of society, addressing a cultivated and homogeneous audience and having as his end the conveyance of "truth," the Romantics found the source of poetry in the particular, unique experience. Blake's marginal comment on Sir Joshua Reynolds' *Discourses* expresses the position with characteristic vehemence: "to generalise is to be an idiot; to particularise is the alone distinction of merit." The poet was seen as an individual distinguished from his fellows by the intensity of his perceptions, taking as his basic subject matter the workings of his own mind. The implied attitude to an audience varied accordingly: although Wordsworth maintained that a poet did not write "for Poets alone, but for Men," for Shelley the poet was "a nightingale who sits in darkness and sings to cheer its own solitude with sweet sounds," and Keats declared "I never wrote one single line of Poetry with the least Shadow of public thought." Poetry was regarded as conveying its own truth; sincerity was the criterion by which it was to be judged. Provided the feeling behind it was genuine, the resulting creation must be valuable.

The emphasis on feeling—seen perhaps at its finest in the poems of Burns—was in some ways a continuation of the earlier "cult of sensibility"; and it is worth remembering that Pope praised his father as having known no language but the language of the heart. But feeling had begun to receive particular emphasis and is found in most of the Romantic definitions of poetry. Wordsworth called it "the spontaneous overflow of powerful feeling," and in 1833 John Stuart Mill defined "natural poetry" as "Feeling itself, employing Thought only as the medium of its utterance." It followed that the best poetry was that in which the greatest intensity of feeling was expressed, and hence a new importance was attached to the lyric. The degree of intensity was affected by the extent to which the poet's imagination had been at work; as Coleridge saw it, the imagination was the supreme poetic quality, a quasi-divine creative force that made the poet a godlike being. Romantic theory thus differed from the neoclassic in the relative importance it allotted to the imagination: Samuel Johnson had seen the components of poetry as "invention, imagination and judgement" but William Blake wrote: "One Power alone makes a Poet: Imagination, the Divine Vision." The judgment, or conscious control, was felt to be secondary; the poets of this period accordingly placed great emphasis on the workings of the unconscious mind, on dreams and reveries, on the supernatural, and on the childlike or primitive view of the world, this last being regarded as valuable because its clarity and intensity had not been overlaid by the restrictions of civilized "reason." Rousseau's sentimental conception of the "noble savage" was often invoked, and often by those who were ignorant that the phrase is Dryden's or that the type was adumbrated in the "poor Indian" of Pope's *Essay on Man.* A further sign of the diminished stress placed on judgment is the Romantic attitude to form: if poetry must be spontaneous, sincere, intense, it should be fashioned primarily according to the dictates of the creative imagination. Wordsworth advised a young poet, "You feel strongly; trust to those feelings, and your poem will take its shape and proportions as a tree does from the vital principle that actuates it." This organic view of poetry is opposed to the classical theory of "genres," each with its own linguistic decorum; and it led to the feeling that poetic sublimity was unattainable except in short passages.

Importance of the imagination

Hand in hand with the new conception of poetry and the insistence on a new subject matter went a demand for new ways of writing. Wordsworth and his followers, particularly Keats, found the prevailing poetic diction of the later 18th century stale and stilted, or "gaudy and inane," and totally unsuited to the expression of their perceptions. It could not be, for them, the language of feeling, and Wordsworth accordingly sought to bring the language of poetry back to that of common speech. His theories of diction have been allowed to loom too large in critical discussion: his own best practice very often differs from his theory. Nevertheless, when Wordsworth published his preface to *Lyrical Ballads* in 1800, the time was ripe for a change: the flexible diction of earlier 18th-century poetry had hardened into a merely conventional language and, with the notable exceptions of Blake and Burns, little first-rate poetry had been produced (as distinct from published) in Britain since the 1740s.

POETRY

Blake, Wordsworth, and Coleridge. Useful as it is to trace the common elements in Romantic poetry, there was little conformity among the poets themselves. It is misleading to read the poetry of the first Romantics—William Blake, Samuel Taylor Coleridge, and William Wordsworth, for example—as if it had been written primarily to express their feelings. Their concern was rather to change the intellectual climate of the age. Blake had been dissatisfied since boyhood with the current state of poetry and the drabness of contemporary thought. His early development of a protective shield of mocking humour with which to face a world in which science had become trifling and art inconsequential is visible in the satirical *An Island in the Moon* (written *c.* 1784–85); he then took the bolder step of setting aside sophistication in the visionary *Songs of Innocence* (1789). His desire for renewal encouraged him to view the outbreak of the French Revolution as a momentous event. Tradition has it that he openly wore the revolutionary red cockade in the streets of London. In powerful works, such as *The Marriage of Heaven and Hell* (1790–93) and *Songs of Experience* (1794), he attacked the hypocrisies of the age and the impersonal cruelties resulting from the dominance of analytic reason in contemporary thought. As it became clear that the ideals of the Revolution were not likely to be realized in his time, he renewed his efforts to revise his contemporaries' view of the universe and to construct a new mythology centred not in the God of the Bible but in Urizen, a figure of reason and law who he believed to be the true deity worshiped by his contemporaries. The story of Urizen's rise to provide a fortification against the chaos created by loss of a true human spirit was set out first in "Prophetic Books" such as *The First Book of Urizen* (1794) and then, more ambitiously, in the unfinished manuscript *Vala,* or *The Four Zoas,* written from about 1796 to about 1807.

Dissatisfaction with the intellectual climate

Later Blake shifted his poetic aim once more. Instead of attempting a narrative epic on the model of *Paradise Lost* he produced the more loosely organized visionary narratives of *Milton* (1804–08) and *Jerusalem* (1804–20) where, still using mythological characters, he portrayed the imaginative artist as the hero of society and forgiveness as the greatest human virtue.

Wordsworth and Coleridge, meanwhile, were exploring the implications of the Revolution more intricately. Neither could easily forget the excitement of the period immediately following its outbreak. Wordsworth, who lived in France in 1791–92 and fathered an illegitimate child

there, was distressed when, soon after his return, Britain declared war on the republic, dividing his allegiance. While sharing the horror of his contemporaries at the massacres in Paris, he knew at first hand the idealism and generosity of spirit to be found among the revolutionaries. For the rest of his career he was to brood on the implications of those events, trying to develop a view of humanity that would be faithful to his twin sense of the pathos of individual human fates and of the unrealized potentialities in humanity as a whole. The first factor emerges in his early manuscript poems "The Ruined Cottage" and "The Pedlar" (both to form part of the later *Excursion*); the second was developed from 1797, when he and his sister, Dorothy, with whom he was living in the west of England, were in close contact with Coleridge. Stirred simultaneously by Dorothy's immediacy of feeling, manifested everywhere in her *Journals* (written 1798–1803, published 1897), and by Coleridge's imaginative and speculative genius, he produced the poems collected in *Lyrical Ballads* (1798). The volume began with Coleridge's "Rime of the Ancient Mariner," continued with poems displaying delight in the powers of nature and the humane instincts of ordinary people, and concluded with the meditative "Lines written a few miles above Tintern Abbey," an attempt to set out his mature faith in nature and humanity.

His investigation of the relationship between nature and the human mind continued in the long autobiographical poem addressed to Coleridge and later entitled *The Prelude* (1805; revised continuously and published posthumously, 1850). Here he traced the value for a poet of having been a child "fostered alike by beauty and by fear" (in true Gothic style) by an upbringing in sublime surroundings. The poem also makes much of the work of memory, a theme that reaches its most memorable expression in the "Ode: Intimations of Immortality from Recollections of Early Childhood." In poems such as "Michael" and "The Brothers," by contrast, written for the second volume of *Lyrical Ballads* (1800), Wordsworth dwelt on the pathos and potentialities of ordinary lives.

Coleridge's poetic development during these years paralleled Wordsworth's. Having briefly brought together images of nature and the mind in "The Eolian Harp" (1796), he had devoted himself to more public concerns in poems of political and social prophecy, such as "Religious Musings" and "The Destiny of Nations." Becoming disillusioned with contemporary politics, however, and encouraged by Wordsworth, he turned back to the relationship between nature and the human mind. Poems such as "This Lime-Tree Bower My Prison," "The Nightingale," and "Frost at Midnight" (now sometimes called the "conversation poems" but entitled more accurately by Coleridge himself "Meditative Poems in Blank Verse") combine sensitive descriptions of nature with subtlety of psychological comment. "Kubla Khan" (1797, published 1816), a poem that Coleridge said came to him in "a kind of Reverie," opened a new vein of exotic writing, which he exploited further in the supernaturalism of "The Ancient Mariner" and the unfinished "Christabel." After his visit to Germany in 1798–99, however, renewed attention to the links between the subtler forces in nature and the human psyche bore fruit in letters and notebooks; simultaneously, his poetic output became sporadic. "Dejection: An Ode" (1802), another meditative poem, which first took shape as a letter to Sara Hutchinson, Wordsworth's sister-in-law, memorably describes the suspension of his "shaping spirit of Imagination."

Nature and the human mind in Coleridge's poetry

The work of both poets was directed back to national affairs during these years by the rise of Napoleon. In 1802 Wordsworth dedicated a number of sonnets to the patriotic cause. The death in 1805 of his brother John, who was serving as a sea captain, was a grim reminder that while he had been living in retirement as a poet others had been willing to sacrifice themselves for the public good. From this time the theme of duty was to be prominent in his poetry. His political essay *Concerning the Relations of Great Britain, Spain and Portugal . . . as Affected by the Convention of Cintra* (1809) agreed with Coleridge's periodical *The Friend* (1809–10) in deploring the decline of principle among statesmen. When *The Excursion* appeared in 1814 (the time of Napoleon's first exile), Wordsworth announced the poem as the central section of a longer projected work, *The Recluse.* This work was to be "a philosophical Poem, containing views of Man, Nature, and Society," and Wordsworth hoped to complete it by adding "meditations in the Author's own Person." The plan was not fulfilled, however, and *The Excursion* was left to stand in its own right as a poem of consolation for those who had been disappointed by the failure of French revolutionary ideals.

Both Wordsworth and Coleridge benefited from the advent in 1811 of the Regency, which brought a renewed interest in the arts. Coleridge's lectures on Shakespeare and literature became fashionable, his plays were briefly produced, and he gained further celebrity from the publication in 1816 of a volume of poems called *Christabel, Kubla Khan, A Vision: The Pains of Sleep. Biographia Literaria* (1817), the account of his own development, combined philosophy and literary criticism in a new way; the account was lastingly influential for the insights it contained. Coleridge settled at Highgate in 1816, and he was sought there as "the most impressive talker of his age" (in the words of the essayist William Hazlitt). His later religious writings made a considerable impact on the Victorians.

Coleridge's *Biographia Literaria*

Other poets of the early Romantic period. Several of the lesser poets of this generation were more popular in their own time. The somewhat insipid *Fourteen Sonnets* (1789) of William Lisle Bowles were received with enthusiasm by Coleridge and Wordsworth. Thomas Campbell is now chiefly remembered for his patriotic lyrics such as "Ye Mariners of England" and "The Battle of Hohenlinden" (1807) and for the critical preface to his *Specimens of the British Poets* (1819); Samuel Rogers has survived for his brilliant table talk (published 1856, after his death, as *Recollections of the Table-Talk of Samuel Rogers*), rather than for his poetry. One of the most popular poets of the day was Thomas Moore, whose *Irish Melodies* began to appear in 1807. His highly coloured Oriental fantasy *Lalla Rookh* (1817) was also immensely popular.

Robert Southey was closely associated with Wordsworth and Coleridge and was looked upon as a prominent member, with them, of the "Lake School" of poetry. His grandiose epic poems, such as *Thalaba the Destroyer* (1801) and *The Curse of Kehama* (1810), were successful in their own time, but his fame is based on his prose work—the vigorous *Life of Nelson* (1813), the *History of the Peninsular War* (1823–32), and his classic formulation of the children's tale "The Three Bears."

George Crabbe wrote poetry of another kind: his sensibility, his values, much of his diction, and his heroic couplet verse form belong very firmly to the 18th century. He differs from the earlier Augustans, however, in his subject matter, concentrating on realistic, unsentimental accounts of the life of the poor and the middle classes. He shows considerable narrative gifts in his collections of verse tales (in which he anticipates many short-story techniques) and great powers of description. His main works, *The Village* (1783), *The Borough* (1810), *Tales in Verse* (1812), and *Tales of the Hall* (1819), gained him great popularity in the earlier 19th century; after a long period of neglect he is widely recognized once more as a major poet.

The later Romantics: Shelley, Keats, and Byron. The poets of the next generation shared their predecessors' passion for liberty (now set in a new perspective by the Napoleonic wars) and were in a position to learn from their experiments. Percy Bysshe Shelley in particular was deeply interested in politics, coming early under the spell of the anarchistic views of William Godwin, whose *Enquiry Concerning Political Justice* had appeared in 1793. Shelley's revolutionary ardour, coupled with a zeal for the liberation of mankind and a passion for poetry, caused him to claim in his critical essay *A Defence of Poetry* (1821, published 1840) that "the most unfailing herald, companion, and follower of the awakening of a great people to work a beneficial change in opinion or institution, is poetry," and that poets are "the unacknowledged legislators of the world." This fervour burns throughout the early *Queen Mab* (1813), the long *Laon and Cythna*

Shelley's political zeal and passion for poetry

(retitled *The Revolt of Islam,* 1818), and the lyrical drama *Prometheus Unbound* (1820). Shelley saw himself at once as poet and prophet, as the fine "Ode to the West Wind" (1819) makes clear. Despite his firm grasp of practical politics, however, it is a mistake to look for concreteness in his poetry, where his concern is with subtleties of perception and with the underlying forces of nature: his most characteristic image is of sky and weather, of lights and fires. His poetic stance invites the reader to respond with similar outgoing aspiration. It adheres to the Rousseauistic belief in an underlying spirit in individuals, one truer to human nature itself than the behaviour evinced and approved by society. In that sense his material is transcendental and cosmic and his expression thoroughly appropriate. Possessed of great technical brilliance, he is, at his best, a poet of excitement and power.

John Keats, by contrast, was a poet so richly sensuous that his early work, such as *Endymion* (1818)—"a trial of my Powers of Imagination" he called it—could produce an over-luxuriant, cloying effect. As the program set out in his early poem "Sleep and Poetry" shows, however, Keats was also determined to discipline himself: even before February 1820, when he first began to cough blood, he may have known that he had not long to live, and he devoted himself to the expression of his vision with feverish intensity. He experimented with many kinds of poem: "Isabella" (published 1820), an adaptation of a tale by Boccaccio, is a tour de force of craftsmanship in its attempt to reproduce a medieval atmosphere. His epic fragment *Hyperion* (begun in 1818 and abandoned, published 1820; later begun again and published as *The Fall of Hyperion,* 1856) has a new spareness of imagery, but Keats soon found the style too Miltonic and decided to give himself up to what he called "other sensations." Some of these "other sensations" are found in the poems of 1819, Keats's annus mirabilis: "The Eve of St. Agnes" and the great odes, "To a Nightingale," "On a Grecian Urn," and "To Autumn." These, with the *Hyperion* poems, represent the summit of Keats's achievement, showing what has been called "the disciplining of sensation into symbolic meaning," the complex themes being handled with a concrete richness of detail. Study of his poems is incomplete without a reading of his superb letters, which show the full range of the intelligence at work in his poetry.

Keats's achievement

George Gordon, Lord Byron, who differed from Shelley and Keats in themes and manner, was at one with them in reflecting their shift toward "Mediterranean" themes. Having thrown down the gauntlet in his early poem *English Bards and Scotch Reviewers* (1809), in which he directed particular scorn at poems and poets of sensibility and sympathy and declared his own allegiance to Milton, Dryden, and Pope, he developed a poetry of dash and flair, in many cases with a striking hero. His two longest poems, *Childe Harold's Pilgrimage* (1812–18) and *Don Juan* (1819–24), his masterpiece, provided alternative personae for himself, the one a bitter and melancholy exile among the historic sites of Europe, the other a picaresque adventurer enjoying a series of amorous adventures. The gloomy and misanthropic vein was further mined in dramatic poems such as *Manfred* (1817) and *Cain* (1821), which helped to secure his reputation in Europe, but he is now remembered best for witty, ironic, and less portentous writings, such as *Beppo* (1818), in which he first used the ottava rima form. The easy, nonchalant, biting style developed there became a formidable device in *Don Juan* and in his satire on Southey, *The Vision of Judgment* (1822).

Minor poets of the later period. Of the lesser poets of this generation the best is undoubtedly John Clare, a Northamptonshire man of humble background. His natural simplicity and lucidity of diction, his intent observation, his almost classical poise, and the unassuming dignity of his attitude to life make him one of the most quietly moving of English poets. Thomas Lovell Beddoes, whose violent imagery and obsession with death and the macabre recall the Jacobean dramatists, represents an imagination at the opposite pole; considerable metrical virtuosity is displayed in the songs and lyrical passages from his oversensational tragedy *Death's Jest-Book* (begun 1825; published posthumously, 1850). Another minor writer who found inspiration in the 17th century was George Darley, some of whose songs from *Nepenthe* (1835) keep their place in anthologies. The comic writer Thomas Hood once enjoyed a great vogue but is now little read, although such poems of social protest as *The Song of the Shirt* (1843) and "The Bridge of Sighs," and the graceful *Plea of the Midsummer Fairies* (1827), are by no means negligible.

THE NOVEL: AUSTEN, SCOTT, AND OTHERS

At the turn of the century the Gothic mode, with its alternations between evocation of terror and appeal to sensibility, reached a peak of popularity with novels such as Ann Radcliffe's *Mysteries of Udolpho* (1794) and *The Italian* (1797) and Matthew Gregory Lewis' sensational *The Monk* (1796). These writers dealt with the supernatural and with human psychology far less adequately than did the poets, however, and appear to modern readers all the more shallow when compared with the great novelist Jane Austen. Her *Northanger Abbey* (begun in 1797; published posthumously, 1817) satirizes the Gothic novel, among other things, with complex irony; *Sense and Sensibility* (begun 1797; published 1811) mocks the contemporary cult of sensibility, while also displaying sympathetic understanding of the genuine sensitivities to which it appealed; *Pride and Prejudice* (begun 1796; published 1813) shows how sanity and intelligence can break through the opacities of social custom. The limitation suggested by her narrow range of settings and characters is illusory; working within these chosen limits, she observed and described very closely the subtleties of personal relationships, while also appealing to a sense of principle which, like Wordsworth and Coleridge, she believed to be threatened in a fragmenting and increasingly cosmopolitan society. These qualities come to full fruition in *Mansfield Park* (1814), *Emma* (1815), and *Persuasion* (1817). A master of dialogue, she wrote with economy, hardly wasting a word.

The nature of society in Scott's works

The underlying debate concerning the nature of society is reflected also in the novels of Sir Walter Scott. After his earlier success as a poet in such narrative historical romances as *The Lay of the Last Minstrel* (1805), *Marmion* (1808), and *The Lady of the Lake* (1810), he turned to prose and wrote more than 20 novels, several of which concerned heroes who were growing up, as he and his contemporaries had done, in a time of revolutionary turmoil. In the best, such as *Waverley* (1814), *Old Mortality* (1816), and *The Heart of Midlothian* (1818), he reconstructs the recent past of his country, Scotland, from still surviving elements. His stress on the values of gallantry, fortitude, and human kindness, along with his picture of an older society in which all human beings have a recognized standing and dignity, appealed to an England in which class divisions were exacerbated by the new industrialism. His historical romances were to inspire many followers in the emerging new nations of Europe. Thomas Love Peacock's seven novels, by contrast, are conversation pieces in which many of the pretensions of the day are laid bare in the course of witty, animated, and genial talk. *Nightmare Abbey* (1818) explores the extravagances of contemporary intellectualism and poetry; the more serious side of his satire is shown in such passages as Mr. Cranium's lecture on phrenology in *Headlong Hall* (1816). The Gothic mode was developed interestingly by Mary Wollstonecraft Shelley (the daughter of William Godwin), whose *Frankenstein; or, The Modern Prometheus* (1818) explores the horrific possibilities of new scientific discoveries, and Charles Robert Maturin, whose *Melmoth the Wanderer* (1820) has, with all its absurdity, a striking intensity. Among lesser novelists may be mentioned Maria Edgeworth, whose realistic didactic novels of the Irish scene inspired Scott; Susan Edmonstone Ferrier, a Scot with her own vein of racy humour; John Galt, whose *Annals of the Parish* (1821) is a minor classic; and James Hogg, remembered for his remarkable *Private Memoirs and Confessions of a Justified Sinner* (1824), a powerful story of Calvinism and the supernatural.

MISCELLANEOUS PROSE

The Romantic emphasis on individualism is reflected in much of the prose of the period, particularly in criti-

cism and the familiar essay. Among the most vigorous, forthright, and least mannered writing is that of William Hazlitt, an energetic, enthusiastic, and subjective critic whose most characteristic work is seen in his collections of lectures *On the English Poets* (1818) and *On the English Comic Writers* (1819) and in *The Spirit of the Age* (1825), a series of valuable portraits of his contemporaries. In *The Essays of Elia* (1823) and *The Last Essays of Elia* (1833) Charles Lamb, an even more personal essayist, projects, with apparent artlessness, a carefully managed portrait of himself—charming, whimsical, witty, sentimental, warm-hearted, nostalgic, and sociable; as his fine *Letters* show, however, he could on occasion produce mordant satire. Thomas De Quincey also appealed to the new interest in personal writing, producing a colourful account of his early experiences in *Confessions of an English Opium Eater* (1821, revised and enlarged in 1856). His unusual gift of evoking states of dream and nightmare is best seen in essays such as "The English Mail Coach" and "On the Knocking at the Gate in *Macbeth*" and in his various autobiographical pieces.

Hazlitt, Lamb, and De Quincey

Of writers who might be called surviving classicists, the most notable is Walter Savage Landor, whose detached, lapidary style is seen at its best in some brief lyrics and in a series of erudite *Imaginary Conversations,* which began to appear in 1824. The anti-Romantic point of view received its most pungent expression in the pages of the journals: the Whig quarterly *Edinburgh Review* (begun 1802), edited by Francis Jeffrey, was followed by its Tory rivals *The Quarterly Review* (begun 1809) and the monthly *Blackwood's Magazine* (begun 1817). Their criticism was by no means always unjust and summed up much contemporary opinion; but the reviewers were too willing to judge the new poetry by their own settled standards, missing what was genuinely innovative. In their attacks on many kinds of prejudice and abuse, on the other hand, they set a notable standard of fearless and independent journalism. Similar independence was shown by Leigh Hunt, whose outspoken journalism, particularly in his *Examiner* (begun 1808), was of considerable influence, and by William Cobbett, whose *Rural Rides* (collected in 1830 from his *Political Register*) gives a telling picture, in forceful and clear prose, of the English countryside of his day.

DRAMA

Despite the unusually strong interest in the theatre, little drama of note emerged at this time. Most major poets produced plays, but although Coleridge's *Osorio* and *Zapolya* were produced in 1813 and 1818, respectively, and Byron's *Marino Falieri* in 1821, the achievements were literary rather than dramatic. At the Theatre Royal in Drury Lane where the acting of John Philip Kemble and his sister, Sarah Siddons, had been much admired, the centre of attention from 1814 onward was Edmund Kean, whose impassioned performances captivated Keats, Hazlitt, and Byron and of whom Coleridge said "To see him act is like reading Shakespeare by flashes of lightning." Coleridge's lectures and notes, which, along with the essays of Lamb and Hazlitt, brought a psychological and historical approach to Shakespeare and other early dramatists, set new standards of dramatic criticism during the period.

(R.P.C.M./J.B.B.)

The Post-Romantic and Victorian eras

Self-consciousness was the quality that John Stuart Mill identified, in 1838, as "the daemon of the men of genius of our time." Introspection was inevitable in the literature of an immediately Post-Romantic period, and the age itself was as prone to self-analysis as were its individual authors. William Hazlitt's essays *The Spirit of the Age* (1825) were echoed by Mill's articles of the same title in 1831, by Thomas Carlyle's essays "Signs of the Times" (1829) and "Characteristics" (1831), and by Richard Henry Horne's *New Spirit of the Age* in 1844.

Introspection in the literature of the age

This persistent scrutiny was the product of an acute sense of change. Britain had emerged from the long war with France (1793–1815) as a great power and as the world's predominant economy. Visiting England in 1847, the American writer Ralph Waldo Emerson observed of the English that "The modern world is theirs. They have made and make it day by day."

This new status as the world's first urban and industrialized society was responsible for the extraordinary wealth, vitality, and self-confidence of the period. Abroad these energies expressed themselves in the growth of the British Empire. At home they were accompanied by rapid social change and fierce intellectual controversy.

The juxtaposition of this new industrial wealth with a new kind of urban poverty is only one of the paradoxes that characterize this long and diverse period. In religion the climax of the Evangelical revival coincided with an unprecedentedly severe set of challenges to faith. In politics a widespread commitment to economic and personal freedom was, nonetheless, accompanied by a steady growth in the power of the state. The prudery for which the Victorian Age is notorious in fact went hand in hand with an equally violent immoralism, seen, for example, in Algernon Charles Swinburne's poetry or the writings of the Decadents. Most fundamentally of all, the rapid change that many writers interpreted as progress inspired in others a fierce nostalgia. Enthusiastic rediscoveries of ancient Greece, Elizabethan England, and, especially, the Middle Ages by writers, artists, architects, and designers made this age of change simultaneously an age of active and determined historicism.

John Stuart Mill caught this contradictory quality, with characteristic acuteness, in his essays on Jeremy Bentham (1838) and Samuel Taylor Coleridge (1840). Every contemporary thinker, he argued, was indebted to these two "seminal minds." Yet Bentham, as the enduring voice of the Enlightenment, and Coleridge, as the chief English example of the Romantic reaction against it, held diametrically opposed views.

A similar sense of sharp controversy is given by Carlyle in *Sartor Resartus* (1833–34). An eccentric philosophical fiction in the tradition of Swift and Sterne, the book argues for a new mode of spirituality in an age that Carlyle himself suggests to be one of mechanism. Carlyle's choice of the novel form and the book's humour, generic flexibility, and political engagement point forward to distinctive characteristics of Victorian literature.

EARLY VICTORIAN LITERATURE: THE AGE OF THE NOVEL

Several major figures of English Romanticism lived on into this period. Coleridge died in 1834, De Quincey in 1859. Wordsworth succeeded Southey as poet laureate in 1843 and held the post until his own death seven years later. Posthumous publication caused some striking chronological anomalies. Shelley's "Defence of Poetry" was not published until 1840. Keats's letters appeared in 1848 and Wordsworth's *Prelude* in 1850.

Despite this persistence critics of the 1830s felt that there had been a break in the English literary tradition, which they identified with the death of Byron in 1824. The deaths of Jane Austen in 1817 and Sir Walter Scott in 1832 should perhaps have been seen as even more significant, for the new literary era has, with justification, been seen as the age of the novel.

Dickens. Charles Dickens first attracted attention with the descriptive essays and tales originally written for newspapers, beginning in 1833, and collected as *Sketches by "Boz"* (1836). On the strength of this volume Dickens contracted to write a historical novel in the tradition of Scott (eventually published as *Barnaby Rudge* in 1841). By chance his gifts were turned into a more distinctive channel. In February 1836 he agreed to write the text for a series of comic engravings. The unexpected result was *The Pickwick Papers* (1836–37), one of the funniest novels in English literature. By July 1837 sales of the monthly installments exceeded 40,000 copies. Dickens' extraordinary popular appeal and the enormous imaginative potential of the Victorian novel were simultaneously established.

The chief technical features of Dickens' fiction were also formed by this success. Serial publication encouraged the use of multiple plot and required that each episode be individually shaped. At the same time it produced an unprecedentedly close relationship between author and

Serial publication of Dickens' work

reader. Part dramatist, part journalist, part mythmaker, and part wit, Dickens took the picaresque tradition of Smollett and Fielding and gave it a Shakespearean vigour and variety.

His early novels have been attacked at times for sentimentality, melodrama, or shapelessness. They are now increasingly appreciated for their comic or macabre zest and their poetic fertility. *Dombey and Son* (1846–48) marks the beginning of Dickens' later period. He thenceforth combined his gift for vivid caricature with a stronger sense of personality, designed his plots more carefully, and used symbolism to give his books greater thematic coherence. Of the masterpieces of the next decade, *David Copperfield* (1849–50) uses the form of a fictional autobiography to explore the great Romantic theme of the growth and comprehension of the self. *Bleak House* (1852–53) addresses itself to law and litigiousness, *Hard Times* (1854) is a Carlylian defense of art in an age of mechanism, and *Little Dorrit* (1855–57) dramatizes the idea of imprisonment, both literal and spiritual. Two great novels, both involved with issues of social class and human worth, appeared in the 1860s: *Great Expectations* (1860–61) and *Our Mutual Friend* (1864–65). His final book, *The Mystery of Edwin Drood* (published posthumously, 1870), was left tantalizingly uncompleted at the time of his death.

Thackeray, Gaskell, and others. Unlike Dickens, William Makepeace Thackeray came from a wealthy and educated background. The loss of his fortune at age 22, however, meant that he too learned his trade in the field of sketch writing and occasional journalism. His early fictions were published as serials in *Fraser's Magazine* or as contributions to the great Victorian comic magazine *Punch* (founded 1841). For his masterpiece, *Vanity Fair* (1847–48), however, he adopted Dickens' procedure of publication in monthly parts. Thackeray's satirical acerbity is here combined with a broad narrative sweep, a sophisticated self-consciousness about the conventions of fiction, and an ambitious historical survey of the transformation of English life in the years between the Regency and the mid-Victorian period. His later novels never match this sharpness. *Vanity Fair* was subtitled "A Novel Without a Hero." Subsequently, it has been suggested, a more sentimental Thackeray wrote novels without villains.

Elizabeth Gaskell began her career as one of the "Condition of England" novelists of the 1840s, responding like Frances Trollope, Benjamin Disraeli, and Charles Kingsley to the economic crisis of that troubled decade. *Mary Barton* (1848) and *Ruth* (1853) are both novels about social problems, as is *North and South* (1854–55), although, like her later work, this book also has a psychological complexity that anticipates George Eliot's novels of provincial life.

Variety of subgenres

Political novels, religious novels, historical novels, sporting novels, Irish novels, crime novels, and comic novels all flourished in this period. The years 1847–48, indeed, represent a pinnacle of simultaneous achievement in English fiction. In addition to *Vanity Fair, Dombey and Son,* and *Mary Barton,* they saw the completion of Disraeli's trilogy of political novels—*Coningsby* (1844), *Sybil* (1845), and *Tancred* (1847)—and the publication of first novels by Anne, Charlotte, and Emily Brontë; Charles Kingsley; and Anthony Trollope. For the first time literary genius appeared to be finding its most natural expression in prose fiction, rather than in poetry or drama. By 1853 the poet Arthur Hugh Clough would concede that "the modern novel is preferred to the modern poem."

The Brontës. In many ways, however, the qualities of Romantic verse could be absorbed, rather than simply superseded, by the Victorian novel. This is suggested clearly by the work of the Brontë sisters. Growing up in a remote but cultivated vicarage in Yorkshire, they invented, as children, the imaginary kingdoms of Angria and Gondal. These inventions supplied the context for many of the poems in their first, and pseudonymous, publication, *Poems by Currer, Ellis and Acton Bell* (1846). Their Gothic plots and Byronic passions also informed the novels that began to be published in the following year.

Charlotte Brontë, like her sisters, appears at first sight to have been writing a literal fiction of provincial life. In her first novel, *Jane Eyre* (1847), for example, the heroine's choice between sexual need and ethical duty belongs very firmly to the mode of moral realism. But her hair's-breadth escape from a bigamous marriage with her employer, and the death by fire of his mad first wife derive from the rather different tradition of the Gothic novel. In *Shirley* (1849) Charlotte Brontë strove to be, in her own words, "as unromantic as Monday morning." In *Villette* (1853) the distinctive Gothic elements return to lend this study of the limits of stoicism an unexpected psychological intensity and drama.

Emily Brontë united these diverse traditions still more successfully in her only novel, *Wuthering Heights* (1847). Closely observed regional detail, precisely handled plot, and a sophisticated use of multiple internal narrators are combined with vivid imagery and an extravagantly Gothic theme. The result is a perfectly achieved study of elemental passions and the strongest possible refutation of the assumption that the age of the novel must also be an age of realism.

EARLY VICTORIAN VERSE

Tennyson. Despite the growing prestige and proliferation of fiction (some 40,000 titles are said to have been published in this period), this age of the novel was in fact also an age of great poetry. Alfred Tennyson made his mark very early with *Poems, Chiefly Lyrical* (1830) and *Poems* (1832; dated 1833), publications that led some critics to hail him as the natural successor to Keats and Shelley. A decade later, in *Poems* (1842), Tennyson combined in two volumes the best of his early work with a second volume of more recent writing. The collection established him as the outstanding poet of the era.

Tennyson's *Poems*

In his early work Tennyson brought an exquisite lyric gift to late-Romantic subject matter. The result is a poetry that, for all its debt to Keats, anticipates the French Symbolists of the 1880s. The death of his friend and supporter Arthur Hallam in 1833, however, left him vulnerable to accusations from less sympathetic critics that this highly subjective verse was insufficiently engaged with the public issues of the day. The second volume of the *Poems* of 1842 contains two remarkable responses to this challenge. One is the dramatic monologue, a technique developed independently by both Tennyson and Browning in the 1830s and the greatest formal innovation in Victorian poetry. The other is the form that Tennyson called the English Idyl, in which he combined brilliant vignettes of contemporary landscape with relaxed debate.

In the major poems of his middle period Tennyson combined the larger scale required by his new ambitions with his original gift for the brief lyric by building long poems out of short ones. *In Memoriam* (1850) is an elegy for Arthur Hallam, formed by 133 individual lyrics. Eloquent, vivid, and ample, it is at the same time an acute pathological study of individual grief and the central Victorian statement of the problems posed by the decline of Christian faith. *Maud* (1855) assembles 27 lyric poems into a single dramatic monologue that disturbingly explores the psychology of violence.

Tennyson became poet laureate in 1850 and wrote some apt and memorable poems on patriotic themes. The chief work of his later period, however, was *Idylls of the King* (1859, revised 1885). An Arthurian epic, it offers a sombre vision of an idealistic community in decay. Some passages are brilliant, but even Tennyson's contemporaries found it on the whole oddly inhibited and lacking in intellectual substance.

G.K. Chesterton described Tennyson as "a suburban Virgil." The elegant Virgilian note was the last thing aimed at by his great contemporary Robert Browning. Browning's work was Germanic rather than Italianate, grotesque rather than idyllic, and colloquial rather than refined. The differences between Browning and Tennyson underline the creative diversity of the period.

Robert Browning and Elizabeth Barrett Browning. Deeply influenced by Shelley, Browning made two false starts. One was as a playwright, an ambition in which he persisted until 1846 and of which the one memorable product is *Pippa Passes* (1841). The other was as the late-Romantic poet of the confessional meditation *Pauline* (1833), the

closet drama *Paracelsus* (1835), and the difficult though innovatory narrative poem *Sordello* (1840).

Browning's *Dramatic Lyrics*

Browning found his individual and distinctively modern voice in 1842, with the volume *Dramatic Lyrics.* As the title suggests, it was a collection of dramatic monologues, among them "Porphyria's Lover," "Johannes Agricola in Meditation," and "My Last Duchess." The monologues make clear the radical originality of Browning's new manner: they involve the reader in sympathetic identification with the interior processes of criminal or unconventional minds, requiring active rather than merely passive engagement in the processes of moral judgment and self-discovery. More such monologues and some equally striking lyrics make up *Men and Women* (1855).

In 1846 Browning married Elizabeth Barrett. Though now remembered chiefly for her love poems *Sonnets from the Portuguese* (1850) and her experiment with the verse novel *Aurora Leigh* (1856; dated 1857), she was in her own lifetime far better known than her husband. Only with the publication of *Dramatis Personae* (1864) did Browning achieve the sort of fame that Tennyson had enjoyed for more than 20 years. The volume contains, in "Rabbi Ben Ezra," the most extreme statement of Browning's celebrated optimism. Hand in hand with this reassuring creed, however, go the skeptical intelligence and the sense of the grotesque displayed in such poems as "Caliban upon Setebos" and "Mr. Sludge, 'The Medium.' "

The Ring and the Book (1868–69) gives the dramatic monologue format unprecedented scope. Published in parts, like a Dickens novel, it tells a sordid murder story in a way that both explores moral issues and suggests the problematic nature of human knowledge. Browning's work after this date, though voluminous, is uneven.

Arnold and Clough. Matthew Arnold's first volume of verse, *The Strayed Reveller, and Other Poems* (1849), combined lyric grace with an acute sense of the dark philosophical landscape of the period. The title poem of his next collection, *Empedocles on Etna* (1852), is a sustained statement of the modern dilemma and a remarkable poetic embodiment of the process that Arnold called "the dialogue of the mind with itself." Arnold later suppressed this poem and attempted to write in a more impersonal manner. His greatest work ("Switzerland," "Dover Beach," "The Scholar-Gipsy") is, however, always elegiac in tone. In the 1860s he turned from verse to prose and became, with *Essays in Criticism* (1865), *Culture and Anarchy* (1869), and *Literature and Dogma* (1873), a lively and acute writer of literary, social, and religious criticism.

Arnold's friend Arthur Hugh Clough died young but managed, nonetheless, to produce three highly original poems. *The Bothie of Tober-na-Vuolich* (1848) is a narrative poem of modern life, written in hexameters. *Amours de Voyage* (1858) goes beyond this to the full-scale verse novel, using multiple internal narrators and vivid contemporary detail. *Dipsychus* (published posthumously in 1865 but not available in an unexpurgated version until 1951) is a remarkable closet drama that debates issues of belief and morality with a frankness, and a metrical liveliness, unequaled in Victorian verse.

EARLY VICTORIAN NONFICTIONAL PROSE

Carlyle's *French Revolution*

Carlyle may be said to have initiated Victorian literature with *Sartor Resartus.* He continued thereafter to have a powerful effect on its development. *The French Revolution* (1837), the book that made him famous, spoke very directly to this consciously postrevolutionary age. *On Heroes, Hero-Worship, and the Heroic in History* (1841) combined the Romantic idea of the genius with a further statement of the German transcendentalist philosophy, which Carlyle opposed to the influential doctrines of empiricism and utilitarianism. Carlyle's political writing, in *Chartism* (1839; dated 1840), *Past and Present* (1843), and the splenetic *Latter-day Pamphlets* (1850), inspired other writers to similar "prophetic" denunciations of laissez-faire economics and utilitarian ethics. The first importance of John Ruskin is as an art critic who, in *Modern Painters,* five volumes (1843–60), brought Romantic theory to the study of painting and forged an appropriate prose for its expression. But in *The Stones of Venice,* three volumes (1851–53), Ruskin took the political medievalism of Carlyle's *Past and Present* and gave it a poetic fullness and force. This imaginative engagement with social and economic problems continued into *Unto This Last* (1860), *The Crown of Wild Olive* (1866), and *Fors Clavigera* (1871–84). John Henry Newman was a poet, novelist, and theologian who wrote many of the tracts, published as *Tracts for the Times* (1833–41), that promoted the Oxford Movement in the Church of England. His subsequent religious development is memorably described in his *Apologia pro Vita Sua* (1864), one of the many great autobiographies of this introspective century.

LATE VICTORIAN LITERATURE

"The modern spirit," Matthew Arnold observed in 1865, "is now awake." In 1859 Charles Darwin had published *On the Origin of Species by Means of Natural Selection.* Historians, philosophers, and scientists were all beginning to apply the idea of evolution to new areas of study of the human experience. Traditional conceptions of man's nature and place in the world were, as a consequence, under threat. Walter Pater summed up the process, in 1866, by stating that "Modern thought is distinguished from ancient by its cultivation of the 'relative' spirit in place of the 'absolute.' "

The economic crisis of the 1840s was long past. But the fierce political debates that led first to the Second Reform Act of 1867 and then to the battles for the enfranchisement of women were accompanied by a deepening crisis of belief.

The novel. Late Victorian fiction may express doubts and uncertainties, but in aesthetic terms it displays a new sophistication and self-confidence. The American novelist Henry James wrote in 1884 that until recently the English novel had "had no air of having a theory, a conviction, a consciousness of itself behind it." Its acquisition of these things was due in no small part to Mary Ann Evans, better known as George Eliot. Initially a critic and translator, she was influenced, after the loss of her Christian faith, by the ideas of Ludwig Feuerbach and Auguste Comte. Her advanced intellectual interests combined with her sophisticated sense of the novel form to shape her remarkable fiction. Her early novels, *Adam Bede* (1859), *The Mill on the Floss* (1860), and *Silas Marner* (1861), are closely observed studies of English rural life that offer, at the same time, complex contemporary ideas and a subtle tracing of moral issues. Her masterpiece, *Middlemarch* (1871–72), is an unprecedentedly full study of the life of a provincial town, focused on the thwarted idealism of her two principal characters. George Eliot is a realist, but her realism involves a scientific analysis of the interior processes of social and personal existence.

George Eliot

Her fellow realist Anthony Trollope published his first novel in 1847 but only established his distinctive manner with *The Warden* (1855), the first of a series of six novels set in the fictional county of Barsetshire and completed in 1867. This sequence was followed by a further series, the six-volume Palliser group (1864–80), set in the world of British parliamentary politics. Trollope published an astonishing total of 47 novels, and his *Autobiography* (1883) is a uniquely candid account of the working life of a Victorian writer.

Trollope's series of novels

The third major novelist of the 1870s was George Meredith, who also worked as poet, journalist, and publisher's reader. His prose style is eccentric and his achievement uneven. His greatest work of fiction, *The Egoist* (1879), however, is an incisive comic novel that embodies the distinctive theory of the corrective and therapeutic powers of laughter expressed in his lecture "The Idea of Comedy" (1877).

This flowering of realist fiction was accompanied, perhaps inevitably, by a revival of its opposite, the romance. The 1860s produced a new subgenre, the sensation novel, seen at its best in the work of Wilkie Collins. Gothic novels and romances by Sheridan Le Fanu, Robert Louis Stevenson, William Morris, and Oscar Wilde; utopian fiction by Morris and Samuel Butler; and the early science fiction of H.G. Wells make it possible to speak of a full-scale romance revival.

Realism continued, however, to flourish, sometimes encouraged by the example of European Realist and Naturalist novelists. Both George Moore and George Gissing were influenced by Émile Zola, though both also reacted against him. The greatest novelist of this generation, however, was Thomas Hardy. His first published novel, *Desperate Remedies,* appeared in 1871 and was followed by 13 more before he abandoned prose to publish (in the 20th century) only poetry. His major fiction consists of the tragic novels of rural life, *The Mayor of Casterbridge* (1886), *Tess of the D'Urbervilles* (1891), and *Jude the Obscure* (1895). In these novels his brilliant evocation of the landscape and people of his fictional Wessex is combined with a sophisticated sense of "the ache of modernism."

Hardy's major fiction

Verse. The Pre-Raphaelite Brotherhood, formed in 1848 and unofficially reinforced a decade later, was founded as a group of painters but also functioned as a school of writers who linked the incipient Aestheticism of Keats and De Quincey to the Decadent movement of the fin de siècle. Dante Gabriel Rossetti collected his early writing in *Poems* (1870), a volume that led the critic Robert Buchanan to attack him as the leader of "The Fleshly School of Poetry." Rossetti combined some subtle treatments of contemporary life with a new kind of medievalism, seen also in *The Defence of Guenevere* (1858) by William Morris. The earnest political use of the Middle Ages found in Carlyle and Ruskin did not die out—Morris himself continued it and linked it, in the 1880s, with Marxism. But these writers also used medieval settings as a context that made possible an uninhibited treatment of sex and violence. The shocking subject matter and vivid imagery of Morris' first volume were further developed by Algernon Charles Swinburne, who, in *Atalanta in Calydon* (1865) and *Poems and Ballads* (1866), combined them with an intoxicating metrical power.

The carefully wrought religious poetry of Christina Rossetti is perhaps truer to the original, pious purposes of the Pre-Raphaelite Brotherhood. More interesting as a religious poet of this period, however, is Gerard Manley Hopkins, a Jesuit priest whose work was first collected as *Poems* in 1918, nearly 30 years after his death. Overpraised by modernist critics, who saw him as the sole great poet of the era, he was in fact an important minor talent and an ingenious technical innovator.

Hopkins' *Poems*

The 1890s witnessed a flowering of lyric verse, influenced intellectually by the critic and novelist Walter Pater and formally by contemporary French practice. Such writing was widely attacked as "decadent" for its improper subject matter and its consciously amoral doctrine of "art for art's sake." This stress upon artifice and the freedom of art from conventional moral constraints went hand in hand, however, with an exquisite craftsmanship and a devotion to intense emotional and sensory effects. Outstanding among the numerous poets publishing in the final decade of the century were John Davidson, Arthur Symons, Francis Thompson, Ernest Dowson, Lionel Johnson, and A.E. Housman. In *The Symbolist Movement in Literature* (1899) Symons suggested the links between this writing and European Symbolism and Impressionism. Thompson provides a vivid example of the way in which a decadent manner could, paradoxically, be combined with fierce religious enthusiasm. A rather different note was struck by Rudyard Kipling, who combined polemical force and sharp observation (particularly of colonial experience) with a remarkable metrical vigour.

THE VICTORIAN THEATRE

Early Victorian drama was a popular art form, appealing to an uneducated audience that demanded emotional excitement rather than intellectual subtlety. Vivacious melodramas did not, however, hold exclusive possession of the stage. The mid-century saw lively comedies by Dion Boucicault and Tom Taylor. In the 1860s T.W. Robertson pioneered a new realist drama, an achievement later celebrated by Arthur Wing Pinero in his charming sentimental comedy *Trelawny of the "Wells"* (1898). The 1890s were, however, the outstanding decade of dramatic innovation. Oscar Wilde crowned his brief career as a playwright with one of the few great high comedies in English, *The Importance of Being Earnest* (1895). At the same time the influence of Henrik Ibsen was helping to produce a new genre of serious "problem plays," such as Pinero's *Second Mrs. Tanqueray* (1893). J.T. Grein founded the Independent Theatre in 1891 to foster such work and staged there the first plays of George Bernard Shaw and translations of Ibsen.

VICTORIAN LITERARY COMEDY

Victorian literature began with such humorous books as *Sartor Resartus* and *The Pickwick Papers.* Despite the crisis of faith, the "Condition of England" question, and the ache of modernism, this note was sustained throughout the century. The comic novels of Dickens and Thackeray; the squibs, sketches, and light verse of Thomas Hood and Douglas Jerrold; the nonsense of Edward Lear and Lewis Carroll; and the humorous light fiction of Jerome K. Jerome and George Grossmith and his brother Weedon Grossmith are proof that this age, so often remembered for its gloomy rectitude, may in fact have been the greatest era of comic writing in English literature. (N.Sh.)

"Modern" English literature: the 20th century

FROM 1900 TO 1945

The Edwardians. The 20th century opened with great hope but also with some apprehension, for the new century marked the onset of a new millennium. For many, mankind was entering upon an unprecedented era. H.G. Wells's utopian studies, the aptly titled *Anticipations of the Reaction of Mechanical and Scientific Progress upon Human Life and Thought* (1901) and *A Modern Utopia* (1905), both captured and qualified this optimistic mood and gave expression to a common conviction that science and technology would transform the world in the century ahead. To achieve such transformation, outmoded institutions and ideals had to be replaced by ones more suited to the growth and liberation of the human spirit. The death of Queen Victoria in 1901 and the accession of Edward VII seemed to confirm that a franker, less inhibited era had begun.

Many writers of the Edwardian period, drawing widely upon the realistic and naturalistic conventions of the 19th century (upon Ibsen in drama and Balzac, Turgenev, Flaubert, Zola, Eliot, and Dickens in fiction) and in tune with the anti-Aestheticism unleashed by the trial of the archetypal Aesthete, Oscar Wilde, saw their task in the new century to be an unashamedly didactic one. In a series of wittily iconoclastic plays, of which *Man and Superman* (performed 1905, published 1903) and *Major Barbara* (performed 1905, published 1907) are the most substantial, George Bernard Shaw turned the Edwardian theatre into an arena for debate upon the principal concerns of the day: the question of political organization, the morality of armaments and war, the function of class and of the professions, the validity of the family and of marriage, and the issue of female emancipation. Nor was he alone in this, even if he was alone in the brilliance of his comedy. John Galsworthy made use of the theatre in *Strife* (1909) to explore the conflict between capital and labour, and in *Justice* (1910) he lent his support to reform of the penal system, while Harley Granville-Barker, whose revolutionary approach to stage direction did much to change theatrical production in the period, dissected in *The Voysey Inheritance* (performed 1905, published 1909) and *Waste* (performed 1907, published 1909) the hypocrisies and deceit of upper-class and professional life.

Didactic literature

Many Edwardian novelists were similarly eager to explore the shortcomings of English social life. Wells—in *Love and Mr. Lewisham* (1900); *Kipps* (1905); *Ann Veronica* (1909), his pro-suffragette novel; and *The History of Mr. Polly* (1910)—captured the frustrations of lower- and middle-class existence, even though he relieved his accounts with many comic touches. In *Anna of the Five Towns* (1902) Arnold Bennett detailed the constrictions of provincial life among the self-made business classes in the area of England known as the Potteries; in *The Man of Property* (1906), the first volume of *The Forsyte Saga,* Galsworthy described the destructive possessiveness of the professional

bourgeoisie; and in *Where Angels Fear to Tread* (1905) and *The Longest Journey* (1907) E.M. Forster portrayed with irony the insensitivity, self-repression, and philistinism of the English middle classes.

These novelists, however, wrote more memorably when they allowed themselves a larger perspective. In *The Old Wives' Tale* (1908) Bennett showed the destructive effects of time on the lives of individuals and communities and evoked a quality of pathos that he never matched in his other fiction; in *Tono-Bungay* (1909) Wells showed the ominous consequences of the uncontrolled developments taking place within a British society still dependent upon the institutions of a long-defunct landed aristocracy; and in *Howards End* (1910) Forster showed how little the rootless and self-important world of contemporary commerce cared for the more rooted world of culture, although he acknowledged that commerce was a necessary evil. Nevertheless, even as they perceived the difficulties of the present, most Edwardian novelists, like their counterparts in the theatre, held firmly to the belief not only that constructive change was possible but also that this change could in some measure be advanced by their writing.

Other writers, including Thomas Hardy and Rudyard Kipling, who had established their reputations during the previous century, and Hilaire Belloc, G.K. Chesterton, and Edward Thomas, who established their reputations in the first decade of the new century, were less confident about the future and sought to revive the traditional forms—the ballad, the narrative poem, the satire, the fantasy, the topographical poem, and the essay—that in their view preserved traditional sentiments and perceptions. The revival of traditional forms in the late 19th and early 20th century was not a unique event. There have been many such revivals during the 20th century, and the traditional poetry of A.E. Housman (whose book *A Shropshire Lad*, originally published in 1896, enjoyed huge popular success during World War I), Walter de la Mare, John Masefield, Robert Graves, and Edmund Blunden represents an important and often neglected strand of English literature in the first half of the century.

Revival of traditional forms

The most significant writing of the period, traditionalist or modern, was inspired by neither hope nor apprehension but by bleaker feelings that the new century would witness the collapse of a whole civilization. The new century had begun with Great Britain involved in the South African War (the Boer War; 1899–1902), and it seemed to some that the British Empire was as doomed to destruction, both from within and from without, as had been the Roman Empire. In his poems on the South African War, Hardy (whose achievement as a poet in the 20th century rivaled his achievement as a novelist in the 19th) questioned simply and sardonically the human cost of empire building and established a tone and style that many British poets were to use in the course of the century, while Kipling, who had done much to engender pride in empire, began to speak in his verse and short stories of the burden of empire and the tribulations it would bring.

James's sense of an imperial civilization in decline

No one captured the sense of an imperial civilization in decline more fully or subtly than the expatriate American novelist Henry James. In *The Portrait of a Lady* (1881) he had briefly anatomized the fatal loss of energy of the English ruling class and in *The Princess Casamassima* (1886) had described more directly the various instabilities that threatened its paternalistic rule. He did so with regret: the patrician American admired in the English upper class its sense of moral obligation to the community. By the turn of the century, however, he had noted a disturbing change. In *The Spoils of Poynton* (1897) and *What Maisie Knew* (1897) members of the upper class no longer seem troubled by the means adopted to achieve their morally dubious ends. Great Britain had become indistinguishable from the other nations of the Old World, in which an ugly rapacity had never been far from the surface. James's dismay at this condition gave to his subtle and compressed late fiction, *The Wings of the Dove* (1902), *The Ambassadors* (1903), and *The Golden Bowl* (1904), much of its gravity and air of disenchantment.

James's awareness of crisis affected the very form and style of his writing, for he was no longer assured that the world about which he wrote was either coherent in itself or unambiguously intelligible to its inhabitants. His fiction still presented characters within an identifiable social world, but he found his characters and their world increasingly elusive and enigmatic and his own grasp upon them, as he made clear in *The Sacred Fount* (1901), the questionable consequence of artistic will.

Another expatriate novelist, Joseph Conrad (pseudonym of Józef Teodor Konrad Korzeniowski, born in the Ukraine of Polish parents), shared James's sense of crisis but attributed it less to the decline of a specific civilization than to the failings of mankind itself. Man was a solitary, romantic creature of will who at any cost imposed his meaning upon the world because he could not endure a world that did not reflect his central place within it. In *Almayer's Folly* (1895) and *Lord Jim* (1900) he had seemed to sympathize with this predicament; but in "Heart of Darkness" (1902), *Nostromo* (1904), *The Secret Agent* (1907), and *Under Western Eyes* (1911) he detailed such imposition, and the psychological pathologies he increasingly associated with it, without sympathy. He did so as a philosophical novelist whose concern with the mocking limits of human knowledge affected not only the content of his fiction but also its very structure. His writing itself is marked by gaps in the narrative, by narrators who do not fully grasp the significance of the events they are retelling, and by characters who are unable to make themselves understood. James and Conrad used many of the conventions of 19th-century realism but transformed them to express what are considered to be peculiarly 20th-century preoccupations and anxieties.

The modernist revolution. *Anglo-American modernism: Pound, Lewis, Lawrence, and Eliot.* From 1908 to 1914 there was a remarkably productive period of innovation and experiment as novelists and poets undertook, in anthologies and magazines, to challenge the literary conventions not just of the recent past but of the entire Post-Romantic era. For a brief moment, London, which up to that point had been culturally one of the dullest of the European capitals, boasted an avant-garde to rival those of Paris, Vienna, and Berlin, even if its leading personality, Ezra Pound, and many of its most notable figures were American.

London's avant-garde

The spirit of modernism—a radical and utopian spirit stimulated by new ideas in anthropology, psychology, philosophy, political theory, and psychoanalysis—was in the air, expressed rather mutedly by the pastoral and often anti-modern poets of the Georgian movement (1912–22) and more authentically by the English and American poets of the Imagist movement, to which Pound first drew attention in *Ripostes* (1912), a volume of his own poetry, and in *Des Imagistes* (1914), an anthology. Prominent among the Imagists were the English poets T.E. Hulme, F.S. Flint, and Richard Aldington and the Americans Hilda Doolittle (H.D.) and Amy Lowell.

Reacting against what they considered to be an exhausted poetic tradition, the Imagists wanted to refine the language of poetry in order to make it a vehicle not for pastoral sentiment or imperialistic rhetoric but for the exact description and evocation of mood. To this end they experimented with free or irregular verse and made the image their principal instrument. In contrast to the leisurely Georgians, they worked with brief and economical forms.

Meanwhile, painters and sculptors, grouped together by the painter and writer Wyndham Lewis under the banner of vorticism, combined the abstract art of the Cubists with the example of the Italian Futurists who conveyed in their painting, sculpture, and literature the new sensations of movement and scale associated with such modern developments as automobiles and airplanes. With the typographically arresting *Blast: Review of the Great English Vortex* (two editions, 1914 and 1915) vorticism found its polemical mouthpiece and in its editor, Wyndham Lewis, its most active propagandist and accomplished literary exponent. His experimental play *Enemy of the Stars*, published in *Blast* in 1914, and his experimental novel *Tarr* (1918) can still surprise with their violent exuberance.

World War I brought this first period of the modernist revolution to an end and, while not destroying its radical

and utopian impulse, made the Anglo-American modernists all too aware of the gulf between their ideals and the chaos of the present. Novelists and poets parodied received forms and styles, in their view made redundant by the immensity and horror of the war, but, as can be seen most clearly in Pound's angry and satirical *Hugh Selwyn Mauberley* (1920), with a note of anguish and with the wish that writers might again make form and style the bearers of authentic meanings.

Lawrence and Eliot on the sickness of modern civilization

In his two most innovative novels, *The Rainbow* (1915) and *Women in Love* (1920), D.H. Lawrence traced the sickness of modern civilization—a civilization in his view only too eager to participate in the mass slaughter of the war—to the effects of industrialization upon the human psyche. Yet as he rejected the conventions of the fictional tradition, which he had used to brilliant effect in his deeply-felt autobiographical novel of working-class family life, *Sons and Lovers* (1913), he drew upon myth and symbol to hold out the hope that individual and collective rebirth could come through human intensity and passion.

On the other hand, the poet and playwright T.S. Eliot, another American resident in London, in his most innovative poetry, *Prufrock and Other Observations* (1917) and *The Waste Land* (1922), traced the sickness of modern civilization—a civilization that, on the evidence of the war, preferred death or death-in-life to life—to the spiritual emptiness and rootlessness of modern existence. As he rejected the conventions of the poetic tradition, Eliot, like Lawrence, drew upon myth and symbol to hold out the hope of individual and collective rebirth, but he differed sharply from Lawrence by supposing that rebirth could come through self-denial and self-abnegation. Even so, their satirical intensity, no less than the seriousness and scope of their analyses of the failings of a civilization that had voluntarily entered upon the first World War, ensured that Lawrence and Eliot became the leading and most authoritative figures of Anglo-American modernism in England in the whole of the postwar period.

During the 1920s, Lawrence (who left England in 1919) and Eliot began to develop viewpoints at odds with the reputations they had established through their early work. In *Kangaroo* (1923) and *The Plumed Serpent* (1926) Lawrence revealed the attraction to him of charismatic, masculine leadership, while in *For Lancelot Andrewes: Essays on Style and Order* (1928) Eliot (whose influence as a literary critic now rivaled his influence as a poet) announced that he was a "classicist in literature, royalist in politics and anglo-catholic in religion" and committed himself to hierarchy and order. Elitist and paternalistic, they did not, however, adopt the extreme positions of Pound (who left England in 1920 and settled permanently in Italy in 1925) or Lewis. Drawing upon the ideas of the left and of the right, Pound and Lewis dismissed democracy as a sham and argued that economic and ideological manipulation was the dominant factor. For some the antidemocratic views of the Anglo-American modernists simply made explicit the reactionary tendencies inherent in the movement from its beginning; for others they came from a tragic loss of balance occasioned by World War I. This issue is a complex one, and judgments upon the literary merit and political status of Pound's ambitious but immensely difficult imagist epic *The Cantos* (1917–70) and Lewis' powerful sequence of politico-theological novels *The Human Age* (*The Childermass,* 1928; *Monstre Gai* and *Malign Fiesta,* both 1955) are sharply divided.

Celtic modernism: Yeats, Joyce, Jones, and MacDiarmid. Pound, Lewis, Lawrence, and Eliot were the principal figures of Anglo-American modernism, but important contributions also were made by the Irish poet and playwright William Butler Yeats and the Irish novelist James Joyce. By virtue of nationality, residence, and, in Yeats's case, an unjust reputation as a poet still steeped in Celtic mythology, they had less immediate impact upon the British literary intelligentsia in the late 1910s and early 1920s than Pound, Lewis, Lawrence, and Eliot, although by the mid-1920s their influence had become direct and substantial. Many contemporary critics argue that Yeats's work as a poet and Joyce's work as a novelist are the most important modernist achievements of the period.

In his early verse and drama Yeats, who had been influenced as a young man by the Romantic and Pre-Raphaelite movements, evoked a legendary and supernatural Ireland in language that was often vague and grandiloquent. As an adherent of the cause of Irish nationalism he had hoped to instill pride in the Irish past. The poetry of *The Green Helmet* (1910) and *Responsibilities* (1914), however, was marked not only by a more concrete and colloquial style but also by a growing isolation from the nationalist movement, for Yeats celebrated an aristocratic Ireland epitomized for him by the family and country house of his friend and patron, Lady Gregory.

The grandeur of his mature reflective poetry in *The Wild Swans at Coole* (1917), *Michael Robartes and the Dancer* (1921), *The Tower* (1928), and *The Winding Stair* (1929) derived in large measure from the way in which (caught up by the violent discords of contemporary Irish history) he accepted the fact that his idealized Ireland was illusory. At its best his mature style combined passion and precision with powerful symbol, strong rhythm, and lucid diction; and even though his poetry often touched upon public themes, he never ceased to reflect upon the Romantic themes of creativity, selfhood, and the individual's relationship to nature, time, and history.

Joyce, who spent his adult life on the continent of Europe, expressed in his fiction his sense of the limits and possibilities of the Ireland he had left behind. In his collection of short stories, *Dubliners* (1914), and his largely autobiographical novel, *A Portrait of the Artist as a Young Man* (1916), he described in fiction at once realist and symbolist the individual cost of the sexual and imaginative oppressiveness of life in Ireland. As if by provocative contrast, his panoramic novel of urban life, *Ulysses* (1922), was sexually frank and imaginatively profuse. (Copies of the first edition were burned by the New York postal authorities, and British customs officials seized the second edition in 1923.) Employing extraordinary formal and linguistic inventiveness, including the so-called stream-of-consciousness method, Joyce depicted the experiences and the fantasies of various men and women in Dublin on a summer's day in June 1904. Yet his purpose was not simply documentary, for he drew upon an encyclopaedic range of European literature to stress the rich universality of life buried beneath the provincialism of pre-independence Dublin, still in 1904 a city within the British Empire. In his even more experimental *Finnegans Wake* (1939), extracts of which had already appeared as *Work in Progress* from 1928 to 1937, Joyce's commitment to cultural universality became absolute. By means of a strange, polyglot idiom of puns and portmanteau words he not only explored the relationship between the conscious and the unconscious but also suggested that the languages and myths of Ireland were interwoven with the languages and myths of many other cultures.

Joyce's inventive fiction

The example of Joyce's experimentalism was followed by the Anglo-Welsh poet David Jones and by the Scottish poet Hugh MacDiarmid (pseudonym of Christopher Murray Grieve). Whereas Jones concerned himself, in his complex and allusive poetry and prose, with the Celtic, Saxon, Roman, and Christian roots of Great Britain, MacDiarmid sought not only to recover what he considered to be an authentically Scottish culture but also to establish, as in his *In Memoriam James Joyce* (1955), the truly cosmopolitan nature of Celtic consciousness and achievement. MacDiarmid's masterpiece in the vernacular, *A Drunk Man Looks at the Thistle* (1926), helped to inspire the Scottish renaissance of the 1920s and '30s.

The literature of World War I and the interwar period. The impact of World War I upon the Anglo-American modernists has been noted. In addition the war brought a variety of responses from the more traditionalist writers, predominantly poets, who saw action. Rupert Brooke caught the idealism of the opening months of the war (and died in service); Siegfried Sassoon and Ivor Gurney caught the mounting anger and sense of waste as the war continued; and Isaac Rosenberg (perhaps the most original of the war poets), Wilfrid Owen, and Edmund Blunden not only caught the comradely compassion of the trenches but also addressed themselves to the larger moral

perplexities raised by the war (Rosenberg and Owen were killed in action).

Cynicism in the postwar years

It was not until the 1930s, however, that much of this poetry became widely known. In the wake of the war the dominant tone, at once cynical and bewildered, was set by Aldous Huxley's satirical novel *Crome Yellow* (1921). Drawing upon Lawrence and Eliot, he concerned himself in his novels of ideas—*Antic Hay* (1923), *Those Barren Leaves* (1925), and *Point Counter Point* (1928)—with the fate of the individual in rootless modernity. His pessimistic vision found its most complete expression in the 1930s, however, in his most famous and inventive novel, the anti-utopian fantasy *Brave New World* (1932), and his account of the anxieties of middle-class intellectuals of the period, *Eyeless in Gaza* (1936).

Huxley's frank and disillusioned manner was echoed by the poet Robert Graves in his autobiography, *Good-bye to All That* (1929), and by the poet Richard Aldington in his *Death of a Hero* (1929), a semiautobiographical novel of prewar bohemian London and the trenches. Exceptions to this dominant mood were found among writers too old to consider themselves, as did Graves and Aldington, members of a betrayed generation. In *A Passage to India* (1924) E.M. Forster examined the quest for and failure of human understanding among various ethnic and social groups in India under British rule. In *Parade's End* (1950; comprising *Some Do Not,* 1924; *No More Parades,* 1925; *A Man Could Stand Up,* 1926; and *Last Post,* 1928) Ford Madox Ford, with an obvious debt to James and Conrad, examined the demise of aristocratic England in the course of the war, exploring on a larger scale the themes he had treated with brilliant economy in his short novel *The Good Soldier* (1915). And in *Wolf Solent* (1929) and *A Glastonbury Romance* (1932), John Cowper Powys developed an eccentric and highly erotic mysticism.

These were, however, writers of an earlier, more confident era. A younger and more contemporary voice belonged to members of the Bloomsbury group. Setting themselves against the humbug and hypocrisy that, they believed, had marked their parents' generation in upper-class England, they aimed to be uncompromisingly honest in personal and artistic life. In Lytton Strachey's iconoclastic biographical study *Eminent Victorians* (1918) this amounted to little more than amusing irreverence, even though Strachey had a profound effect upon the writing of biography; but in the fiction of Virginia Woolf the rewards of this outlook were both profound and moving.

Virginia Woolf's fiction and essays

In short stories and novels of great delicacy and lyrical power she set out to portray the limitations of the self, caught as it is in time, and suggested that these could be transcended, if only momentarily, by engagement with another self, a place, or a work of art. This preoccupation not only charged the act of reading and writing with unusual significance but also produced, in *To the Lighthouse* (1927), *The Waves* (1931)—perhaps her most inventive and complex novel—and *Between the Acts* (1941), her most sombre and moving work, some of the most daring fiction produced in the 20th century.

Woolf believed that her viewpoint offered an alternative to the destructive egotism of the masculine mind, an egotism that had found its outlet in World War I, but she did not consider this viewpoint, as she made clear in her essay *A Room of One's Own* (1929), to be the unique possession of women. In her fiction she presented men who possessed what she held to be feminine characteristics, a regard for others and an awareness of the multiplicity of experience; but she remained pessimistic about women gaining positions of influence, even though she set out the desirability of this in her feminist study *Three Guineas* (1938). Together with Joyce, who greatly influenced her *Mrs. Dalloway* (1925), Woolf transformed the treatment of subjectivity, time, and history in fiction and helped create a feeling among her contemporaries that traditional forms of fiction—with their frequent indifference to the mysterious and inchoate inner life of characters—were no longer adequate. Her eminence as a literary critic and essayist did much to foster an interest in the writing of other significant women novelists, such as Katherine Mansfield and Dorothy Richardson.

The 1930s. World War I created a profound sense of crisis in English culture, and this became even more intense with the worldwide economic collapse of the late 1920s and early '30s, the rise of Fascism, the Spanish Civil War (1936–39), and the approach of another full-scale conflict in Europe. It is not surprising, therefore, that much of the writing of the 1930s was bleak and pessimistic: even Evelyn Waugh's sharp and amusing satire on contemporary England, *Vile Bodies* (1930), ended with another, more disastrous war.

Divisions of class and the burden of sexual repression became common and interrelated themes in the fiction of the 1930s, a fiction that largely neglected the modernist revolution in technique of the 1920s and returned to the realist modes of the first decade of the century. In *A Scots Quair* (*Sunset Song,* 1932; *Cloud Howe,* 1933; and *Grey Granite,* 1934) the novelist Lewis Grassic Gibbon (pseudonym of James Leslie Mitchell) gives a panoramic account of Scottish rural and working-class life. The work resembles Lawrence's novel *The Rainbow* in its historical sweep and intensity of vision. Walter Greenwood's *Love on the Dole* (1933) is a bleak record, in the manner of Bennett, of the economic depression in a northern working-class community; and Graham Greene's *It's a Battlefield* (1934) and *Brighton Rock* (1938) are desolate studies, in the manner of Conrad, of the loneliness and guilt of men and women trapped in a contemporary England of conflict and decay. *A Clergyman's Daughter* (1935) and *Keep the Aspidistra Flying* (1936), by George Orwell, are evocations, in the manner of Wells and, in the latter case unsuccessfully, of Joyce, of contemporary lower middle-class existence, and *The Road to Wigan Pier* (1937) is a report of northern working-class mores. Elizabeth Bowen's *Death of the Heart* (1938) is a sardonic analysis, in the manner of James, of contemporary upper-class values.

Realist modes of the 1930s

Yet the most interesting writing of the decade grew out of the determination to supplement the diagnosis of class division and sexual repression with their cure. It was no accident that the poetry of W.H. Auden and his Oxford contemporaries, C. Day-Lewis, Louis MacNeice, and Stephen (later Sir Stephen) Spender, became quickly identified as the authentic voice of the new generation, for it matched despair with defiance. These self-styled prophets of a new world envisaged freedom from the bourgeois order being achieved in various ways. For Day-Lewis and Spender technology held out particular promise. This, allied to Marxist precepts, would in their view bring an end to poverty and the suffering it caused. For Auden especially, sexual repression was the enemy, and here the writings of Sigmund Freud and D.H. Lawrence were valuable. Whatever their individual preoccupations, these poets produced in the very play of their poetry, with its mastery of different genres, its rapid shifts of tone and mood, and its strange juxtapositions of the colloquial and esoteric, a blend of seriousness and high spirits irresistible to their peers.

The adventurousness of the new generation was shown, in part, by its love of travel (as in Christopher Isherwood's novels *Mr. Norris Changes Trains* [1935] and *Goodbye to Berlin* [1939], which reflect his experiences of postwar Germany); in part by its readiness for political involvement; and in part by its openness to the writing of the avant-garde of the Continent. The verse dramas coauthored by Auden and Isherwood, of which *The Ascent of F6* (1936) is the most notable, owed much to Bertolt Brecht; the political parables of Rex Warner, of which *The Aerodrome* (1941) is the most accomplished, owed much to Franz Kafka; and the complex and often obscure poetry of David Gascoyne and Dylan Thomas owed much to the Surrealists. Even so, Yeats's mature poetry and Eliot's *Waste Land,* with its parodies, its satirical edge, its multiplicity of styles, and its quest for spiritual renewal, provided the most significant models and inspiration for the young writers of the period. On the whole, however, despite the breadth, diversity, and liveliness of the writing of the 1930s, the decade was not one of great originality or innovation but rather one of imitation and emulation.

The literature of World War II (1939–45). The outbreak of war in 1939, as in 1914, brought to an end an era

of great intellectual and creative exuberance. Individuals were dispersed; the rationing of paper affected the production of magazines and books; the poem and the short story, convenient forms for men under arms, became the favoured means of literary expression. It was hardly a time for new beginnings, although the poets of the New Apocalypse movement produced three anthologies (1940–45) inspired by neo-Romantic anarchism. No important new novelists or playwrights appeared, and only three new poets (all of whom died on active service) showed promise: Alun Lewis, Sidney Keyes, and Keith Douglas, the most gifted and distinctive, whose eerily detached accounts of the battlefield revealed a poet of potential greatness.

Eliot's *Four Quartets*

It was a poet of an earlier generation, T.S. Eliot, who produced in his *Four Quartets* (1935–42; published as a whole, 1943) the masterpiece of the war. Reflecting upon language, time, and history, he searched, in the three quartets written during the war, for moral and religious significance in the midst of destruction and strove to counter the spirit of nationalism inevitably present in a nation at war. The creativity that had seemed to end with the tortured religious poetry and verse drama of the 1920s and '30s had a rich and extraordinary late flowering as Eliot concerned himself, on the scale of *The Waste Land* but in a very different manner and mood, with the well-being of the society in which he lived. (H.A.Da.)

LITERATURE AFTER 1945

Postwar poetry and prose. When World War II ended the prevailing mood in literature was one of disillusionment, exhaustion, and sterility. Joyce, Yeats, and Virginia Woolf were all dead, and to George Orwell, writing in 1945, the younger English writers seemed like "fleas hopping among the ruins of a civilisation." Cyril Connolly, whose magazine *Horizon* had done so much to keep literary culture alive during the war, later remarked that, far from producing rapid change, the "effect of wars and catastrophes is to slow up the movement (so much more profound) of the human spirit." The novelist William Golding felt that the horrors of the war had beggared description: "We have discovered a limit to literature."

But if this sense of gloom and enervation was common to a wide range of writers at the end of the war, the responses it evoked were, as one might expect, various. For some writers the social and political unease of the 1930s, culminating in the experience of war, put an end to the further possibilities of modernism and created a hunger for more traditional values: T.S. Eliot, Dame Edith Sitwell, Evelyn Waugh, W.H. Auden, and Graham Greene turned increasingly to Christianity, while Aldous Huxley and Christopher Isherwood dabbled in mysticism and Eastern philosophy to the detriment of their later fiction. Alongside these spiritual hungers can be detected a certain restlessness typified by the later novels of Greene and by the fact that so many important writers—Huxley, Robert Graves, Auden, Isherwood—chose to live abroad.

Orwell. By contrast George Orwell stayed close to home, deriving his inspiration directly from the mood of Britain in the '40s. *Animal Farm* (1945) confronted the unpalatable truth that the victory over Fascism would in some respects unwittingly aid the advance of totalitarianism, while *Nineteen Eighty-four* (1949) warns of the dangers to the individual of encroaching collectivism. In these last, bleak fables Orwell attempted to make an art of political writing in the tradition of Swift and Defoe.

Eliot's verse dramas

Eliot. At the opposite end of the political spectrum was Eliot. After the *Four Quartets* he produced no more poetry, but he remained influential as a critic and publisher. His main creative effort now went into the theatre. Unlike his earlier poetic tragedies, his three postwar comedies (*The Cocktail Party,* 1950; *The Confidential Clerk,* 1954; and *The Elder Statesman,* 1959) constitute an attempt to write verse plays within the somewhat tired conventions of the commercial theatre. In consequence they now seem dated, although their intelligence and linguistic verve set them apart from the humdrum, if solidly crafted, drama of the period, typified at its best by plays such as J.B. Priestley's *An Inspector Calls* (1945).

Auden and Graves. With Eliot silent, the best poetry in the decade after the war was written by Auden and Graves, both still at the height of their powers. The brilliance and sharpness of Auden's earlier manner never deserted him, but he now began to develop the complex yet easily vernacular mixture of Horatian and Christian moralizing that formed the basis of his later style. In spite of his physical absence, the civilization and restrained charm of Auden's later voice, with its insistence on the private virtues, was to be a major and enduring influence on postwar English poetry. The influence of Graves was less direct but almost as important. Graves lived on Majorca like Prospero on his island, cultivating his magical powers as a poet unaffected by any literary fashion or movement—meanwhile supporting himself with a stream of highly competent popular novels and scholarly writings. A minor poet able to stand comparison with Auden and Graves is William Empson, whose *Collected Poems* (1949) marked the end of his slender poetic output. The power of his poetry is to convey moral toughness and moral nicety with an obscure passion that resists paraphrase or definition. The verse of John Betjeman is highly accessible, and he was undoubtedly the most popular poet laureate (1972–84) since Tennyson. His adherence to and mastery of traditional forms, his apparent simplicity, and his lightness of touch meant that his reputation was always uncertain; indeed, no poet of his quality has been more condescended to by the critics. But Betjeman was an innovator, not a sentimentalist; his sensibility was a modern one, keenly alive to the absurd. His nostalgia was built upon an exact sense of time and place and an instinct for the genuine.

The virtues of all these poets were more generally perceived in the 1950s, however, than in the period immediately after the war, when the dominant strain in English poetry ran counter to the cool irony and social observation of the '30s. There developed instead, for reasons partly connected with the war, an apocalyptic, neo-Romantic, and rhetorical tone in poetry with much emphasis placed on surrealism and the status of myth. The unruly deity of this cult was Dylan Thomas, its high priestess Dame Edith Sitwell, and its acolytes David Gascoyne and George Barker. Thomas was a wayward genius, a phrasemaker of power and originality who could seldom concentrate his thoughts through a whole poem, and whose effects, in consequence, are wearyingly random.

Waugh and his generation. A very different reaction to the war was perhaps the most lasting and also served as a necessary preface to many of the finest achievements in postwar literature. Very early in the war Evelyn Waugh predicted that "its chief use would be to cure artists of the illusion that they were men of action." Waugh's own honourable, if frustrating, wartime career was to confirm this view: "I don't want to influence opinions or events, or expose humbug or anything of that kind. I don't want to be of service to anyone or anything. I simply want to do my work as an artist." *Brideshead Revisited* (1945), Waugh's first attempt at the "magnum opus" that would widen the perspective of his prewar novels and tackle the operation of grace in human affairs, was, as he later acknowledged, deeply flawed by nostalgia and sentimentality. He was able to rework the theme completely in his late masterpiece *Sword of Honour* (1965; published separately as *Men at Arms,* 1952; *Officers and Gentlemen,* 1955; and *Unconditional Surrender,* 1961), bringing to the task new resources of humility and creative cunning. Passionate dedication to his art also enriches *The Ordeal of Gilbert Pinfold* (1957), a genuinely comic novel shot through with the sombre poignancy of Waugh's mature self-appraisal.

The other novelist of Waugh's generation to achieve a comparable stature in the postwar period was Anthony Powell. Powell's five prewar novels, never as popular as Waugh's, nonetheless show the emergence of a distinctive talent that was elaborated in his 12-novel sequence "A Dance to the Music of Time" (1951–75). Powell and Waugh are the master stylists of a generation that succeeded, in Powell's words, in "throwing overboard a good deal of Edwardian débris." They took hints about dialogue and presentation from the novels of Ronald Firbank and Dame Ivy Compton-Burnett, as well as the American writers Ernest Hemingway and e.e. cummings, and they both

were preoccupied with the "naturalist" problem of finding literary means to convey the essence of what people sound like, instead of merely reproducing what they say. But Powell is a very different novelist from Waugh. Much of Waugh's imaginative energy derives from a certain blinkered quality, an instinct for what can safely be left out, so that his themes and characters are sculpted with a hard and brilliant edge. Powell is a much more open and inclusive writer. His involvement with his characters is both more detached and more curious, he is interested in subtler distinctions and capable of a more genuine tenderness and lyricism, he is laconic but not cynical, and his wit, though quieter, is more deeply suffused through his work.

Two other novelists of this period were Henry Green and Joyce Cary. Green's novels are intriguingly empty at the centre; he has a viewpoint but no point of view. He is supremely a novelist of linguistic atmosphere. Each of his books takes a small subject (no two are similar) and transforms it into a self-sufficient world whose consistency is entirely made up of Green's delicate, sometimes whimsical, patterning of language and symbol. The technique is seen at its best in *Loving* (1945), a tenderly menacing study of servants and their masters in an Irish country house during the war. By contrast Cary, who began writing only after a career spent in colonial administration, is a gigantic and protean novelist of powerfully Protestant conviction expressed in his two trilogies (*Herself Surprised,* 1941; *To Be a Pilgrim,* 1942; and *The Horse's Mouth,* 1944; and *Prisoner of Grace,* 1952; *Except the Lord,* 1953; and *Not Honour More,* 1955).

Most of the writers so far considered were born well before World War I, but it would be misleading to suggest that no younger talents had yet emerged. Several good poets in their early 30s stood aside from the fashionable apocalyptic vein. R.S. Thomas, an admirer of the Metaphysical poet George Herbert, wrote spare, often bitter, lyrics arising from his experience as an Anglican priest in Wales. Roy Fuller was a poet of wry and modest exactitudes. The skill of Lawrence Durrell's mandarin and soberly reflective poetry has been regrettably eclipsed by the later success of his baroque and overwritten fiction. Two novelists of a distinctly unusual flavour were Malcolm Lowry (*Under the Volcano,* 1947) and Jocelyn Brooke (*The Military Orchid,* 1948; *A Mine of Serpents,* 1949; *The Goose Cathedral,* 1950; *The Dog at Clambercrown,* 1955). The most important new voice to be heard in the decade was Philip Larkin. Though *The North Ship* (1945) only hints at his development as a poet, it and his two novels (*Jill,* 1946; *A Girl in Winter,* 1947) were hopeful auguries for the new writing of the 1950s.

The 1950s and after. The 1950s are often conveniently categorized as the period in which the welfare state wrought great changes in British society, the time of the Angry Young Men, when in literature, as in other areas, class barriers were broken down. Such accounts have only a very limited use, for the period was one of great diversity. As in the '30s, writers new and old produced work that was lively and energetic. If they sometimes formed alliances, they also knew the wisdom of D.J. Enright's remark that "the best movement is one that doesn't move far in the same direction." It is difficult to discern any real populism in the writing of the '50s. The revolution, if there was one, was founded on honest impatience with the cant and hypocrisy, genteel pretentiousness, and shifty incompetences that find shelter in the trenches of carelessly perpetuated privilege. The iconoclastic writers of the '50s resembled those of the '30s. They valued common sense, order, clarity, wit, and self-knowledge, and they were not scrupulous in their conduct toward those who appeared to lack these qualities. In later decades, when, as Orwell had ruefully predicted, cant and hypocrisy became as much a weapon of the left as of the right, it is hardly surprising that many of the Angry Young Men were to be found on the opposite side of the barricades.

Novels of Amis, Murdoch, and Wilson

Prose. Kingsley Amis, at different stages of his life the writer of official pamphlets on behalf of both the Labour and Conservative parties, was by far the best of the iconoclastic novelists to emerge in the '50s. (The others included John Wain, John Braine, and Alan Sillitoe.) *Lucky Jim* (1953) established from the first Amis' continuing qualities—his baleful comic stare, his uncanny ear for the quirks of contemporary speech, and the enormous cunning with which he establishes the authority of a central persona who is entirely ordinary (and beset with the usual failings) yet also improbably alert to the most telling distinctions and deceptions in the life lived around him. Like Waugh, Amis is a relentless tease who courts outrage and rejection. His weaker novels lapse sometimes into facetiousness, but the uniqueness of this persona, more interesting than any question of ideology, has been remarkably consistent from *Lucky Jim* to *Stanley and the Women* (1984).

Amis remained a realist in the novel, a contemporary practitioner of the long, liberal humanist tradition, which puts the novelist's imaginative and linguistic gifts primarily at the service of character and therefore of life. His two most important contemporaries, Iris Murdoch and Sir Angus Wilson, also stand solidly within that tradition, but they are more concerned with the structural problems of writing such novels at a time when society no longer supplies a coherent and communal pattern of experience. Iris Murdoch's novels explore good and evil, the nature of power, and the possibility of love from a standpoint that is neither traditional nor modernist but creates its own flavour, as do the novels of Dame Ivy Compton-Burnett. Murdoch's lively gift of social observation is powerfully, sometimes grotesquely, combined with an insistent psychological, sexual, or mythical patterning: it is as though the transparent surface of the comedy of manners has been stretched and darkened to embrace the calamitous events of tragedy. Even more directly than Iris Murdoch, Sir Angus Wilson takes as his subject the crisis of educated middle-class society in England since World War I. Novelists such as C.P. Snow (*Strangers and Brothers,* 1940–70) treated similar themes in an entirely conventional way, as though they were writing 19th-century novels in modern dress. But if Snow's sequence is compared with Wilson's panoramic novel *No Laughing Matter* (1967), with its ingenious combination of realism, fantasy, and parody, it will be seen that it is Wilson who has contrived to tell the reader more about reality.

Such accommodations between the novel of character and the pressures of contemporary fictional theory have been extremely important: they have preserved the English novel's relation to life (elsewhere fiction sometimes risks being swallowed up by an ever more complex body of theory) while renewing its vitality as an art. A welcome feature of the period is the cross-fertilization between the newer writers and a number of older novelists. Ivy Compton-Burnett has already been mentioned. Other examples are Elizabeth Bowen (*The Heat of the Day,* 1949; *A World of Love,* 1955); L.P. Hartley (*The Go-Between,* 1953; *The Hireling,* 1957); Nancy Mitford (*The Blessing,* 1951; *Don't Tell Alfred,* 1960); Rebecca West (*The Fountain Overflows,* 1956; *The Birds Fall Down,* 1966); Jean Rhys (*Wide Sargasso Sea,* 1966); Richard Hughes (*The Human Predicament,* 1961–73); Olivia Manning (*The Balkan Trilogy,* 1960–65); Elizabeth Taylor (*Angel,* 1957); and Sybille Bedford (*A Legacy,* 1956). Realism, arguably, is what the English novel does best, but complacency on that score can lead to a deadly predictability. Yet Iris Murdoch's insistence that "the function of the writer [is] to write the best books he knows how to write" is a salutary reminder of the strength of the intuitive English tradition. In the 1960s and after, the better novelists may have become more overtly concerned with problems of form, but they still derived strength and variety from grafting these concerns onto their firm adherence to the liberal novel, in marked contrast to the arid pretentiousness of so much continental fiction. Examples of this strength may be found in the work of William Golding (*Lord of the Flies,* 1954; *Pincher Martin,* 1956; *Rites of Passage,* 1980); Anthony Burgess (*A Clockwork Orange,* 1962; *Inside Mr. Enderby,* 1963; *Earthly Powers,* 1980); Doris Lessing (*The Golden Notebook,* 1962); Muriel Spark (*Memento Mori,* 1959; *The Driver's Seat,* 1970; *The Takeover,* 1976); and V.S. Naipaul (*A House for Mr. Biswas,* 1961; *The Mimic Men,* 1967; *In a Free State,* 1971).

Poetry. The state of poetry in the 1950s in many ways

resembled that of the novel; indeed the period was remarkable in that Fuller, Larkin, Wain, Amis, and Enright were competent practitioners in both genres. These poets formed the nucleus of a group briefly known as The Movement, represented in Robert Conquest's anthology *New Lines* (1956). As ever, the grouping conceals diversity, but it is largely true that the Movement poets cultivated plainsong rather than polyphony. The typical Movement poem (as A. Alvarez demonstrated with a roguish concoction of disparate lines in his anti-Movement anthology *The New Poetry,* 1962) is wryly sober, reflectively public, and somewhat flat. It parades the poet as ordinary man, his tones and themes defined by his membership in the educated middle class. The poet who partakes of the Movement's virtues but transcends its defects is Philip Larkin. Larkin uses words and rhythms to paint subtle and individual impressions on the mind. He has a rare gift of control and organization, and he can distill beauty from ordinariness and dullness and pain, renewing the force of Keats's assertion that "Beauty is truth, truth beauty." He is the latest in that honourable line of English poets who demonstrate that greatness can speak in a minor key. In the '60s those who found the Movement poets limited and insular championed the work of Ted Hughes (who succeeded Betjeman as poet laureate in 1984) with its controlled violence, inwardness with animal instinct, and powerful investigation of the untamed part of human personality. Also interesting are the more compact, tautly elegant poet Thom Gunn; the Australian poet Peter Porter; and the learned, ambiguous, and resonant poetry of Geoffrey Hill. The poet who built most fruitfully on the Larkin–Hughes dichotomy of the '60s, gradually acquiring his own oblique but authoritative voice, is the Irishman Seamus Heaney, who emerged in the 1970s as the strongest and most influential poet writing today. His works include *North,* 1975; *Field Work,* 1979; and *Station Island,* 1984.

Drama. It was in the theatre, far more than in poetry or the novel, that genuinely radical changes took place in the postwar period. In *Look Back in Anger* (1957) John Osborne was determined to ignore the suffocating conventions of the well-made West End play in order to allow the pressures and excitements of contemporary life to be heard in the theatre. In the process he developed a heightened realism that, in plays such as *The Entertainer* (1957) and *A Patriot for Me* (1966), combined the passionate immediacy of drama with the complex psychological portraiture of the novel. Osborne's revolution was one of scale, attitude, and feeling rather than formal invention, but the revolution of method inaugurated by the Irish playwright Samuel Beckett was even more important. *Waiting for Godot* (1954) showed how the simplest of means (a bare stage, a tree, lighting) and the sparest of verbal exchanges could move and delight audiences by dramatizing the interior, subverbal workings of the human spirit. Beckett refused the seductive illusions of art, seeking instead the simplest and most essential bones of meaning. This minimalist stance has obvious limitations, and Beckett's subsequent plays *Endgame* (1958), *Happy Days* (1961), *Breath* (1969), and *Not I* (1973) lovingly described them, until his ultimate dramatic goal came to be a pregnant silence. Harold Pinter—author of *The Birthday Party,* 1958; *The Caretaker,* 1960; and *The Homecoming,* 1965, among other plays—learned from Beckett the art of writing plays that give nothing away, but he developed it in a highly distinctive manner. Where more conventional dramatists feel compelled to explain what in life is often opaque or incommunicable, Pinter shows that there is another drama to be made out of blankly presenting the psychic power struggles and neurotic menace that everyone experiences without understanding. Something of this oblique and slightly surreal vision survives in the bold and overtly radical drama of Edward Bond (*The Pope's Wedding,* 1962; *Saved,* 1965; *Lear,* 1971), with its contrasting of contemporary horror with the possibility of innocence and redemption. Politics surface again in the rambunctious and anarchical comedies of Joe Orton (*Entertaining Mr. Sloane,* 1963; *Loot,* 1964; and *What the Butler Saw,* 1967). Stylistic invention of a very different kind was to be seen in the plays of Tom Stoppard (*Rosencrantz and Guildenstern Are Dead,* 1967; *Jumpers,* 1972; *Travesties,* 1975), a linguistic dandy whose virtuosity gives sparkling theatrical form to his philosophical concern with questions of art and reality.

An important characteristic of the period following 1975 is its undirected openness to different styles of writing and different perceptions of reality. In the theatre, which has remained the most political genre, several impressive heirs to the radical tradition such as Trevor Griffiths, Howard Brenton, David Hare, and David Edgar have widened their dramatic scope with techniques adapted from films and television, but similar skills have been as richly exploited by bourgeois ironists such as Simon Gray, Alan Bennett, Michael Frayn, Alan Ayckbourn, and Stoppard. In the novel the rapturous reception accorded to such self-consciously avant-garde writers as D.M. Thomas (*The White Hotel,* 1981) and Salman Rushdie (*Midnight's Children,* 1981) suggests an intellectual hunger for experimentation, but at the same time due recognition is given to the careful and utterly unpretentious fiction of Anita Brookner (*A Start in Life,* 1981; *Hotel du Lac,* 1984). It is notable that, although certain important modernist achievements have come to be more widely respected in recent years, their influence has never really taken root. Examples are provided by the novels of Beckett (*Murphy,* 1938; *Molloy,* 1955; *Malone Dies,* 1956), the poetry of Hugh MacDiarmid and Basil Bunting, and the work of David Jones (*In Parenthesis,* 1937; *The Anathemata,* 1952).

In the 1960s it briefly seemed possible that the traditional roots of English writing would be significantly shifted—that literature would become less metropolitan and academic and would answer more closely to the needs of the young, the working class, and the ideologically committed. This trend was particularly evident in poetry (pop poetry, performance poetry, protest poetry), but with hindsight it is clear that its influence was short-lived and limited and that contemporary writing has retreated, if not to the ivory tower, then at least to the "palace of art." It is a symptom of the change that new writers such as the poets Douglas Dunn and Tony Harrison actually emphasized the tension between the practice of their art and their commitment to their working-class origins, while the most interesting new writing exhibits a dandyish delight in verbal and formal manipulations combined with a serious underlying concern with the nature of art and the individual imagination. Examples may be found in the "Martian" poetry of Craig Raine (*The Onion Memory,* 1978; *A Martian Sends a Postcard Home,* 1979; *Rich,* 1984), the novels of Martin Amis (especially *Money,* 1984), and Stoppard's play *The Real Thing* (1982). Writing, it may be concluded, has remained an inescapably bourgeois and liberal activity, but, as such, it faces serious difficulties both within and without. Social and economic changes have progressively turned the retreat of writers toward the universities, which began in the 1950s, into a stampede. Meanwhile, in spite of the publicity and enthusiasm created by literary prizes, the habit of reading is threatened on all sides, by television, by falling standards of education, and by the erosion of communal myths or frames of reference. The Movement

Openness to diversity in the theatre

Radical changes in the theatre

BIBLIOGRAPHY

General works: A comprehensive reference source with emphasis on British authors and their writings is the *Oxford Companion to English Literature.* The 4th edition, edited by SIR PAUL HARVEY and revised by DOROTHY EAGLE (1969), and the 5th edition, edited by MARGARET DRABBLE (1985), have somewhat different but overlapping coverage. *The Oxford History of English Literature,* a multivolume series, provides comprehensive coverage of the subject, as does *The Cambridge History of English Literature,* edited by A.W. WARD and A.R. WALLER, 15 vol. (1907–33, reprinted 1976). Another useful source is PETER CONRAD, *The Everyman History of English Literature* (1985).

Old English and Early Middle English literature: DEREK PEARSALL, *Old English and Middle English Poetry* (1977), is a good critical survey of both periods. STANLEY B. GREENFIELD and FRED C. ROBINSON, *A Bibliography of Publications on Old English Literature to the End of 1972* (1980, reprinted 1982), lists more than 6,500 items covering published materials on the subject and has a good index. STANLEY B. GREENFIELD and DANIEL G. CALDER, *A New Critical History of Old English Literature* (1986), serves as a good introductory survey. GEORGE

PHILIP KRAPP and ELLIOTT VAN KIRK DOBBIE (eds.), *The Anglo-Saxon Poetic Records,* 6 vol. (1931–53), is the standard edition of Old English poetry; and S.A.J. BRADLEY (ed. and trans.), *Anglo-Saxon Poetry* (1982), is an anthology of Old English poems in prose translation. R.M. WILSON, *Early Middle English Literature,* 3rd ed. (1968), is a critical survey of the period; J. BURKE SEVERS and ALBERT E. HARTUNG (eds.), *A Manual of the Writings in Middle English, 1050–1500* (1967–), a multivolume reference, seven volumes of which were published by 1986, contains commentaries on the individual works and extensive bibliographies; and J.A.W. BENNETT and G.V. SMITHERS (eds.), *Early Middle English Verse and Prose,* 2nd ed. (1968, reprinted 1982), is an authoritative anthology, with a glossary.

The Middle English period: A.S.G. EDWARDS (ed.), *Middle English Prose: A Critical Guide to Major Authors and Genres* (1984), includes bibliographies and surveys of scholarship. See also A.S.G. EDWARDS and DEREK PEARSALL (eds.), *Middle English Prose: Essays on Bibliographical Problems* (1981). BORIS FORD (ed.), *The New Pelican Guide to English Literature,* vol. 1, *Medieval Literature,* Part One: *Chaucer and the Alliterative Tradition,* rev. ed. (1982), is an anthology with extensive bibliographies; another valuable source is CARL J. STRATMAN, *Bibliography of Medieval Drama,* 2nd ed. rev. and enlarged, 2 vol. (1972). Analytical studies include PIERO BOITANI, *English Medieval Narrative in the Thirteenth and Fourteenth Centuries* (1982; originally published in Italian, 1980); J.A. BURROW, *Ricardian Poetry: Chaucer, Gower, Langland, and the Gawain Poet* (1971); PAMELA GRADON, *Form and Style in Early English Literature* (1971, reprinted 1974); RICHARD FIRTH GREEN, *Poets and Princepleasers: Literature and the English Court in the Late Middle Ages* (1980); DAVID LAWTON (ed.), *Middle English Alliterative Poetry and Its Literary Background* (1982); CHARLES MUSCATINE, *Poetry and Crisis in the Age of Chaucer* (1972); ROBERT A. POTTER, *The English Morality Play: Origins, History, and Influence of a Dramatic Tradition* (1975); V.J. SCATTERGOOD, *Politics and Poetry in the Fifteenth Century* (1971); A.C. SPEARING, *Medieval Dream-Poetry* (1976), and *Medieval to Renaissance in English Poetry* (1985); R.M. WILSON, *Lost Literature of Medieval England,* 2nd rev. ed. (1970); GEORGE KANE, *Middle English Literature* (1951, reissued 1979); DOROTHY EVERETT, *Essays on Middle English Literature* (1955, reprinted 1978); C.S. LEWIS, *The Allegory of Love: A Study in Medieval Tradition* (1936, reprinted 1977); DIETER MEHL, *The Middle English Romances of the Thirteenth and Fourteenth Centuries* (1969; originally published in German, 1967); ARTHUR K. MOORE, *The Secular Lyric in Middle English* (1951, reprinted 1970); ROSEMARY WOOLF, *The English Religious Lyric in the Middle Ages* (1968); ROBERTO WEISS, *Humanism in England During the Fifteenth Century,* 3rd ed. (1967); M.J.C. HODGART, *The Ballads,* 2nd ed. (1964); THORLAC TURVILLE-PETRE, *The Alliterative Revival* (1977); and ROSEMARY WOOLF, *The English Mystery Plays* (1972, reissued 1980).

The Renaissance and the 17th century: (*Elizabethan poetry and prose*): C.S. LEWIS, *English Literature in the Sixteenth Century: Excluding Drama* (1954, reprinted 1973), is a standard literary survey. CHRISTOPHER RICKS (ed.), *English Poetry and Prose, 1540–1674* (1970); and BORIS FORD (ed.), *The Age of Shakespeare,* rev. ed. (1982), are useful collections of essays. FRANCES A. YATES, *Astraea: The Imperial Theme in the Sixteenth Century* (1975); JOHN BUXTON, *Elizabethan Taste* (1963); and LOUIS B. WRIGHT, *Middle-Class Culture in Elizabethan England* (1935, reissued 1980), explore the backgrounds of literature, including politics and patronage of the period. Specific topics are discussed in HALLETT SMITH, *Elizabethan Poetry: A Study in Conventions, Meaning, and Expression* (1952, reprinted 1964); PAUL J. ALPERS (ed.), *Elizabethan Poetry: Modern Essays in Criticism* (1967); FRANK KERMODE, *Shakespeare, Spenser, Donne: Renaissance Essays* (1971; U.K. title, *Renaissance Essays: Shakespeare, Spenser, Donne,* 1973); DOUGLAS L. PETERSON, *The English Lyric from Wyatt to Donne* (1967); J.W. LEVER, *The Elizabethan Love Sonnet,* 2nd ed. (1966); and ROSEMOND TUVE, *Elizabethan and Metaphysical Imagery* (1947, reissued 1968), on rhetoric. Anthologies include NORMAN AULT (ed.), *Elizabethan Lyrics from the Original Texts,* 4th ed. (1966); NIGEL ALEXANDER (ed.), *Elizabethan Narrative Verse* (1967); and EDWARD LUCIE-SMITH (ed.), *The Penguin Book of Elizabethan Verse* (1965). (*Elizabethan and early Stuart drama*): The theatrical background is surveyed in ANDREW GURR, *The Shakespearean Stage, 1574–1642,* 2nd ed. (1980); and KENNETH MUIR and S. SCHOENBAUM (eds.), *A New Companion to Shakespeare Studies* (1971, reprinted 1976). CHRISTOPHER RICKS (ed.), *English Drama to 1710* (1971), is a collection of essays. Surveys of the literature include MADELEINE DORAN, *Endeavors of Art: A Study of Form in Elizabethan Drama* (1954, reprinted 1964); M.C. BRADBROOK, *The Growth and Structure of Elizabethan Comedy,* new ed. (1973, reprinted 1979); and ALFRED HARBAGE, *Shakespeare and the Rival Traditions* (1952, reissued 1968), on the companies of schoolboy actors. The following are special studies: J.M.R. MARGESON, *The Origins of English Tragedy* (1967); DAVID BEVINGTON, *From Mankind to Marlowe: Growth of Structure in the Popular Drama of Tudor England* (1962); C.L. BARBER, *Shakespeare's Festive Comedy: A Study of Dramatic Form and Its Relation to Social Custom* (1959, reprinted 1972); E.M.W. TILLYARD, *Shakespeare's History Plays* (1944, reprinted 1980); A.C. BRADLEY, *Shakespearean Tragedy: Lectures on Hamlet, Othello, King Lear, Macbeth,* 2nd ed. (1985); BRIAN GIBBONS, *Jacobean City Comedy,* 2nd ed. (1980); MARGOT HEINEMANN, *Puritanism and Theatre: Thomas Middleton and Opposition Drama Under the Early Stuarts* (1980, reprinted 1982); J.W. LEVER, *The Tragedy of State: A Study in Jacobean Drama* (1971, reprinted 1980); and ENID WELSFORD, *The Court Masque: A Study in the Relationship Between Poetry and Revels* (1927, reissued 1962). (*Early Stuart poetry and prose*): DOUGLAS BUSH, *English Literature in the Earlier Seventeenth Century,* 2nd rev. ed. (1962, reprinted 1976), is a standard survey. Historical background is explored in HIRAM HAYDN, *The Counter-Renaissance* (1950, reprinted 1966); ALAN SINFIELD, *Literature in Protestant England, 1560–1660* (1983); CHRISTOPHER HILL, *Intellectual Origins of the English Revolution* (1965, reprinted with corrections 1980), and *The World Turned Upside Down: Radical Ideas During the English Revolution* (1972, reissued 1982); and BASIL WILLEY, *The Seventeenth Century Background: Studies in the Thought of the Age in Relation to Poetry and Religion* (1934, reprinted 1977). Information on the court is found in D.J. GORDON, *The Renaissance Imagination* (1975); and ROY STRONG, *Van Dyck: Charles I on Horseback* (1972). Special topical studies include LOUIS L. MARTZ, *The Poetry of Meditation: A Study in English Religious Literature of the Seventeenth Century,* rev. ed. (1962, reprinted 1978); MAREN-SOFIE RØSTVIG, *The Happy Man: Studies in the Metamorphoses of a Classical Ideal,* 2nd ed., 2 vol. (1962–71), on the Cavalier poetry; C.A. PATRIDES and RAYMOND B. WADDINGTON (eds.), *The Age of Milton: Backgrounds to Seventeenth-Century Literature* (1980); BRIAN VICKERS, *Essential Articles for the Study of Francis Bacon* (1968); JOAN WEBBER, *The Eloquent "I": Style and Self in Seventeenth-Century Prose* (1968); and STANLEY E. FISH (ed.), *Seventeenth-Century Prose: Modern Essays in Criticism* (1971).

The Restoration and the 18th century: Helpful introductions to the period can be found in the relevant volumes of the Oxford History of English Literature series: JAMES SUTHERLAND, *English Literature of the Late Seventeenth Century* (1969); BONAMY DOBRÉE, *English Literature in the Early Eighteenth Century, 1700–1740* (1959, reprinted with corrections 1964); and JOHN BUTT, *The Mid-Eighteenth Century,* ed. and completed by GEOFFREY CARNALL (1979); and in such monographs as A.R. HUMPHREYS, *The Augustan World: Life and Letters in Eighteenth-Century England* (1954, reprinted 1978); MAXIMILLIAN E. NOVAK, *Eighteenth-Century English Literature* (1983); PAT ROGERS, *The Augustan Vision* (1974, reissued 1978); PAT ROGERS (ed.), *The Eighteenth Century* (1978); LESLIE STEPHEN, *English Literature and Society in the Eighteenth Century* (1904, reprinted 1965); and STEPHEN COPLEY (ed.), *Literature and the Social Order in Eighteenth-Century England* (1984). Useful studies that focus on more restricted topics but cover the whole of the period include HOWARD ERSKINE-HILL, *The Augustan Idea in English Literature* (1983); PAUL FUSSELL, *The Rhetorical World of Augustan Humanism: Ethics and Imagery from Swift to Burke* (1965, reprinted 1969); JEAN H. HAGSTRUM, *Sex and Sensibility: Ideal and Erotic Love from Milton to Mozart* (1980); IAN JACK, *Augustan Satire: Intention and Idiom in English Poetry, 1660–1750* (1952, reprinted 1966); JAMES WILLIAM JOHNSON, *The Formation of English Neo-Classical Thought* (1967, reprinted 1978); MARTIN PRICE, *To the Palace of Wisdom: Studies in Order and Energy from Dryden to Blake* (1964, reissued 1970); ERIC ROTHSTEIN, *Restoration and Eighteenth-Century Poetry, 1660–1780* (1981); JAMES SUTHERLAND, *A Preface to Eighteenth-Century Poetry* (1948, reprinted 1970); and RACHEL TRICKETT, *The Honest Muse: A Study in Augustan Verse* (1967). Among important thematic or general studies with a narrower chronological range are JOHN BARRELL, *English Literature in History, 1730–80* (1983); WALTER JACKSON BATE, *From Classic to Romantic: Premises of Taste in Eighteenth-Century England* (1946, reprinted 1961); DONALD DAVIE, *A Gathered Church: The Literature of the English Dissenting Interest, 1700–1930* (1978); CHRISTOPHER HILL, *The Experience of Defeat: Milton and Some Contemporaries* (1984); EARL MINER, *The Restoration Mode from Milton to Dryden* (1974); SAMUEL H. MONK, *The Sublime: A Study of Critical Theories in XVIII-Century England* (1935, reissued 1960); MARJORIE HOPE NICOLSON, *Newton Demands the Muse: Newton's Opticks and the Eighteenth Century Poets* (1946, reprinted 1979), and *Science and Imagination* (1956, reprinted 1976); RONALD PAULSON, *Satire and the Novel in Eighteenth-Century England* (1967); JOHN PRESTON, *The Created Self: The Reader's Role in Eighteenth-Century Fiction* (1970); JOHN J. RICHETTI,

Popular Fiction Before Richardson: Narrative Patterns, 1700–1739 (1969); PAT ROGERS, *Hacks and Dunces: Pope, Swift, and Grub Street* (1980); PATRICIA MEYER SPACKS, *Imagining a Self: Autobiography and Novel in Eighteenth-Century England* (1976), and *The Poetry of Vision: Five Eighteenth-Century Poets* (1967); GEOFFREY TILLOTSON, *Augustan Poetic Diction* (1964); IAN WATT, *The Rise of the Novel: Studies in Defoe, Richardson, and Fielding* (1957, reprinted 1971); BASIL WILLEY, *The Eighteenth Century Background: Studies on the Idea of Nature in the Thought of the Period* (1940, reprinted 1980); and JOHN HAROLD WILSON, *The Court Wits of the Restoration: An Introduction* (1948, reissued 1967). Interesting explorations of individual major writers include MAXIMILLIAN E. NOVAK, *Defoe and the Nature of Man* (1963); G.A. STARR, *Defoe and Spiritual Autobiography* (1965, reissued 1971); C.J. RAWSON, *Henry Fielding and the Augustan Ideal Under Stress: "Nature's Dance of Death" and Other Studies* (1972); WALTER JACKSON BATE, *Samuel Johnson* (1977); REUBEN A. BROWER, *Alexander Pope: The Poetry of Allusion* (1959, reprinted 1968); MAYNARD MACK, *The Garden and the City: Retirement and Politics in the Later Poetry of Pope, 1731–1743* (1969), and *Alexander Pope: A Life* (1985); AUBREY L. WILLIAMS, *Pope's "Dunciad": A Study of Its Meaning* (1955, reprinted 1968); MARGARET ANNE DOODY, *A Natural Passion: A Study of the Novels of Samuel Richardson* (1974); DAVID M. VIETH, *Attribution in Restoration Poetry: A Study of Rochester's Poems of 1680* (1963); and IRVIN EHRENPREIS, *Swift: The Man, His Works, and the Age,* 3 vol. (1962–83). Theatrical history is chronicled in ROBERT D. HUME, *The Development of English Drama in the Late Seventeenth Century* (1976); PETER HOLLAND, *The Ornament of Action: Text and Performance in Restoration Comedy* (1979); RICHARD BEVIS, *The Laughing Tradition: Stage Comedy in Garrick's Day* (1980); and ARTHUR SHERBO, *English Sentimental Drama* (1957). Among collections and anthologies are DONALD DAVIE (ed.), *Augustan Lyric* (1974); H.T. DICKINSON (ed.), *Politics and Literature in the Eighteenth Century* (1974); SCOTT ELLEDGE (ed.), *Eighteenth-Century Critical Essays,* 2 vol. (1961); H.G.C. GRIERSON and G. BULLOUGH (eds.), *Oxford Book of Seventeenth Century Verse* (1934, reprinted 1976); DAVID W. LINDSAY (ed.), *English Poetry, 1700–1780: Contemporaries of Swift and Johnson* (1974); GEORGE DE F. LORD *et al.* (eds.), *Poems on Affairs of State: Augustan Satirical Verse, 1660–1714,* 7 vol. (1963–75); HAROLD LOVE (ed.), *The Penguin Book of Restoration Verse* (1968); GEORGE H. NETTLETON and ARTHUR E. CASE (eds.), *British Dramatists from Dryden to Sheridan* (1939, reprinted 1975); DAVID NICHOL SMITH (ed.), *Characters from the Histories and Memoirs of the Seventeenth Century* (1918, reprinted 1967), *Eighteenth Century Essays on Shakespeare,* 2nd ed. (1963), and *The Oxford Book of Eighteenth Century Verse* (1926, reprinted 1965); ROGER LONSDALE (ed.), *The New Oxford Book of Eighteenth Century Verse* (1984); CHARLES PEAKE (ed.), *Poetry of the Landscape and the Night: Two Eighteenth-Century Traditions* (1967, reissued 1970); FRANCIS VENABLES (ed.), *The Early Augustans* (1972); and TIMOTHY WEBB (ed.), *English Romantic Hellenism, 1700–1824* (1982).

The Romantic period: General literary history of the period is presented in the relevant volumes of the Oxford History of English Literature series: W.L. RENWICK, *English Literature, 1789–1815* (1963), and IAN JACK, *English Literature, 1815–1832* (1963); as well as in R.A. FOAKES, *The Romantic Assertion: A Study in the Language of Nineteenth Century Poetry* (1958, reprinted 1971); JOHN O. HAYDEN (ed. and comp.), *Romantic Bards and British Reviewers: A Selected Edition of the Contemporary Reviews of the Works of Wordsworth, Coleridge, Byron, Keats, and Shelley* (1971, reprinted 1976); and THEODORE REDPATH (comp.), *The Young Romantics and Critical Opinion, 1807–1824: Poetry of Byron, Shelley, and Keats as Seen by Their Contemporary Critics* (1973). Social and intellectual background of the period is the subject of numerous works: RAYMOND WILLIAMS, *Culture and Society, 1780–1950* (1958, reprinted 1983); M.H. ABRAMS, *The Mirror and the Lamp: Romantic Theory and the Critical Tradition* (1953, reprinted 1971), and *Natural Supernaturalism: Tradition and Revolution in Romantic Literature* (1971); MARILYN BUTLER, *Jane Austen and the War of Ideas* (1975), and *Romantics, Rebels, and Reactionaries: English Literature and Its Background, 1760–1830* (1981); HERBERT W. PIPER, *The Active Universe* (1962); CARL WOODRING, *Politics in English Romantic Poetry* (1970); H.G. SCHENK, *The Mind of the European Romantics: An Essay in Cultural History* (1966, reissued 1969); STEPHEN PRICKETT, *The Romantics* (1981), and *Romanticism and Religion: The Tradition of Coleridge and Wordsworth in the Victorian Church* (1976); and LILIAN R. FURST, *Romanticism in Perspective: A Comparative Study of Aspects of the Romantic Movements in England, France, and Germany,* 2nd ed. (1979). Analytical studies of narrower topics include J.R. WATSON, *English Poetry of the Romantic Period, 1789–1830* (1985), and *Picturesque Landscape and English Romantic Poetry* (1970); THOMAS WEISKEL, *The Romantic Sublime: Studies in the Structure and Psychology of Transcendence* (1976); THOMAS MCFARLAND, *Romanticism and the Forms of Ruin: Wordsworth, Coleridge, and Modalities of Fragmentation* (1981), and *Coleridge and the Pantheist Tradition* (1969); ELIZABETH SEWELL, *The Orphic Voice: Poetry and Natural History* (1960, reissued 1971); C.M. BOWRA, *The Romantic Imagination* (1949, reissued 1969); MICHAEL G. COOKE, *The Romantic Will* (1976); HAROLD BLOOM, *The Visionary Company: A Reading of English Romantic Poetry,* rev. ed. (1971), and *Poetry and Repression: Revisionism from Blake to Stevens* (1976); PAUL A. CANTOR, *Creature and Creator: Myth-Making and English Romanticism* (1984); G. WILSON KNIGHT, *The Starlit Dome: Studies in the Poetry of Vision,* rev. ed. (1959, reissued 1971); DAVID MORSE, *Perspectives on Romanticism: Transformational Analysis* (1981), and *Romanticism, a Structural Analysis* (1982); ALBERT S. GÉRARD, *English Romantic Poetry: Ethos, Structure, and Symbol in Coleridge, Wordsworth, Shelley, and Keats* (1968); and DAVID G. JAMES, *The Romantic Comedy* (1948, reprinted 1980). Comprehensive collections are represented by H.S. MILFORD (comp.), *The Oxford Book of English Verse of the Romantic Period, 1798–1830* (1935, reprinted 1974); HAROLD BLOOM (ed.), *English Romantic Poetry: An Anthology,* 2 vol. (1963); and HAROLD BLOOM and LIONEL TRILLING (eds.), *Romantic Poetry and Prose* (1973).

Victorian literature: Comprehensive studies of the period, introducing the literary background, include WALTER E. HOUGHTON, *The Victorian Frame of Mind, 1830–1870* (1957, reprinted 1966); JEROME HAMILTON BUCKLEY, *The Victorian Temper: A Study in Literary Culture* (1951, reprinted 1981); BASIL WILLEY, *Nineteenth Century Studies: Coleridge to Matthew Arnold* (1949, reissued 1980); ARTHUR POLLARD (ed.), *The Victorians* (1970); and G.K. CHESTERTON, *The Victorian Age in Literature* (1913). Studies of special subjects are presented in GEORGE LEVINE and WILLIAM MADDEN (eds.), *The Art of Victorian Prose* (1968), on nonfiction; MICHAEL WHEELER, *English Fiction of the Victorian Period: 1830–1890* (1985); KATHLEEN TILLOTSON, *Novels of the Eighteen-Forties* (1954, reprinted 1983); ROBERT LANGBAUM, *The Poetry of Experience: The Dramatic Monologue in Modern Literary Tradition* (1957, reprinted 1985), on Victorian poetry; GEORGE ROWELL, *The Victorian Theatre, 1792–1914,* 2nd ed. (1978); and ROGER B. HENKLE, *Comedy and Culture, 1820–1900* (1980).

Modern English literature (1900–45): MALCOLM BRADBURY, *The Social Context of Modern English Literature* (1971), is a discussion of the effects of modernization on the form and content of English literature and on the role of the modern writer. MALCOLM BRADBURY and JAMES MCFARLANE (eds.), *Modernism: 1890–1930* (1976), is a collection of essays focusing on the international context of Anglo-American modernism. MICHAEL H. LEVENSON, *A Genealogy of Modernism: A Study of English Literary Doctrine, 1908–1922* (1984), is a meticulously detailed history of the modernist movement in England. *From James to Eliot* (1983) is a comprehensive collection of essays on the social and cultural background of the literature of the early 20th century; it is the seventh volume in BORIS FORD (ed.), *The New Pelican Guide to English Literature,* 8 vol., rev. ed. (1982–83). CHRISTOPHER GILLIE, *Movements in English Literature, 1900–1940* (1975), is a straightforward introduction to the history of fiction, poetry, and drama of the period. The historical background is also explored in SAMUEL HYNES, *The Auden Generation: Literature and Politics in England in the 1930s* (1976, reissued 1982); and ROBERT HEWISON, *Under Siege: Literary Life in London 1939–1945* (1977). DAVID PERKINS, *A History of Modern Poetry: From the 1890s to the High Modernist Mode* (1976), is a broad study with emphasis on the interplay between British and American poetry. JOHN PRESS, *A Map of Modern English Verse* (1969), is an analysis of traditional and modernist poetry from the 1900s to the 1950s.

Literature after 1945: ROBERT HEWISON, *In Anger: Culture in the Cold War, 1945–60* (1981), is a general historical study of the period; and BORIS FORD (ed.), *The Present* (1983), is a sound general survey. BERNARD BERGONZI, *The Situation of the Novel,* 2nd ed. (1979), presents a comprehensive treatment of contemporary fiction; MALCOLM BRADBURY and DAVID PALMER (eds.), *The Contemporary English Novel* (1980), reflects the critical opinion of the 1970s; as does MALCOLM BRADBURY (ed.), *The Novel Today: Contemporary Writers on Modern Fiction* (1977). JOHN ELSOM, *Post-War British Theatre,* rev. ed. (1979), is a historical survey; and JOHN RUSSELL BROWN, *A Short Guide to Modern British Drama* (1983), gives brief accounts of general trends and individual plays. EDWARD LUCIE-SMITH (ed.), *British Poetry Since 1945* (1970); D.J. ENRIGHT (ed.), *The Oxford Book of Contemporary Verse, 1945–1980* (1980); and BLAKE MORRISON and ANDREW MOTION (eds.), *The Penguin Book of Contemporary British Poetry* (1982), are representative anthologies with critical information on the movements and trends.

Epistemology

Epistemology is one of the main branches of philosophy; its subject matter concerns the nature, origin, scope, and limits of human knowledge. The name is derived from the Greek terms *epistēmē* (knowledge) and *logos* (theory), and accordingly this branch of philosophy is also referred to as the theory of knowledge.

For coverage of related topics in the *Macropædia* and the *Micropædia,* see the *Propædia,* sections 10/51, 10/52, and 10/53, and the *Index.*

This article is divided into the following sections:

Issues of epistemology

EPISTEMOLOGY AS A DISCIPLINE

Why should there be such a subject as epistemology? Aristotle provided the answer when he said that philosophy begins in wonder, in a kind of puzzlement about things. Nearly all human beings wish to comprehend the world they live in, a world that includes the individual as well as other persons, and most people construct hypotheses of varying degrees of sophistication to help them make sense of that world. No conjectures would be necessary if the world were simple; but its features and events defy easy explanation. The ordinary person is likely to give up somewhere in the process of trying to develop a coherent account of things and to rest content with whatever degree of understanding he has managed to achieve.

Philosophers, in contrast, are struck by, even obsessed by, matters that are not immediately comprehensible. Philosophers are, of course, ordinary persons in all respects except perhaps one. They aim to construct theories about the world and its inhabitants that are consistent, synoptic, true to the facts and that possess explanatory power. They thus carry the process of inquiry further than people generally tend to do, and this is what is meant by saying that they have developed a philosophy about these matters. Epistemologists, in particular, are philosophers whose theories deal with puzzles about the nature, scope, and limits of human knowledge.

Like ordinary persons, epistemologists usually start from the assumption that they have plenty of knowledge about the world and its multifarious features. Yet, as they reflect upon what is presumably known, epistemologists begin to discover that commonly accepted convictions are less secure than originally assumed and that many of man's firmest beliefs are dubious or possibly even chimerical. Such doubts and hesitations are caused by anomalous features of the world that most people notice but tend to minimize or ignore. Epistemologists notice these things too, but, in wondering about them, they come to realize that they provide profound challenges to the knowledge claims that most individuals blithely and unreflectingly accept as true.

What then are these puzzling issues? While there is a vast array of such anomalies and perplexities, which will be discussed below in the section on the history of epistemology, two of these issues will be briefly described in order to illustrate why such difficulties call into question common claims to have knowledge about the world.

TWO EPISTEMOLOGICAL PROBLEMS

"Our knowledge of the external world." Most people have noticed that vision can play tricks on them. A straight stick put in water looks bent to them, but they know it is not; railroad tracks are seen to be converging in the distance, yet one knows that they are not; the wheels of wagons on a movie screen appear to be going backward, but one knows that they are not; and the pages of English-language books reflected in mirrors cannot be read from left to right, yet one knows that they were printed to be read that way. Each of these phenomena is thus misleading in some way. If human beings were to accept the world as being exactly as it looks, they would be mistaken about how things really are. They would think the stick in water really to be bent, the railway tracks really to be convergent, and the writing on pages really to be reversed.

Visual anomalies

These are visual anomalies, and they produce the sorts of epistemological disquietudes referred to above. Though they may seem to the ordinary person to be simple problems, not worth serious notice, for those who ponder them they pose difficult questions. For instance, human beings claim to know that the stick is not really bent and the tracks not really convergent. But how do they know that these things are so?

Suppose one says that this is known because, when the stick is removed from the water, one can see that it is not bent. But does seeing a straight stick out of water provide a good reason for thinking that it is not bent when seen in water? How does one know that, when the stick is put into the water, it does not bend? Suppose one says that the tracks do not really converge because the train passes over them at that point. How does one know that the wheels on the train do not happen to converge at that point? What justifies opposing some beliefs to others, especially when

all of them are based upon what is seen? One sees that the stick in water is bent and also that the stick out of the water is not bent. Why is the stick declared really to be straight; why in effect is priority given to one perception over another?

One possible response to these queries is that vision is not sufficient to give knowledge of how things are. One needs to correct vision in some other way in order to arrive at the judgment that the stick is really straight and not bent. Suppose a person asserts that his reason for believing the stick in water is not bent is that he can feel it with his hands to be straight when it is in the water. Feeling or touching is a mode of sense perception, although different from vision. What, however, justifies accepting one mode of perception as more accurate than another? After all, there are good reasons for believing that the tactile sense gives rise to misperception in just the way that vision does. If a person chills one hand and warms the other, for example, and inserts both into a tub of water having a uniform medium temperature, the same water will feel warm to the cold hand and cold to the warm hand. Thus, the tactile sense cannot be trusted either and surely cannot by itself be counted on to resolve these difficulties.

Another possible response is that no mode of perception is sufficient to guarantee that one can discover how things are. Thus, it might be affirmed that one needs to correct all modes of perception by some other form of awareness in order to arrive at the judgment, say, that the stick is really straight. Perhaps that other way is the use of reason. But why should reason be accepted as infallible? It also suffers from various liabilities, such as forgetting, misestimating, or jumping to conclusions. And why should one trust reason if its conclusions run counter to those gained through perception, since it is obvious that much of what is known about the world derives from perception?

Reason as a corrective perception

Clearly there is a network of difficulties here, and one will have to think hard in order to arrive at a clear and defensible explanation of the apparently simple claim that the stick is really straight. A person who accepts the challenge will, in effect, be developing a theory for grappling with the famous problem called "our knowledge of the external world." That problem turns on two issues, namely, whether there is a reality that exists independently of the individual's perception of it—in other words, if the evidence one has for the existence of anything is what one perceives, how can one know that anything exists unperceived?—and, second, how one can know what anything is really like, if the perceptual evidence one has is conflicting.

The "other-minds problem." The second problem also involves seeing but in a somewhat unusual way. It deals with that which one cannot see, namely the mind of another. Suppose a woman is scheduled to have an operation on her right knee and her surgeon tells her that when she wakes up she will feel a sharp pain in her knee. When she wakes up, she does feel the pain the surgeon alluded to. He can hear her groaning and see certain contortions on her face. But he cannot feel what she is feeling. There is thus a sense in which he cannot know what she knows. What he claims to know, he knows because of what others who have undergone operations tell him they have experienced. But, unless he has had a similar operation, he cannot know what it is that she feels.

Indeed, the situation is still more complicated; for, even if the doctor has had such a surgical intervention, he cannot know that what he is feeling after his operation is exactly the same sensation that the woman is feeling. Because each person's sensation is private, the surgeon cannot really know that what the woman is describing as a pain and what he is describing as a pain are really the same thing. For all he knows, she could be referring to a sensation that is wholly different from the one to which he is alluding.

In short, though another person can perceive the physical manifestations the woman exhibits, such as facial grimaces and various sorts of behaviour, it seems that only she can have knowledge of the contents of her mind. If this assessment of the situation is correct, it follows that it is impossible for one person to know what is going on in another person's mind. One can conjecture that a person is experiencing a certain sensation, but one cannot, in a strict sense of the term, know it to be the case.

If this analysis is correct, one can conclude that each human being is inevitably and even in principle cut off from having knowledge of the mind of another. Most people, conditioned by the great advances of modern technology, believe that in principle there is nothing in the world of fact about which science cannot obtain knowledge. But the "other-minds problem" suggests the contrary—namely, that there is a whole domain of private human experience that is resistant to any sort of external inquiry. Thus, one is faced with a profound puzzle, one of whose implications is that there can never be a science of the human mind.

Implications. These two problems resemble each other in certain ways and differ in others, but both have important implications for epistemology.

First, as the divergent perceptions about the stick indicate, things cannot just be as they appear to be. People believe that the stick which looks bent when it is in the water is really straight, and they also believe that the stick which looks straight when it is out of the water is really straight. But, if the belief that the stick in water is really straight is correct, then it follows that the perception human beings have when they see the stick in water cannot be correct. That particular perception is misleading with respect to the real shape of the stick. Hence, one has to conclude that things are not always as they appear to be.

Distinction between appearance and reality

It is possible to derive a similar conclusion with respect to the mind of another. A person can exhibit all the signs of being in pain, but he may not be. He may be pretending. On the basis of what can be observed, it cannot be known with certitude that he is or that he is not in pain. The way he appears to be may be misleading with respect to the way he actually is. Once again vision can be misleading.

Both problems thus force one to distinguish between the way things appear and the way they really are. This is the famous philosophical distinction between appearance and reality. But, once that distinction is drawn, profound difficulties arise about how to distinguish reality from mere appearance. As will be shown, innumerable theories have been presented by philosophers attempting to answer this question since time immemorial.

Second, there is the question of what is meant by "knowledge." People claim to know that the stick is really straight even when it is half-submerged in water. But, as indicated earlier, if this claim is correct, then knowledge cannot simply be identical with perception. For whatever theory about the nature of knowledge one develops, the theory cannot have as a consequence that knowing something to be the case can sometimes be mistaken or misleading.

Third, even if knowledge is not simply to be identified with perception, there nevertheless must be some important relationship between knowledge and perception. After all, how could one know that the stick is really straight unless under some conditions it looked straight? And sometimes a person who is in pain exhibits that pain by his behaviour; thus there are conditions that genuinely involve the behaviour of pain. But what are those conditions? It seems evident that the knowledge that a stick is straight or that one is in great pain must come from what is seen in certain circumstances: perception must somehow be a fundamental element in the knowledge human beings have. It is evident that one needs a theory to explain what the relationship is—and a theory of this sort, as the history of the subject all too well indicates, is extraordinarily difficult to develop.

The two problems also differ in certain respects. The problem of man's knowledge of the external world raises a unique difficulty that some of the best philosophical minds of the 20th century (among them, Bertrand Russell, H.H. Price, C.D. Broad, and G.E. Moore) spent their careers trying to solve. The perplexity arises with respect to the status of the entity one sees when one sees a bent stick in water. In such a case, there exists an entity—a bent stick in water—that one perceives and that appears to be exactly where the genuinely straight stick is. But clearly it cannot be; for the entity that exists exactly where the

straight stick is is the stick itself, an entity that is not bent. Thus, the question arises as to what kind of a thing this bent-stick-in-water is and where it exists.

The responses to these questions have been innumerable, and nearly all of them raise further difficulties. Some theorists have denied that what one sees in such a case is an existent entity at all but have found it difficult to explain why one seems to see such an entity. Still others have suggested that the image seen in such a case is in one's mind and not really in space. But then what is it for something to be in one's mind, where in the mind is it, and why, if it is in the mind, does it appear to be "out there," in space where the stick is? And above all, how does one decide these questions? The various questions posed above only suggest the vast network of difficulties, and in order to straighten out its tangles it becomes indispensable to develop theories.

RELATION OF EPISTEMOLOGY TO OTHER BRANCHES OF PHILOSOPHY

Philosophy viewed in the broadest possible terms divides into many branches: metaphysics, ethics, aesthetics, logic, philosophy of language, philosophy of mind, philosophy of science, and a gamut of others. Each of these disciplines has its special subject matter: for metaphysics it is the ultimate nature of the world; for ethics, the nature of the good life and how people ideally ought to comport themselves in their relations with others; and for philosophy of science, the methodology and results of scientific activity. Each of these disciplines attempts to arrive at a systematic understanding of the issues that arise in its particular domain. The word systematic is important in this connection, referring, as explained earlier, to the construction of sets of principles or theories that are broad-ranging, consistent, and rationally defensible. In effect, such theories can be regarded as sets of complex claims about the various matters that are under consideration.

Epistemology stands in a close and special relationship to each of these disciplines. Though the various divisions of philosophy differ in their subject matter and often in the approaches taken by philosophers to their characteristic questions, they have one feature in common: the desire to arrive at the truth about that with which they are concerned—say, about the fundamental ingredients of the world or about the nature of the good life for man. If no such claims were asserted, there would be no need for epistemology. But, once theses have been advanced, positions staked out, and theories proposed, the characteristic questions of epistemology inexorably follow. How can one know that any such claim is true? What is the evidence in favour of (or against) it? Can the claim be proven? Virtually all of the branches of philosophy thus give rise to epistemological ponderings.

These ponderings may be described as first-order queries. They in turn inevitably generate others that are, as it were, second-order queries, and which are equally or more troubling. What is it to know something? What counts as evidence for or against a particular theory? What is meant by a proof? Or even, as the Greek Skeptics asked, is human knowledge possible at all, or is human access to the world such that no knowledge and no certitude about it is possible? The answers to these second-order questions also require the construction of theories, and in this respect epistemology is no different from the other branches of philosophy. One can thus define or characterize epistemology as that branch of philosophy which is dedicated to the resolution of such first- and second-order queries.

THE NATURE OF KNOWLEDGE

As indicated above, one of the basic questions of epistemology concerns the nature of knowledge. Philosophers normally interpret this query as a conceptual question, *i.e.,* as an issue about a certain conception or idea or notion called knowledge. The question raises a perplexing methodological issue, namely, how does one go about investigating such conceptual questions? It is frequently assumed, though the matter is controversial, that one can determine what knowledge is if one can understand what the word "knowledge" means, that is, what notion or concept the word "knowledge" expresses or embodies.

The word and its meaning

Philosophers who proceed in this way draw a distinction between a word and its meaning, and a meaning is generally considered to be the concept which that particular word has or expresses. It is usually further assumed that though concepts are not identical with words, that is, with linguistic expressions, language is the medium in which the meaning of such concepts is displayed or expressed.

The investigation into the nature of knowledge often begins in a similar fashion with the study of the use of the word "knowledge" and of certain cognate expressions and phrases found in everyday language. A survey of such locutions reveals important differences in their uses: one finds such expressions as "know him," "know that," "know how," "know where," "know why," or "know whether." These differences have been explored in detail, especially in the 20th century. The expression "know *x,*" where "*x*" can be replaced by a proper name, as in "I know Jones" or "He knows Rome," has been taken by some philosophers, notably Bertrand Russell (1872–1970), to be a case of knowledge by acquaintance. Russell thought its characteristic use was to express the kind of knowledge one has when one has first-hand familiarity with a certain object, person, or place. Thus, one could not properly say in the 20th century, "I know Julius Caesar," since this would imply that one had met or was directly acquainted with a person who had died some 2,000 years ago. This sense or use of "know" becomes important in the theory of perception and in sense-data theory, since some philosophers, such as Russell and G.E. Moore (1873–1958), have held that one's awareness of a sense-datum (a notion to be discussed later) is a case of direct acquaintance, whereas one's acquaintance with a physical object, such as a human hand, is not.

The phrases "know that" and "know how" have also played fundamental roles in the theory of knowledge. The British philosopher Gilbert Ryle (1900–76), for instance, argued that "know how" is normally used to refer to a kind of skill that a person has, such as knowing how to swim. One could have such knowledge without being able to explain to another what it is that one knows in such a case, that is, without being able to convey to another the knowledge required for that person to develop the same skill. "Know that," in contrast, does not seem to denote the possession of a skill or aptitude but rather the possession of specific pieces of information, and the person who has knowledge of this sort can generally convey it to others. To know that the Concordat of Worms was signed in the year 1122 would be an example of this sort of knowledge. Ryle has argued that, given these differences, some cases of knowing how cannot be reduced to cases of knowing that and, accordingly, that the kinds of knowledge expressed by these phrases are independent of one another.

In general, the philosophical tradition from the Greeks to the present has focused on the kind of knowledge expressed when it is said that someone knows that such and such is the case, *e.g.,* that A knows that snow is white. This sort of knowledge, called propositional knowledge, raises the classical epistemological questions about the truth or falsity of the asserted claim, the evidence for it, and a host of other problems. Among them is the much debated issue of what kind of thing is known when one knows that *p, i.e.,* what counts as a substitution instance of *p.* The list of such candidates includes beliefs, propositions, statements, sentences, and utterances of sentences. Each has or has had its proponents, and the arguments pro and con are too subtle to be explored here. Two things should, however, be noted in this connection: first, that the issue is closely related to the problem of universals (*i.e.,* whether what is known to be true is an abstract entity, such as a proposition, or whether it is a linguistic expression, such as a sentence or a sentence-token) and, second, that it is agreed by all sides that one cannot have knowledge, in this sense of "knowledge," of that which is not true. One of the necessary conditions for saying that A knows that *p* is that *p* must be true, and this condition can therefore be regarded as one of the main elements in any accurate characterization of knowledge.

Propositional knowledge

SIX DISTINCTIONS OF KNOWLEDGE

Mental versus nonmental conceptions of knowledge. Philosophers have asked whether knowledge is a state of mind, *i.e.,* a special kind of awareness of things. That it is has been argued by philosophers since at least the 5th century BC. In *The Republic* Plato provided the first extensive account of such a view. He regarded knowing as a mental faculty, akin to but different from believing or opining. Contemporary versions of this sort of theory regard knowing as one member of a sequence of mental states that involve increasing certitude. This spectrum would begin with guessing or conjecturing at the lowest end of certitude, would include thinking, believing, and feeling sure as expressing stronger attitudes of conviction, and would end with knowledge as the highest of all these states of mind. Knowledge, in all views of this type, is a form of consciousness, the strongest degree of awareness humans possess, and accordingly it is common for proponents of such views to hold that, if A knows that *p,* A must be conscious of what he knows. This view is normally expressed by saying that, if A knows that *p,* A knows that he knows that *p.*

Knowledge as a form of consciousness

Many 20th-century philosophers have rejected the notion that knowledge is a mental state. In *On Certainty* (1969) Ludwig Wittgenstein says: " 'Knowledge' and certainty belong to different *categories.* They are not two mental states like, say surmising and being sure." But, if knowing is not a mental state, then what is it? These philosophers have accepted the challenge of trying to give a different characterization of what it means to say that a person knows something. They typically begin by pointing out that a person can know that *p* without knowing that he knows it (a good example is in fact to be found in Plato's *Meno,* where Socrates gradually elicits from a slave boy geometrical knowledge that the boy was not aware he had). They then proceed to argue that it is a mistake to assimilate cases of knowing to cases of doubting, feeling a pain, or having a certain opinion about something. All of these latter are mental states, and they are such that a person who has such a state is aware that he does.

These philosophers, moreover, typically deny that knowing can be described as being a single thing, such as a state of consciousness. Instead, they claim that one can ascribe knowledge to someone, or to oneself, when certain complex conditions are satisfied, among them certain behavioral conditions. For example, if a person can always give the right answers to questions under test conditions, one would be entitled to say that the person has knowledge of the issues under consideration. Knowing on this account seems tied to the capacity to perform in certain ways under certain standard conditions. Accordingly, though such performances may involve the exercise of intelligence or other mental factors, the attribution of knowledge to someone is not merely the attribution of a certain mental state or state of awareness to that person (as seen in the case of the slave boy in the *Meno*).

A well-known variant of such a view was advanced by J.L. Austin in his 1946 paper "Other Minds." Austin claimed that, when one says "I know," one is not describing anything, let alone one's psychology or a mental state. Instead, one is engaging in a social act, *i.e.,* one is indicating that one is in the position (has the credentials and the reasons) to assert *p* in circumstances where it is necessary to resolve a doubt. When these conditions are satisfied, one can correctly be said to know.

Occurrent versus dispositional conceptions of knowledge. A distinction closely related to the previous one is that between occurrent and dispositional conceptions of knowledge. The difference between occurrences and dispositions can be illustrated with respect to sugar. A sugar cube will dissolve if put into water. One can thus say that, even if the cube is not now dissolving as it sits on the table, it will do so under certain conditions. This propensity to dissolve is what is meant by a disposition, and it is a feature sugar has at all times and in all conditions. It can be contrasted with sugar's actually dissolving when immersed in liquid, which is an occurrence, that is, an event happening at a specific place and at a specific time.

These terms also apply to mental events. One can say of Smith, who is working on a problem, that he has just seen the solution. According to this way of speaking, there is a certain answer that Smith is presently aware of and to which he is attending. In such a case Smith's knowledge is occurrent. But one can also ascribe a different sort of knowledge to Smith. Though Smith is perhaps not now thinking of his home address, he certainly knows it in the sense that, if he were asked, he could produce the correct answer. One can thus have knowledge that one is not aware of at a given moment. One can thus say, as with sugar, that knowledge may be either occurrent or dispositional in character, *i.e.,* that one may or may not be in an immediate state of self-awareness with respect to *p,* but that in either case it can be said that the person knows that *p.*

It should be noted that the distinction between dispositional and occurrent knowledge thus applies to cases of "knowing that" as well as to cases of "knowing how" and thus is a powerful conceptual tool for analyzing different sorts of epistemic notions. The concept of a disposition has itself been further analyzed, for example by Roderick M. Chisholm (b. 1916), in counterfactual terms, and it has been proposed by many philosophers that the knowledge expressed by causal laws (laws of nature) is counterfactual and thus dispositional in character.

Counterfactual knowledge

A priori versus a posteriori knowledge. A sharp distinction has been drawn since at least the 17th century between two types of knowledge: a priori knowledge and a posteriori knowledge. The distinction plays an especially important role in the philosophies of David Hume (1711–76) and Immanuel Kant (1724–1804). It is also found in many contemporary, empirically oriented theories of knowledge, which typically hold that all knowledge about matters of fact derives from experience and is therefore a posteriori and that in consequence such knowledge is never certain but at most only probable.

The difference between these types of knowledge is easy to illustrate by means of examples. Consider the sentences "All husbands are married" and "All Model-T Fords are black" and assume that both statements are true. But how does one come to know that they are true? In the case of the first, the answer is that, if one thinks about the meaning of the various words in the sentence, one can see that the sentence is true. One can see that this is so because what is meant by "husband" is the same as what is meant by "married male." Thus, by definition, every husband is a married male, and, accordingly, every husband is married. In calling such knowledge a priori, philosophers are pointing out that one does not have to engage in a factual or empirical inquiry in order to determine whether the sentence is true or not. One can know this merely on the basis of reflection and thus prior to or before any investigation of the facts.

In contrast, the second statement can be determined to be true only after such an investigation. One may well know that the Model-T Ford was an automobile built prior to World War II and accordingly would understand what all the words in the sentence mean. Nonetheless, understanding alone would not be sufficient to allow one to determine whether the sentence is true or not. Instead, some kind of empirical investigation is required in order to arrive at such a judgment; the knowledge thus acquired is a posteriori, or knowledge after the fact.

There are sets of distinctions related to the one just developed and in terms of which the two propositions can also be differentiated. They are necessary versus contingent, analytic versus synthetic, tautological versus significant, and logical versus factual.

Necessary versus contingent propositions. A proposition is said to be necessary if it holds (is true) under all possible circumstances or conditions. "All husbands are married" is such a proposition. There are no possible or conceivable conditions under which this statement would not be true (on the assumption, of course, that the words "husband" and "married" are taken to mean what they ordinarily mean). In contrast, "All Model-T Fords are black" holds in some circumstances (those actually obtaining, and that is why the proposition is true), but it is easy to imagine circumstances in which it would not be true—for instance,

if somebody painted one of those cars a different colour. To say, therefore, that a proposition is contingent is to say that it holds in some but not in all possible circumstances. Some necessary propositions, such as "All husbands are married" are a priori (though not all are) and most contingent propositions are a posteriori.

Analytic versus synthetic propositions. A proposition is often said to be analytic if the meaning of the predicate term is contained in the meaning of the subject term. Thus, "All husbands are married" is analytic because the term "husband" includes as part of its meaning "being married." A term is said to be synthetic if this is not so. Therefore, "All Model-T Fords are black" is synthetic since the term "black" is not included in the meaning of "Model-T Ford." Some analytic propositions are a priori, and most synthetic propositions are a posteriori. These distinctions were used by Kant to ask one of the most important questions in the history of epistemology, namely, whether a priori synthetic judgments are possible (see below for a discussion of this question).

Tautological versus significant propositions. A proposition is said to be tautological if its constituent terms repeat themselves or if they can be reduced to terms that do, so that the proposition is of the form "a = a." In such a case the proposition is said to be trivial and empty of cognitive import. A proposition is said to be significant if its constituent terms are such that the proposition does provide new information about the world. It is generally agreed that no significant propositions can be derived from tautologies. One of the objections to the ontological argument is that no existential (significant) proposition can be derived from the tautological definition of "God" with which the argument begins. Tautologies are generally known to be true a priori, are necessary, and are analytic; and significant statements are generally a posteriori, contingent, and synthetic.

In the ontological argument, for example, God is defined (roughly speaking) as the only perfect being. It is then argued that no being can be perfect unless it exists; therefore, God exists. But, as Hume and Kant pointed out, it is fallacious to derive a factual statement about the existence of God from the definition of God as a perfect being (see the discussion of St. Anselm below).

Logical versus factual propositions. The term "logical" in this connection is used in a wide sense to include a proposition such as "All husbands are married." By analyzing the meaning of its constituent terms one can reduce the proposition to a logical truth, *e.g.*, to "A and B implies A." In contrast, factual propositions, such as "All Model-T Fords are black," have syntactical and semantic structures that differentiate them from any propositions belonging to logic, even in the broad sense mentioned above. The theorems of logic are often a priori (though not always), are always necessary, and are typically analytic. Factual propositions are generally a posteriori, contingent, and synthetic.

These various distinctions are widely appealed to in present-day philosophy. For instance, Saul Kripke (b. 1941) in "Naming and Necessity" (1972) has used these notions in an effort to solve a long-standing problem, namely, how true identity statements can be nontrivial. The problem, first articulated by Gottlob Frege in "On Sense and Reference" (1893) and later independently addressed by Russell, begins with the assumption that the sentences "Scott is Scott" and "Scott is the author of *Waverley*" are both identity sentences and are true and that the former is trivial while the latter is not. The puzzle arises from the further assumption that any true identity sentence simply says of some object that it is identical with itself. Hence, all such sentences should be trivial. Clearly, however, "Scott is the author of *Waverley*" is not trivial. But, if it is not, how is this possible?

Trivial and nontrivial identity sentences

Kripke argues that all true identity sentences are necessary (*i.e.*, that they hold in all possible worlds) and that some of these, such as "Scott is Scott," are known a priori and accordingly are trivial; but, he argues, some true identity sentences are not known a priori but only a posteriori and are not trivial. In cases of the latter sort, their nontriviality is a function of their being known to be true only after some sort of inquiry or investigation. It is the investigation that provides new information.

A good example would be the following. At one time in human history, ancient peoples did not know that what they called "the evening star" was the same planet called "the morning star." But eventually the Babylonians discovered through astronomical observation that the morning star is the planet Venus as it appears in the morning sky and that the evening star is the planet Venus as it appears in the evening sky. The discovery that these two appearances are appearances of the same object amounted to discovering more than that Venus is Venus. It provided new information, and that is why "the morning star is identical with the evening star" is significant in a way in which "Venus is Venus" is not, even though all of the descriptive terms in both sentences refer to exactly the same object. In similar fashion, the a posteriori finding that it was Scott who wrote *Waverley* explains the nontriviality of "Scott is the author of *Waverley*." But no such investigation was needed to determine that Scott is Scott.

Knowledge by acquaintance and knowledge by description. The distinction between knowledge by acquaintance and knowledge by description was introduced by Bertrand Russell in connection with his celebrated theory of descriptions. Here only the epistemological (as distinct from the logical) version of his theory will be considered. It was invented by Russell to lend support to the basic thesis of empiricism that all knowledge of matters of fact (*i.e.*, all a posteriori knowledge) derives from experience. Russell's program is both reductive and foundationalist. It tries to show that man's system of knowledge is stratified: that some types of knowledge depend on others but that some do not and that the latter form the foundational units which give support to the whole epistemic system. He argued that, because these basic units rest upon direct experience, ultimately all factual knowledge is derivable from experience.

Russell's argument begins with a distinction between two different types of knowledge, that which is and that which is not based on direct experience. Nearly all of man's knowledge is of the latter type. For example, it is known that some 2,000 years ago there lived a Roman statesman named Augustus, that he was the successor to Julius Caesar, who had been assassinated, and that he was a friend of the historian Livy. But, since none of these pieces of information is presently known on the basis of personal experience, what justification is there for calling them instances of knowledge?

Russell argued that information based on direct experience is basic and needs no justification; he called it "knowledge by acquaintance." Information not based on direct experience he called "knowledge by description." One is justified in calling such information knowledge, if one can show that it can be traced back to and thus ultimately rests upon knowledge by acquaintance. To show how this is so in a particular case is to legitimate that particular piece of information as a specimen of knowing. Here is how this reductive process would work in the case of what is known about Augustus.

Whatever information people in the 20th century have about Augustus probably comes to them from literary works, such as Livy's history of Rome. Such information thus comes secondhand, via descriptions in books about the life and activities of Augustus. But why call such descriptions knowledge? The answer is that through a historical process one can trace such information back to an original source like Livy, who was a contemporary of Augustus. One learns, via this process, that Livy in his history of Rome is reporting events that he had witnessed himself or that he had learned from other eyewitnesses. One can call what he tells about Augustus knowledge, because it is testimony that is based upon his or someone else's direct experience. Thus, knowledge by description is a legitimate form of knowledge, even though it is ultimately dependent upon knowledge by acquaintance.

Russell's reductive thesis then was that all legitimate specimens of knowledge are either based upon direct experience or can be shown to be dependent upon such direct experience via a chain of tight historical or causal links.

His theory was therefore a form of empiricism, because it tried to show how all knowledge of matters of fact could be derived from experience.

But there is a further feature of the theory, stemming from the empirical tradition of John Locke (1632–1704) and David Hume, that gives a special twist to the notion of "knowledge by acquaintance." According to this tradition, knowledge by acquaintance is always knowledge based upon what Hume called "impressions," or upon what Russell called "sense-data." These for Russell were mental entities that generally, but not always, reflected the characteristics actually possessed by physical objects. But, unlike physical objects, sense-data were the objects directly apprehended in an act of perception. What Russell meant by "direct apprehension" or "direct perception" was itself explicated in terms of the concepts of inference and non-inference. He held that direct perception, *i.e.,* the perceptual awareness of a sense-datum, involves no inference and, accordingly, that knowledge by acquaintance is identical with the perception of sense-data.

Sense-data

The difference between inferential and noninferential perception can be illustrated by an example. Suppose one is working in a room and hears a sound that emanates from an outside source. (Russell considered hearing to be a form of perception.) In such a case the sound is a sense-datum. One need not infer that one is hearing a sound; there is a direct awareness of it. This would be a case of knowledge by acquaintance. On the basis of what one hears in this direct fashion, one might then infer (guess, conjecture, hypothesize) that what is causing the sound is a motorcycle located outside of the room, something that one who is in the room cannot see directly. If one is correct in this supposition, the information obtained in this way would be a case of indirect knowledge. In such a case, one's knowledge that there is a motorcycle in the street is dependent on (and in Russell's sense, reducible to) one's direct awareness of a sound. The example illustrates how indirect knowledge, such as knowledge by description, is derived from direct knowledge, such as knowledge by acquaintance, and in turn how this latter depends upon the direct awareness of sense-data.

It should be mentioned that the distinction between knowledge by acquaintance and knowledge by description can be defended as legitimate and useful independently of a commitment to sense-data theory. In Russell's work the objects of direct awareness are sense-data, but sense-data theory today has few proponents. A philosopher thus might hold that one at least sometimes directly perceives physical objects (which are not sense-data) while accepting that one's knowledge of past events and persons is indirect and is thus knowledge by description.

Description versus justification. Epistemology during its long history has engaged in two different sorts of tasks. One of these is descriptive in character. It aims to depict accurately certain features of the world, including the contents of the human mind, and to determine whether these should count as specimens of knowledge. A philosophical system with this orientation is, for example, the phenomenology of Edmund Husserl (1859–1938). Husserl's aim was to give an exact description of the notion of intentionality, which he characterized as consisting of a certain kind of "directedness" toward an object. Suppose the object is an ambiguous drawing, such as the duck/rabbit sketch found in the *Philosophical Investigations* of Ludwig Wittgenstein. A person looking at the sketch is not sure whether it is a drawing of a duck or of a rabbit. Husserl claimed that the light rays reaching the eye from such an ambiguous drawing are identical whether one sees the image of a duck or of a rabbit and that the difference in perception is due to the viewer's structuring of what he sees in the two cases. The theory tries to describe how such structuring takes place, and it ultimately becomes very complex in the account it gives.

In a famous passage in *Philosophical Investigations* (1953), Wittgenstein states that "explanation must be replaced by description," and much of his work was devoted to carrying out that task, as, for example, in his account of what it is to follow a rule. Another example of descriptive epistemology is found in the writings of such sense-data theorists as Moore, Price, and Russell. They begin with the question of whether there are basic apprehensions of the world, free from any form of inference, and in those cases where they have argued that the answer is yes, they have tried to describe what these are and why they should count as instances of knowledge. Russell's thesis that the whole edifice of knowledge is built up from a foundation composed of ingredients with which human beings are directly acquainted illustrates the close connection between the attempt to characterize various types of knowledge and this descriptive endeavour. The search by some logical positivists, such as Moritz Schlick (1882–1936), Otto Neurath (1882–1945), and A.J. Ayer (b. 1910) for protocol sentences, sentences that describe what is given in experience without inference, is a closely related example of this kind of descriptive practice.

Epistemology has a second function, which, in contrast to the descriptive one, is justificatory or normative. Philosophers concerned with this function start from the fact that all human beings have beliefs about the world, some of which are erroneous and some of which are not. The question to them is how one can justify (defend, support, or provide evidence for) certain sets of beliefs. The question has a normative import since it asks, in effect, what one ideally ought to believe. (In this respect epistemology has close parallels to ethics, where normative questions about how one ought ideally to act are asked.) This approach quickly takes one into the central domains of epistemology. It raises such questions as: Is knowledge identical with justified true belief? Is the relationship between evidence for a belief and the belief itself a probability function? If not, what is it? What indeed is meant by "justification" and what sorts of conditions have to be satisfied before one is entitled to say that a belief or set of beliefs is justified? These two differing aspects of epistemology are not inconsistent and indeed are often found intertwined in the writings of contemporary philosophers.

Normative function of epistemology

Knowledge and certainty. The relationship between knowledge and certainty is complex, and there is considerable disagreement about the matter. Are these concepts the same? If not, how do they differ? Is it possible for someone to know that p without being certain that p? Is it possible for someone to be certain that p without knowing that p? These are the central issues around which the debate revolves. The various answers that have been proffered depend on how the concepts of knowledge and certainty are analyzed. If one holds, for instance, that knowing is not a psychological state but that certainty is, then one would deny that the concepts are identical. But if one holds that knowing represents the highest degree of assurance which humans can obtain with respect to the truth of p, and that such a maximal degree of assurance is a psychological state, one will interpret the concepts to be equivalent. There have been proponents on both sides of this issue.

Further complicating the discussion are subtle distinctions drawn by 20th-century philosophers. For instance, in "Certainty" (1941) G.E. Moore claimed that there are four main types of idioms in which the word "certain" is commonly used: "I feel certain that," "I am certain that," "I know for certain that," and finally "It *is* certain that." He points out that "I feel certain that p" may be true when p is not true but that there is at least one use of "I know for certain that p" and "It is certain that p" which is such that neither of these sentences can be true unless p is true. Moore argues that it would be self-contradictory to say "I knew for certain that he would come but he didn't," whereas it would not be self-contradictory to say "I felt certain he would come but he didn't." In the former case, the fact that he did not come proves that one did not know that he would come, but, in the latter, the fact that he did not come does not prove that one did not feel certain he would. "I am certain that" differs from "I know for certain that" in allowing the substitution of the word "sure" for the word "certain." One can say "I feel sure (rather than certain)" without a change of meaning, whereas in "I know for certain" or "It is certain that" this substitution is not possible. On the basis of these sorts of considerations Moore contends that "a thing can't be certain unless it

is *known.*" He states that this is what distinguishes the word "certain" from the word "true." A thing that nobody knows may well be true, but it cannot possibly be certain. He thus infers that a necessary condition for the truth of "It is certain that *p*" is that somebody should know that *p* is true. Moore is therefore one of the philosophers who answers in the negative the question of whether it is possible for *p* to be certain without being known.

Moore also argues that to say "Someone knows that *p* is true" cannot be a sufficient condition for "It is certain that *p.*" If it were, it would follow that, in any case in which at least someone did know that *p* was true, it would always be false for anyone to say "It is not certain that *p*"; but clearly this is not so. If one person says that it is not certain that Smith is still alive, he is not thereby committing himself to the statement that nobody knows that Smith is still alive: the speaker's statement is consistent with Smith's still being alive, and both he himself and other persons know this. Moore is thus among those philosophers who would answer in the negative the question of whether the concepts of knowledge and certainty are the same. Though it is widely accepted that to affirm that somebody knows that *p* implies that somebody is certain that *p,* the case of the slave boy in Plato's *Meno* seems, at least at first glance, to be a counterinstance. Meno may know, in a dispositional sense, certain theorems of geometry without knowing that he knows, and, if he does not know that he knows, then it would seem that he cannot be certain that he does know. But it has also been argued that, once his disposition to know has been actualized and his knowledge has become occurrent, then, insofar as he does know in this occurrent sense, he is certain of what he knows.

The most radical position on these matters is to be found in Wittgenstein's *On Certainty,* published posthumously in 1969. Wittgenstein holds that knowledge is radically different from certitude and that neither concept entails the other. It is thus possible to be in a state of knowledge without being certain and to be certain without having knowledge. As he writes: "Instead of 'I know' . . . couldn't Moore have said: 'It stands fast for me that . . .' ? and further: 'It stands fast for me and many others. . . .' "

Standing fast

"Standing fast" is one of the terms Wittgenstein uses for certitude and is to be distinguished from knowing. For him certainty is to be identified with acting, not with seeing propositions to be true, the kind of seeing that issues in knowledge. As he says: "Giving grounds, justifying the evidence comes to an end—but the end is not certain propositions striking us immediately as true—*i.e.,* it is not a kind of *seeing* on our part; it is our *acting* which lies at the bottom of the language game."

ORIGINS OF KNOWLEDGE

Philosophers not only wish to know what knowledge is but also how it originates. This motivation is based, at least in part, on the supposition that an investigation into the provenance of knowledge can help cast light on its nature. From the time of the Greeks to the present, therefore, one of the major themes of epistemology has been a quest into the sources of knowledge.

Plato's *The Republic* contains one of the earliest systematic arguments to the effect that sense experience cannot be a source of knowledge. The argument begins with the assertion that ordinary persons have a clear grasp of certain concepts, that of equality, for instance. In other words, people know what it means to say that A and B are equal, no matter what A and B are. But where does such knowledge come from? One may wonder, for instance, whether it is provided by vision and consider the claim that two pieces of wood are of equal length. A close inspection of these pieces of wood, however, shows them to differ slightly, and the more detailed the inspection, via various degrees of magnification, the more disparity one notices. It follows that visual experience cannot be the fount of the concept of equality. Plato applies this result to the operations of all the five senses and concludes that sense experience in general cannot be the origin of such knowledge. It must therefore have another source, which he regards as prenatal (one such account is found in the myth of Er in Book X).

The mathematical example Plato selects to illustrate that the origin of knowledge is not in sense experience is highly significant; indeed it is one of the signs of his perspicacity that he should pick such an example. For, as the subsequent history of philosophy reveals, the strongest case for the notion that at least some knowledge does not derive from sense experience lies in mathematics. Mathematical entities are abstractions—perfect triangles, disembodied surfaces and edges, lines without thickness, and extensionless points—and none of these exists in the physical world, *i.e.,* the world apprehended by the senses. It might be thought that, had Plato selected a different example, say, the colour red, his argument would have been less convincing. But it is a further sign of his genius that he discusses colours as well as mathematical notions and provides good reasons for holding that seeing examples or specimens of red (or any other colour) is not equivalent to knowing what that colour is. Such knowledge must therefore have a different genesis than sense experience.

Innate versus learned. The puzzle about origins of knowledge has led historically to two different kinds of issues. One of these is the question of whether knowledge (or at least certain kinds of knowledge) is innate, meaning that it is not acquired or learned through experience but in some important sense is present in the human psyche at birth. The matter is still a live issue today, not only in philosophy but also in linguistics and psychology. The linguist Noam Chomsky (b. 1928), for example, has asserted that the "projection phenomenon"—the ability of children to construct sentences that they have never heard before and that are grammatical—is proof of inherent conceptual structures, whereas the experimental psychologist B.F. Skinner (b. 1904) has tried to show that all knowledge is the product of learning through environmental conditioning by means of the processes of reinforcement and reward.

In the extensive historical literature on this topic both the notion of "innateness" and that of "learning" have been given various interpretations. Sometimes, for instance, innateness carries only the sense of a disposition or propensity, but in stronger versions of the thesis, such as Plato's, it is affirmed that humans possess actual pieces of prenatal knowledge. "Learning" also is given a variety of meanings, ranging from trial-and-error methods to inexplicit types of "absorption" of information. There are also a range of "compromise" theories. These typically claim that humans have some knowledge that is innate—the awareness of God, the principles of moral rightness and wrongness, and certain mathematical theorems being favoured examples—whereas other kinds of knowledge—such as knowledge by acquaintance—are gained through experience.

Interpretations of innateness and learning

Rationalism versus empiricism. The second issue that emerges from considerations of the origins of knowledge focuses on the distinction between rationalism and empiricism. Though closely related to the issue of innateness versus learning, the question in this case concerns the nature of the source from which knowledge arises. The history of discussion of the issue indicates that two main sources have been identified and argued for: reason and experience.

Rationalism is the thesis that the ultimate source of knowledge is to be found in human reason. What reason is, in turn, is a difficult question. But, generally speaking, it is assumed that reason is a feature of the human mind that differs not just in degree but in kind from bodily sensations, feelings, and certain psychological attitudes, such as disgust or enthusiasm. For some writers, such as Plato, reason is a faculty, a special facility or structure of the mind. Many later philosophers reject any sort of faculty psychology, and some of them tend to interpret reason in dispositional or behavioral ways. But, whatever the interpretation, a rationalist must hold that reason has a special power for grasping reality. It is the exercise of reason that allows human beings to understand the world they live in. Such a thesis is double-sided: it holds, on the one hand, that reality is in principle knowable and, on the other hand, that there are human, distinctively mental, powers capable of apprehending it. One thus might define

rationalism as the theory that there is an isomorphism (a mirroring relationship) between reason and reality which makes it possible for the former to apprehend the latter just as it is. Rationalists affirm that, if such a correspondence were lacking, the effort of human intelligence to understand the world would be impossible.

Empiricism is often defined as the doctrine that all knowledge comes from experience. Almost no philosopher, however, has ever literally held that all knowledge comes from experience. Locke, who is the empiricist par excellence, thought there is some knowledge human beings have—which he calls "trifling ideas" (or trivialities), such as $a = a$—that does not derive from experience; but he regarded such knowledge as empty of content. Hume held similar views.

Empiricism thus generally allows for a priori knowledge while denigrating its significance, and accordingly it is more accurate to define it as the theory that all knowledge about matters of fact derives from experience. When defined in this way empiricism does represent a significant contrast to rationalism. Rationalists hold that human beings have knowledge about matters of fact which is anterior to experience and yet which does tell them something significant about the world and its various features. Empiricists would deny that this is possible.

The meaning of the term experience is generally limited to the impressions and sensations received by the senses. Thus, knowledge is the information apprehended by the five sense modalities—hearing, seeing, touching, tasting, and smelling. Such knowledge is always about matters of fact, about what one can see, touch, hear, taste, or smell. For strict empiricists this definition has the implication that the human mind is passive—a tabula rasa, in Locke's idiom; it is an organ that receives impressions and more or less records them as they are. This conception of the mind has seemed counterintuitive to many philosophers, especially those in the Kantian tradition. But it also poses serious challenges for empiricists. For example, it raises the question of how one can have knowledge of items, such as a dragon, that cannot be found in experience.

In response, the classical empiricists such as Locke and Hume have tried to show how the complex concept of a dragon can be reduced to simple concepts (such as wings, the body of a snake, the head of a horse), all of which derive from direct impressions of such items. On such a view the mind is still considered to be primarily passive, but it is conceded that it has some active functions, such as being able to combine simple impressions and ideas into complex ideas.

Challenges to empiricism

There are further difficulties: the empiricist must explain how abstract ideas, such as the concept of a perfect triangle, can be reduced to elements apprehended by the senses when no perfect triangles are actually found in nature, and he must also give an account of how general notions are possible. It is obvious that one does not experience "mankind," but only particular individuals, through the senses; yet such general notions are meaningful, and propositions containing these concepts are known to be true. The same difficulty applies to colour concepts. Some empiricists have argued that one arrives at the concept of red, for example, by abstracting from individual items that are red. But the difficulty with this suggestion is that one would not know what to count as an instance of red unless one already had such a concept in mind; and, if that is so, it would seem that experience cannot be the source of the concept. It is generally felt that, despite ingenious attempts by empiricists to deal with such issues, their solutions have not been wholly successful. Indeed, the history of epistemology has to a large extent been a dialectic between rationalism and empiricism in an effort to meet skeptical challenges that are designed to undermine both positions.

SKEPTICISM

Many philosophers past and present and many nonphilosophers who are studying philosophy for the first time have been struck by the seemingly indecisive nature of philosophical argumentation. For every argument, there seems to be a counterargument; and for every position, a counterposition. To a considerable extent skepticism is born of such reflection. Some of the ancient skeptics contended, for example, that all arguments are equally bad and, accordingly, that nothing can be proved. The American philosopher Benson Mates claims to be a modern representative of this tradition, except that he believes all philosophical arguments to be equally good. But he insists that, because they are, they invariably issue in conceptual deadlocks and resolve nothing.

Ironically, skepticism is itself a type of philosophy, and the question has been raised whether it manages to escape its own demurrers. Does it offer arguments, and, if so, are they decisive? The answers to these questions depend on what is meant by skepticism. Historically, the term refers to a complex set of practices taking many different forms—from stating explicit theories to assuming negative attitudes without much propositional content. Thus, it is difficult to define. But, however it is understood, skepticism represents a set of challenges to the claim that human beings do possess or can acquire knowledge.

In giving even this minimal characterization, it is important to emphasize that both dogmatists and skeptics accept a definition of knowledge that implies two things: that, if a person, A, knows that *p*, then *p* is true and that, if a person, A, knows that *p*, then A cannot be mistaken, meaning that it is logically impossible that A could be wrong. If a person says that he knows Smith will arrive at 9:00 AM, and Smith is not there at 9:00 AM, then that person would have to withdraw the claim to know. He might say instead that he thought he knew or that he felt sure. But he could not continue rationally to insist that he knew if what he claimed to know turned out to be false.

It should also be stressed that, given this definition of knowledge, the skeptic does not have to show that A is actually mistaken in claiming to know that *p*. All he has to show is that it is possible that A might be mistaken. Hence arises the skeptic's practice of searching for a possible counterexample to a claim. If A states that he has had a certain experience, for instance, that of having personally spoken with Smith, who assured him he would keep his appointment at 9:00 AM, then the skeptic can point out that, although one could have such an experience, it is still possible that Smith might not show up; and, if so, A's claim to know is untenable. In effect, by emphasizing the notion of possibility, the skeptic is pointing out that there is a logical gap between the criteria that support the claim and the claim itself. The criteria might be satisfied, and yet the claim might be false; but, if such a possibility exists, the original assertion cannot be a specimen of knowing.

More generally, radical skepticism has tried to show that one might (*i.e.*, could possibly) have all the experiences associated with normal perception or behaviour and yet be wholly mistaken in thinking that these experiences correlate with anything in the external world. For example, a brain in a vat might be programmed by scientists to have the sensation of seeing a tree, even though it is not in fact seeing a tree. Thus, there is a gap between the experience the brain is having and external reality; accordingly, its claim to know on the basis of such a visual experience is mistaken. The skeptic's point is that the disparity between external reality and felt experience is always possible and, accordingly, that knowledge claims based upon such experience cannot be defended.

The gap between external reality and felt experience

The ability to find counterexamples explains why skeptics do not challenge but indeed accept the dogmatist's definition of knowledge. That they do so is important because it means that they are not arguing at cross-purposes with their opponents. What they challenge is not the meaning of knowledge but the contention that anybody actually has knowledge in that sense.

Nearly all of the major epistemological theories of philosophy have given rise to skeptical reactions. Many of the greatest thinkers in the Western tradition have assumed that by means of reason or sense experience one can come to have knowledge of reality. But skepticism has challenged the validity of both of these appeals. Skeptics have developed wholesale arguments to undermine the efforts to show that reason and sense experience, which seem to be the only possible candidates, are reliable sources

of knowledge. Descartes, for example, considered the hypothesis that an evil genius may delude people into thinking that they are experiencing the real world when they are not. With regard to major epistemological problems, such as the "other-minds problem," the problem of memory, the problem of induction, and the problem of self-knowledge, skeptical doubts have challenged the validity of reason and of sense experience and thus of claims to have knowledge of various aspects of reality. How some of these moves and countermoves actually take place are addressed below. (AV.S.)

The history of epistemology

ANCIENT PHILOSOPHY

Pre-Socratics. The central focus of ancient Greek philosophy was its attempt to solve the problem of motion. Many pre-Socratic philosophers thought that no logically coherent account of motion and change could be given. This problem was a concern of metaphysics, not epistemology, however, and in the present context it suffices merely to allude to the arguments of Parmenides and Zeno of Elea against the possibility that anything moves or changes. The consequence of this position for epistemology was that all major Greek philosophers held that knowledge must not itself change or be changeable in any respect. This requirement motivated Parmenides, for example, to hold that thinking is identical with being (what exists or is unchanging) and that it is impossible to think of "nonbeing" or "becoming" (what changes) in any way.

Plato. Plato (*c.* 427–347 BC) accepted the Parmenidean constraint on any theory of knowledge that both knowledge and its objects must be unchanging. One consequence of this, as Plato pointed out in *Theaetetus,* is that knowledge cannot have physical reality as its object. In particular, since sensation and perception have various kinds of motions as their objects, knowledge cannot be the same as sensation or perception. The negative thesis of Plato's epistemology consists, then, in the denial that sense experience can be a source of knowledge on the ground that the objects apprehended through the senses are subject to change. To the extent that humans have knowledge, they attain it by transcending the information provided by the senses in order to discover unchanging objects. But this can be done only by the exercise of reason, and in particular by the application of the dialectical method of inquiry inherited from Socrates.

The Platonic theory of knowledge is thus divided into two parts: a quest first to discover whether there are any unchanging objects and to identify and describe them and second to illustrate how they could be known by the use of reason, that is, via the dialectical method. Plato used various literary devices for illustrating his theory; the most famous of these is the allegory of the cave in Book VII of *The Republic.* The allegory depicts ordinary people as living locked in a cave, which represents the world of sense-experience; in the cave people see only unreal objects, shadows, or images. But through a painful process, which involves the rejection and overcoming of the familiar sensible world, they begin an ascent out of the cave into reality; this process is the analogue of the application of the dialectical method, which allows one to apprehend unchanging objects and thus acquire knowledge. In the allegory, this upward process, which not everyone is competent to engage in, culminates in the direct vision of the sun, which represents the source of knowledge.

In searching for unchanging objects, Plato begins his quest by pointing out that every faculty in the human mind apprehends a set of unique objects: hearing apprehends sounds but not odours; the sense of smell apprehends odours but not visual images; and so forth. Knowing is also a mental faculty, and therefore there must be objects that it apprehends. These have to be unchanging, whatever they are. Plato's discovery is that there are such entities. Roughly, they are the items denoted by predicate terms in language: such words as "good," "white," or "triangle." To say "This is a triangle" is to attribute a certain property, that of being a triangle, to a certain spatiotemporal object, such as a particular figure drawn on a blackboard. Plato is here distinguishing between specific triangles that can be drawn, sketched, or painted and the common property they share, that of being triangular. Objects of the former kind he calls particulars. They are always located somewhere in the space-time order, that is, in the world of appearance. But such particular things are different from the common property they share. That is, if x is a triangle, and y is a triangle, and z is a triangle, x, y, and z are particulars that share a common property, triangularity. That common property is what Plato calls a "form" or "idea" (not using this latter term in any psychological sense). Unlike particulars, forms do not exist in the space-time order. Moreover, they do not change. They are thus the objects that one must apprehend in order to acquire knowledge.

Similar remarks apply, for example, to goodness, whiteness, or being to the right of. Particular things change; they come into and go out of existence. But whiteness never changes, and neither does triangularity; and, if they do not change, they are not subject to the ravages of time. In that sense, they are eternal.

Dialectical method

The use of reason for discovering unchanging forms is exercised in the dialectical method. The method is one of question and answer, designed to elicit a real definition. By a "real definition" is meant a set of necessary and sufficient conditions that exactly delimit a concept. One may, for example, consider the concept of being the brother of Y. This can be explained in terms of the concepts of being male and of being a sibling of Y. These concepts together lay down necessary and sufficient conditions for anything's being a brother. One who grasps these conditions understands precisely what it is to be a brother.

The Republic begins with the use of the dialectical method to discover what justice is. Cephalus proposes the thesis that "justice" means the same as "honesty in word and deed." Socrates searches for and finds a counterexample to this proposal. It is just, he points out, under some conditions, not to tell the truth or to repay debts. If one had borrowed a weapon from an insane person, who then demanded it back in order to kill an innocent person, it would be just to lie to him, stating that one no longer had the weapon. Therefore, "justice" cannot mean the same as "honesty in word" (*i.e.,* telling the truth). By this technique of proposing one definition after another and subjecting each to possible counterexamples, Socrates attempts to find a definition that would be immune to counterexamples. To find such a definition would be to define the concept of justice, and in this way to discover the true nature of justice. In such a case one would be apprehending a form, the common feature that all just things share.

Plato's search for definitions and thereby the nature of forms is a search for knowledge. But how should knowledge in general be defined? In *Theaetetus* Plato argues that it involves true belief. No one can know what is false. A person may mistakenly believe that he knows something, which is in fact false, but this is only thinking that one knows, not knowing. Thus, a person may confidently assert, "I know that Columbus was the first European to land in North America" and be unaware that other Europeans, including Erik the Red, preceded Columbus. So knowledge is at least true belief, but it must also be something more. Suppose that someone believes there will be an earthquake in September because of a dream he had in April and that there in fact is an earthquake in September, although there is no connection between the dream and the earthquake. That person has a true belief about the earthquake but not knowledge. What the person lacks is a good reason supporting his true belief. In a word, the person lacks justification for it. Thus, in *Theaetetus,* Plato concludes that knowledge is justified true belief.

Although it is difficult to explain what justification is, most philosophers accepted the Platonic analysis of knowledge as fundamentally correct until 1963, when the American philosopher Edmund L. Gettier produced a counterexample that shook the foundations of epistemology: suppose that Kathy knows Oscar very well and that Oscar is behind her, out of sight, walking across the mall. Further, suppose that in front of her she sees walking toward her someone who looks exactly like Oscar; unbe-

knownst to her, it is Oscar's twin brother. Kathy forms the belief that Oscar is walking across the mall. Her belief is true, because he is walking across the mall (though she does not see him doing it). And her true belief seems to be justified, because she formed it on the same basis she would have if she had actually seen Oscar walking across the mall. Nonetheless, Kathy does not know that Oscar is walking across the mall, because the justification for her true belief is not the right kind. What her true belief lacks is an appropriate causal connection to its object.

Aristotle. In *Posterior Analytics,* Aristotle (384–22 BC) analyzes scientific knowledge in terms of necessary propositions that express causal relations. Such knowledge takes the form of categorical syllogisms, in which the middle term causally and necessarily connects the major and minor terms. For example, because all stars are distant and all distant objects twinkle, it follows that all stars twinkle. That is, the middle term, "distant objects," connects the minor term, "stars," to the major term, "twinkle," in order to yield the conclusion that all stars twinkle. Aristotle, however, recognizes that not all knowledge is provable. Thus, the premises of the most basic syllogisms are known but not provable. In contrast with scientific knowledge, there is opinion, which is not provable and is about what happens to be true but need not be.

Since the knowledge formulated in syllogisms resides in the mind, which is part of or one faculty of the soul, much of what Aristotle says about knowledge is part of his doctrine about the nature of soul and, in particular, human soul. As he uses the term, every living thing, including plant life, has a soul (*psyche*), a soul being what makes a thing alive. Thus it is important not to equate soul with mind or intellect. The intellect (*nous*) might variously be described as a power, faculty, part, or aspect of the human soul. It should be stressed that for Aristotle the terms soul (*psyche*) and intellect (*nous*) and its constituents were understood to be scientific terms.

Knowledge is something that a person has. Thus it must be in him somewhere, and the location must be his mind or intellect. Yet there can be no knowledge if the knower and the thing known are wholly separate. What then is the relation between the knowledge in the person or his mind and the object of his knowledge? Aristotle's answer is one of his most enigmatic claims. He says, "Actual knowledge is identical with its object."

Here is one suggestion about what Aristotle means. When a person learns something, he acquires something. What he acquires must either be something different from the thing he knows or identical with it. If it is something different, then there is a discrepancy between what he has in mind and the intended object of his knowledge. But such a discrepancy seems to be incompatible with the existence of knowledge. For knowledge, which must be true and accurate, cannot deviate from its object in any way. One cannot know that blue is a colour if the object of that knowledge is something other than that blue is a colour. This idea that knowledge is identical with its object is dimly reflected in the repetition of the variable p in the standard formula about knowledge: S knows that p just in case it is true that p. Although the line of thinking being attributed to Aristotle is defective in several ways, something like it seems to have motivated Aristotle and many other thinkers over the centuries.

To assert that knowledge and its object must be identical raises a question: In what way is knowledge in a person? Suppose that Smith knows Fido. Then Fido is in Smith. Obviously, Fido is not there as he exists in the nonmental world of space and time. In what sense can it be true that a person who knows what a dog is has that object in his mind? Aristotle derives his answer from his general theory of reality. According to him, all (terrestrial) substances

Matter and form

are composed of two principles: matter and form. If there are four dogs—Bowser, Fido, Spot, and Spuds—they are the same in some respect and different in some respect. They are the same in that each belongs to the same kind and each functions similarly. Thus, Aristotle reasons, just as Plato had, that there must be something in virtue of which they are the same, and this he calls "form." That is, Bowser, Fido, Spot, and Spuds each have the very same form of being a dog. They are different in that they are made out of different matter, different parcels of stuff. The form that a thing has is more important than its matter because it is the form that makes the thing what it is. If Fido were to lose the form of being a dog and acquire another, he would no longer be the same thing. The stuff out of which Fido is made is not similarly important, and in fact that stuff changes periodically, as body cells change through metabolic processes, without Fido ceasing to be Fido.

To return to the explanation of knowledge, what is in the knower when he knows what dogs are is the form of being a dog minus the matter. According to Aristotle, matter is literally unintelligible and not essential to what Fido or any other dog is; thus its absence is inconsequential for knowledge, though not for Fido.

In his sketchy account of the process of thinking in *De anima* (*On the Soul*), Aristotle says that the intellect, like everything else, must have two parts: something analogous to matter and something analogous to form. The first of these is the passive intellect; the second is active intellect, of which Aristotle speaks tersely. "Intellect in this sense is separable, impassible, unmixed, since it is in its essential nature activity. . . . When intellect is set free from its present conditions it appears as just what it is and nothing more: it alone is immortal and eternal . . . and without it nothing thinks."

This part of Aristotle's views about knowledge is an extension of what he says about sensation. According to Aristotle, sensation occurs when the sense organ is stimulated by the sense object, typically through some medium, such as light for vision and air for hearing. This stimulation causes a "sensible species" to be generated in the sense organ itself. This "species" is some sort of representation of the object sensed. As Aristotle describes the process, the sense receives "the form of sensible objects without the matter, just as the wax receives the impression of the signet-ring without the iron or the gold." But, since there are different species for each of the five external senses that Aristotle recognized—sight, hearing, touch, taste, and smell—"species" does not mean "image."

Ancient Skepticism. After the development of Aristotle's psychology the next significant event for the theory of knowledge was the rise of Skepticism, of which there were at least two kinds. The first, Academic Skepticism, arose in the Academy after Plato's death and was propounded by the Greek philosopher Arcesilaus (*c.* 315–*c.* 240 BC), about whom the philosophers Cicero, Sextus Empiricus, and Diogenes Laërtius provide information. Academic Skepticism is also called "dogmatic Skepticism" when it is interpreted as arguing for the thesis that nothing is known. The thesis was inspired by Socrates' avowal that the only thing he knew was that he knew nothing. Thus, it asserts that knowledge is impossible. This form of Skepticism seems to be susceptible to an objection raised by the Stoic Antipater (fl. *c.* 135 BC) and others that the view is self-contradictory. To know that knowledge is impossible is to know something; hence, dogmatic Skepticism is false.

Carneades (*c.* 213–129 BC), a member of the Academy, gave a subtle reply. Academic Skepticism, he claimed, should not be interpreted as a claim about how the world is in itself or about a correspondence between thought (or language) and the world, but as a judicial decision. Just as a defendant in a trial does not prove his innocence but relies upon its presumption and defends it against attack, so the Skeptic does not try to prove that he knows nothing but presumes it and defends this presumption against attacks.

Carneades' construal of Academic Skepticism brings it close to the other kind, Pyrrhonism, named after Pyrrho of Elis (*c.* 365–275 BC). None of his works survive, and scholars rely principally on the early 3rd-century-AD writings of Sextus Empiricus to understand Pyrrhonism. Pyrrhonists assert or deny nothing but lead people to give up making any claims to knowledge. The Pyrrhonist's strategy is to show that, for each proposition with some evidence for it, an opposed proposition has equally good evidence supporting it. These arguments for refuting each side of an issue are called "tropes." For example, the judgment that a

Pyrrhonism

tower is round when seen at a distance is contradicted by the judgment that the tower is square when seen up close. The judgment that Providence cares for all things, based upon the orderliness of the heavenly bodies, is opposed by the judgment that many good people suffer misery and many bad people enjoy happiness. The judgment that apples have many properties—shape, colour, taste, and aroma—each of which affects a sense organ, is opposed by the equally good possibility that apples have only one property that affects each sense organ differently.

Pyrrhonists diagnose dogmatism as the unjustifiable preference for one mode of existence over another. Dogmatists prefer wakefulness and sanity over sleep and insanity. But why should sleep and insanity not be the norm? If the dogmatist answers that it is because sleep and insanity involve some deficiency or abnormal physical states, the Skeptic replies, "By what nonquestion-begging criterion are these things said to be deficient or abnormal? Why should insanity not be taken as the primary notion and sanity be defined as the lack of insanity? If it were, then it would not be difficult to see sanity as a deficiency or abnormality, just as insanity currently is. Or why should wakefulness not be seen as the deficient condition in which people do not dream?" The Skeptic does not advocate insanity or sleep but merely argues that a preference for them is no less justified than a preference for sanity and wakefulness.

What is at stake in the preceding Skeptical arguments is "the problem of the criterion," that is, the problem of deciding how one can determine a justifiable standard against which to measure judgments. Truth seems to need a criterion. But every criterion is either groundless or inconclusive. Suppose that something is proffered as a criterion. The Skeptic will ask what proof there is for it. If no proof is offered, the criterion is groundless. If, on the other hand, a proof is produced, a vicious circle begins to close around the dogmatist: What judgment justifies belief in the proof? If there is no judgment, the proof is unsupported; and if there is a judgment, it requires a criterion, which is just what the dogmatist was supposed to have provided in the first place.

If the Skeptic needed to make judgments in order to survive, he would be in trouble. In fact there is another method of survival that bypasses judgment. The Skeptic can live quite nicely, according to Sextus, by following custom and the way things appear to him. In doing this, the Skeptic does not judge the correctness of anything but merely accepts appearances for what they are.

Ancient Pyrrhonism is not strictly an epistemology since it has no theory of knowledge and is content to undermine the dogmatic epistemologies of others, especially of the Stoics and Epicureans. Pyrrho himself was said to have had moral and ethical motives for attacking dogmatists. Being reconciled to not knowing anything, Pyrrho thought, induced serenity (*ataraxia*).

St. Augustine. St. Augustine of Hippo (354–430) claimed that human knowledge would be impossible if God did not illumine the human mind and thereby allow it to see, grasp, or understand ideas. There are two components to his theory: ideas and illumination. Ideas as Augustine construed them are the same as Plato's; they are timeless, immutable, and accessible only to the mind, not to the senses. They are indeed in some mysterious way part of God and seen in God. Illumination, the other element of the theory, was for Augustine and his many followers, at least through the 14th century, a technical term, built upon a metaphor. Since the mind is immaterial, it cannot be literally lighted. Yet the entire theory of illumination rested upon the extended visual metaphor, inherited from Plotinus (205–270) and other Neoplatonic sources, of the human mind as an eye that can see when and only when God, the source of light, illumines it. Still, it is a powerful metaphor relied upon even in the 17th century by René Descartes (*Discourse on Method;* 1637). Varying his metaphor, Augustine sometimes says that the human mind participates in God and even, as in *On the Teacher,* that Christ illumines the mind by dwelling in it. It is important to emphasize that Augustine's theory of illumination concerns all knowledge, and not specifically mystical or spiritual knowledge. In addition to its historical significance, his theory is interesting for showing how diverse epistemological theories have been.

illumination

Before he articulated this theory in his mature years and soon after his conversion to Christianity, Augustine was concerned to refute the Skepticism of the Academy. In *Against the Academicians* Augustine claims that, if nothing else, humans know such disjunctive tautologies as that either there is one world or there is not one world and that either the world is finite or it is infinite. Humans also know many propositions that begin with the phrase "It appears to me that," such as "It appears to me that what I perceive is made up of earth and sky, or what appears to be earth and sky." And they know logical (or what he calls "dialectical") propositions, for example, "If there are four elements in the world, there are not five; if there is one sun, there are not two; one and the same soul cannot die and still be immortal; and man cannot at the same time be happy and unhappy."

Many other refutations of Skepticism occur in later works, notably, in *On the Free Choice of the Will, On the Trinity,* and *The City of God.* In the latter work Augustine proposes other examples of things about which people are absolutely certain. Again in explicit refutation of the Skeptics of the Academy, Augustine argues that if a person is deceived, then it is certain that he exists. Like Descartes, Augustine puts the point in the first person, "If I am deceived, then I exist" (*Si fallor, sum*). A variation on this line of reasoning occurs in *On the Trinity,* when he says that if he is deceived, he is at least certain that he is alive.

Augustine also points out that, since he knows, he knows that he knows; and he notes that this can be reiterated an infinite number of times: If I know that I know that I am alive, then I know that I know that I know that I am alive. This point was codified in 20th-century epistemic logic as the axiom "If X knows that *p,* then X knows that X knows that *p.*" In *The City of God* Augustine claims that he knows that he loves: "For neither am I deceived in this, that I love, since in those things which I love I am not deceived." With Skepticism thus refuted, Augustine simply denies that he has ever been able to doubt what he had learned through his sensations or even the testimony of most people.

Skepticism did not recover from Augustine's criticisms for a thousand years; but then it arose again like the phoenix in Egyptian mythology. Augustine's Platonic epistemology dominated the Middle Ages until the mid-13th century, when St. Albertus Magnus (1200–80) and then his student St. Thomas Aquinas developed an alternative to Augustinian illuminationism.

MEDIEVAL PHILOSOPHY

St. Anselm of Canterbury. The phrase St. Anselm of Canterbury (*c.* 1033–1109) used to describe his own project, namely, "faith seeking reason" (*fides quaerens intellectum*), well characterizes medieval philosophy as a whole. All the great medieval philosophers, Christian, Jewish, and Islāmic alike, were also theologians. Virtually every object of interest was related to their belief in God, and virtually every solution to every problem, including the problem of knowledge, contained God as an essential part. Anselm himself said that, while true propositions are those that signify what is, ultimately truth is God. This presented Anselm with a problem, which he discusses at the beginning of *Proslogium* as a prelude to his famous ontological argument for the existence of God. There is a tension between the view that God is truth and intelligibility and the fact that humans have no perception of God. How can there be knowledge of God, he asks, when all knowledge comes through the senses and God, being immaterial, cannot be sensed? His solution is to distinguish between knowing something by being acquainted with it in sensation and knowing something by describing it. Knowledge by description is possible because of the concepts that one forms from sensation. All knowledge about God depends upon the description that he is "the thing than which a greater cannot be conceived." From this premise Anselm argues that humans can know, for example, that God exists, is all-powerful, all-knowing, all-just, all-merciful, and immaterial. Eight hundred years later Bertrand Russell

would use the same distinction between knowledge by acquaintance and knowledge by description to develop his influential philosophy, although he would have vigorously denied that the distinction could be employed as Anselm had, namely, to prove that God exists.

St. Thomas Aquinas. While a Platonic and Augustinian epistemology dominated the early Middle Ages, the translation of Aristotle's *On the Soul* in the early 13th century had a dramatic effect. Following Aristotle, Thomas Aquinas (1225–74) recognized that there are different kinds of knowledge. Sense knowledge is what results from sensing individual things: thus, one sees a tree, hears the song of an oriole, and tastes or smells a peach. Thomas considered sense knowledge to be low-grade because it has individual things as its object and is also shared with brute animals. Sensation itself does not involve the intellect and is not properly speaking knowledge (*scientia*).

It is characteristic of scientific knowledge to be universal; the more general in scope a piece of knowledge is, the better. This is not to diminish the importance of specificity. Scientific knowledge should also be rich in detail, and God's knowledge is the most detailed. The detail, however, must be essential to the thing being studied and not peculiar to just some instances of that kind. Although Thomas thought that the highest knowledge humans can possess is knowledge of God, knowledge of physical objects is more attuned to human capabilities, and only that kind of knowledge will be discussed here.

In his discussion of knowledge in *Summa theologiae,* Thomas Aquinas argues that human beings do not know material objects directly, nor are such things the principal object of knowledge. Knowledge aims at what is universal, while material things are individual and can be known only indirectly. Elaborating on the thought of Aristotle, Thomas claims that the process of thinking that accompanies knowledge consists of the active intellect (*intellectus agens*) abstracting (*abstrahens*) a concept from an image (*phantasma*) received from the senses.

In one of Thomas' accounts of the process, abstraction is the process of isolating the universal elements of an image of a particular object from those elements that are peculiar to the object. For example, from the image of a dog the intellect abstracts the ideas of being alive, being capable of reproduction, movement, and whatever else might be essential to being a dog. All these ideas are common to all dogs because they are essential to them. These ideas can be contrasted with the ideas of being owned by Dion and weighing five pounds, namely, with properties that vary from dog to dog.

As stated earlier, Aristotle typically spoke of a form as being in the intellect of the knower, whereas the matter of an object is unintelligible and remains extramental. While it was necessary for Aristotle to say something like this in order to escape the absurdity of holding that a material object is in the mind in exactly the same way it is in the physical world, there is also something unsatisfying about it. Physical things contain matter as an essential element, and, if their matter is no part of what is known, then it seems that human knowledge is lacking. In order to counter this worry, Thomas revised Aristotle's theory. He said that not the form alone but the species of an object is also in the intellect. A species is a combination of form and "common matter" (*materia communis*), where common matter is contrasted with individuated matter (*materia signata vel individualis*), which actually gives bulk to a material object. Common matter is something like a general idea of matter. Since every animal must have a body, it is not enough to conceive of an animal merely as something that is alive. Having flesh and bones, that is, being material, is part of the essence of being an animal. Of course this materiality, which is common to every animal, is not the same as the actual flesh and bone that constitute Fido—hence the distinction between common and individuated matter.

Species

This abstracted species resides in a part of the soul called "the passive intellect," where it is described as being illumined by the active intellect. What this process amounts to is the isolation of those features of the intelligible species that are universal and necessary to it. Thus, to know what a human being is is to have abstracted the ideas of being rational and being capable of sensation, movement, reproduction, and nutrition and to have excluded the ideas of living in a particular place or having a certain appearance, all of which are not essential to being human.

One objection that Thomas anticipated being raised against his theory is that it gives the impression that ideas, not things, are what are known. If knowledge is something that humans have and if what humans have in their intellect is a species of a thing, then it is the species that is known and not the thing. It might seem, then, that Thomas' view is a type of idealism.

Thomas had prepared for this kind of objection in several ways. His insistence that what the knower has in his intellect is a species, which includes matter, is supposed to make what is in the intellect seem more like the object of knowledge than an immaterial Aristotelian form. Also, scientific knowledge does not aim at knowing any individual object but at what is common to all things of a certain sort. In this, Thomas' views are similar to those of 20th-century science. The billiard ball that John Jones drops from his porch is of no direct concern to physics. Even though its laws apply to John Jones's ball, physics is interested in what happens to any object dropped from any height, just as what Thomas says about apples in general also applies to each individual apple.

As assuaging as these considerations might be, they do not blunt the main force of the objection. For this purpose Thomas Aquinas introduced the distinction between what is known and that by which it is known. To specify what is known, say, an individual dog, is to specify the object of knowledge; to specify that by which it is known, say, the phantasm or the species of a dog, is to specify the apparatus of knowledge. The species of something is that by which the thing is known; but it is not itself the object of that knowledge, although it can become an object of knowledge by being reflected upon.

The philosophical optimism of the 13th century dissolved as a consequence of the secular and ecclesiastical condemnations in 1270 and 1277 of certain aspects of Aristotelian philosophy, and worries about Skeptical consequences began to emerge. While the philosophy of Thomas Aquinas was one of the targets of these condemnations, John Duns Scotus was also worried about the Skeptical consequences that could be elicited from the major competitor to Aristotelianism, the Augustinianism of Henry of Ghent (1217–93). According to Henry, God must "illumine" the human intellect on every occasion of its knowing. Not only could no good literal meaning be given to this sense of illumination, but the view also sounds as if all human knowledge were supernatural. Henry's insistence that God's illumination is a natural divine illumination did not persuade many people.

John Duns Scotus. While he accepted some aspects of Aristotelian abstractionism and also held that there need to be some a priori principles of perception, principles that he attributed to Augustine, John Duns Scotus (*c.* 1266–1308) did not rest the certainty of human knowledge on either of them. He distinguished four different classes of things that are certain: First, there are things that are knowable simply (*simpliciter*). These include both true identity statements such as "Cicero is Tully" and propositions, later to be called analytic, such as "Man is rational." According to Duns Scotus, such truths coincide with what makes them true. A consequence of this is that the negation of a simple truth is inconsistent even though it may not be explicitly contradictory. For example, the negation of "The whole is greater than any proper part" is not explicitly contradictory in the way that "Snow is white and snow is not white" is; nonetheless, "The whole is not greater than any proper part" cannot possibly be true and hence is contradictory.

The second class of certainly known propositions consists of things knowable through experience, where "experience" has the Aristotelian sense of something that is encountered numerous times. The knowledge afforded by experience is grounded in the a priori epistemic principle that "whatever occurs in a great many instances by a cause that is not free is the natural effect of that cause." It is

important to note that Duns Scotus' pre-Humean confidence in induction did not survive the Middle Ages. The 14th-century philosopher Nicholas of Autrecourt, who has been called "the medieval Hume," argued at length that there is no necessary connection between any two events and that there is no rational justification for the belief in causal relations.

The third class of certainly known propositions consists of things knowable that concern one's own actions (*de actibus nostris*). Humans know when they are awake immediately and not through any inference; they know with certainty that they think (*me intelligere*) and that they hear and have other sense experiences. Even if a sense experience is caused by a defective sense organ, it remains true that one is aware of the sensuous content of the sensation: for example, one sees white even if one is mistaken in thinking that the seeing is caused by snow.

The fourth class of certainly known objects consists of things knowable through human senses (*per sensus*). Duns Scotus said that humans learn about the heavens, the earth, the sea, and all that are in them. This last class of objects that are certainly known things seems to be posited without regard to the threat of Skepticism at all.

Duns Scotus' rendition of intuitive knowledge, however, has the purpose of forestalling the Skeptical move of interposing something between the knower and the thing known that might enable belief to deviate from its object. Intuitive knowledge is indubitable knowledge that something exists. It is knowledge "precisely of a present object [known] as being present and of an existent object [known] as being existent." Further, the object of knowledge must be the cause of the knowledge. If a person sees Socrates before him, then, according to Duns Scotus, he has intuitive knowledge of the proposition that Socrates is white and that Socrates and his whiteness cause that knowledge. Intuitive knowledge contrasts with abstractive knowledge, such as knowledge of universals, for which the object need not be present or even existent. For example, for all one knows from contemplating the nature of dogs or unicorns, they are equally likely or unlikely to exist.

It may appear that intuitive knowledge is absolute; either one has it or one does not. But that is not Duns Scotus' doctrine. He held that there is imperfect intuitive knowledge of the past, which is more certain than abstractive knowledge but less certain than present intuitive knowledge. However plausible or implausible this may be, it is worth noting that Russell held the same view but expressed it by using the terms "knowledge by acquaintance" (intuitive cognition) and "knowledge by description" (abstractive cognition).

William of Ockham. There are several places in Duns Scotus' account where Skeptical challenges can gain a foothold, for example, when he endorses the certainty of sense knowledge and when he holds that intuitive cognition must be of an existent object. William of Ockham (*c.* 1285–1349?) took his stand against the Skeptical challenge by radically revising Duns Scotus' idea of intuitive cognition. Unlike Duns Scotus, Ockham does not require intuitive knowledge to have an existent object, and the object of intuitive knowledge need not be its cause. To the question "What is the basis for the distinction between intuitive and abstractive knowledge?" given that it is not the existence of the object and not a causal relation between an object and the knower, Ockham answered that they are simply different. His answer notwithstanding, it is characteristic of intuitive knowledge that it is unmediated. There is no gap between the knower and the known that might undermine certainty: "I say that the thing itself is known immediately without any medium between itself and the act by which it is seen or apprehended."

ıowledge

According to Ockham, there are two kinds of intuitive knowledge: natural and supernatural. In natural intuitive knowledge, the object exists, the knower judges that the object exists, and the object causes the knowledge. In supernatural intuitive knowledge, the object does not exist, the knower judges that the object does not exist, and God is the cause of the knowledge. In neither case is knowledge a relation; it is something a person has, a property of the person.

Ockham recognized that God might cause a person to think that he has intuitive knowledge of an existent object when there in fact is no such object. But such a condition is not intuitive knowledge but a false belief. Unfortunately, in acknowledging that a person has no way to distinguish between genuine intuitive cognitions and divine counterfeits of them, Ockham has in effect lost the argument to the Skeptics.

Later medieval philosophy followed a fairly straight path to Skepticism. John of Mirecourt was condemned in 1347 for holding among other things that there is no certainty of external reality because God could cause illusions to seem real. Nicholas of Autrecourt was also condemned in the same year for holding that only purely sensory reports of human experience are certain and that the only certain principle is that of contradiction, namely, that a thing cannot be and not be something at the same time. He denied that humans know that causal relations exist or that there are substances, two of many errors he credited to Aristotle, about whom he said, "In all his natural philosophy and metaphysics, Aristotle had hardly reached two evidently certain conclusions, perhaps not even a single one. . . ." The link between Skepticism and criticism of Aristotle was fairly strong, and Petrarch, in *On My Ignorance and That of Many Others* (1367), cited Aristotle as "the most famous" of those who do not have knowledge.

From scientific theology to secular science. For most of the Middle Ages there was no split between theology and science (*scientia*). Science was knowledge that was deduced from self-evident principles, and theology received its principles from the source of all principles, God. In every way, theology was superior to the other sciences, according to Thomas Aquinas. By the 14th century the ideas of science and theology began to be separated. Roughly, theologians began to argue that human knowledge was much more narrowly circumscribed than earlier believed. They often exploited the omnipotence of God in order to undercut the arrogance and pretension of human reason. Their motive was to enhance the dignity of God at the expense of human reason, and in place of rationalism in theology, they promoted a kind of fideism.

Gregory of Rimini (*c.* 1300–*c.* 1358) exemplified the growing split between natural reason and theology. According to Gregory, theology is not a science, and theological propositions are not scientific. In the new view of Gregory, who was inspired by Ockham, science deals only with what is accessible to humans through natural means, that is, through the ordinary operations of their senses and intelligence. Theology in contrast deals with what is accessible in some supernatural way. Thus, theology is not scientific. The role of theology is to explain the meaning of the Bible and the articles of faith and to deduce conclusions from them. Since the credibility of the Bible rests upon belief in divine revelation and revelation upon the authority of God, theology lacks a rational foundation. Further, since there is neither self-evident knowledge of God nor any natural experience of him, humans can have only an abstract understanding of what he is.

Ockham and Gregory did not at all intend their views to undermine theology. For them, natural science is built on probabilities, not certainties. Since humans are fallible, their natural science is fallible, unlike theology, which is built upon propositions that have the authority of God. Unfortunately for theology, the prestige of natural science rose in the 16th century and skyrocketed in the 17th and 18th centuries; modern thinkers preferred coming to their own conclusions based upon experience and reason, even if these were only probable, to trusting the authority of anyone, even God. (This attitude has been called "the Faustian ethos," after Goethe's character Faust.) As the theologians tended to lose confidence in reason, other thinkers who had no or virtually no commitment to Aristotelian thought became the champions of reason and helped give birth to modern science.

MODERN PHILOSOPHY

Faith and reason. Modern philosophers as a group are usually thought to be purely secular thinkers. Nothing could be further from the truth. From the early 17th cen-

tury until the middle of the 18th century, all of the great philosophers incorporated substantial religious elements into their work. Descartes, in his *Meditations* (1641), offered two different proofs for the existence of God, and he asserted that no one who does not believe in a cogent proof for the existence of God can have knowledge in the proper sense of the term. Benedict Spinoza began his *Ethics* (1677) with a proof for the existence of God, after which he expatiated on its implications for understanding all reality. And George Berkeley explained the stability of the sensible world by relying upon God's constant thought of it.

Among the reasons modern philosophers are mistakenly thought to be primarily secular thinkers is that many of their epistemological principles, including some that were intended to defend religion, were later interpreted as subverting the rationality of religious belief. The role of Thomas Hobbes (1588–1679) and John Locke might be briefly considered in this connection. In contrast with the standard view of the Middle Ages that propositions of faith are rational, Hobbes argued that propositions of faith belong not to the intellect but to the will. To profess religious propositions is a matter of obeying the commands of a lawful authority. One need not even understand the meanings of the words professed: an obedient mouthing of the appropriate confession of faith is sufficient. In any case, the linguistic function of virtually every religious proposition is not cognitive in the sense of expressing something that is intended to represent a fact about the world but rather to give praise and honour to God. Further, in contrast to the medieval view, according to which theology is the highest science, theology is not a science at all since its propositions are not susceptible to rational dispute.

The subordination of religious propositions to reason

In *An Essay Concerning Human Understanding* (1689), Locke further eroded the intellectual status of religious propositions by making them subordinate to reason in several dimensions. First, reason can dictate what the possible content of a proposition allegedly revealed by God might be; in particular, no proposition of faith can be a contradiction. Consequently, if the proposition that Jesus is both fully God and fully man is contradictory, it cannot be revealed and cannot be a matter of faith. Also, no revelation can be communicated that contains an idea not based upon sense experience. Thus, St. Paul's experience of things "as eye hath not seen, nor ear heard, nor hath it entered into the heart of man to conceive," are things in which other people can have no faith. To move to another dimension in which reason takes precedence over faith, direct sense knowledge (what Locke calls "intuitive knowledge") is always more certain than any alleged revelation. Thus, a person who sees that someone is soaking wet cannot have it revealed to him that the person is at that moment dry. Rational proofs, in mathematics and science, also cannot be contradicted by divine revelation. The interior angles of a rectangle equal 360°, and no alleged revelation to the contrary is credible. In short, "*Nothing that is contrary to, and inconsistent with, the clear and self-evident dictates of reason, has a right to be urged or assented to as a matter of faith. . . .* "

What space, then, does faith occupy within the mansion of human beliefs? According to Locke, it shares a room with probable truths, those propositions of which reason cannot be certain. There are two types: claims about observable matters of fact and claims that go "beyond the discovery of our sense." Religious propositions belong to each category, as do empirical or scientific ones. That Caesar crossed the Rubicon and that Jesus walked on water belong to the first type of probable proposition. That heat is caused by the friction of imperceptibly small bodies and that angels exist are propositions that belong to the second category.

While mixing religious claims with scientific ones might seem to secure a place for the former, in fact it did not. For Locke also held that whether something is a revelation or not "reason must judge," and more generally that "*Reason must be our last judge and guide in everything.*" Although this maxim was intended to reconcile reason and revelation—indeed, he calls reason "natural revelation" and revelation "*natural reason enlarged* by a new set of discoveries communicated by God"—over the course of 200 years reason repeatedly judged that alleged revelations had no scientific or intellectual standing.

Although there is a strong religious element in modern thinkers, especially before the middle of the 18th century, the purely secular aspects of their thought predominate in the following discussion, because it is these that are of contemporary interest to epistemologists.

Impact of modern science on epistemology. Nicolaus Copernicus (1473–1543), a cleric, argued in *On the Revolutions of the Celestial Spheres* (1543) that the Earth revolves around the Sun. His theory was epistemologically shocking for at least two reasons. First, it goes directly counter to how humans experience their relation to the Sun; it is everyone's prescientific view that the Sun revolves around the Earth. If science can overthrow such a belief, then scientific reasoning seems to lead to knowledge in a way that nonscientific reasoning cannot. Indeed, the nonscientific reasoning of everyday life may seem to be a kind of superstition. Second, his theory was shocking because it contradicts the view that is presented in several books of the Bible, most importantly the explicit account in Genesis of the structure of the cosmos, according to which Earth is at the centre of creation and the Sun hangs from a celestial ceiling that holds back the waters which once flooded the Earth. If Copernicus is right, then the Bible can no longer be taken as a reliable scientific treatise. Scientific beliefs about the world, then, must be gathered in a radically new way.

Many of the discoveries of Galileo Galilei (1564–1642) had the same two shocking consequences. His telescope seemed to reveal that unaided human vision gives false or seriously incomplete information about the nature of celestial bodies. His mathematical formulations of physical phenomena seem to indicate that most sensory information may contribute nothing to knowledge. Like his contemporary, the astronomer Johannes Kepler, he distinguished between two kinds of properties. Primary qualities, such as shape, quantity, and motion, are genuine properties of things and are knowable by mathematics. Secondary qualities, namely, odour, taste, sound, colour, warmth, or coldness, exist only in human consciousness and are not part of the objects to which they are normally attributed.

René Descartes. Both the rise of modern science and the rediscovery of Skepticism were important influences on René Descartes (1596–1650). While he believed that humans were capable of knowledge and certainty and that modern science was developing the superstructure of knowledge, he thought that Skepticism presented a legitimate challenge that needed an answer, one that only he could provide.

The challenge of Skepticism, as Descartes saw it, is vividly portrayed in his *Meditations.* He considered the supposition that all of one's beliefs are false, being the delusions of an evil genius who has the power to impose beliefs on people unbeknownst to them. But Descartes claimed that it is not possible for all of one's beliefs to be false, for anyone who has false beliefs is thinking and knows that he is thinking, and if the person is thinking, then that person exists. Nonexistent things cannot think. This line of argument is summarized in Descartes's formula, "Cogito, ergo sum" ("I think; therefore, I am").

Descartes' refutation of Skepticism

Descartes distinguished two sources of knowledge: intuition and deduction. Intuition is an unmediated mental seeing or direct apprehension of something experienced. The truth of the proposition "I think" is guaranteed by the intuition one has of one's own experience of thinking. One might think that the proposition "I am" is guaranteed by deduction, as is suggested by the "ergo." In *Objections and Replies* (1642), however, Descartes explicitly says that the certainty of "I am" is also based upon intuition.

If one could know only that one thinks and exists, human knowledge would be depressingly narrow. So Descartes proceeded to broaden the limits of human knowledge. After showing that all human knowledge depended upon thought or reason, not sensation or imagination, he then proceeded to prove to his own satisfaction that God exists;

that the criterion for knowledge is clearness and distinctness; that mind is more easily known than body; that the essence of matter is extension; and that most of his former beliefs are true.

Few of these proofs convinced many people in the form in which Descartes presented them. One major problem is what has come to be known as the Cartesian circle. In order to escape from the possibility that an evil genius is deluding him about everything he believes, Descartes proves that God exists. He then argues that clearness and distinctness is the criterion for all knowledge because God does not deceive man. But, since this criterion is arrived at only after the existence of God has been proven, he cannot appeal to this criterion when he presents his proof for the existence of God; hence he cannot know that his proof is cogent.

John Locke. *An Essay Concerning Human Understanding* by John Locke (1632–1704) is often taken to be the first major empiricist work. Book I discusses innate ideas in order to deny that there are any; Book II discusses various genuine kinds of ideas; Book III discusses language with an emphasis on the meaning of words; and Book IV discusses knowledge and related cognitive states and processes.

Innate ideas are ideas that humans are born with. Rationalist philosophers, like Descartes and Gottfried Wilhelm Leibniz (1646–1716), thought that there have to be such ideas in order to explain the existence of some of the ideas which humans have. One argument for innate ideas is that, while the ideas of blue, dog, and large, for example, can be explained as the result of certain sense impressions, other ideas seem unable to be attributed to sensation. Numbers, for example, seem to be outside the realm of sensation. Another argument is that some principles are accepted by all human beings, as, for example, the principle that out of nothing nothing comes. Locke did not think either of these arguments had any force. He held that all ideas can be explained in terms of sensation, and he set as one of his projects the task of providing such an explanation. Instead of directly attacking the hypothesis of innate ideas, Locke's strategy was to refute it by showing that it is otiose and hence dispensable.

In Book II of the *Essay* Locke supposes the mind to be like a blank sheet of paper that is to be filled with writing. How does the paper come to be filled? "To this I answer, in one word," says Locke, "Experience." He divides experience into two types: observation of external objects and observation of the internal operations of the mind.

Observation of external objects is another description for sensation. Observation of the internal operations of the mind does not have its own word in ordinary language, and Locke stipulated "reflection" to designate it, because people arrive at ideas by reflecting on the operations of their own minds. Examples of reflection are perceiving, thinking, doubting, believing, reasoning, knowing, and willing.

An idea is anything that the mind "perceives *in itself,* or is the immediate object of perception." Qualities are the powers that objects have to cause ideas. Many words have dual senses. The word *red,* for example, might mean either the idea of red in the mind or the quality in a body that causes the idea of red in the mind. Some qualities are primary in the sense that all bodies have them. Solidity, extension, figure, and mobility are primary qualities. Secondary qualities are those powers that, in virtue of the primary qualities, cause the sensations of sound, colour, odour, and taste. Locke's view is that the phenomenal redness of a fire engine is not in the fire engine itself, nor is the phenomenal sweet smell of a rose in the flower itself. Rather, certain configurations of the primary qualities cause phenomena such as the appearance of red or the taste of sweetness, and in virtue of these configurations the object itself is said to have the quality of redness or sweetness. But there is no resemblance between the idea in the mind (phenomenon) and the secondary quality that causes it. Locke claims, without justification, as George Berkeley was later to argue, that there is, however, a resemblance between primary qualities and the ideas of them. (Locke distinguishes a third sort of quality, *e.g.,* the power of fire to produce a new colour or consistency in wax or clay, but he makes nothing of it.)

Primary and secondary qualities

Although Locke along with most distinguished modern philosophers repudiated Aristotelianism and the Scholasticism to which it gave rise, a doctrine of abstraction survives in his philosophy. Abstraction occurs when "ideas taken from particular beings become general representatives of all of the same kind." That is, to abstract is to ignore the particular circumstances of time and place and to use an idea to represent all things of a certain kind.

In Book IV Locke finally defines knowledge as "*the perception of the connexion of and agreement, or disagreement and repugnancy of any of our ideas.*" He also distinguishes several degrees of knowledge. The first is knowledge in which the mind "perceives the agreement or disagreement of two ideas *immediately by themselves,* without the intervention of any other," which he calls "intuitive knowledge." His first examples are such analytic propositions as "*white* is not *black,*" "a *circle* is not a *triangle,*" and "*three* are more than *two.*" But later he says, "The knowledge of our own being we have by intuition." Relying on the metaphor of light as Augustine and others had, Locke says of this knowledge that "the mind is presently filled with the clear light of it. *It is on this intuition that depends all the certainty and evidence of all our knowledge.*"

The second degree of knowledge occurs when "the mind perceives the agreement or disagreement of . . . ideas, but not immediately." Some mediating idea makes it possible to see the connection between two other ideas. Proofs are things that show the mediating connections between ideas, and a clear and plain proof is a demonstration. Demonstrative knowledge is certain but not as evident as intuitive knowledge, says Locke, because it requires effort and attention to go through the steps needed to recognize the certainty of the conclusion.

A third degree of knowledge, "sensitive knowledge," approximates to what Duns Scotus and Ockham called "intuitive cognition," namely, the perception of "*the particular existence of finite beings without us.*" Unlike medieval intuitive cognition, Locke's sensitive knowledge is less certain than his intuitive or demonstrative knowledge.

Beneath knowledge is probability, which is the appearance of agreement or disagreement of ideas with each other. Etymologically, probability is a likeliness to be true, and it guides in matters "whereof we have no certainty." Locke suggests that probability rests upon the testimony of others and, like knowledge, comes in degrees, which depend upon the likely veracity of the sources of the proposition. The highest degree of probability attaches to propositions endorsed by the general consent of all people in all ages. Locke may have in mind the virtually general consent of his contemporaries in the proposition that God exists. But he explicitly mentioned beliefs about causal relations, which are not perceived but inferred. To argue from such beliefs is called "an argument from the nature of things." The next degree of probability or assurance in probable propositions attaches to matters that hold not universally but for the most part, such as that persons prefer their own private advantage to the public good. This sort of proposition is typically derived from history. The next degree of probability or assurance attaches to claims about specific facts, for example, that a man named Julius Caesar lived a long time ago. Problems arise when testimonies conflict, as they often do, but there is no simple rule or set of rules that instructs one how to resolve such controversies.

In addition to these probabilities, all of which concern particular matters of fact, there are also probabilities about things that are not within the power of the senses. The existence, nature, and operation of angels, devils, microbes, magnets, and molecules all fall into this class. It is important to recognize that for people as scientific as Locke, who was a member of the Royal Society, all of these were part of the same class. It took many centuries to separate science from religion and superstition.

George Berkeley. Locke is part of a philosophical tradition called empiricism, that is, the view that the sole or at least the major source of human knowledge is sensory experience. George Berkeley (1685–1753) was the next

great adherent of empiricism. In his major work, *Treatise Concerning the Principles of Human Knowledge* (1710), he divides ideas into three types: Ideas that come from sense correspond to Locke's simple ideas of sensation. Ideas that come from "attending to the passions and operations of the mind" correspond to Locke's ideas of reflection. Ideas that come from compounding, dividing, or otherwise representing ideas, correspond to Locke's compound ideas. An apple, for example, is a compound of the simple ideas of colour, taste, smell, and figure associated with it.

In addition to ideas, what exists are spirits or souls or minds. By "spirit," Berkeley means "one simple, undivided, active being." Spirit exercises itself in two ways: in understanding and in willing. Understanding is spirit perceiving ideas, and will is spirit producing ideas. It is evident, says Berkeley, that no idea, including those of sensation, can exist outside of a mind. This is evident, not merely in virtue of the meaning of "idea" but what it means to exist. For a table to exist is for someone to see or feel it. To be an odour is to be smelled. To be a sound is to be heard. In short, for nonthinking beings, *esse* is *percipi* (to be is to be perceived).

The question whether a tree falling in a virgin forest makes a sound is inspired by Berkeley's philosophy, though he never asked it in those terms. He did, however, consider the thrust of the objection and gave various answers to it. He sometimes says that a table in a room unperceived is a table that would be perceived if someone were there. This conditional response, however, is not sufficient. Granted that the table would exist if it were perceived, does it exist when it is not perceived? Berkeley's other answer is that, when no human is perceiving a table or other such object, God is; and it is his thinking that keeps the otherwise unperceived object in existence.

However strange his doctrine may initially sound, Berkeley claimed that he was merely describing the commonsense view of reality. To say that colours, sounds, trees, dogs, and tables are ideas is not to say that they do not really exist. It is merely to say what they are. To say that animals and pieces of furniture are ideas is not to say that they are diaphanous, gossamer, and evanescent. Opacity, density, and permanence are also ideas that partially constitute these objects.

Berkeley has a syllogistic argument for his main point: physical things, such as trees, dogs, and houses, are things perceived by sense, and things perceived by sense are ideas; therefore, physical things are ideas. If one objects that the first premise is false, Berkeley in reply would challenge the objector to point out one example of something that is not sensed. The only way to identify such an example is through some sensation, either by sight, touch, taste, or hearing. In this way, any proffered counterexample becomes an example of Berkeley's point.

If one objects that the second premise of the syllogism is false on the grounds that people sense things, not ideas, Berkeley would reply that there are no sensations without ideas and that it makes no sense to speak of some additional thing which ideas are supposed to represent or resemble. Unlike Locke, Berkeley does not believe that there is anything "behind" ideas in a world external to the mind. There could not be. If the alleged external objects, of which ideas are supposed to be representations, exist, then they are themselves either ideas or not. If they are ideas, then Berkeley's point that everything perceived is an idea is vindicated. If they are not ideas, then they are unperceived; in particular, they would be invisible colours, intangible textured things, odourless smells, and silent sounds. If someone objects that he can imagine trees or books in a closet unperceived, Berkeley would reply that this proves nothing except that there are imagined trees and books. People who think that there are unperceived objects are deceived because they do not take into account their own thinking of the allegedly unperceived object.

A consequence of this argument is that Locke's distinction between primary and secondary qualities is spurious. Extension, figure, motion, rest, and solidity are as much ideas as green, loud, and bitter are; there is nothing special about the former kinds of ideas. Furthermore, matter, as philosophers conceive it, does not exist and indeed is contradictory. For matter is supposedly unsensed extension, figure, and motion, but since extension, figure, and motion are ideas, they must be sensed.

Berkeley's doctrine that things unperceived by human beings continue to exist in the thought of God was also not novel. It was part of the traditional belief of Christian philosophers from Augustine onward through Aquinas and at least to Descartes that God not only creates all things but keeps them in existence by thinking of them. In this view if he were ever to stop thinking of a creature, it would immediately be annihilated.

On another matter, the doctrine of abstraction, Berkeley made a clean break with the past. Berkeley rejected it completely, because he thought it led to belief in unperceived, nonspiritual substances. Abstractionism, according to Berkeley, illicitly warrants the separation of existence from being perceived. For him every idea is particular and of a particular object. There cannot be an idea of motion in general but only of a certain body moving slowly or quickly. To reject abstract ideas is not to reject general ideas. An idea is general in virtue of "being made to represent or stand for all the other particular ideas of the same sort." That is, each general idea is a particular idea that stands for many things.

David Hume. Although Berkeley rejected the Lockean notions of primary and secondary qualities and matter, he retained Locke's beliefs in the existence of mind, substance, and cause as a power or secret force. David Hume (1711–76), in addition to rejecting all the Lockean notions that Berkeley did, also rejected what Berkeley had retained. His justification for this step was empiricist and scientific, for he thought that all science is empiricist and that there is no empirical justification for belief in mind or spirit.

Hume aspired to be the Newton of philosophy. As stated in *A Treatise of Human Nature* (1730–40), he wanted to formulate universal principles to explain "all effects from the simplest and fewest causes," but a boundary condition on these principles is that they "cannot go beyond experience." Further, the ultimate principles that humans can form will themselves lack justification. They will explain experience without having an explanation of their own.

Kinds of perceptions. Hume has a twofold division of perceptions: impressions and ideas. Impressions are perceptions that enter with "most force and violence." Ideas are "faint images" of impressions. Hume thinks the distinction so obvious that he demurs from explaining it at any length. Impressions are felt; ideas are thought, he indicates in his summary explication. He also concedes that, although one can always discern the difference between an impression and an idea by its force, sleep, fever, and madness sometimes produce ideas that approximate to the force of impressions, and certain impressions approach the weakness of ideas. But such occasions are rare.

The distinction has a problem that Hume did not notice. The impression (experience) of anger has an unmistakable quality and intensity, but it is not the case that the idea of anger always makes a person feel angry. Thinking of anger no more guarantees being angry than thinking of the idea of happiness guarantees being happy, even if thinking happy thoughts tends to make people happy. So there is a difference between the experience of anger and the idea of anger that Hume's philosophy does not capture.

In addition to impressions and ideas, perceptions can be divided into the categories of simple and complex. Whereas simple perceptions are not subject to further separation or distinction, complex perceptions are. For example, apples, although unitary objects in one view, are in fact complex perceptions; they are divisible into a certain shape, colour, texture, and aroma. It is noteworthy that for every simple impression there is a simple idea that corresponds to it and differs from it only in force and vivacity, and vice versa. So, corresponding to the impression of red is the idea of red. This does not hold true in general for complex perceptions. Although there is a correspondence between the impression of an apple and the idea of an apple, there is not always a correspondence between impressions and ideas. There is no impression that corresponds to the idea of Pegasus or a unicorn; these complex ideas do not have a correlate in reality. There are also complex impressions

that do not have a corresponding idea. A traveler who has seen an extensive part of Rome nonetheless does not have an idea of Rome that corresponds in every respect to his perceptions.

Because of their correspondence, there seems to be a special connection between simple impressions and simple ideas: the former cause the latter. Hume deduces this on the following grounds. A simple impression always precedes the corresponding idea, and the idea invariably follows the conjoined impression. Thus, because of the temporal priority of impressions and the constant conjunction of impressions and ideas, Hume concludes that impressions cause ideas.

There are two kinds of impressions: sensation and reflection. Sensation "arises in the soul originally from unknown causes." Hume says little more about sensation because discussion of it belongs to anatomists and scientists. (Many late 20th-century philosophers do not accept this division between philosophy and anatomy.) To explain reflection is rather complicated because it derives from a complex mental operation. After people feel heat or cold, thirst or hunger, pleasure or pain, they form ideas of heat or cold, thirst or hunger, pleasure or pain. And, following the formation of these ideas—at a third stage of cogitation—they form from the ideas the second kind of impressions: impressions of "desire and aversion, hope and fear." These impressions are the result of reflecting on ideas caused by sensation.

Reflection

Since imagination can divide and assemble disparate ideas as it will, some explanation is needed for why the mind seems to run in predictable channels. Hume says that the mind is guided by three principles: resemblance, contiguity, and cause and effect. Thus a person who thinks of one idea is likely to think of another idea that resembles it. For example, a person's thought, if one accepts Hume's account, will run from red to pink to white, or from dog to wolf to coyote. Hume also uses the principle of resemblance to explain how general ideas function. Hume agrees with Berkeley in denying that there are abstract ideas, and he affirms that all ideas are particular. Some of them, however, are used to represent many objects by inclining the mind to think of other ideas that resemble the first. These particular ideas that represent many things are general ideas. Concerning contiguity, people are inclined to think of things that are next to each other in space and time. Finally and most importantly, people associate ideas on the basis of cause and effect relations. Fire and smoke, parent and child, disease and death are tied in the mind because of their causal relations. But cause and effect relations play a more central role in Hume's thought than these brief remarks might suggest.

Cause and effect. Although people gain much information from their impressions, most matters of fact depend upon reasoning about causes and effects, even though people do not directly experience causal relations. What, then, are causal relations? According to Hume they have three components: contiguity of time and place, temporal priority of the cause, and constant conjunction. In order for x to be the cause of y, x and y must exist adjacent to each other in space and time, x must precede y, and x and y must invariably exist together. There is nothing more to the idea of causality than this; in particular, people do not experience and do not know of any power, energy, or secret force that causes possess and that they transfer to the effect. Still, all judgments about causes and their effects are based upon experience. To cite examples from *An Enquiry Concerning Human Understanding* (1748), since there is nothing in the experience of seeing a fire close by which logically requires that one will feel heat, and since there is nothing in the experience of seeing one rolling billiard ball contact another that logically requires the second one to begin moving, why does one expect heat to be felt and the second ball to roll? The explanation is custom. In previous experiences, the feeling of heat has regularly accompanied the sight of fire, and the motion of one billiard ball has accompanied the motion of another. Thus the mind becomes accustomed to certain expectations. "All inferences from experience, therefore, are effects of custom, not of reasoning." Thus it is that custom, not reason, is the great guide of life. In short, the idea of cause and effect is neither a relation of ideas nor a matter of fact. Although it is not a perception and not rationally justified, it is crucial to human survival and a central aspect of human cognition.

Substance. One of the cornerstones of philosophy from Plato to Berkeley was the notion of substance, that which exists in itself and does not depend upon anything else for its existence. Substance is contrasted with accident or modes of being, which exist in substances and depend on them for their existence. A dog is a substance, and its colour, shape, weight, and bark exist in the dog and depend on it for their existence. One of the reasons for Hume's place in the history of philosophy is that he denied the existence of substance, using the epistemological principles he shared, not simply with empiricists like Locke and Berkeley, but with Aristotle and Aquinas as well. As argued in the *Treatise,* since all human knowledge must be traced back to sensation, the idea of substance must be also. But what sensation can give rise to the idea of substance? It is not a colour, shape, sound, or taste. Substance, by its proponents' own definition, is not an accident or mode. Hume concludes, "We have therefore no idea of substance, distinct from that of a collection of particular qualities, nor have we any other meaning when we either talk or reason concerning it." What then are the things that earlier philosophers designated substances? They are "nothing but a collection of simple ideas, that are united by the imagination, and have a particular name assigned to them." Gold, to take Hume's example, is nothing but the collection of the ideas of yellow, malleable, fusible, and so on. Even the mind is only a collection, "a heap or collection of different perceptions united together by certain relations and suppos'd tho' falsely, to be endow'd with a perfect simplicity or identity."

Relations of ideas and matters of fact. Human thought concerns two kinds of things: relations of ideas and matters of fact. Relations of ideas can either be intuited, that is, seen directly, or deduced from other propositions. That a is identical with a, that b resembles c, and that d is larger than e are examples of propositions that are intuited. The opposites of true propositions expressing relations of ideas are contradictory. Arithmetic and algebra are the subjects about which there can be the most certainty. In his *Treatise* Hume says that geometry is almost as certain as these, but not quite, because its original principles derive from sensation, and about sensation there can never be absolute certainty. He revised his views about geometry later, and in the *Enquiry* he puts geometry on an equal footing with the other mathematical sciences.

In contrast with relations of ideas, matters of fact are derived from experience. Experience, however, would be quite limited if it did not include causal relations, which go beyond what is experienced.

Skepticism. Hume's discussion about relations of ideas and matters of fact gives the impression that he thought that human knowledge is possible. Relations of ideas seem to be the object of knowledge, while matters of fact seem to be the object of probability. In Part II of the *Treatise* he denies this and argues forcefully for Skepticism.

Until the beginning of Part IV of Book I of the *Treatise,* there is little or no hint of Skepticism. The distinction between knowledge (of the mathematical sciences) and probability (of matters of fact) seems to presuppose that there is knowledge. But one then discovers that Skepticism undermines it all. Although the rules of science are certain and infallible, the application of those rules by humans is uncertain and fallible because humans are prone to error. It does no good for a person to try to check his chain of reasonings because the process of checking is no more immune to error than the original calculation. How can one know that the checking process was performed correctly? And, if the checking procedure seems to identify a mistake in the original calculation, how can one determine whether the error is in the original or in the seeming identification of an error? Adding a checking procedure is in one respect worse than leaving the original calculation alone. It introduces a second event, which, like the original calculation, is possibly flawed. And it is more probable

that one of two possibly flawed events is flawed than either one of the two alone. "By this means," Hume says, "all knowledge degenerates into probability." Another way to see this consequence is to consider that reason is a cause of truth. But, since all causal relations are probable, not certain, all human reasoning is at best probable.

If one thinks further about the matter, the probability of knowledge diminishes and doubt increases. Each judgment of the probability of some judgment introduces further reasons for doubt and thus lowers the overall probability. The joint probability of p and q is lower than the probability of p; and the joint probability of p, q, and r is lower than the probability of p and q. Ultimately, "when I proceed still farther, to turn the scrutiny against every successive estimation I make of my faculties all the rules of logic require a diminution, and at last a total extinction of belief and evidence." If one should say, "Surely, you are kidding," Hume's answer would be a beguiling one: In a sense, "yes," for nature has so made human beings that they cannot in fact be skeptical even though the argument for Skepticism is cogent. As Hume says in his *Enquiry,* people conduct their lives for the most part governed by custom and nature, not reason. Skepticism is true even though there are no Skeptics, because, as in Berkeley's philosophy, the arguments for Skepticism "*admit of no answer and produce no conviction.*"

There is another way of expressing Hume's position. If one examines the grounds that human beings have for trusting their reasoning, one will not be able to find rational grounds. Reason cannot be rationally grounded, and the ground of rationality is wholly nonrational: "*belief is more properly an act of the sensitive, than of the cogitative part of our natures.*"

Some people have tried to make short shrift of Skepticism by pointing out that if the Skeptic recognizes his arguments to be rationally compelling, then he must recognize the sovereignty of reason and hence the falsity of Skepticism. Hume points out that the battle against Skepticism cannot be won in this way. Skepticism is a refutation of the claims of reason. As such, one assumes the truth of rationalism in order to show that it is contradictory and hence false. In other words, Hume's proof is a *reductio ad absurdum* argument against belief in rationality. The Skeptical argument proceeds by arguing that, if rationalism is true, then it is not rational to be rational. Since the consequent is contradictory, the assumption that rationalism is true must be false. Thus, rationalism is false.

Hume has been called "the complete Pyrrhonist," but Hume himself denied that he was one, in large part because he did not distinguish between Pyrrhonism and Academic Skepticism, both of which, according to him, advocate the suspension of belief even as one conducts one's ordinary affairs. Hume thought such a program impossible for human beings: humans are condemned to believe. Unlike the Pyrrhonist, Hume does not suspend judgment or abandon reason. He judges according to reason because it is his nature to do so even though Skeptical arguments against reason are cogent. This philosophical schizophrenia—the use and trust in reason coupled with the recognition that rationality has no rational justification—is part of what Hume calls "mitigated Skepticism." Another part of it is restricting one's investigations to topics that are within the "narrow capacity of human understanding," namely to experience and the mathematical sciences.

Mitigated Skepticism

Given his Skepticism, one might wonder whether it could be directed against Hume's own positive doctrine. It can. At the end of Part I of his *Treatise* Hume says, "Can I be sure, that in leaving all establish'd opinions I am following truth; and by what criterion shall I distinguish her, even if fortune shou'd at last guide me on her foot-steps? After the most accurate and exact of my reasonings, I can give no reason why I shou'd assent to it; and feel nothing but a *strong* propensity to consider objects *strongly* in that view, under which they appear to me." Ultimately one judges according to custom and the way nature dictates one must judge. The *Enquiry Concerning Human Understanding* is intended to be an accurate description of how people judge, not a justification of it.

Immanuel Kant. Idealism is often defined as the view that everything which exists is mental; that is, everything is either a mind or depends for its existence upon a mind, as do ideas and thinking. Immanuel Kant (1724–1804) was not strictly an idealist according to this definition, although he called himself a "transcendental idealist." On his view, humans can know only what is presented to their senses or what is contributed by their own mind. Every sensory experience is a mixture of a sensory content, which is simply given to a person, and a spatial and temporal form, which is contributed by the mind itself. Further, if one formulates a sensory experience into a judgment, then the mind also contributes certain additional objective features: the judgment incorporates ideas of something being a substance or quality of that substance, ideas of one thing causing another, or one thing being related by necessity or by accident to another. In short, the raw data of sensory input is only a small part of what constitutes human knowledge. Most of it is contributed by the human mind itself; and, so far as human knowledge is concerned, rather than the mind trying to accommodate itself to the external world, the world conforms to the requirements of human sensibility and rationality. Kant compared his radical reorientation of the way philosophers ought to study human knowledge to the Copernican revolution in astronomy. Just as the Earth revolves around the Sun, contrary to common sense, objects conform themselves to the human mind, contrary to common sense.

Kant's idealism notwithstanding, he also believed that a world existed independent of the human mind and completely unknowable by it. This world consists of things-in-themselves, which do not exist in space and time, are not organized in causal relations, and so on, because these are elements contributed by the human mind as conditions for knowing. Because of his commitment to realism (minimal though it may be) Kant was disturbed by Berkeley's uncompromising idealism, which amounted to a denial of the external world. Kant found this incredible and rejected "the absurd conclusion that there can be appearance without anything that appears."

Kant's goal, as developed in *Critique of Pure Reason* (1781), was to supplant Berkeley's crude idealism with a transcendental idealism. The difference, as Kant saw it, is that, while Berkeley began empirically by noting that everything that humans are rationally justified in asserting to exist is related to consciousness, he went on to ask what necessary conditions underlie any empirical experience at all. Kant did not deny that there is empirical experience, but he was critical of Berkeley for not excavating its rational underpinnings. Kant is called a "rationalist" because he thought that the conditions for empirical experience can only be reasoned to, not discovered in, experience; he called his idealism "transcendental" because the conditions he was looking for are common to—they transcend—any experience. In his notorious "proof of an external world," he claimed that he experienced himself as an object in time, that time requires something permanent outside of his consciousness as a precondition for his existence in time, and hence that an external world exists. In other words, the claim is that inner experience presupposes an outer or external world. But few philosophers have claimed to understand why this should be so, and the very contrast of inner and outer seems to beg the question.

Transcendental idealism

Kant believed that all objects of sensation must be experienced within the limits of space or time. Thus, all physical objects have a spatiotemporal location. Because space and time are the backdrop for all sensations, he called them pure forms of sensibility. In addition to these forms, there are also pure forms of understanding, that is, categories or general structures of thought that the human mind contributes in order to understand physical phenomena. Thus, every empirical object is thought to have some cause, to be either a substance or part of some substance, and so on. The structure of judgments finally leads to the question of what properties the propositions that express judgments (or knowledge) have.

From a logical point of view, the propositions that express human knowledge can be divided according to two distinctions. First is the distinction between propositions that are a priori, in the sense that they are knowable prior

to experience, and those that are a posteriori, in the sense that they are knowable only after experience. Second is the distinction between propositions that are analytic, that is, those in which the predicate is included in the subject, and those that are synthetic, that is, those in which the predicate is not included in the subject. Putting the terms of these two distinctions together yields a fourfold classification of propositions. (1) Analytic a priori propositions include "All bachelors are unmarried" and "All squares have four sides." (2) Analytic a posteriori propositions do not exist, according to Kant, because, if the predicate is conceptually included in the subject, the appeal to experience is irrelevant and unnecessary. Also, the negation of an analytic proposition is a contradiction; but, because any experience is contingent, its opposite is logically possible and hence not contradictory. (3) Synthetic a priori propositions include "Every event has a cause" and "7 + 5 = 12." Although it is not part of the concept of an event that it be a cause, it is universally true and necessary that every event has a cause. And, because 12 is a different concept from seven, five, and plus, it does not include any of them singly or jointly as a part of it. (4) Finally, synthetic a posteriori propositions include, "The cat is on the mat" and "It is raining." They are straightforwardly and uncontroversially empirical propositions that are not necessary and are discoverable through observation.

Kant's view that human experience is bounded by space and time and that it is intelligible only as a system of completely determined causal relations existing between events in the world and not between the world and anything outside of it has the consequence that there can be no knowledge of God, freedom, or human immortality. Each of these ideas exceeds the bounds of empirical experience and hence is banished from the realm of reason. As he said, he "found it necessary to deny *knowledge,* in order to make room for faith."

G.F.W. Hegel. G.F.W. Hegel (1770–1831) developed his epistemology pari passu with ontology. Since his positive views are difficult and replete with technical terms, his epistemology is not susceptible of summary here. Some of his criticisms of earlier epistemological views, however, should be mentioned since they helped to bring modern philosophy to a close.

Empiricism takes cognition of particular sensed objects as the foundation for knowledge. But, Hegel argues, no sensation is purely particular. For every sensation consists of something that has a certain feature, quality, or feel, and this feature, quality, or feel is something common to other sensations and hence not particular. Also, all knowledge must be expressible in language, and all fully articulated language uses predicates, which express concepts. Even if the empiricist attempts to represent his knowledge with a single, purely demonstrative word, say, "this" or "now," his view is contradictory. For "this" is common to any indicated object, and "now" can be used to refer to any time. An analogous argument holds against anyone who, like Descartes or Kant, wants to begin with the referent of "I."

Another mistake common to empiricism and rationalism is to think that knowledge requires a correspondence between a person's beliefs and reality. The search for such correspondence is logically absurd since every such search ends with some belief about whether the correspondence holds or not, and thus one has not advanced beyond belief. Kant's distinction between the thing-in-itself and the phenomenon of consciousness is an instance of this absurdity. To make the distinction is to have the object in itself in consciousness and hence not in itself. Thus, Hegel concludes that knowledge and reality cannot be two things but must be identical. Knowledge cannot be perspectival or relative to each person; it is as absolute and objective as reality.

CONTEMPORARY PHILOSOPHY

Contemporary philosophy begins in the late 19th and early 20th century. Much of what sets contemporary philosophy off from modern philosophy is its explicit criticism of the modern tradition and sometimes its apparent indifference to it. There are two basic strains of contemporary philosophy: Continental philosophy, which designates the philosophical style of western European philosophers, and Anglo-American, or analytic, philosophy, which includes the work of many European philosophers who immigrated to Britain, the United States, and Australia shortly before World War II.

Continental philosophy. In epistemology, Continental philosophers during the first quarter of the 20th century were preoccupied with the problem of overcoming the apparent gap between the knower and the known. If a human being has access only to his own ideas of the world and not the world itself, how can there be knowledge at all?

The German philosopher Edmund Husserl (1859–1938) thought that the standard epistemological theories had become intrusive because philosophers were attending to repairing or complicating them rather than focusing on the phenomena of knowledge as humans experience them. To emphasize this reorientation of thinking, he adopted the slogan, "To the things themselves." Philosophers needed to recover the sense of what is given in experience itself, and this could only be accomplished through a careful description of phenomena. Thus, Husserl called his philosophy "phenomenology," which was to begin as a purely descriptive science and only later to ascend to a theoretical, or "transcendental," science. Phenomenology

Husserl thought that the philosophies of Descartes and Kant presupposed a gap between the aspiring knower and what is known and that the experience of the external world was thus dubious and had to be proven. These presuppositions violated Husserl's belief that philosophy, as the most fundamental science, should be free of presuppositions. Thus, he held that it is illegitimate to assume there to be any problem of knowledge or of the external world prior to an investigation of the matter without any presuppositions. Husserl's device to cut through the Gordian knot of such assumptions was to introduce an "*epochē*." In other words, he would bracket or refuse to consider traditional philosophical problems until after the phenomenological description had been completed.

The *epochē* was just one of a series of so-called transcendental reductions that Husserl proposed in order to ensure that he was not presupposing anything. One of these reductions supposedly gave one access to "the transcendental ego," or "pure consciousness." Although one might expect phenomenology then to describe the experience or contents of this ego, Husserl instead aimed at "eidetic reduction," that is, the discovery of the essences of various sorts of ideas, such as redness, surface, or relation. All of these moves were part of Husserl's desire to discover the one, perfect methodology for philosophy in order to ensure absolute certainty.

Because Husserl's transcendental ego seems very much like the Cartesian mind that thinks of a world but does not have either direct access to or certainty of it, Husserl tried in *Cartesianische Meditationen* (1931; "Cartesian Meditations") to overcome the apparent gap, the very thing he had set out either to destroy or bypass. Because the transcendental ego seems to be the only genuinely existent consciousness, Husserl also tried to overcome the problem of solipsism.

Many of Husserl's followers, including his most famous student, Martin Heidegger (1889–1976), recognized that something had gone radically wrong with the original direction of phenomenology. According to Heidegger's diagnosis, the root of the problem was Husserl's assumption that there is an "Archimedean point" for human knowledge, to use Husserl's own phrase; but, there is no ego detached from the world and filled with ideas or representations, according to Heidegger. In *Being and Time* (1927) Heidegger returned to the original formulation of the phenomenological project as a return to the things themselves. Thus, all the transcendental reductions are abandoned. What he claimed to discover is that human beings are inherently world-bound. The world does not need to be derived; it is presupposed by human experience. In their prereflective experience, humans inhabit a sociocultural environment, in which the primordial kind of cognition is practical and communal, not theoretical or individual ("egoistic"). Human beings interact with the

things of their everyday world (*Lebenswelt*) as a workman interacts with his tools; they hardly ever approach the world as a philosopher or scientist would. The theoretical knowledge of a philosopher is a derivative and specialized form of cognition, and the major mistake of epistemology from Descartes to Kant to Husserl was to take philosophical knowledge as the paradigm for all knowledge.

Heidegger's insistence that a human being is something that inhabits a world notwithstanding, he marked out human reality as ontologically special. He called this reality *Dasein,* the being, apart from all others, which is present to the world. Thus, like the transcendental ego, a cognitive being takes pride of place in Heidegger's philosophy.

In France the principal phenomenological proponent of the mid-century was Maurice Merleau-Ponty (1908–61). But he rejected Husserl's bracketing of the world, that is, his mistake in not recognizing that human experience of the world is primary, a view capsulized in Merleau-Ponty's phrase "the primacy of perception." He furthermore held that dualistic analyses of knowledge, such as the Cartesian mind–body dualism, are inadequate. In fact, no conceptualization of the world can be complete in his view. Because human cognitive experience requires a body and the body a position in space, human experience is necessarily perspectival and thus incomplete. Although humans experience material beings as multidimensional objects, part of the object always exceeds the cognitive grasp of the person just because of his limited perspective. In *Phenomenology of Perception* (1945), Merleau-Ponty develops these ideas (along with a detailed attack on the sense-datum theory, discussed below).

The epistemological views of Jean-Paul Sartre (1905–80) share some features with Merleau-Ponty's. Both reject Husserl's transcendental reductions, and both think of human reality as being-in-the-world. But Sartre's views have Cartesian elements that were anathema to Merleau-Ponty. Sartre distinguished between two basic kinds of being. Being-in-itself (*en soi*) is the inert and determinate world of nonhuman existence. Over and against it is being-for-itself (*pour soi*), which is the pure consciousness that defines human reality.

Later Continental philosophers attacked the entire philosophical tradition from Descartes to the 20th century for its explicit or implicit dualisms. Being/nonbeing, mind/body, knower/known, ego/world, being-in-itself/being-for-itself are all variations on a way of philosophizing that the philosophers of the last third of the 20th century have tried to undermine. The structuralist Michel Foucault (1926–84) wrote extensive historical studies, most notably *The Archaeology of Knowledge* (1969), in order to demonstrate that all concepts are historically conditioned and that many of the most important ones serve the political function of controlling people rather than any purely cognitive purpose. Jacques Derrida has claimed that all dualisms are value-laden but indefensible. His technique of "deconstruction" attempts to show that every philosophical dichotomy is incoherent, because whatever can be said about one term of the dichotomy can also be said of the other.

Michel Foucault

Dissatisfaction with the Cartesian philosophical tradition can also be found in the United States. The American pragmatist John Dewey (1859–1952) directly challenged the idea that knowledge is primarily theoretical; experience, he argued, consists of an interaction between a living being and his environment. Knowledge is not a fixed staring at something but a process of acting and being acted upon. Richard Rorty has done much to reconcile Continental and Anglo-American philosophy. He has argued that Dewey, Heidegger, and Ludwig Wittgenstein are the three greatest philosophers of the 20th century, specifically because of their attacks on the epistemological tradition of modern philosophy. (A.P.Ma.)

Analytic philosophy. Analytic philosophy, the prevailing philosophy in the Anglo-American world in the 20th century, has its origins in symbolic logic on the one hand and in British empiricism on the other. Some of its important contributions have been nonepistemological in character, but in the area of epistemology its contributions have also been of the first order. Its main characteristics have been the avoidance of system building and a commitment to detailed, piecemeal analyses of specific issues. Within this tradition there have been two main approaches: a formal style, deriving from logic; and an approach emphasizing ordinary language. Among those who can be identified with the first method are Bertrand Russell, Gottlob Frege, Rudolf Carnap, Alfred Tarski, and W.V.O. Quine; and among those with the second are G.E. Moore, Gilbert Ryle, J.L. Austin, Norman Malcolm, P.F. Strawson, and Zeno Vendler. Wittgenstein can be situated in both groups, his early work belonging to the former tradition and his posthumous works, *Philosophical Investigations* (1953) and *On Certainty* (1969), to the latter.

Perhaps the most distinctive feature of analytic philosophy is its emphasis upon the role that language plays in the creation and resolution of philosophical problems. These problems, it is said, arise through the misuses, oversimplifications, and unwarranted generalizations of everyday language. Wittgenstein said in this connection: "Philosophy is a battle against the bewitchment of the intelligence by means of language." The idea that philosophical problems are in some important sense linguistic (or conceptual) is called the "linguistic turn."

The linguistic turn

Commonsense philosophy, logical positivism, and naturalized epistemology. Three of the most notable achievements of analytic philosophy are commonsense philosophy, logical positivism, and naturalized epistemology. G.E. Moore (1873–1958) made a defense of what he called the commonsense view of the world. According to Moore, virtually everybody knows certain propositions to be true, such as that the Earth exists, that it is very old, and that other persons now exist on it. Furthermore, any philosophical theory that runs counter to this commonsense view can be rejected out of hand as mistaken. All forms of idealism fall into this category. Wittgenstein, for whom certainty is that "which stands fast for all of us," extended this view. In *On Certainty* he argued that certitude is connected with action and that "Action lies at the bottom of the language game."

The development of logical positivism (also called logical empiricism) was a product of the Vienna Circle under the leadership of the German logical empiricist philosopher Moritz Schlick, and it became a dominant form of philosophy in England with the publication of A.J. Ayer's *Language, Truth, and Logic* (1936). Logical positivism holds that all significant propositions are either those of logic or mathematics on the one hand or those of science on the other. Since the utterances of traditional philosophy (especially metaphysics) fall into neither of these groups, they are unverifiable in principle and accordingly can be rejected as nonsense. The only legitimate function for philosophy is conceptual analysis, *i.e.,* the clarification of various notions, such as "probability" or "causality."

W.V.O. Quine (b. 1908), in "Two Dogmas of Empiricism" (1950), launched an attack upon the notion that there is a difference in kind between analytic and synthetic statements. Quine argued powerfully that the so-called difference is one of degree. In a later work, *Word and Object* (1960), Quine developed a new type of philosophy, which he called "naturalized epistemology." He rejected the notion that epistemology has a normative function and claimed that its only legitimate role is to describe the way knowledge is actually obtained. In effect, its function is to describe how present science arrives at the beliefs accepted by the scientific community.

Perception and knowledge. To a great extent the epistemological interests of analytic philosophers in the 20th century have been concentrated upon the relationship between knowledge and perception. The major figures in this development have been Bertrand Russell, G.E. Moore, H.H. Price, C.D. Broad, A.J. Ayer, and H.P. Grice. Although their views differed considerably—Russell, Broad, and Ayer were phenomenalists, Grice was a defender of the causal theory of perception, and Moore attempted to construct a theory of direct realism—all of them were defenders of sense-data theory (see below).

Sense-data theory was criticized by proponents of the so-called theory of appearing, such as G.A. Paul and W.H.F. Barnes, who claimed that the arguments for the existence

of sense-data are spurious. Those arguments assume, for example, that because a penny looks elliptical from a certain perspective, it follows that there exists an elliptical object (sense-datum), which an observer is directly apprehending. They denied the inference, saying that the introduction of a separate entity, a sense-datum, does not follow from the fact that a circular object looks elliptical and to believe that it does is simply to misdescribe certain common perceptual situations. The most powerful attack on sense-data theory was generated by J.L. Austin in *Sense and Sensibilia* (1962).

Many philosophers, in turn, rejected the theory of appearing. They felt that puzzles about the status of illusions and other visual anomalies still require explanation. Their aim was to give a coherent account of how knowledge is possible despite the existence of perceptual error. Realism and phenomenalism are the two main types of theories developed to account for these difficulties.

Both realism and phenomenalism have had numerous variants. Two forms of realism, direct (naive) realism and representative realism (also called "the causal theory"), are historically important.

Realism. Realism is both a metaphysical and an epistemological theory. The realist is committed to two principles: first, that some of the objects apprehended through perception are public and, second, that some of those objects are mind-independent. It is especially the second of these notions that distinguishes realists from phenomenalists.

The realist believes that there is an intuitive commonsense distinction among various classes of entities perceived by human beings. One class consists, among others, of headaches, thoughts, pains, or desires, and the other of tables, rocks, planets, persons, animals, and certain physical phenomena such as rainbows, lightning, and shadows. The metaphysical aspect of realism sees the former as mental, the latter as physical. A realist metaphysics maintains that the classes are mutually exclusive. What a realist epistemology adds to this metaphysics is that mental entities are private, whereas physical objects are public. By "private" it is meant that each item belonging to the category of the mental is apprehensible by one person only. Thus, only one person can have a particular headache or a particular pain. In contrast, physical objects are public; more than one person can see or touch the same chair.

The realist also believes that items belonging to the class of the physical are mind-independent. What is meant by this notion is that the existence of these objects does not depend upon their being perceived by anyone. Thus, whether or not a particular table is being seen or touched by someone has no effect upon its existence. Even if nobody is looking at it, it would still exist (other things being equal). But this is not true of mental phenomena. If somebody is not actually having a headache, realists would deny that the headache exists. A headache is thus mind-dependent in a way in which tables, rocks, and shadows are not.

Realist theories of knowledge thus begin by assuming the public–private distinction, and most realists start by assuming that one does not have to prove the existence of mental phenomena. These are things of which each person is directly aware, and there is no special "problem" about their existence. But they do not assume this to be true of physical phenomena. As the existence of visual aberrations, illusions, and other anomalies shows, one cannot be sure that in any perceptual situation one is apprehending physical objects. All a person can be sure of is that he is aware of something, an appearance of some sort, say of a bent stick in water; but whether that appearance corresponds to anything actually existing in the external world is an open question.

In the *Foundations of Empirical Knowledge* (1940) Ayer called this difficulty "the egocentric predicament." When a person looks at what he thinks is a physical object, such as a chair, what he is directly apprehending is a certain visual appearance. But such an appearance seems to be private to that person; it seems to be something mental and not publicly accessible. What then justifies the individual's belief in the existence of supposedly external objects—*i.e.*, physical entities that exist external to the human mind? Direct realism and representative realism are the two main theoretical responses to this challenge.

Both direct realism and representative realism rely strongly on sense-data theory. The technical term "sense-datum," which played an important role in the development of versions of both theories, is sometimes explained by using examples. If one is hallucinating and sees pink rats, one is seeing a sense-datum. Although no real rats are there, one is having a certain visual sensation as of coloured rats, and this sensation is what is called a sense-datum. The image one sees with one's eyes closed after looking fixedly at a bright light is another example. But, even in normal vision, one can be said to be apprehending sense-data. For instance, in looking at a round penny from a certain angle, one will see the penny to be elliptical. In such a case, there is an elliptical sense-datum in one's visual field. This last example was held by Broad, Price, and Moore to be particularly important, for it makes a strong case for holding that one always sees sense-data, whether perception is normal or abnormal.

Sense-data theory

According to defenders of sense-data theory, what these examples have in common is that in every perceptual act one is directly aware of something. A sense-datum is thus frequently defined as an entity that is the object of direct perception. By "direct" these philosophers mean that no inference is necessary in order to apprehend these entities. According to Broad, Price, and Ayer, sense-data differ from physical objects in having the properties they appear to have; *i.e.*, they cannot appear to have properties they do not really have. The problem for a realist who accepts sense-data is to show how these private sensations allow justification of the intuitive belief that there are physical objects which exist outside of the individual's perception. Russell in particular tried to show in such works as *The Problems of Philosophy* (1912) and *Our Knowledge of the External World* (1914) how knowledge of the external world could be built up from such mental, private apprehensions.

Direct realism

During the 20th century direct realism took many forms; indeed there were direct realists, such as James J. Gibson who, in *The Ecological Approach to Visual Perception* (1979), rejected sense-data theory and claimed that the outside aspects (the physical surfaces) of physical objects are normally directly observed. But many realists, such as G.E. Moore and his followers, believed that the existence of sense-data must be accepted. Moore took the unusual step of suggesting that such sense-data might not be mental entities but could be a physical part of the surface of the perceived material object. Thompson Clarke in "Perceiving Physical Objects and Surfaces" (1965) went beyond Moore in arguing that one normally directly perceives the whole physical object itself.

All of these views have problems in dealing with perceptual anomalies. In fact, Moore, in his last published paper, "Visual Sense-Data" (1957), abandoned the attempt to defend direct realism. He held that, because the elliptical sense-datum one perceives when one looks at a round coin cannot be identical with the circular surface of the coin, one cannot be seeing the coin directly but only the sense-datum. Hence, one cannot have direct knowledge of external objects.

Because of the problems associated with direct realism, many philosophers, including H.H. Price, H.P. Grice, and Robert E. French, have argued for the causal theory, that is, the theory of representative realism. This is an old view whose most famous exponent in early modern philosophy was Locke. It is also sometimes called "the scientific theory" because it seems to be supported by findings in optics and physics. According to this form of realism there are real physical objects that exist external to the human mind, and there are also sense-data (or their equivalents, such as so-called mental representations). Visual perception is then explained as follows. Light is reflected from external objects, moves through space according to well-known laws of physics, is picked up by the human visual system, which includes the eye, the optic nerve, and the retina, and then is ultimately processed by the brain. This is a causal sequence. Light causes a reaction in the eye, that

Representative realism

reaction is the cause of a response in the optic nerve, and so forth. The last event in this causal sequence is "seeing."

What one is apprehending in such a case is a mental representation (sense-datum) of the original object; and, through various processes in the brain, this representation gives human beings a depiction of the object as it is. Visual illusion is explained in various ways, but usually as the result of some anomaly in the causal chain that gives rise to distortions and other types of aberrant visual phenomena. In such a view, human observers are directly aware of mental representations, or sense-data, and only indirectly aware of the physical objects that cause these data in the brain.

The difficulty with this view is that, since one cannot compare the sense-datum that is directly perceived with the original object, one cannot ever be sure that it gives an accurate representation of it; and therefore human beings cannot know that the real world corresponds to their perception of it. They are still confined within the circle of appearance after all. It thus seems that neither version of realism satisfactorily solves the problem it began with.

Phenomenalism. In light of these difficulties with realist theories of perception some philosophers, so-called phenomenalists, proposed a completely different way of analyzing the relationship between perception and knowledge. In particular, they rejected the distinction between independently existing physical objects and mind-dependent sense-data that direct realism presupposes. They claimed that either the very notion of an independent existence is nonsense because human beings have no evidence for it or that what is meant by "independent existence" must be reinterpreted in such a way as not to go beyond the sort of perceptual evidence human beings do or could have for the existence of things. In effect, these philosophers challenged the cogency of the intuitive ideas that the ordinary person supposedly has about independent existence.

All variants of phenomenalism are strongly verificationist in thrust. That is, they wish to maintain that belief in an external world must be capable of verification or confirmation, and this entails that such a belief cannot be acceptable if it goes beyond the realm of possible perceptual experience.

Phenomenalists have thus tried to analyze in wholly perceptual terms what it means to say that any object, say a tomato, exists. They claim that any such analysis must start by deciding what is meant by a tomato. In their view a tomato is something that has certain properties, including a certain size, weight, colour, and shape. If one were to abstract the total set of such observed properties from the object, nothing would be left over; there would be no presumed Lockean "substratum" that supports these properties and which is itself unperceived. There is thus no evidence in favour of such an unperceivable feature, and no reference to it is needed in explaining what a tomato or any so-called physical object is.

To talk about any existent object is thus to talk about a collection of perceivable features localized in a particular portion of space-time. Hence, what one means by a tomato is something that in principle must be perceivable. Accordingly, to say that a tomato exists is either to describe a collection of properties that an observer is actually perceiving or a collection that such an observer would perceive under certain specified conditions. To say, for instance, that a tomato exists in the next room is to say that, if one went to that room, one would see a familiar reddish shape, would obtain a certain taste if one bit into it, or would feel something soft and smooth if one touched it. To speak about that tomato's existing unperceived in the next room thus does not entail that it is unperceivable. In principle, everything that exists is perceivable. Therefore, the notion of existing independently of perception has been misunderstood or mischaracterized by both philosophers and nonphilosophers. Once it is understood that objects are merely sets of properties and that such collections of properties are in principle always perceivable, the notion that there is some sort of unbridgeable gap between people's perceptual evidence and the existence of an object is just a mistake, a confusion between the concepts of actually being perceived and of being perceivable.

In this view, perceptual error is explained in terms of coherence and predictability. To say with truth that one is perceiving a tomato means that one's present set of perceptual experiences and an unspecified set of future experiences will "cohere." That is, if the object a person is looking at is a tomato, then he can expect that, if he touches, tastes, and smells it, he will receive a recognizable grouping of sensations. If the object he has in his visual field is hallucinatory, then there will be a lack of coherence between what he touches, tastes, and smells. He might see a red shape but not be able to touch or taste it.

The criterion of coherence

The theory is generalized to include what others would touch, see, and hear as well, so that what the realists call "public" will also be defined in terms of the coherence of perceptions. A so-called physical object is public if the perceptions of many persons cohere or agree, and otherwise it is not. This explains why a headache is not a public object. In similar fashion, a so-called physical object will be said to have an independent existence if the expectations of future perceptual experiences are borne out. If tomorrow, or the day after, a person has similar perceptual experiences to those he had today, then he can say that the object he is perceiving has an independent existence. The phenomenalist thus attempts to account for all the facts that the realist wishes to explain without positing the existence of anything that transcends possible experience.

The criticisms of this view tend to be technical. Generally speaking, however, realists have objected to it on the ground that it is counterintuitive to think of a tomato as being a set of actual or possible perceptual experiences. The realist argues that human beings do have such experiences, or under certain circumstances would have them, because there is an object out there that exists independently of them and is their source. Phenomenalism, they contend, has the implication that, if no perceivers existed, then the world would contain no objects; and, if this is a consequence of the view, then it is surely inconsistent both with what ordinary persons believe and with the known scientific fact that all sorts of objects existed in the universe long before there were any perceivers. But its supporters deny that phenomenalism carries such an implication, and the debate about its merits remains unresolved.

PHILOSOPHY OF MIND AND EPISTEMOLOGY

In the late 1970s a series of developments occurred in a variety of intellectual fields that promise to cast new light on the nature of the human mind. There have been explosive advances in neuroscience, psychology, cognitive science, neurobiology, artificial intelligence, and computer studies. These have resulted in a new understanding of how seeing works, how the mind forms representations of the external world, how information is stored and retrieved, and the ways in which calculations, decision procedures, and other intellectual processes resemble and differ from the operations of sophisticated computers, especially those capable of parallel processing.

The implications for epistemology of these developments are equally exciting. They promise to give philosophers new understandings of the relationship between common sense and theorizing, that is, whether some form of materialism which eliminates reference to mental phenomena is true or whether the mental–physical dualism which common sense assumes is irreducible, and they also open new avenues for dealing with the classical problem of other minds. It is too early to make an assessment of the relevance for epistemology of what has already been achieved in these areas. There is no doubt, however, that these advances are revolutionary and that a new area of intellectual discovery has begun. (Av.S.)

BIBLIOGRAPHY. The texts of the classics mentioned below for which specific editions have not been noted are available in many English-language translations; two notable collections are *The Loeb Classical Library* and *Oxford Classical Text* series.

The history of epistemology: (Ancient): An excellent collection on skepticism is MILES BURNYEAT (ed.), *The Skeptical Tradition* (1983). For Greek Skepticism in particular, see CHARLOTTE L. STOUGH, *Greek Skepticism: A Study in Epistemology* (1969). The chief epistemological works of PLATO are his *Meno, Theaetetus,* and *Republic,* especially Books V–VII. The views

of ARISTOTLE can be found in *On the Soul, Metaphysics,* Book IV, ch. 5 and 6, and *Posterior Analytics,* Book I, ch. 3. The locus classicus for ancient skepticism is R.G. BURY (trans.), *Sextus Empiricus,* 4 vol. (1933–49), in *The Loeb Classical Library* series. From among the voluminous writings of AUGUSTINE, see *Against the Academicians,* trans. by MARY PATRICIA GARVEY (1942, reissued 1978).

(*Medieval*): For the period as a whole, see appropriate articles in *The Cambridge History of Later Greek and Early Medieval Philosophy,* ed. by A.H. ARMSTRONG (1967); and *The Cambridge History of Later Medieval Philosophy: From the Rediscovery of Aristotle to the Disintegration of Scholasticism, 1100–1600,* ed. by NORMAN KRETZMANN, ANTHONY KENNY, and JAN PINBORG (1982). For the thoughts of ANSELM OF CANTERBURY, see his *Proslogium,* ch. 1, and *On Truth.* THOMAS AQUINAS, *Summa Theologiae,* discusses the soul in general in part I, question 77, and the intellectual powers of the soul in part I, question 79. The views of JOHN DUNS SCOTUS can be found in the relevant sections of his *Philosophical Writings,* trans. by ALLAN WOLTER (1962, reprinted 1987); and in A.P. MARTINICH, "Duns Scotus on the Possibility of an Infinite Being," *Philosophical Topics,* supplementary vol. 80, pp. 23–29 (1982). The ideas of WILLIAM OF OCKHAM can be found in the relevant sections of his *Philosophical Writings,* trans. by PHILOTHEUS BOEHNER (1957, reissued 1967).

(*Modern*): Two excellent and now classic histories of early modern philosophy from different perspectives are EDWIN ARTHUR BURTT, *The Metaphysical Foundations of Modern Physical Science,* rev. ed. (1972), which emphasizes the effect of modern science on philosophy; and RICHARD H. POPKIN, *The History of Scepticism from Erasmus to Spinoza,* rev. and expanded ed. (1979), which emphasizes the rediscovery of skepticism in the 16th century. RENÉ DESCARTES's greatest work is *Meditations on First Philosophy,* trans. by JOHN COTTINGHAM (1986; originally published in Latin, 1641). JOHN LOCKE attacks the doctrine of innate ideas in Book I of his *An Essay Concerning Human Understanding,* ed. by PETER H. NIDDITCH (1975), while his position on knowledge is developed in Books II and IV. A good introduction to Locke's thought is JOHN W. YOLTON, *Locke: An Introduction* (1985). The best work of GEORGE BERKELEY is *A Treatise Concerning the Principles of Human Knowledge,* ed. by KENNETH WINKLER (1982); a more popular presentation of his views is *Three Dialogues Between Hylas and Philonous,* ed. by ROBERT MERRIHEW ADAMS (1979). DANIEL E. FLAGE, *Berkeley's Doctrine of Notions: A Reconstruction Based on His Theory of Meaning* (1987), discusses a central but neglected aspect of Berkeley's epistemology. DAVID HUME's most expansive discussion of knowledge is in Book I of *A Treatise of Human Nature,* 2nd ed., edited by L.A. SELBY-BIGGE and rev. by P.H. NIDDITCH (1978). A later and more accessible statement of Hume's view is presented in *An Enquiry Concerning Human Understanding,* ed. by ERIC STEINBERG (1977). IMMANUEL KANT, *Critique of Pure Reason,* trans. by NORMAN KEMP SMITH (1929, reissued 1978; originally published in German, 1781), is Kant's greatest work. The best clear, brief, and accurate explanation of Kant's epistemology is A.C. EWING, *A Short Commentary on Kant's "Critique of Pure Reason"* (1938, reprinted 1987). An important book that rejects the view of Kant as a phenomenalist or subjective idealist is HENRY E. ALLISON, *Kant's Transcendental Idealism: An Interpretation and Defense* (1983). For G.F.W. HEGEL's criticisms of Kant, see his *Lectures on the History of Philosophy,* trans. from German by ELIZABETH S. HALDANE and FRANCES H. SIMSON (1896, reprinted 1974), part III, section iii, B. A major study on the relationship between Kant and Hegel is ROBERT B. PIPPIN, *Hegel's Idealism: The Satisfactions of Self-Consciousness* (1989).

(*Contemporary*): A short and readable history of Continental philosophy is ROBERT C. SOLOMON, *Continental Philosophy Since 1750: The Rise and Fall of the Self* (1988). MARTIN HEIDEGGER, *Being and Time,* trans. by JOHN MACQUARRIE and EDWARD ROBINSON (1962, reissued 1978; originally published in German, 1927), presents an alternative epistemological scheme. JOHN DEWEY, *The Quest for Certainty: A Study of the Relation of Knowledge and Action* (1929, reissued 1979), is an attack on modern epistemology by an American pragmatist. RICHARD RORTY, *Philosophy and the Mirror of Nature* (1979), a history of modern and contemporary philosophy, has attracted great attention as an attack on classical epistemology from an analytically trained philosopher. PAUL FEYERABEND, *Against Method,* 2nd ed. (1988), advocates what he describes as "an anarchistic theory of knowledge." KARL R. POPPER, *Objective Knowledge: An Evolutionary Approach,* rev. ed. (1979), argues against a tradition that goes back at least to Aristotle and rejects the subjective interpretation of knowledge, according to which knowledge is located in individual people.

The 20th-century literature on perception and knowledge is vast. A good general collection is ROBERT J. SWARTZ (ed.), *Perceiving, Sensing, and Knowing* (1965, reissued 1976), which includes two important attacks upon sense-data theory—W.H.F. BARNES, "The Myth of Sense-Data," and G.A. PAUL, "Is There a Problem About Sense-Data?"—and a strong defense of the sense-datum view by C.D. BROAD, "The Theory of Sensa." The most important pre-World War II books on perception and knowledge are BERTRAND RUSSELL, *The Problems of Philosophy* (1911, reissued 1988), and *Our Knowledge of the External World* (1926, reissued 1972); G.E. MOORE, *Philosophical Studies* (1922, reissued 1970), especially the important articles defending sense-data theory, "Some Judgments of Perception" and "The Status of Sense-Data"; H.H. PRICE, *Perception* (1932, reprinted 1981), which invokes the notion of a sense-datum in defense of the causal theory of perception; and ALFRED J. AYER, *The Foundations of Empirical Knowledge* (1940, reissued 1971), which merges sense-data theory with the principles of logical positivism. Notable works since World War II include GILBERT RYLE, *The Concept of Mind* (1949, reprinted 1984), which defends a sophisticated form of epistemological behaviourism; RODERICK M. CHISHOLM, *Perceiving: A Philosophical Study* (1957); and J.L. AUSTIN, *Sense and Sensibilia* (1962), which contains a withering assault on the sense-data theory from the standpoint of ordinary-language philosophy. Surfaces, perception, and knowledge are discussed in THOMPSON CLARKE, "Seeing Surfaces and Physical Objects," in MAX BLACK (ed.), *Philosophy in America* (1965); JAMES J. GIBSON, *The Ecological Approach to Visual Perception* (1979, reissued 1986); and AVRUM STROLL, *Surfaces* (1988). The theory of representative realism is given a sophisticated defense in FRANK JACKSON, *Perception* (1977); and S. ULLMAN, "Against Direct Perception," *Behavioral & Brain Sciences,* 3(3):373–415 (September 1980), attacks direct realism, especially J.J. Gibson's version of that theory, from a standpoint of modern cognitive science. A comprehensive survey of the literature from about 1980 to 1984 on direct realism and representative realism is to be found in EDMOND WRIGHT, "Recent Work in Perception," *American Philosophical Quarterly,* 21:17–30 (January 1984).

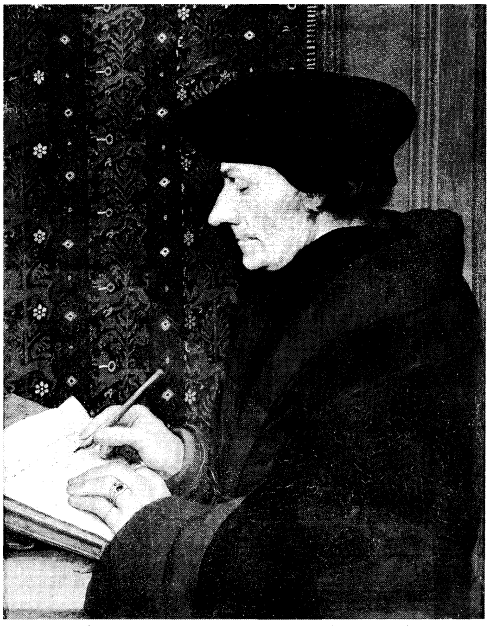
Knowledge and the commonsense view of the world are discussed by G.E. MOORE, "A Defence of Common Sense," in his *Philosophical Papers* (1959); LUDWIG WITTGENSTEIN, *On Certainty,* trans. from German (1969); NORMAN MALCOLM, *Thought and Knowledge* (1977); and JOHN R. SEARLE, *Intentionality: An Essay in the Philosophy of Mind* (1983). An excellent simple survey of the impact of computer studies, work in artificial intelligence, neuroscience, and neurobiology on our knowledge of other minds is found in PAUL M. CHURCHLAND, *Matter and Consciousness: A Contemporary Introduction,* rev. ed. (1988).

Two excellent anthologies are HAROLD MORICK (ed.), *Challenges to Empiricism* (1972, reprinted 1980); and PAUL K. MOSER and ARNOLD VANDER NAT (eds.), *Human Knowledge: Classical and Contemporary Approaches* (1987). EDMUND L. GETTIER, "Is Justified True Belief Knowledge?" in *Analysis,* 23:121–23 (June 1963), is considered by many to be a decisive refutation of the justified, true-belief analysis of knowledge. NOAM CHOMSKY, *Language and the Problems of Knowledge* (1988), discusses innateness, language, and psychology. RODERICK M. CHISHOLM, *Theory of Knowledge,* 3rd ed. (1989); and ROBERT AUDI, *Belief, Justification, and Knowledge* (1988), are two good introductions to standard epistemological problems. (A.P.Ma./Av.S.)

Erasmus

Born in Rotterdam in 1469, Desiderius Erasmus was the greatest European scholar of the 16th century. Using the philological methods pioneered by Italian humanists, he helped lay the groundwork for the historical-critical study of the past, especially in his studies of the Greek New Testament and the Church Fathers. His educational writings contributed to the replacement of the older scholastic curriculum by the new humanist emphasis on the classics. By criticizing ecclesiastical abuses, while pointing to a better age in the distant past, he encouraged the growing urge for reform, which found expression both in the Protestant Reformation and in the Catholic Counter-Reformation. Finally, his independent stance in an age of fierce confessional controversy—rejecting both Luther's doctrine of predestination and the powers that were claimed for the papacy—made him a target of suspicion for loyal partisans on both sides and a beacon for those who valued liberty more than orthodoxy.

Giraudon—Art Resource/EB Inc.



Erasmus, oil painting by Hans Holbein the Younger, 1523. In the Louvre, Paris.

Early life and career. Erasmus was the second illegitimate son of Roger Gerard, a priest, and Margaret, a physician's daughter. He advanced as far as the third-highest class at the chapter school of St. Lebuin's in Deventer. One of his teachers, Jan Synthen, was a humanist, as was the headmaster, Alexander Hegius. The schoolboy Erasmus was clever enough to write classical Latin verse that impresses a modern reader as cosmopolitan.

School years

After both parents died, the guardians of the two boys sent them to a school in 's Hertogenbosch conducted by the Brethren of the Common Life, a lay religious movement that fostered monastic vocations. Erasmus would remember this school only for a severe discipline intended, he said, to teach humility by breaking a boy's spirit.

Having little other choice, both brothers entered monasteries. Erasmus chose the Augustinian canons regular at Steyn, near Gouda, where he seems to have remained about seven years (1485–92). While at Steyn he paraphrased Lorenzo Valla's *Elegantiae,* which was both a compendium of pure classical usage and a manifesto against the scholastic "barbarians" who had allegedly corrupted it. Erasmus' monastic superiors became "barbarians" for him by discouraging his classical studies. Thus, after his ordination to the priesthood (April 1492), he was happy to escape the monastery by accepting a post as Latin secretary to the influential Henry of Bergen, bishop of Cambrai. His *Antibarbarorum liber,* extant from a revision of 1494–95, is a vigorous restatement of patristic arguments for the utility of the pagan classics, with a polemical thrust against the cloister he had left behind: "All sound learning is secular learning."

Erasmus was not suited to a courtier's life, nor did things improve much when the bishop was induced to send him to the University of Paris to study theology (1495). He disliked the quasi-monastic regimen of the Collège de Montaigu, where he lodged initially, and pictured himself to a friend as sitting "with wrinkled brow and glazed eye" through Scotist lectures. To support his classical studies, he began taking in pupils; from this period (1497–1500) date the earliest versions of those aids to elegant Latin—including the *Colloquia* and the *Adagia*—that before long would be in use in humanist schools throughout Europe.

The wandering scholar. In 1499 a pupil, William Blount, Lord Mountjoy, invited Erasmus to England. There he met Thomas More, who became a friend for life. John Colet quickened Erasmus' ambition to be a "primitive theologian," one who would expound Scripture not in the argumentative manner of the scholastics but in the manner of Jerome and the other Church Fathers, who lived in an age when men still understood and practiced the classical art of rhetoric. The impassioned Colet besought him to lecture on the Old Testament at Oxford, but the more cautious Erasmus was not ready. He returned to the Continent with a Latin copy of St. Paul's Epistles and the conviction that "ancient theology" required mastery of Greek.

Thomas More and John Colet

On a visit to Artois, Fr. (1501), Erasmus met the fiery preacher Jean Voirier, who, though a Franciscan, told him that "monasticism was a life more of fatuous men than of religious men." Admirers recounted how Voirier's disciples faced death serenely, trusting in God, without the solemn reassurance of the last rites. Voirier lent Erasmus a copy of works by Origen, the early Greek Christian writer who promoted the allegorical, spiritualizing mode of scriptural interpretation, which had roots in Platonic philosophy. By 1502 Erasmus had settled in the university town of Louvain (Brabant) and was reading Origen and St. Paul in Greek. The fruit of his labours was *Enchiridion militis Christiani* (1503/04; *Handbook of a Christian Knight*). In this work Erasmus urged readers to "inject into the vitals" the teachings of Christ by studying and meditating on the Scriptures, using the spiritual interpretation favoured by the "ancients" to make the text pertinent to moral concerns. The *Enchiridion* was a manifesto of lay piety in its assertion that "monasticism is not piety." Erasmus' vocation as a "primitive theologian" was further developed through his discovery at Park Abbey, near Louvain, of a manuscript of Valla's *Adnotationes* on the Greek New Testament, which he published in 1505 with a dedication to Colet.

Travels to Italy

Erasmus sailed for England in 1505, hoping to find support for his studies. Instead he found an opportunity to travel to Italy, the land of promise for northern humanists, as tutor to the sons of the future Henry VIII's physician. The party arrived in the university town of Bologna in time to witness the triumphal entry (1506) of the warrior pope Julius II at the head of a conquering army, a scene that figures later in Erasmus' anonymously published satiric dialogue, *Julius exclusus e coelis* (written 1513–14). In Venice Erasmus was welcomed at the celebrated printing house of Aldus Manutius, where Byzantine émigrés enriched the intellectual life of a numerous scholarly company. For the Aldine press Erasmus expanded his *Adagia,* or annotated collection of Greek and Latin adages, into a

monument of erudition with over 3,000 entries; this was the book that first made him famous. The adage "Dutch ear" (*auris Batava*) is one of many hints that he was not an uncritical admirer of sophisticated Italy, with its theatrical sermons and its scholars who doubted the immortality of the soul; his aim was to write for honest and unassuming "Dutch ears."

De pueris instituendis, written in Italy though not published until 1529, is the clearest statement of Erasmus' enormous faith in the power of education. With strenuous effort the very stuff of human nature could be molded, so as to draw out (*e-ducare*) peaceful and social dispositions while discouraging unworthy appetites. Erasmus, it would almost be true to say, believed that one is what one reads. Thus the "humane letters" of classical and Christian antiquity would have a beneficent effect on the mind, in contrast to the disputatious temper induced by scholastic logic-chopping or the vengeful amour propre bred into young aristocrats by chivalric literature, "the stupid and tyrannical fables of King Arthur."

The celebrated *Moriae encomium,* or *Praise of Folly,* conceived as Erasmus crossed the Alps on his way back to England and written at Thomas More's house, expresses a very different mood. For the first time the earnest scholar saw his own efforts along with everyone else's as bathed in a universal irony, in which foolish passion carried the day: "Even the wise man must play the fool if he wishes to beget a child."

Little is known of Erasmus' long stay in England (1509–14), except that he lectured at Cambridge and worked on scholarly projects, including the Greek text of the New Testament. His later willingness to speak out as he did may have owed something to the courage of Colet, who risked royal disfavour by preaching a sermon against war at the court just as Henry VIII was looking for a good war in which to win his spurs. Having returned to the Continent, Erasmus made connections with the printing firm of Johann Froben and traveled to Basel to prepare a new edition of the *Adagia* (1515). In this and other works of about the same time Erasmus showed a new boldness in commenting on the ills of Christian society—popes who in their warlike ambition imitated Caesar rather than Christ; princes who hauled whole nations into war to avenge a personal slight; and preachers who looked to their own interests by pronouncing the princes' wars just or by nurturing superstitious observances among the faithful. To remedy these evils Erasmus looked to education. In particular, the training of preachers should be based on "the philosophy of Christ" rather than on scholastic methods. Erasmus tried to show the way with his annotated text of the Greek New Testament and his edition of St. Jerome's *Opera omnia,* both of which appeared from the Froben press in 1516. These were the months in which Erasmus thought he saw "the world growing young again," and the full measure of his optimism is expressed in one of the prefatory writings to the New Testament: "If the Gospel were truly preached, the Christian people would be spared many wars."

The function of education

Erasmus' home base was now in Brabant, where he had influential friends at the Habsburg court of the Netherlands in Brussels, notably the grand chancellor, Jean Sauvage. Through Sauvage he was named honorary councillor to the 16-year-old archduke Charles, the future Charles V, and was commissioned to write *Institutio principis Christiani* (1516; *The Education of a Christian Prince*) and *Querela pacis* (1517; *The Complaint of Peace*). These works expressed Erasmus' own convictions, but they also did no harm to Sauvage's faction at court, which wanted to maintain peace with France. It was at this time too that he began his *Paraphrases* of the books of the New Testament, each one dedicated to a monarch or a prince of the church. He was accepted as a member of the theology faculty at nearby Louvain, and he also took keen interest in a newly founded Trilingual College, with endowed chairs in Latin, Greek, and Hebrew. *Ratio verae theologiae* (1518) provided the rationale for the new theological education based on the study of languages. Revision of his Greek New Testament, especially of the copious annotations, began almost as soon as the first edition appeared. Though Erasmus certainly made mistakes as a textual critic, in the history of scholarship he is a towering figure, intuiting philological principles that in some cases would not be formulated explicitly until 150 years after his death. But conservative theologians at Louvain and elsewhere, mostly ignorant of Greek, were not willing to abandon the interpretation of Scripture to upstart "grammarians," nor did the atmosphere at Louvain improve when the second edition of Erasmus' New Testament (1519) replaced the Vulgate with his own Latin translation.

The Protestant challenge. From the very beginning of the momentous events sparked by Martin Luther's challenge to papal authority, Erasmus' clerical foes blamed him for inspiring Luther, just as some of Luther's admirers in Germany found that he merely proclaimed boldly what Erasmus had been hinting. In fact, Luther's first letter to Erasmus (1516) showed an important disagreement over the interpretation of St. Paul, and in 1518 Erasmus privately instructed his printer, Froben, to stop printing works by Luther, lest the two causes be confused. As he read Luther's writings, at least those prior to *The Babylonian Captivity of the Church* (1520), Erasmus found much to admire, and he could even describe Luther, in a letter to Pope Leo X, as "a mighty trumpet of Gospel truth." Being of a suspicious nature, however, he also convinced himself that Luther's fiercest enemies were men who saw the study of languages as the root of heresy and thus wanted to be rid of both at once. Hence he tugged at the slender threads of his influence, vainly hoping to forestall a confrontation that could only be destructive to "good letters." When he quit Brabant for Basel (December 1521), he did so lest he be faced with a personal request from the Emperor to write a book against Luther, which he could not have refused.

Erasmus and Luther

Erasmus' belief in the unity of the church was fundamental, but, like the Hollanders and Brabanters with whom he was most at home, he recoiled from the cruel logic of religious persecution. He expressed his views indirectly through the *Colloquia,* which had started as schoolboy dialogues but now became a vehicle for commentary. For example, in the colloquy "Inquisitio de fide" (1522) a Catholic finds to his surprise that Lutherans accept all the dogmas of the faith, that is, the articles of the Apostles' Creed. The implication is that bitter disputes like those over papal infallibility or Luther's doctrine of predestination are differences over mere opinion, not over dogmas binding on all the faithful. For Erasmus the root of the schism was not theology but anticlericalism and lay resentment of the laws and "ceremonies" that the clergy made binding under pain of hell. As he wrote privately to the Netherlandish pope Adrian VI (1522–23), whom he had known at Louvain, there was still hope of reconciliation, if only the church would ease the burden; this could be accomplished, for instance, by granting the chalice to the laity and by permitting priests to marry: "At the sweet name of liberty all things will revive."

When Adrian VI was succeeded by Clement VII, Erasmus could no longer avoid "descending into the arena" of theological combat, though he promised the Swiss reformer Huldrych Zwingli that he would attack Luther in a way that would not please the "pharisees." *De libero arbitrio* (1524) defended the place of human free choice in the process of salvation and argued that the consensus of the church through the ages is authoritative in the interpretation of Scripture. In reply Luther wrote one of his most important theological works, *De servo arbitrio* (1525), to which Erasmus responded with a lengthy, two-part *Hyperaspistes* (1526–27). In this controversy Erasmus lets it be seen that he would like to claim more for free will than St. Paul and St. Augustine seem to allow.

Controversy over free will

The years in Basel (1522–29) were filled with polemics, some of them rather tiresome by comparison to the great debate with Luther. Irritated by Protestants who called him a traitor to the Gospel as well as by hyper-orthodox Catholic theologians who repeatedly denounced him, Erasmus showed the petty side of his own nature often enough. Although there is material in his apologetic writings that scholars have yet to exploit, there seems no doubt that on the whole he was better at satiric barbs, such as the

colloquy representing one young "Pseudo-Evangelical" of his acquaintance as thwacking people over the head with a Gospel book to gain converts. Meanwhile he kept at work on the Greek New Testament (there would be five editions in all), the *Paraphrases,* and his editions of the Church Fathers, including Cyprian, Hilary, and Origen. He also took time to chastise those humanists, mostly Italian, who from a "superstitious" zeal for linguistic purity refused to sully their Latin prose with nonclassical terms (*Ciceronianus,* 1528).

Final years. In 1529, when Protestant Basel banned Catholic worship altogether, Erasmus and some of his humanist friends moved to the Catholic university town of Freiburg im Breisgau. He refused an invitation to the Diet of Augsburg, where Philipp Melanchthon's Augsburg Confession was to initiate the first meaningful discussions between Lutheran and Catholic theologians. He nonetheless encouraged such discussion in *De sarcienda ecclesiae concordia* (1533), which suggested that differences on the crucial doctrine of justification might be reconciled by considering a *duplex justitia,* the meaning of which he did not elaborate. Having returned to Basel to see his manual on preaching (*Ecclesiastes,* 1535) through the press, he lingered on in a city he found congenial; it was there he died on July 12, 1536. Like the disciples of Voirier, he seems not to have asked for the last sacraments of the church. His last words were in Dutch: "*Lieve God*" ("dear God").

Influence and achievement. Always the scholar, Erasmus could see many sides of an issue. But his hesitations and studied ambiguities were appreciated less and less in the generations that followed his death, as men girded for combat, theological or otherwise, in the service of their beliefs. For a time, while peacemakers on both sides had an opportunity to pursue meaningful discussions between Catholics and Lutherans, some of Erasmus' practical suggestions and his moderate theological views were directly pertinent. Even after ecumenism dwindled to a mere wisp of possibility, there were a few men willing to make themselves heirs of Erasmus' lonely struggle for a middle ground, like Jacques-Auguste de Thou in France and Hugo Grotius in the Netherlands; significantly, both were strong supporters of state authority and hoped to limit the influence of the clergy of their respective established churches. This tradition was perhaps strongest in the Netherlands, where Dirck Volckertszoon Coornhert and others found support in Erasmus for their advocacy of limited toleration for religious dissenters. Meanwhile, however, the Council of Trent and the rise of Calvinism ensured that such views were generally of marginal influence. The Catholic *index expurgatorius* of 1571 contained a long list of suspect passages to be deleted from any future editions of Erasmus' writings, and those Protestant tendencies that bear some comparison to Erasmus' defense of free will—current among the Philippists in Germany and the Arminians in the Netherlands—were bested by defenders of a sterner orthodoxy. Even in the classroom, Erasmus' preference for putting students directly in contact with the classics gave way to the use of compendiums and manuals of humanist rhetoric and logic that resembled nothing so much as the scholastic curriculum of the past. Similarly, the bold and independent scholarly temper with which Erasmus approached the text of the New Testament was for a long time submerged by the exigencies of theological polemics.

Erasmus' reputation began to improve in the late 17th century, when the last of Europe's religious wars was fading into memory and scholars like Richard Simon and Jean Le Clercq (the editor of Erasmus' works) were once again taking a more critical approach to biblical texts. By Voltaire's time, in the 18th century, it was possible to imagine that the clever and rather skeptical Erasmus must have been a philosophe before his time, one whose professions of religious devotion and submission to church authority could be seen as convenient evasions. This view of Erasmus, curiously parallel to the strictures of his orthodox critics, was long influential. Only in the past several decades have scholars given due recognition to the fact that the goal of his work was a Christianity purified by a deeper knowledge of its historic roots. Yet it was not entirely wrong to compare Erasmus with those Enlightenment thinkers who, like Voltaire, defended individual liberty at every turn and had little good to say about the various corporate solidarities by which human society holds together. Some historians would now trace the enduring debate between these complementary aspects of Western thought as far back as the 12th century, and in this very broad sense Erasmus and Voltaire are on the same side of a divide, just as, for instance, Machiavelli and Rousseau are on the other. In a unique manner that fused his multiple identities—as Netherlander, Renaissance humanist, and pre-Tridentine Catholic—Erasmus helped to build what may be called the liberal tradition of European culture.

MAJOR WORKS

THEOLOGICAL WORKS: *Enchiridion militis Christiani* (1503; *The Manuell of the Christen Knyght,* trans. by W. Tyndale, 1533); *Annotationes in Novum Testamentum* (1516); *Paraphrases in Novum Testamentum* (1517; *Paraphrase of Erasmus upon the Newe Testamente,* 1548); *Ratio verae theologiae* (1519); *De libero arbitrio diatribe* (1524); *Hyperaspistes diatribae adversus servum arbitrium Martini Lutheri* (1526).

EDUCATIONAL AND OCCASIONAL WRITINGS: *Adagia* (1500; *Proverbs or Adagies,* 1539); *Moriae encomium* (1511; *The Praise of Folie,* 1549); *Institutio principis Christiani* (1516; *The Education of a Christian Prince,* 1936); *Querela pacis* (1517; *The Complaint of Peace,* 1559); *Colloquia* (1522–33); *Ciceronianus* (1528; *Ciceronianus: or, A Dialogue on the Best Style of Speaking,* 1908); *De pueris instituendis* (1529).

COLLECTIONS AND TRANSLATIONS: *Opera omnia, emendatiora et auctiora,* 10 vol. in 11, ed. by Jean Leclerq (1703–06, reprinted 1961–62), remains the most complete and authoritative among the early editions. *Opera omnia Desiderii Erasmi Roterodami: recognita et adnotatione critica instructa notisque illustrata* (1969–) is a modern critical and annotated edition by an international team of scholars, under the auspices of the Royal Academy of The Netherlands. The multivolume edition is arranged not chronologically but according to the canon laid down by Erasmus himself. *Opus epistolarum Des. Erasmi Roterdami,* ed. by P.S. Allen, 12 vol. (1906–58), is a standard edition of the correspondence of Erasmus, whose letters are indispensable for any understanding of his work. For translations, the ongoing series *Collected Works of Erasmus* (1974–), published by the University of Toronto Press, has set high standards for accuracy. Other notable translations include *The "Adages" of Erasmus: A Study with Translations,* by Margaret Mann Phillips (1964); and *The Colloquies of Erasmus,* trans. by Craig R. Thompson (1965).

Ethics

How should we live? Shall we aim at happiness or at knowledge, virtue, or the creation of beautiful objects? If we choose happiness, will it be our own or the happiness of all? And what of the more particular questions that face us: Is it right to be dishonest in a good cause? Can we justify living in opulence while elsewhere in the world people are starving? If conscripted to fight in a war we do not support, should we disobey the law? What are our obligations to the other creatures with whom we share this planet and to the generations of humans who will come after us?

Ethics deals with such questions at all levels. Its subject consists of the fundamental issues of practical decision making, and its major concerns include the nature of ultimate value and the standards by which human actions can be judged right or wrong.

The terms ethics and morality are closely related. We now often refer to ethical judgments or ethical principles where it once would have been more common to speak of moral judgments or moral principles. These applications are an extension of the meaning of ethics. Strictly speaking, however, the term refers not to morality itself but to the field of study, or branch of inquiry, that has morality as its subject matter. In this sense, ethics is equivalent to moral philosophy.

Although ethics has always been viewed as a branch of philosophy, its all-embracing practical nature links it with many other areas of study, including anthropology, biology, economics, history, politics, sociology, and theology. Yet, ethics remains distinct from such disciplines because it is not a matter of factual knowledge in the way that the sciences and other branches of inquiry are. Rather, it has to do with determining the nature of normative theories and applying these sets of principles to practical moral problems.

This article is divided into the following sections:

The origins of ethics

MYTHICAL ACCOUNTS

When did ethics begin and how did it originate? If we are referring to ethics proper—*i.e.*, the systematic study of what we ought to do—it is clear that ethics can only have come into existence when human beings started to reflect on the best way to live. This reflective stage emerged long after human societies had developed some kind of morality, usually in the form of customary standards of right and wrong conduct. The process of reflection tended to arise from such customs, even if in the end it may have found them wanting. Accordingly, ethics began with the introduction of the first moral codes.

Virtually every human society has some form of myth to explain the origin of morality. In the Louvre in Paris there is a black Babylonian column with a relief showing the sun god Shamash presenting the code of laws to Hammurabi. The Old Testament account of God giving the Ten Commandments to Moses on Mt. Sinai might be considered another example. In Plato's *Protagoras* there is an avowedly mythical account of how Zeus took pity on the hapless humans, who, living in small groups and with inadequate teeth, weak claws, and lack of speed, were no match for the other beasts. To make up for these deficiencies, Zeus gave humans a moral sense and the capacity for law and justice, so that they could live in larger communities and cooperate with one another.

Notion of divine origin

That morality should be invested with all the mystery and power of divine origin is not surprising. Nothing else could provide such strong reasons for accepting the moral law. By attributing a divine origin to morality, the priesthood became its interpreter and guardian, and thereby secured for itself a power that it would not readily relinquish. This link between morality and religion has been so firmly forged that it is still sometimes asserted that there

can be no morality without religion. According to this view, ethics ceases to be an independent field of study. It becomes, instead, moral theology.

There is some difficulty, already known to Plato, with the view that morality was created by a divine power. In his dialogue *Euthyphro,* Plato considered the suggestion that it is divine approval that makes an action good. Plato pointed out that if this were the case, we could not say that the gods approve of the actions because the actions are good. Why then do the gods approve of these actions rather than others? Is their approval entirely arbitrary? Plato considered this impossible and so held that there must be some standards of right or wrong that are independent of the likes and dislikes of the gods. Modern philosophers have generally accepted Plato's argument because the alternative implies that if the gods had happened to approve of torturing children and to disapprove of helping one's neighbours, then torture would have been good and neighbourliness bad.

A modern theist might say that since God is good, he could not possibly approve of torturing children nor disapprove of helping neighbours. In saying this, however, the theist would have tacitly admitted that there is a standard of goodness that is independent of God. Without an independent standard, it would be pointless to say that God is good; this could only mean that God is approved of by God. It seems therefore that, even for those who believe in the existence of God, it is impossible to give a satisfactory account of the origin of morality in terms of a divine creation. We need a different account.

There are other possible connections between religion and morality. It has been said that even if good and evil exist independently of God or the gods, only divine revelation can reliably inform us about good and evil. An obvious problem with this view is that those who receive divine revelations, or who consider themselves qualified to interpret them, do not always agree on what is good and what is evil. Without an accepted criterion for the authenticity of a revelation or an interpretation, we are no better off, so far as reaching moral agreement is concerned, than we would be if we were to decide on good and evil ourselves with no assistance from religion.

Traditionally, a more important link between religion and ethics was that religious teachings were thought to provide a reason for doing what is right. In its crudest form, the reason was that those who obey the moral law will be rewarded by an eternity of bliss while everyone else roasts in hell. In more sophisticated versions, the motivation provided by religion was less blatantly self-seeking and more of an inspirational kind. Whether in its crude or sophisticated version, or something in between, religion does provide an answer to one of the great questions of ethics: Why should I do what is right? As will be seen in the course of this article, however, the answer provided by religion is by no means the only answer. It will be considered after the alternatives have been examined.

PREHUMAN ETHICS

Can we do better than the religious accounts of the origin of morality? Because, for obvious reasons, we have no historical record of a human society in the period before it had any standards of right and wrong, history cannot tell us the origins of morality. Nor is anthropology able to assist because all human societies studied have already had, except perhaps during the most extreme circumstances, their own form of morality. Fortunately there is another mode of inquiry open to us. Human beings are social animals. Living in a social group is a characteristic we share with many other animal species, including our closest relatives, the apes. Presumably, the common ancestor of humans and apes also lived in a social group, so that we were social beings before we were human beings. Here, then, in the social behaviour of nonhuman animals and in the evolutionary theory that explains such behaviour, we may find the origins of human morality.

Social life, even for nonhuman animals, requires constraints on behaviour. No group can stay together if its members make frequent, no-holds-barred attacks on one another. Social animals either refrain altogether from attacking other members of the social group, or, if an attack does take place, the ensuing struggle does not become a fight to the death—it is over when the weaker animal shows submissive behaviour. It is not difficult to see analogies here with human moral codes. The parallels, however, go much further than this. Like humans, social animals may behave in ways that benefit other members of the group at some cost or risk to themselves. Male baboons threaten predators and cover the rear as the troop retreats. Wolves and wild dogs bring meat back to members of the pack not present at the kill. Gibbons and chimpanzees with food will, in response to a gesture, share their food with others of the group. Dolphins support sick or injured animals, swimming under them for hours at a time and pushing them to the surface so they can breathe.

Apparent altruistic behaviour among nonhuman animals

It may be thought that the existence of such apparently altruistic behaviour is odd, for evolutionary theory states that those who do not struggle to survive and reproduce will be wiped out in the ruthless competition known as natural selection. Research in evolutionary theory applied to social behaviour, however, has shown that evolution need not be quite so ruthless after all. Some of this altruistic behaviour is explained by kin selection. The most obvious examples are those in which parents make sacrifices for their offspring. If wolves help their cubs to survive, it is more likely that genetic characteristics, including the characteristic of helping their own cubs, will spread through further generations of wolves.

Less obviously, the principle also holds for assistance to other close relatives, even if they are not descendants. A child shares 50 percent of the genes of each of its parents, but full siblings too, on the average, have 50 percent of their genes in common. Thus a tendency to sacrifice one's life for two or more of one's siblings could spread from one generation to the next. Between cousins, where only 12½ percent of the genes are shared, the sacrifice-to-benefit ratio would have to be correspondingly increased.

When apparent altruism is not between kin, it may be based on reciprocity. A monkey will present its back to another monkey, who will pick out parasites; after a time the roles will be reversed. Reciprocity may also be a factor in food sharing among unrelated animals. Such reciprocity will pay off, in evolutionary terms, as long as the costs of helping are less than the benefits of being helped and as long as animals will not gain in the long run by "cheating"—that is to say, by receiving favours without returning them. It would seem that the best way to ensure that those who cheat do not prosper is for animals to be able to recognize cheats and refuse them the benefits of cooperation the next time around. This is only possible among intelligent animals living in small, stable groups over a long period of time. Evidence supports this conclusion: reciprocal behaviour has been observed in birds and mammals, the clearest cases occurring among wolves, wild dogs, dolphins, monkeys, and apes.

In short, kin altruism and reciprocity do exist, at least in some nonhuman animals living in groups. Could these forms of behaviour be the basis of human ethics? There are good reasons for believing that they could. A surprising proportion of human morality can be derived from the twin bases of concern for kin and reciprocity. Kinship is a source of obligation in every human society. A mother's duty to look after her children seems so obvious that it scarcely needs to be mentioned. The duty of a married man to support and protect his family is almost equally as widespread. Duties to close relatives take priority over duties to more distant relatives, but in most societies even distant relatives are still treated better than strangers.

Concern for kin and reciprocity

If kinship is the most basic and universal tie between human beings, the bond of reciprocity is not far behind. It would be difficult to find a society that did not recognize, at least under some circumstances, an obligation to return favours. In many cultures this is taken to extraordinary lengths, and there are elaborate rituals of gift giving. Often the repayment has to be superior to the original gift, and this escalation can reach such extremes as to threaten the economic security of the donor. The huge "potlatch" feasts of certain American Indian tribes are a well-known example of this type of situation. Many Melanesian soci-

eties also place great importance on giving and receiving very substantial amounts of valuable items.

Many features of human morality could have grown out of simple reciprocal practices such as the mutual removal of parasites from awkward places. Suppose I want to have the lice in my hair picked out and I am willing in return to remove lice from someone else's hair. I must, however, choose my partner carefully. If I help everyone indiscriminately, I will find myself delousing others without getting my own lice removed. To avoid this, I must learn to distinguish between those who return favours and those who do not. In making this distinction, I am separating reciprocators and nonreciprocators and, in the process, developing crude notions of fairness and of cheating. I will strengthen my links with those who reciprocate, and bonds of friendship and loyalty, with a consequent sense of obligation to assist, will result.

This is not all. The reciprocators are likely to react in a hostile and angry way to those who do not reciprocate. Perhaps they will regard reciprocity as good and "right" and cheating as bad and "wrong." From here it is a small step to concluding that the worst of the nonreciprocators should be driven out of society or else punished in some way, so that they will not take advantage of others again. Thus a system of punishment and a notion of desert constitute the other side of reciprocal altruism.

Although kinship and reciprocity loom large in human morality, they do not cover the entire field. Typically, there are obligations to other members of the village, tribe, or nation even when these are strangers. There may also be a loyalty to the group as a whole that is distinct from loyalty to individual members of the group. It may be at this point that human culture intervenes. Each society has a clear interest in promoting devotion to the group and can be expected to develop cultural influences that exalt those who make sacrifices for the sake of the group and revile those who put their own interests too far ahead of the interests of the group. More tangible rewards and punishments may supplement the persuasive effect of social opinion. This is simply the start of a process of cultural development of moral codes.

Before considering the cultural variations in human morality and their significance for ethics, let us draw together this discussion of the origins of morality. Since we are dealing with a prehistoric period and morality leaves no fossils, any account of the origins of morality will necessarily remain to some extent speculative. It seems likely that morality is the gradual outgrowth of forms of altruism that exist in some social animals and that are the result of the usual evolutionary processes of natural selection. No myths are required to explain its existence.

ANTHROPOLOGY AND ETHICS

It is commonly believed that there are no ethical universals—*i.e.*, there is so much variation from one culture to another that no single principle or judgment is generally accepted. We have already seen that such is not the case. Of course, there are immense differences in the way in which the broad principles so far discussed are applied. The duty of children to their parents meant one thing in traditional Chinese society and means something quite different in contemporary Anglo-Saxon society. Yet, concern for kin and reciprocity to those who treat us well are considered good in virtually all human societies. Also, all societies have, for obvious reasons, some constraints on killing and wounding other members of the group.

Beyond that common ground, the variations in moral attitudes soon become more striking than the similarities. Man's fascination with such variations goes back a long way. The Greek historian Herodotus relates that Darius, king of Persia, once summoned Greeks before him and asked them how much he would have to pay them to eat their fathers' dead bodies. They refused to do it at any price. Then Darius brought in some Indians who by custom ate the bodies of their parents and asked them what would make them willing to burn their fathers' bodies. The Indians cried out that he should not mention so horrid an act. Herodotus drew the obvious moral: each nation thinks its own customs best.

Variations in morals were not systematically studied until the 19th century, when knowledge of the more remote parts of the globe began to increase. At the beginning of the 20th century, Edward Westermarck published *The Origin and Development of the Moral Ideas* (1906–08), two large volumes comparing differences among societies in such matters as the wrongness of killing (including killing in warfare, euthanasia, suicide, infanticide, abortion, human sacrifices, and duelling); whose duty it is to support children, the aged, or the poor; the forms of sexual relationship permitted; the status of women; the right to property and what constitutes theft; the holding of slaves; the duty to tell the truth; dietary restrictions; concern for nonhuman animals; duties to the dead; and duties to the gods. Westermarck had no difficulty in demonstrating tremendous diversity in all these issues. More recent, though less comprehensive, studies have confirmed that human societies can and do flourish while holding radically different views about all such matters.
