2013 IFCS-EFTF Proceedings

This conference marks the 60th anniversary of the IEEE Ultrasonics, Ferroelectrics, and Frequency Control Society and is a joint meeting of four related groups. This year we have the 6th joint meeting between the International Frequency Control Symposium (IFCS) and the European Frequency and Time Forum (EFTF), and the 3rd joint meeting between the International Symposium on the Applications of Ferroelectrics (ISAF) and the Piezoresponse Force Microscopy Workshop (PFM). These proceedings includes papers from IFCS and EFTF.

A prime focus of these ongoing meetings is to establish progress through communication and collaboration. That communication is the core reason we publish these proceedings. A total of 268 papers are presented in this joint IFCS and EFTF product covering 6 major areas:

- Materials, Resonators, and Resonator Circuits
- Oscillators, Synthesizers, Noise, and Circuit Techniques
- Microwave Frequency Standards
- Sensors and Transducers
- Timekeeping, Time and Frequency Transfer, and GNSS Applications
- Optical Frequency Standards and Applications

I would like to thank all the authors for their contributions to this year's proceedings.

Sincerely,

Aaron Partridge, IFCS/EFTF Editorial Chair
Founder and Chief Scientist, SiTime Corp.
Sunnyvale California.

UHF Quartz MEMS Oscillators for Dynamics-Based System Enhancements

Abstract— **Processes for fabricating full wafers of UHF quartz MEMS oscillators bonded to Si have been developed at HRL over the past several years. These devices have shown state-of-the-art noise and stability along with extremely small vacuum packaged die size of less than 3 mm^2. An interesting by-product of the high frequency, small size, and wafer-scale fabrication of these devices is that several novel dynamics-based enhancements can be considered. These include the use of nonlinear dynamics for reducing oscillator phase noise at CMOS capable voltages and co-integration with more complex structures for sensing vibration and serving as a local timing reference for reducing thermally-induced sensor drifts. Several of these novel concepts made possible by wafer-scale MEMS-based processing will be reviewed.**

Keywords- Quartz MEMS, phase noise, duffing, nonlinear operation, vibration compensation, force rebalance, frequency locking, ovenization, and Si Disk Resonator Gyro.

I. INTRODUCTION

A long standing goal of RF MEMS is to allow large-scale integration of both active and passive components on chip for reduced size, weight, and costs. These goals have driven much of the research for Si MEMS devices based on processing and material compatibility with analog and digital Si electronics. However, it was realized almost a decade ago, that MEMS-based processing can be applied to many other resonator materials, including quartz [1], AlN [2], and diamond [3]. These other material systems provide several advantages that can enhance their usefulness in a variety of markets. In particular, piezoelectric quartz has been universally used for many decades as a timing standard in most all commercial and military communication and navigation systems. As such, there is a wealth of knowledge in designing, packaging, and performance testing quartz oscillators that can aid in developing new devices.

In addition to some of the obvious advantages of size and costs for directly integrated quartz resonators on Si-based circuits, quartz MEMS processing allows several new capabilities to be considered. These include adding more functionality to the resonator and the control electronics to explore new ways to improve the overall system performance. Moreover, one can also integrate quartz resonators with other structures and sensors to provide "system-on-chip" capability and then use each sensor in an optimal fashion to reduce overall system errors. This synergy with multiple sensors co-located on a single chip and sensing similar dynamic environmental inputs provides the system designer with a new tool to improve the system performance. In this paper, we will first briefly review the status of quartz MEMS devices and their performance and then review several of these new ideas.

This work was sponsored in part by DARPA'S MTO office under the DEFYS program, issued by DARPA /CMO under contract No. HR0011-10-C-0109. The views and conclusions contained in this document are those of the authors and should not be interpreted as representing the official policies, either expressly or implied, of DARPA or the U.S. Government.

II. UHF QUARTZ MEMS

A. Fabrication and Packaging

The process flow for integrating UHF quartz resonators to Si substrates has been described previously [1], so it will not be repeated here in detail. In summary, ebeam evaporated Al is first deposited and patterned on a piezoelectric quartz wafer for top-side metallization, and the quartz is then fusion bonded at low temperature to a Si handle wafer. Grinding and CMP (Chemical Mechanical Polishing) are used to thin the quartz to the desired thickness for shear-mode operation. Vias are then plasma etched in the quartz and bottom-side Al electrode metal, via, and bond metals are applied and patterned. A photoresist layer is then used as a mask for plasma etching to define the quartz resonator. The wafer is then bonded to a Si-based substrate using Au/In eutectic bonding which allows subsequent higher temperature processing. Finally, the Si handle wafer is removed by SF_6 plasma etching, thereby releasing the resonators.

The devices at this point in the processing are shown in Figures 1 and 2. Note the spacing between the bottom of the quartz and the substrate is typically between 5 to 8 microns. We have been processing 3" quartz wafers to date, but larger quartz wafers up to 6" in diameter are expected to be available in the future. A Si capping wafer with a recessed cavity is then

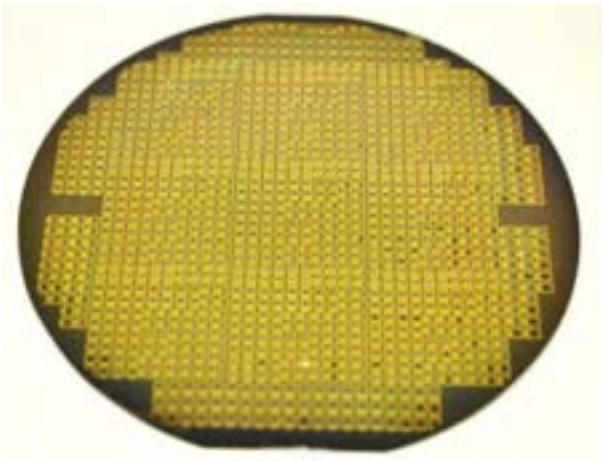

Fig. 1. Completed AT-cut UHF quartz resonators on a 3" Si wafer before encapsulation..

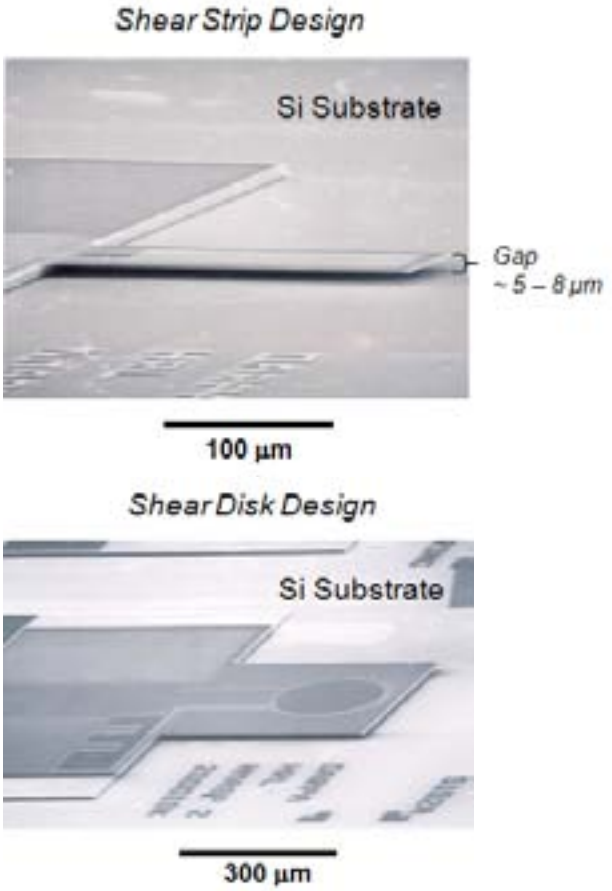

Fig. 2. SEM microphotographs of rectangular quartz strip (top) and disk (bottom) designs bonded to a Si substrate.

patterned with a Au/In or Au/Sn bonding layer and bonded to the base wafer in a roughly 10^{-4} to 10^{-5} Torr vacuum for packaging at wafer level. The capping wafer is then plasma etched to define the bond pad slits, and the wafer is singulated by sawing. The capped and singulated die are shown in Figure 3. The typical die size for UHF quartz resonators in the 300 – 1000 MHz frequency range is ~ 1.5 x 1.5 mm^2.

B. Resonator and Oscillator Test Results

Our devices have been tested with an Agilent admittance meter (model E4991A) as resonators on a probe station and have been hybridized as surface mount components in Pierce and Clapp oscillator and VCOs (voltage controlled oscillators). A typical admittance characteristic for an AT-cut, shear-mode,

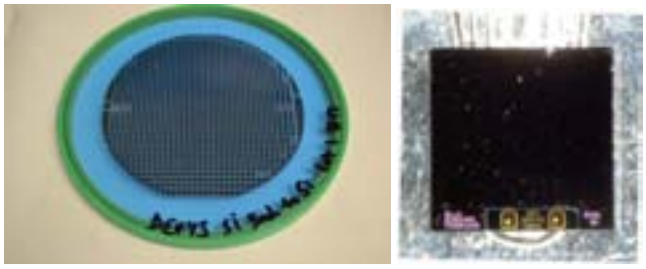

Fig. 3. Singulated die at wafer level (left) and close-up of die (right) after vacuum packaging.

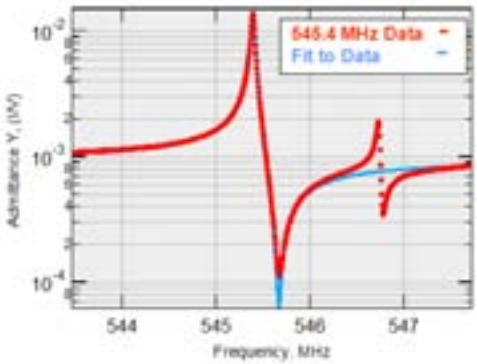

Fig. 4. Admittance plot of AT-cut strip resonator in air. Quartz plate dimensions: 225 x 80 µm, Al electrode dimensions: 160 x 50 x 0.08 µm.

545 MHz strip resonator in air is shown in Figure 4 showing a Q of 14.8 K, R_1 = 70 Ω, C_o = 2.8 x 10^{-13} F, C_1 = 2.8 x 10^{-16} F, and a L_1 = 3.0 x 10^{-4} H. This gives an f x Q product of 8.0 x 10^{12}. f x Q products >1.0 x 10^{13} can be obtained for resonant frequencies near 1 GHz. We have noted that at UHV frequencies, there is no difference in the equivalent circuit values for resonators operated in air or vacuum.

The f/T profile of a 367-MHz 200-µm-diameter disk resonator is shown in Figure 5 and follows the expected "S" shape profile for an AT-cut angle of 35° 18'. After a bake-out in air at >100° C, the hysteresis was about 1 ppm. For stable hysteresis <<1 ppm, two things are required: (1) hermetic or vacuum packaging to remove and prevent contamination from forming on the electrodes and (2) stress isolation from the mounts. Recent COMSOL models [4, 5] of the effects of stress propagation from the mounts to the electrodes over temperature have shown that for quartz resonators it is important to reduce the thermally-induced stress in the active regions to <100 kPa. This is particularly important for very thin UHF designs. Temperature dependent stress can rotate the f/T curves and stress relaxation can produce hysteresis. Stress isolation can be accomplished in the design of the resonator.

Both Pierce and Clapp oscillators have been constructed for testing the phase noise of these resonators. A picture of a Clapp VCO is shown in Figure 6, and its phase noise is plotted in Figure 7. In Figure 7, we also plotted the phase noise of a 16-

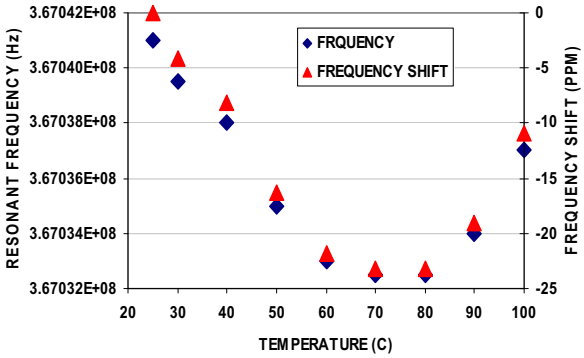

Fig. 5. f/T profile of a 200-um-diameter disk resonator in air after a >100° C bake.

Fig. 6. A 705-MHz Clapp VCO using a capped AT-cut quartz MEMs resonator.

MHz Vectron quartz VCC1 series XO multiplied up to 705 MHz with a noiseless multiplier. One can see that for high offset frequencies, the phase noise for the quartz MEMS VCO is lower. At 10 Hz offset, the commercial HF part is about -8 dB better. Thus, for portable communication applications, if one wishes to minimize power by not employing a frequency synthesizer or PLL, these UHF oscillators offer new capabilities with reasonably good performance. Commercial testing of these oscillators has demonstrated the ability to acquire and track GPS signals with roughly 300 times less local oscillator power than is currently used in existing systems [6]. One of the key issues in moving to low noise 1-GHz operation is integrating the resonator with an appropriately designed high gain, low noise amplifier.

III. Nonlinear Performance Enhancements

A. Operation Near a Bifurcation Point

Drive level dependency [7] has been well studied for quartz resonators and is believed to result (ignoring heating effects) from a nonlinearity in the elastic modulus in the crystal. This nonlinearity can be described with an additional term in the standard electrical harmonic oscillator equation:

$$\frac{V}{L} = \ddot{q} + \frac{\omega_0}{Q}\dot{q} + {\omega_0}^2 q(1 + \beta q^2) \qquad (1)$$

where β describes the degree of third-order nonlinear behavior of the elastic modulus. At high drive levels, this nonlinearity

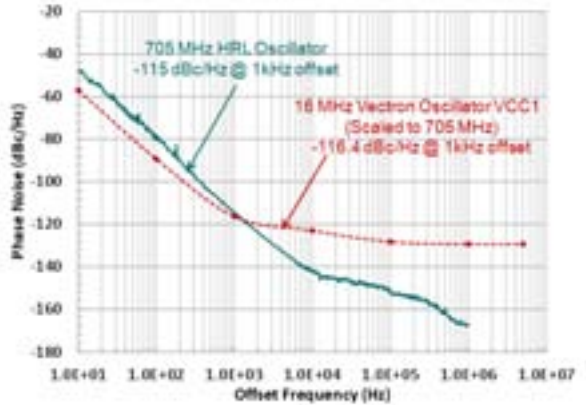

Fig. 7. Phase noise of the 705-MHz Clapp VCO shown in Fig. 6. For comparison, the phase noise of a commercial Vectron 16-MHz VCC1 series XO is shown by multiplying its phase noise to 705 MHz with a noiseless multiplier.

distorts the normal admittance profile and increases the phase slope of the resonator. This increase in phase slope is equivalent to an increase in Q, and thus one could expect the contribution of phase noise from the electronics would be reduced if the oscillator operates near the region where the phase slope approaches infinity (the bifurcation point). This is the basis of the Yurke [8] model for "amplifier-noise evasion" in oscillators using a nonlinear resonator. The key to using this concept in real world oscillators is (1) driving the resonator to a high enough amplitude to reach the bifurcation point, (2) controlling the circuit's operating point to find and stabilize the operation of the loop near a region of high phase slope, and (3) preventing amplitude noise in the drive signal from adding phase noise (AM to PM noise conversion).

The first step in studying this effect is determining the drive level necessary to reach the bifurcation point. As shown in Figure 8, for a 995-MHz resonator, the resonator becomes highly nonlinear near a drive level of 400 mV (peak) and shows a corresponding 125 ppm frequency shift. For comparison, similar voltage drive levels were applied to a

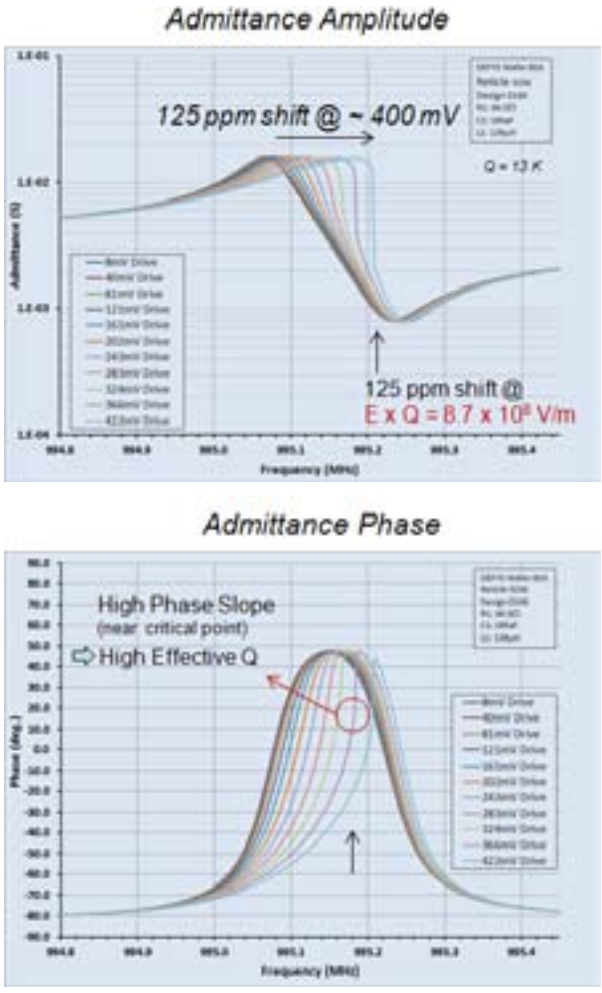

Fig. 8. Admittance amplitude (top) and phase (bottom) of a 100-µm-diameter disk resonator with a fundamental mode resonance at 995 MHz. The resonator reaches the bifurcation point at a drive level of approximately 300 - 400 mV (peak).

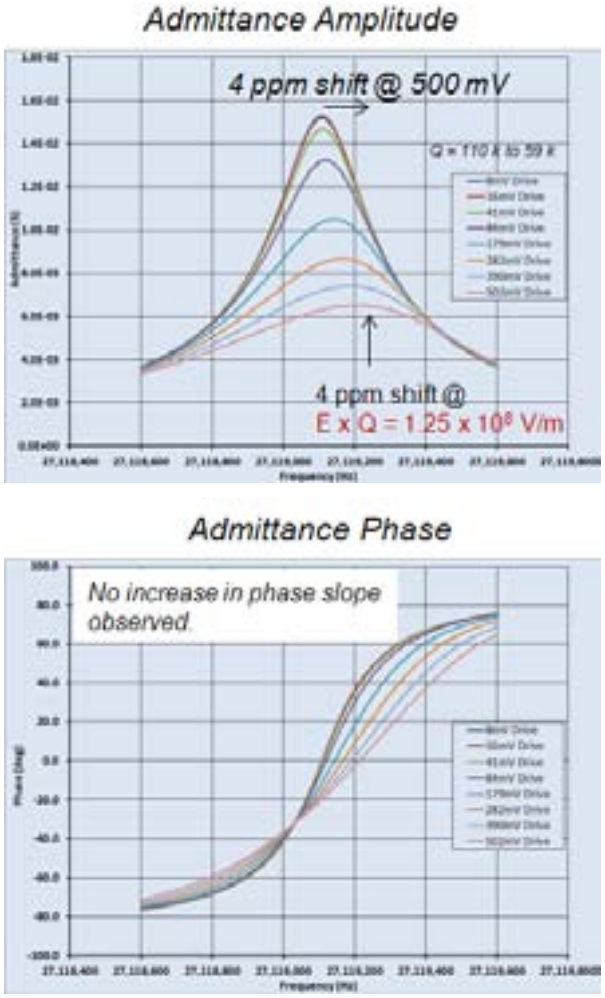

Fig. 9. The admittance amplitude (top) and phase (bottom) of a commercial 27-MHz miniaturized resonator (Epson FA-180T). Note the phase slope decreases as the drive level is increased. Voltages are peak values.

commercial HF resonator from Epson (model # FA-180T) operating at 27 MHz. The results are shown in Figure 9. For this resonator, a 500 mV (peak) drive produces much less nonlinearity and a frequency shift of only 4 ppm. (This part also shows a drop in Q as the drive voltage is increased.) From equation (2) below, it can be shown that a constant electric field (E) applied to devices with different thicknesses produces the same degree of nonlinearity for a similar Q. We have found that E x Q is a useful metric for determining the degree of nonlinearity exhibited by a resonator since it represents the degree of local strain in the crystal. For the 995-MHz resonator at a drive level of ~ 400 mV, E x Q = 8.7 x 10^8 V/m while for the 27-MHz resonator at a drive level of 500 mV, E x Q = 1.25 x 10^8 V/m. Thus, UHF resonators seem ideally suited for nonlinear studies and operation at voltages <1 volt.

In order to study "amplifier-noise evasion", we constructed a breadboard control loop [9] in which the phase and gain in the loop around the resonator could be varied while the amplitude of the resonator admittance was measured in closed loop operation using a high speed differential probe configuration.

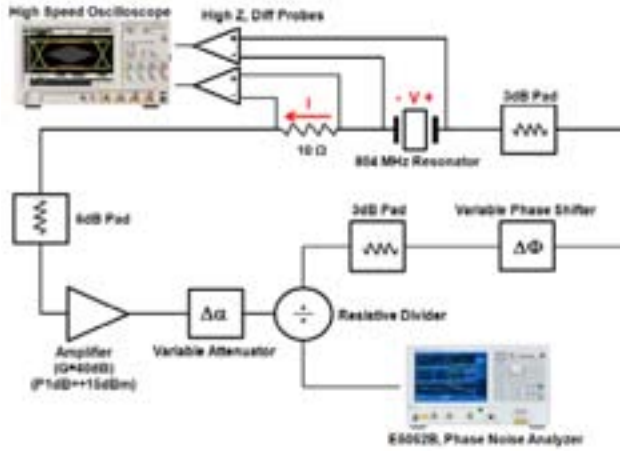

Fig. 10. Breadboard circuit for measuring the amplitude of the admittance of the resonator in closed loop operation while adjusting the gain and phase of the electronics to sweep the frequency of operation.

This allowed us to predetermine the best open- loop phase slope operating point for the resonator and then to adjust the phase and gain of the loop to sweep the frequency and measure the phase noise at various operating points. This set-up did not provide ideal conditions for the lowest phase noise measurements but was constructed to allow a wide range of operating points to be evaluated for relative phase noise improvements. The circuit is shown in Fig. 10, and the resulting admittance and phase noise plots are shown in Fig. 11

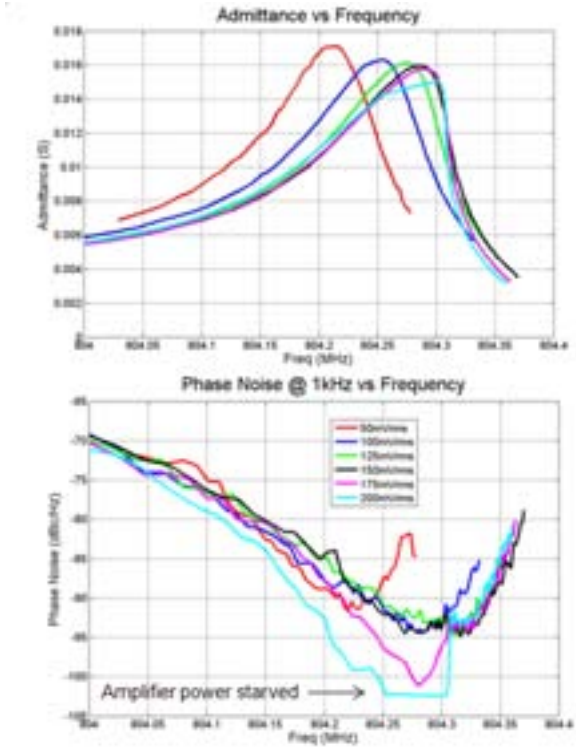

Fig. 11. Amplitude of admittance (top) and phase noise (bottom)of a nonlinear 804-MHz AT-cut oscillator at 1 kHz offset versus frequency showing a sharp drop in phase noise near the expected high phase slope region of the resonator admittance curve.

for an 804-MHz resonator. As seen in the closed-loop admittance plot, the gain of the amplifier at 804 MHz was starting to saturate even when the attenuator was completely removed from the loop near the bifurcation point. However, a sharp drop in phase noise was seen at a point near the highest phase slope. We believe this is the first strong evidence of noise evasion for quartz oscillators. In the future, we will need to redesign the loop with higher gain stages to further study this encouraging new result.

B. Nonlinear Modal Coupling

It is very common for quartz oscillators to be operated not only at the fundamental shear-mode resonance but also at the third and fifth overtones. These overtones usually do not fall directly at a third or fifth harmonic of the fundamental frequency, but particular electrode and plate design can bring the overtone mode frequencies close to the harmonic frequencies. We have studied the possibilities of nonlinear mode coupling from the fundamental to higher order overtones with a Matlab Simulink model. The initial governing two-dimensional equations [10] for this study are as follows:

$$C_{66}u_{1,22} + \eta_{66}\dot{u}_{1,22} + e_{26}\varphi_{,22} - \rho\ddot{u}_1 = -\gamma[(u_{1,2})^3]_{,2} \quad (2)$$

$$e_{26}u_{1,22} - \varepsilon_{22}\varphi_{,22} = 0 \quad (3)$$

$$C_{66}u_{1,2} + \eta_{66}\dot{u}_{1,2} + e_{26}\varphi_{,2} \pm 2\rho' h'\ddot{u}_1 = -\gamma(u_{1,3})^3 \text{ at } X_2 = \pm h \quad (4)$$

$$\varphi = \pm\frac{1}{2}Ve^{i\omega t} \text{ at } X_2 = \pm h \quad (5)$$

$$\gamma = \frac{1}{2}C_{22} + C_{266} + \frac{1}{6}C_{6666} \quad (6)$$

where C_{ik} is the elastic shear-mode stiffness matrix, η_{ik} is the damping matrix, e_{ik} is the piezoelectric matrix, ρ is the quartz density, γ is the nonlinear third-order coefficient containing the second, third and fourth order elastic constants, u is the displacement, ε is the dielectric matrix, 2h is the quartz plate thickness, 2h' is the electrode thickness, φ is the electric potential, and V is the applied voltage. The x_1 axis is in the shearing direction and the x_2 axis is normal to the quartz plate.

One can now assume both the fundamental and third overtone modes with amplitudes A_1 and A_2, respectively, are present at the same time and substitute a dual eigenmode solution into equation (2):

$$u_1(X_2,t) = A_1(t)\,Sin(\frac{\pi X_2}{2h}) + A_2(t)\,Sin(\frac{3\pi X_2}{2h}) \quad (7)$$

If ones then multiplies the resulting equation by each eigenmode solution and integrates through the thickness, one obtains the following nonlinear coupled equations of motion:

where ω_1 and ω_2 are drive frequencies in the neighborhood of the natural fundamental and third overtone frequencies, ω_{n1} and ω_{n2}, respectively. The expressions in equations (8) and (9) are defined as the following, which can be derived from the linear equations except for the gamma terms:

Table of expressions

$$\omega_{n1} = \eta_1\sqrt{\frac{\overline{C}_{66}}{\rho}}(1-\frac{4k_{26}^2}{\pi^2}-R),\ \omega_{n2} = \eta_2\sqrt{\frac{\overline{C}_{66}}{\rho}}(1-\frac{4k_{26}^2}{9\pi^2}-R),\ \eta_1 = \frac{\pi}{2h},\ \eta_2 = \frac{3\pi}{2h},\ \gamma_1 = \frac{\eta_1^2\gamma}{\overline{C}_{66}},\ \gamma_2 = \frac{\eta_2^2\gamma}{\overline{C}_{66}},$$

$$\overline{C}_{66} = C_{66} + \frac{e_{26}^2}{\varepsilon_{22}},\ k_{26}^2 = \frac{e_{26}^2}{\overline{C}_{66}\varepsilon_{22}},\ R = \frac{2\rho' h'}{\rho h},\ K_1 = \frac{-e_{26}V_1e^{i\omega t}}{2h(C_{66}-2\rho' h'\omega_1^2 h)},\ K_2 = \frac{-e_{26}V_2e^{i\omega t}}{2h(C_{66}-2\rho' h'\omega_2^2 h)}$$

By solving equations (8) and (9) in a Matlab model, one can study the nonlinear coupling between the two modes for various drive levels and different frequency matching conditions between the two modes. We have found that if the fundamental mode is driven strongly into a nonlinear regime while the third overtone is very lightly excited, the third overtone mode can be pumped to a higher amplitude and the Q (defined by the full-width at half-maximum of its response curve or the phase slope) is predicted to be higher. The results are shown in Figure 12 for a ~ 1.6 GHz third overtone device. Several curves are shown for the pumped third overtone mode for different frequency matching conditions. For $f_{n2} = 3f_{n1}$, the Q enhancement is predicted to be ~ 8X. For $f_{n2} = 3f_{n1}$ + 800 kHz, the Q enhancement is predicted to be 4X. As the voltage on V2 is increased, the Q enhancement is decreased. The origin of this predicted increase in Q is still being studied. The model assumes a constant f x Q product of ~ 1 x 10^{13} Hz for the fundamental and third overtone modes. Thus, the third overtone is being pumped with a drive with a three times higher Q. This may explain part of the Q enhancement. Experiments are currently being performed at HRL with mode matching to within 100 ppm to verify these predictions.

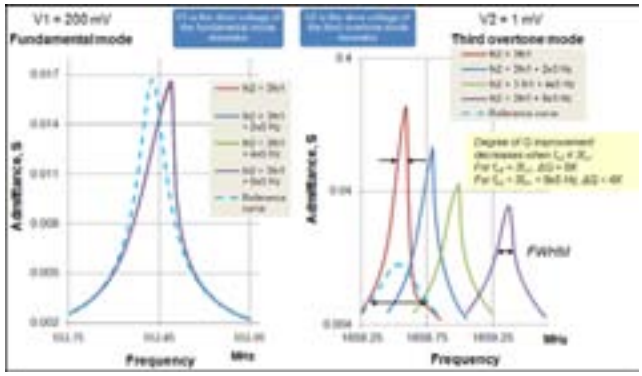

Fig. 12. The admittance curves for the nonlinear coupling of the fundamental to third overtone modes when V1 is driven with a 200 mV peak voltage and V2 is driven with a 1 mV peak voltage.

$$\ddot{A}_1 + \frac{\omega_{n1}}{Q_1}\dot{A}_1 + \omega_{n1}^2 A_1(1+\gamma_1(\frac{3}{4}A_1^2 + \frac{9}{4}A_1A_2 + \frac{27}{2}A_2^2)) = -\frac{8K_1h\omega_1^2}{\pi^2} \quad (8)$$

$$\ddot{A}_2 + \frac{\omega_{n2}}{Q_2}\dot{A}_2 + \omega_{n2}^2 A_2(1+\gamma_2(\frac{3}{4}A_2^2 + \frac{1}{6}A_1^2 + \frac{27A_1^3}{2A_2})) = \frac{8K_2h\omega_2^2}{9\pi^2} \quad (9)$$

IV. Sensor Synergy for Improved Performance

The ability to define complex structures both on and around the quartz resonator using quartz MEMS processing is very useful for mitigating system errors in navigation and communication systems [11]. As an example, a precise clock can be used to correct for thermal drifts in navigation sensors. A set of IMU sensors can be used to detect motion and reduce vibration induced phase noise errors in clocks. Autonomous IMUs can correct for errors in GPS location when GPS signals are not available, and GPS timing signals can be used to correct for local clock inaccuracies. These are just a few examples of the synergistic interplay that is possible when devices are allowed to communicate. If these devices share a common package or housing, thermal gradients can be minimized while vibration compensation can be simplified. In this section, we will give an overview and initial modeling results for a few of these topics.

A. Dynamical Control for Reduced Vibration Sensitivity

Vibration sensitivity of clocks is of primary concern when the clock is located in a moving vehicle. We have tested our UHF oscillators on a shaker table to determine their vibration sensitivity. Care was used to reduce stray capacitance changes during the measurements, but all extraneous signals have likely not been eliminated due to our hybrid board construction as seen in Figure 6. Figure 13 shows the measured out-of-plane gamma for a 645-MHz oscillator using a 200-µm-disk design with a 0.5 g peak sinusoidal input. The measured out-of-plane (along the y axis of quartz) gamma was typically ~ 5.0 x 10^{-10}/g. Predicted vibration sensitivities from quartz models for 500-MHz designs and 0.5 g inputs have yielded 1.8 x 10^{-10}/g, 9 x 10^{-13}/g, and 3.0 x 10^{-15}/g in the y, x, and z axes, respectively. Thus, reducing the out-of-plane vibration sensitivity is of particular interest.

One method that is currently being developed is to add additional electrodes to the underside and top of the quartz plate for capacitance sensing and force rebalance. This allows active force rebalancing of the inertial forces on the quartz plate in the out-of-plane direction. A schematic of the new design is shown in Figure 14. FEA COMSOL analysis has been used to calculate the tip cantilever displacement for several designs from 500 MHz to 1 GHz fundamental operation. The results are shown in Figure 15. For the design parameters given in this figure, the change in the capacitance for 1 g acceleration is between 1 – 5 aF. Fortunately, these capacitance values are commonly detected by circuits used for MEMS accelerometers. Assuming a differential capacitance detection system as shown in Figure 14 with a bandwidth of 1 kHz and a clock drive of ±1 volt @ 1 GHz, we calculate that a detection noise floor of between 4 to 1 mg is possible for resonators with fundamental shear-mode resonances between 500 MHz to 1 GHz, respectively. Thus, within the constraints of the typical dimensions of a UHF quartz shear-mode resonator, a combined accelerometer/resonator structure is possible. A small sub-10 µm gap between the quartz resonator and the substrate and cap is needed to maintain the required acceleration sensitivity and low operating voltages.

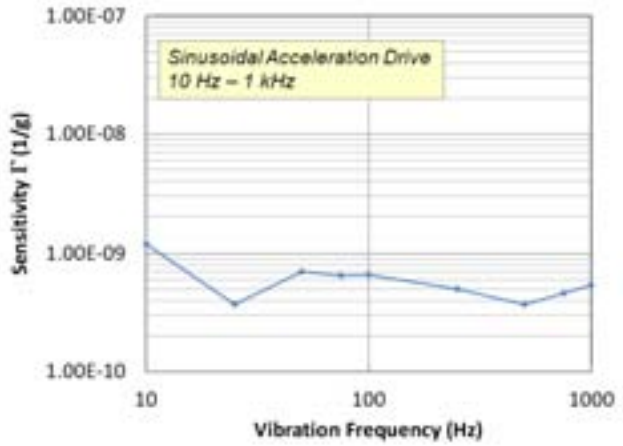

Fig. 13. The out-of-plane (y axis) vibration sensitivity of a 645-MHz oscillator with a 0.5 g peak sinusoidal input.

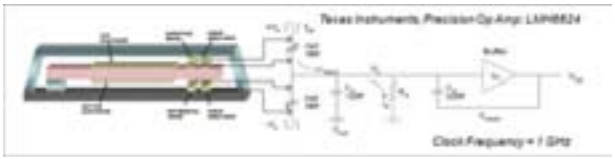

Fig. 14. Schematic of a new design in which the quartz plate serves as both a UHF resonator and an accelerometer with mg sensitivity for force rebalancing of inertial forces on the clock.

B. Frequency Locking for Sensor Ovenization

Another interesting combination of sensors and oscillators on chip is the use of a precision clock for the thermal control of inertial units [12]. For typical Si-based gyroscopes, the uncompensated frequency sensitivity to temperature is roughly -30 ppm/ºC, being due to the change in the elastic constant of Si. In addition, measurements of the bias drift over temperature for the Si Disk Resonator Gyro (DRG) [13] have shown 5-10 deg./hr/º C sensitivity. Since similar temperature-induced drift

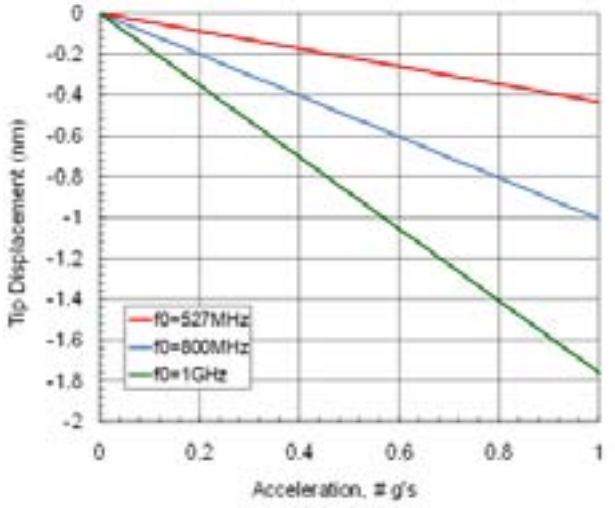

Fig. 15. Tip displacement of several shear-mode resonators as a function of resonance frequency. The quartz plate is 380 x 165 µm^2 and the capacitance sense electrodes are assumed to be 65 x 130 µm^2. The gap spacing between the capacitance sense electrodes on the quartz resonator and the substrate and cap wafer is taken as 5 µm.

is a major factor limiting many applications of MEMS gyros, controlling the temperature in a small ovenized housing is highly beneficial.

The common approach to controlling the temperature of a resonator is by using a thermistor or RTD sensor in the package for monitoring the temperature and then using a heater element in a servo loop. Due to inaccuracies in the temperature sensor itself and temperature gradients between the resonator and the sensor, these approaches are usually limited to controlling the temperature to within 1 – 10 mK. However, quartz manufacturers developed years ago a self-temperature sensing mechanism with high accuracy using two resonant modes of a resonator [14]. This technique relied on the temperature sensitivity differences between the two modes to sense the temperature of the resonator without the need of a separate sensor. For example, the fundamental mode and the third overtone mode of a shear-mode SC-cut resonator have different f/T profiles and the difference $3f_{n1} - f_{n2}$ can be used as the error signal for ovenization. This approach was developed for the microcomputer compensated crystal oscillator (MCXO).

Using this idea, we have designed and are fabricating an integrated Si Disk Resonator Gyro (DRG) and a quartz SC-cut shear-mode resonator in which the difference in the temperature sensitivity of the resonators can be used for ovenization control. The integrated structure is shown in Figure 16. The quartz resonator sits within the base pedestal of the Si DRG and on a common heater for both resonators. This provides maximum coupling from the heater to the resonators, minimizes thermal gradients, and minimizes the total size of the package. If the resonant frequency of the gyro is then locked to that of the quartz clock by means of a thermal feedback loop as shown in Figure 17, the gyro is effectively thermally stabilized [12]. For a short-term stability of the clock of 3 x 10^{-9} over temperature and a frequency stability of the gyro of -30 ppm/^{o}C, one can stabilize the effective temperature of the gyro to 100 μK. This is measured at the gyro itself and provides a highly robust method for improving the bias drift and turn-on to turn-on bias stability over temperature.

V. Conclusions

We have shown that microfabrication techniques that are commonly used in MEMS processing can be applied to piezoelectric quartz resonators for a wide variety of new studies and applications. The use of wafer-scale processing allow the device designer to incorporate new features that rely on small structures and gaps, high electric fields produced with low supply voltages, tightly coupled control electrodes, and co-integration with other sensors. In these cases, novel nonlinear dynamics can be explored as well as dynamical control of vibration and thermal instabilities. The synergistic use of multiple navigation and timing units co-located on a single chip for error correction schemes provides new possibilities for advanced communication and navigation systems.

***Abstract*—In this work we discuss the self-heating dynamics of aluminum nitride contour mode resonators. The self-heating introduces a quadratic coupling between the resonator motion and its temperature. This coupling produces a nonlinear frequency response identical to the Duffing resonator in steady-state. However, since the thermal relaxation rate is much smaller than the mechanical relaxation rate the dynamics of the resonator differ from the conventional Duffing resonator.**

***Keywords*—Aluminum nitride contour-mode resonator, nonlinear, self-heating, MEMS.**

I. Introduction

In the past several years aluminum nitride (AlN) contour mode resonators (CMRs) have recieved a great deal of attention as a candidate technology for the monolithic integration of high-quality passive elements in radio frequency (RF) circuits [1]–[6]. Monolithic intregration promises to enable compact, low-power, and reconfigurable or agile RF devices that exhibit unprecidented performance. AlN resonators are CMOS compatible, possess low motional resistance due to large electromechanical coupling coefficients, and have fundamental frequencies set by lithographically defined dimensions [1]. The low motional resistance of these resonators allows for integration with existing 50Ω based RF systems and lithographically defined frequencies allows for integration of multi-frequency systems [7]. Moreover, AlN CMRs have been demonstrated with frequencies in the GHz range with an $f \cdot Q$ product of $\sim 4.6 \cdot 10^{12}$ in air [1], [2], [8]. These attributes make AlN CMRs amenable to monolithic integration and a strong candidate for the construction of reconfigurable RF systems.

AlN CMRs consist of a film of AlN sandwiched between two metal patterned layers. The resonator considered in this work is a rectangular device excited by apodized interdigitated electrode on the top layer, see figure 1 [9]. The bottom metal layer is left floating.

One important aspect of AlN CMRs is a relatively large temperature coefficient of frequency (TCF). Values around -20 to -30 ppm/°C are typical and thus AlN CMRs require temperature compensation for some applications [6], [10]. This same temperature sensitivity has been shown to be the leading source of a softening nonlinear behavior exhibited by AlN CMRs [11], [12]. In [11] it was illustrated that the measured resonator admittance exhibits a softening behavior, but that the amount of bending in the resonance depends on the rate of frequency sweep employed in the measurement. In [12] it was shown that self-heating AlN CMRs can be described with a Duffing resonator model. However, this analysis was performed in the quasi-static limit. Both works show that the nonlinearity arises from self-heating. In this work we consider the complete dynamic model of a self-heating AlN CMR and discuss the response of the resonator to a frequency sweep through resonance and its relationship to the sweep rate. In addition, we illustrate that while the self-heating nonlinearity appears similar to the Duffing nonlinearity in the quasi-static case, its dynamics are different. This has important ramifications for some appliciations. For example, the ability of these resonators to evade amplifier noise in oscillators using the techniques described in [13].

AlN CMRs can be described by an equivalent lumped-element circuit: the modified Butterworth Van Dyke (MBVD) model. The lumped-parameter circuit is shown in figure 2 and the fitting of this model to an AlN CMR is shown in figure 3. It is at this level of abstraction that we begin our analysis. However, for a discussion of the reduction of the distributed model to a lumped-parameter ODE the interested reader is direct to [1] and references therein. For these devices Joule heating reduces the Young's modulus of the AlN film, changing the motional lumped parameters (R_m, C_m, and L_m) according to the power dissipated by the resonator [1], [12]. We have indicated this modification to the MBVD model by using variable circuit elements in figure 2.

Our discussion of the nonlinear dynamics of AlN CMRs is arranged as follows. In section II we describe the self-heating model of an AlN CMR. We analyze this model using perturbation techniques in section III. The results of this section are compared with measurements in section IV. Discussion and conclusions are given in section V.

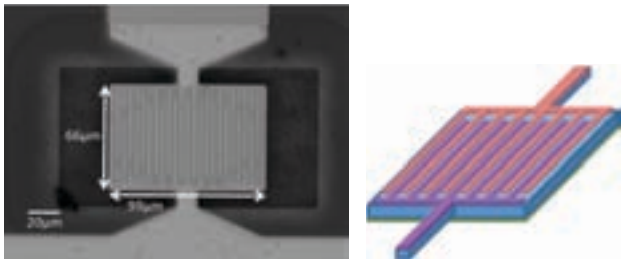
II. Extended MBVD model

We begin with the MBVD circuit model shown in figure 2 and allow L_m, R_m, and C_m to be functions of the resonator temperature deviation from ambient, T. The charge equations for this circuit are

$$L_m \ddot{q}_m + \epsilon \left(R_m + R_s\right) \dot{q}_m + \frac{1}{C_m} q_m = \epsilon V - \epsilon R_s \dot{q}_0, \quad (1)$$

$$(R_0 + R_s)\dot{q}_0 + \frac{1}{C_0} q_0 = V - R_s \dot{q}_m, \quad (2)$$

This material is based on work supported by the Defense Advanced Research Project Agency under the MTO-DEFYS program, award # FA86501217264.



(a) (b)

Fig. 1: Microscope image (a) and cartoon diagram (b) of an aluminum nitride (AlN) contour-mode resonator (CMR). The microscope image shows an apodized resonator [9]

where q_m is the charge on capacitor C_m, q_0 is the charge on capacitor C_0, and V is the voltage applied across the terminals of the circuit. ϵ is a book-keeping parameter marking the terms we will treat as perturbations in section III. We assume that temperature changes are relatively small and so we keep only the first order change in L_m, R_m, and C_m. Thus, we have

$$L_m \approx L_m^{(0)} + \epsilon L_m^{(1)} T, \tag{3}$$

$$R_m \approx R_m^{(0)} + R_m^{(1)} T, \tag{4}$$

$$C_m \approx C_m^{(0)} + \epsilon C_m^{(1)} T. \tag{5}$$

Following [12], we augment the MBVD model with a lumped parameter temperature model for the resonator

$$C_{\text{th}} \dot{T} = -\epsilon \frac{T}{R_{\text{th}}} + \epsilon P_{\text{diss}}, \tag{6}$$

where C_{th} is the resonator heat capacity, R_{th} is the thermal resistance between the resonator and ambient, and P_{diss} is the power dissipated through the resistive elements. P_{diss} is maximum at resonance and in this case the current flows mostly through the mechanical branch of the circuit, the upper branch in figure 2. Thus, for simplicity, we keep only this current in our expression for the dissipated power. Moreover, The principle component of R_m should dominate the variation due to temperature, and so we drop $R_m^{(1)}$ in P_{diss} as well. Accordingly, we approximate the dissipated power as

$$P_{\text{diss}} \approx (R_m^{(0)} + R_s) \dot{q}_m^2. \tag{7}$$

Equations (1)-(7) complete the extended MBVD model. The introduction of temperature dependent coefficients, equations (3)-(5), and the form of (7) introduce a nonlinear coupling between the charge equation (1) and the temperature equation (6). The nonlinear coupling between the resonator and its temperature makes this system difficult to treat exactly. However, these resonators exhibit a separation of time scales due to their large quality factors, making them accessible by perturbation analysis.

III. Envelope Equations

In this section we treat equations (1)-(7) as a weakly nonlinear resonator employing the method of averaging [14]. The terms that we will treat as perturbations have already been marked by ϵ. We consider the primary resonance with weak forcing, and thus we choose

$$V = V_0 \cos \omega t, \tag{8}$$

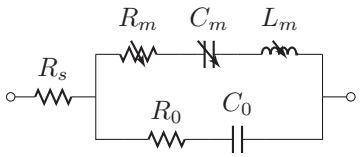


Fig. 2: Modified Butterworth Van Dyke (MBVD) circuit model with nonlinear motional elements.

with ω being close to the resonator's natural frequency. Next we employ the coordinate change

$$q_m = a_0 u e^{i\omega t} + \text{c.c.}, \tag{9}$$

$$\dot{q}_m = i\omega a_0 u e^{i\omega t} + \text{c.c.}, \tag{10}$$

where a_0 is the characteristic amplitude of oscillation, u is the complex amplitude of the resonator, and c.c. stands for the complex conjugate of the preceding terms. Application of this coordinate transformation places equations (1), (2), and (6) in a form amenable to perturbation analysis.

For this system q_0 is a 'fast' variable and is enslaved to the 'slow' evolution of u. Accordingly, we substitute equations (8) and (10) into (2) and solve for q_0 under the assumption that u is constant. This gives

$$q_0 = \frac{C_0}{2} \frac{V_0 - 2i\omega R_s a_0 u}{1 + i\omega C_0 (R_0 + R_s)} e^{i\omega t} + \text{c.c.}. \tag{11}$$

From equaiton (11) we find that the admittance of the resonator is given by

$$Y = \frac{i\omega}{1 + i\omega C_0 (R_0 + R_s)} \left(C_0 + (1 + i\omega C_0 R_0) \frac{2 a_0 u}{V_0} \right). \tag{12}$$

To arrive at an approximate equation for the 'slow' evolution of the resonator's complex amplitude and temperature we substitute equation (11) into equations (1) and (6) and then drop the fast oscillating terms. Moreover, when we substitute for $\dot{q}_0$, we take the time derivative of the $e^{i\omega t}$ term, but not the time derivative of u. The reason being that the slow evolution of u makes this term in $\dot{q}_0$ negligible. In addition, it is convenient to introduce a scaling of both temperature and time in order to simplify the resulting equations. We therefore introduce the the non-dimensional time variable, $\mathfrak{t}$, and the non-dimensional temperature, τ. The relationship between t and $\mathfrak{t}$ and T and τ is given in table I. From this point onward we will use the overdot, $\dot{\square}$, to indicate the derivative with respect to $\mathfrak{t}$ and we also set $\epsilon = 1$ since this book-keeping parameter has served its purpose for the perturbation analysis [14]. Thus we arrive at an approximate set of resonator equations,

$$\dot{u} = -(1 + i\sigma) u - (\delta + i) u \tau + \nu, \tag{13}$$

$$\dot{\tau} = -\frac{1}{\gamma} \tau + |u|^2, \tag{14}$$

where, as we stated above, u is the non-dimensional complex amplitude of oscillation and τ is the non-dimensional resonator temperature. In addition we have introduced the reduced parameters in table I.

To show that a self-heating AlN CMR gives a Duffing-like frequency response, we solve for the fixed points of

$t = \frac{1}{\rho}\mathfrak{t}$	$a_0 = \frac{T_0 \rho C_{\text{th}}}{2\omega^2 (R_m^{(0)} + R_s)}$	$\rho = \frac{R_m^{(0)} + R_s + \omega^2 C_0^2 (R_0 + R_s)(R_m^{(0)} R_s + R_m^{(0)} R_0 + R_0 R_s)}{2 L_m^{(0)} (1 + \omega^2 C_0^2 (R_0 + R_s)^2)}$
$T = T_0 \tau$	$\delta = \frac{T_0 R_m^{(1)}}{2\rho L_m^{(0)}}$	$\sigma = \frac{\omega}{2\rho} - \frac{1}{2\rho\omega L_m^{(0)} C_m^{(0)}} - \frac{\omega C_0 R_s^2}{2\rho L_m^{(0)} (1 + \omega^2 C_0^2 (R_0 + R_s)^2)}$
$T_0 = \frac{2\rho\omega (C_m^{(0)} L_m^{(0)})^2}{L_m^{(0)} C_m^{(1)} + L_m^{(1)} C_m^{(0)}}$	$\gamma = \rho R_{\text{th}} C_{\text{th}}$	$\nu = \frac{V_0}{4 i \omega \rho L_m^{(0)} a_0} \frac{1 + i\omega C_0 R_0}{1 + i\omega C_0 (R_0 + R_s)}$

TABLE I: Reduced parameter definitions.

equations (13) and (14). It is easiest to solve for the frequency response by assuming that $|u|$ is known and solve for the frequency detuning, σ, the phase of the resonator, $\angle u$, and the temperature τ. The result is

$$\sigma = -\gamma|u|^2 \pm \sqrt{\left|\frac{\nu}{u}\right|^2 - (1 + \delta\gamma|u|^2)^2}, \tag{15}$$

$$\angle u = \angle\nu \mp \tan^{-1}\left(\sqrt{\frac{|\nu|^2}{(|u| + \delta\gamma|u|^3)^2} - 1}\right), \tag{16}$$

$$\tau = \gamma|u|^2. \tag{17}$$

The frequency response described by equations (15)-(17) matches the conventional Duffing frequency response [14] when $\delta \to 0$. This slight difference arises from the nonlinear damping imposed by the temperature variations of the motional resistance, R_m.

While the quasi-steady state frequency response of equations (13) and (14) appears similar to that of the Duffing resonator, the added temperature dynamics cause the resonator to behave differently in non-steady-state situations. For most AlN CMRs the temperature dynamics are much slower than the resonator amplitude dynamics. In our formulation this is manifested by the condition $\gamma \gg 1$. Accordingly, when the resonator is probed by a frequency sweep the temperature dynamics can reveal themselves during the sweep even though the sweep rate is much slower than the resonator's mechanical relaxation rate. This was observed in [11]. In order to explore this further, we suppose that σ changes in time as it will during a frequency sweep. In addition, we suppose that γ is indeed large and therefore the dynamics of u are much faster than that of τ. To arrive at a simple model for the swept resonator we solve (13) for the quasi-static fixed point $u(\mathfrak{t}, \tau)$ and insert this solution into (14). This gives a simplified model for the swept resonator

$$\dot{\tau} = -\frac{1}{\gamma}\tau + \frac{|\nu|^2}{(1 + \delta\tau)^2 + (\sigma(\mathfrak{t}) + \tau)^2}, \tag{18}$$

$$u(\mathfrak{t}, \tau) = \frac{\nu}{(1 + \delta\tau) + i(\sigma(\mathfrak{t}) + \tau)}. \tag{19}$$

While equation (18) is difficult to solve, we can again employ a perturbation approach to obtain an approximate solution for a linear frequency sweep in the weak heating limit. In this case we use a direct perturbation scheme. First we let $\sigma(\mathfrak{t}) = \sigma_0 + r\mathfrak{t}$. Then we let $\tau = \tau_0 + \epsilon\tau_1$ and $|\nu|^2 \to \epsilon|\nu|^2$. The zero$^{\text{th}}$ order equation is $\dot{\tau}_0 = -\tau_0/\gamma$. We will assume that equilibrium has been obtained prior to sweeping, and thus $\tau_0 = 0$. The first order equation is

$$\dot{\tau}_1 = -\frac{1}{\gamma}\tau_1 + \frac{|v|^2}{1 + (\sigma_0 + r\mathfrak{t})^2}. \tag{20}$$

$L_m = 19.146\ \mu\text{H}$	$C_m = 1.2768$ fF	$R_m = 57.082\ \Omega$
$C_0 = 160.09$ fF	$R_0 = 16.976\ \Omega$	$R_s = 9.4207\ \Omega$
$a_0 = 6.3 \times 10^{-15}$	$\gamma = 1.5876 \times 10^{-4}$	$\delta = 0.01$

TABLE II: Resonator parameter values.

The solution to (20) is

$$\tau(\mathfrak{t}) \approx \frac{|\nu|^2}{r} \operatorname{Im}\left[e^z \left(\Gamma(0, z_0) - \Gamma(0, z)\right)\right], \tag{21}$$

$$z(\mathfrak{t}) = \frac{i - \sigma(\mathfrak{t})}{r\gamma}, \tag{22}$$

where $\Gamma(0, z)$ is the incomplete Gamma function. For $\sigma_0/r\gamma \ll -1$, that is starting the sweep sufficiently far from resonance, the solution depends very weakly on the starting frequency, σ_0. In this case, the Gamma function $\Gamma(0, z_0)$ can be dropped and we have

$$\tau(\mathfrak{t}) \approx -\frac{|\nu|^2}{r} \operatorname{Im}\left[e^z \Gamma(0, z)\right]. \tag{23}$$

This solution is appropriate for very weak driving such that the self-heating is small. When the resonator is driven strongly equation (18) must be solved numerically. This can be done readily using commonly available numeric solvers.

IV. Experimental Results

The self-heating dynamics of the resonator can be exposed via a rapid frequency sweep using a vector network analyzer (VNA) under high power. The VNA employed for this work was the Agilent N5230A. The resonator we employed is shown in figure 1 (a). The low power admittance of the resonator is shown in figure 3. From this admittance data we fit the linear MBVD parameters using least squares regression. The parameters are shown in the top two rows of table II.

Under higher power the peak of the admittance plot bends toward lower frequencies, a softening behavior similar to a Duffing resonator. However, when the VNA sweep rate is increased the admittance plot changes. This is illustrated in figure 4 which shows a zoomed in view of the admittance peak as a function of the normalized frequency detuning. The black dashed line shows the fixed points for the resonator system, *i.e.* equations (15)-(17). The blue, red, and green lines are the numeric solutions to the sweeping model, equation (18), and the blue, red, and green marks are the measured data. The nonlinear resonator parameters a_0, γ, and δ were fit to the data shown. The fourth nonlinear parameter, e.g. T_0

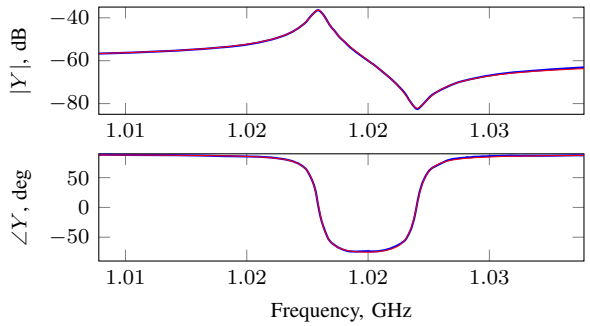

Fig. 3: Resonator admittance for low power. The blue curve is the measured admittance and the red curve is the admittance of the MBVD model.

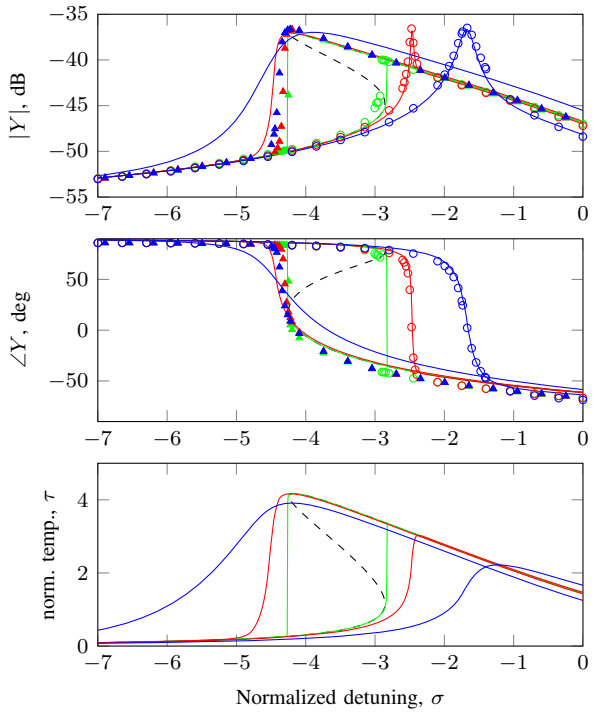

Fig. 4: 11dBm sweeps at 2.7 GHz/sec sweep up, ○, and down ▲, 0.28 GHz/sec sweep up, ○, and down ▲, and 3.4 MHz/sec sweep up, ○, and down ▲. The detuning range shown corresponds to a frequency range of 3.375 MHz. The drive power was 11 dBm.

could not be fit because the resonator temperature could not be measured during the sweep. The figure illustrates how the sweep response adiabatically tracks the steady-state solution for a slow sweep, see the green line and marks for 3.4 MHz/sec sweep rate. However, for a fast sweep (0.28 and 2.7 GHz/sec) the temperature lags the steady-state solution and so does the admittance. The sweeps upward in frequency show a very nice agreement with the model. The sweep down, however, falls from the peak more rapidly than the model predicts. This is a strange phenomenon because the relaxation time of the resonator appears different as the frequency is swept up or down. This phenomenon is currently unexplained and requires further investigation.

V. Conclusions

In this work we examined the nonlinear dynamics of a self-heating AlN CMR using perturbation techniques. We demonstrated that the resonator exhibits a Duffing like response in steady-state, but differs from the conventional Duffing resonator due to the slowness of the temperature dynamics. The temperature dynamics can be revealed via rapid frequency sweeps using a VNA. Using perturbation analysis to predict the response to the VNA frequency sweep we obtained good agreement with experimental results.

***Abstract*—Phase Noise noise reduction in oscillators can be accomplished by using nonlinearly driven resonators locked into a particular nonlinear state that fulfill specific frequency and phase conditions. In this work, we experimentally demonstrate this theory by showing a substantial improvement of the close-in phase noise (lowered by as much as -20dBc/Hz @ 100Hz) of a 222 MHz oscillator that incorporates a nonlinearly driven AlN contour mode resonator (CMR).**

I. Introduction

Microelectromechanical Systems (MEMS) resonators are considered a promising alternative to quartz and surface acoustic wave (SAW) resonators for building stable oscillator circuits for modern sensing and communication applications. Major advantages of the MEMS technology are its compatibility with semiconductor fabrication techniques, which permit its integration with integrated circuit (IC) devices, and its relatively small form factor, which enables new functionalities in a given chip area. On the other hand, the use of miniaturized devices in electronic applications comes with limitations in terms of power handling. As the device size shrinks, MEMS resonators exhibit a larger nonlinear behavior. Although this could be seen as a disadvantage for the implementation of oscillators, a study [1] has first claimed that introducing a nonlinear resonator in the feedback loop can improve the output Phase Noise (PN). It is suggested that by locking the non-linear device into a particular operating state (referred here as critical operating state (COS)) the PN introduced by the amplifier and filtered by the resonator can be evaded [1].

AlN Contour Mode Resonators (CMRs) are an emerging class of piezoelectric MEMS devices exhibiting high quality factor (Q) and low motional resistance at high frequencies (f_r), which make them good candidates for the implementation of frequency references in RF front-end systems [2]. A previous study [3] on 1GHz AlN CMRs has demonstrated that by driving the resonator at a relative high power and with a slowly modulated input (slower than the device thermal time constant (τ_{TH})) pronounced nonlinearities associated with thermal effects are present. Lower frequency AlN CMRs also exhibit the same kind of non-linearity. In this work a 222.5 MHz resonator with Q=3000 is used as a frequency reference in an oscillator circuit. In this particular case, when the resonator is driven nonlinearly, the measured resonance response shows the combined impact of thermal effects and variable damping [4]. These two phenomena are here exploited for the synthesis of a low PN oscillator.

Specifically, we demonstrate a clear improvement of the PN close-in of a 222 MHz oscillator that incorporates a nonlinearly driven AlN CMR. The oscillator circuit of this paper is built by using coaxial electronic components. The experiments reveal that the offset frequency (f_{off}) up to which the PN is reduced is limited by the device τ_{TH}, hence related to the thermal non-linearities of the CMR. Finally, a modified Lesson equation is used to explain the PN reduction achieved by locking the resonator around the COS.

II. Nonlinear AlN Contour Mode Resonator (CMR) Characterization

The resonator used in the oscillator circuit of this work is known as a one port AlN CMR, whose principle of operation was previously introduced in [5]. An AlN plate is sandwiched between a bottom metal plate and a patterned top electrode. The number of electrodes is equivalent to the number of fingers (n) (or sub-resonators). Each electrode is alternatively connected to signal and ground voltages, which generate an electric field across the piezoelectric material. Hence, a lateral strain is induced in the direction of the finger width (Fig. 1). The resonance frequency (f_r) of this type of resonator is set by two parameters: the width of the finger (W), that is related to the wavelength of the first mode of vibration (λ), and the acoustic velocity of the resonator stack $(Y/\rho)^{1/2}$.

The AlN CMR was fabricated by a three masks process as described in [3]. For the device employed in this study the AlN thickness is set to be 1 µm, and both electrodes are

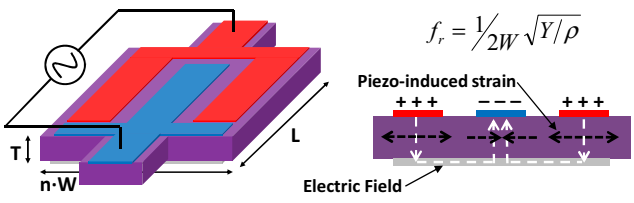

Fig. 1. Schematic representation of an AlN CMR made to vibrate if by applying opposite potentials to adjacent electrodes.

This work was supported by the DEFYS DARPA contract #FA8650-10-1-7030

selected to be around 100 nm thick. The choice of metals for this specific resonator is Pt for the bottom plate, which is used to attain AlN films with a good c-axis orientation, and Al for the top electrodes, which is selected to reduce the series resistance induced by the smaller electrodes. The top view dimensions of the 222 MHz resonant plate are 60 μm (width) by 140 μm (length). *n* is equal to 3 and the width of each finger is 20 μm. The anchors' geometry is optimized to achieve a high quality factor (*Q*) according to previous studies on anchor losses in AlN CMRs [6]. Thus, both anchor length and width are set to be 20 μm, which is equal to λ/2 (Fig. 2).

The resonance response of AlN CMRs is described by the Modified Butterworth Van Dike (MBVD) model (more detail about the circuit can be found in [3]). To experimentally extract the electrical response of the 222 MHz resonator this was mounted on a PCB and connected in series between input and output SMA connectors (this is the same configuration that will be used in the oscillator circuit). One port is then connected to an Agilent N5230A network analyzer (VNA) and the other port is 50 Ω terminated (Fig. 3). The reflection coefficient (S_{11}) is recorded on the VNA and translated into the admittance magnitude (Y_{11}). The *Q* can be directly computed from this measurement as the ratio $f_r/\Delta f_{-3dBs}$ when the device is subjected to small power levels (below -5dBm the device is working in the linear regime). If the device is instead subjected to an increasing power level, the reported admittance manifests a Duffing-like response, which is indicative of a pronounced nonlinear behavior (Fig. 4).

Experimental protocols for characterizing the nonlinear performance of AlN CMRs have been developed for 1GHz devices in [3]. In that work, both Amplitude-frequency (A-f) and 3rd order intermodulation distortion (IMD3) measurements were performed to extract the nonlinear elastic coefficient (α), and fit the recorded admittance for different power levels. The analysis also revealed that the origin of the elastic nonlinearities was mostly thermal when the input was slowly modulated (the input was kept constant for longer than the device τ_{TH}).

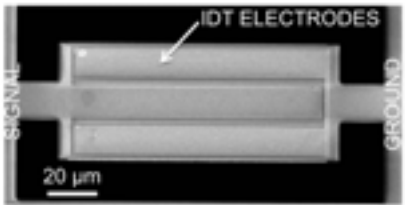

Fig. 2. SEM image of the 222MHz AlN CMR used in the oscillator circuit.

Fig. 3. 222MHz AlN CMR wire bonded on a 2 port FR4 circuit board (PCB).

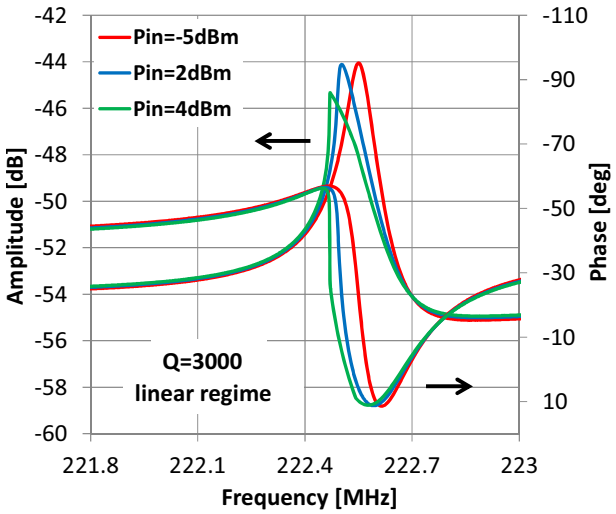

Fig. 4. Tested admittance response (amplitude and phase) of the 222MHz AlN CMR wirebonded on a PCB for different values of input power (Pin=-5dBm, 2dBm, and 4dBm).

It is important to note that the 222 MHz AlN CMR tested here exhibited a certain deviation from the typical Duffing-like behavior. On Fig. 3 we can see that as P_{in} is increased the frequency shift of the peak is also accompanied by a reduction of its magnitude. This phenomenon indicates the dual source of nonlinearities. In fact, not only elastic nonlinearities (related to thermal effects) are at play, but also a variable damping [4]. Although the origin of the latter is still unclear, we believe it has a direct impact on the oscillator performance. We identify the COS as the set of points for which we observe close to infinite phase to frequency slope. Fig. 4 shows the forward and backward sweeps of the amplitude and phase of the 222 MHz resonator for P_{in}=4 dBm. Since the direction of the sweeping does not almost alter the resonance profile we can claim that the COS condition is roughly fulfilled for a large range of phases in this particular case.

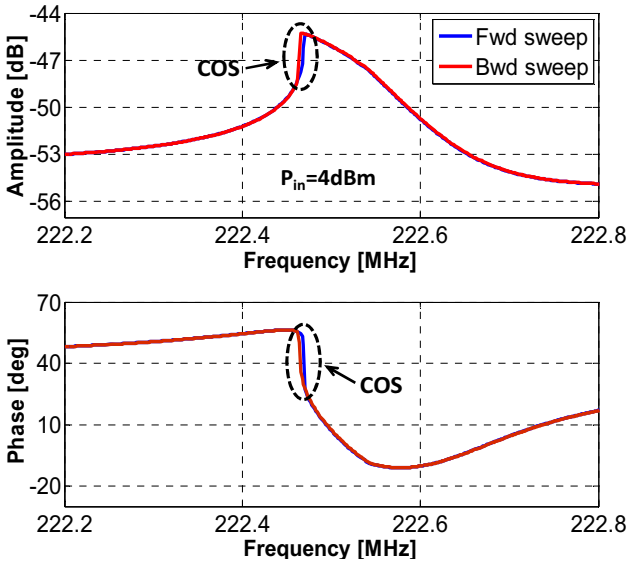

Fig. 5. Amplitude and phase of the admittance response of the 222 MHz AlN CMR mounted on a FR4 circuit board when Pin=4dBm and the frequency is swept back and forward.

III. Nonlinear Oscillator Phase Noise

A. Oscillator Setup

The 222 MHz oscillator of this study is built by using coaxial electronic components (Fig. 5). The AlN CMR is mounted on a 2-port PCB (Fig. 3) that is connected in series with the rest of components in the circuit. The design of the strip lines and the selection of the 2 ports connectors are optimized in order to reduce the parasitic capacitances of the PCB. All the discrete elements, SMA connectors, and cables are chosen to have the characteristic impedance equal to 50 Ω for matching purposes. An external DC power supply is used to bias the RF amplifier (Mini-circuits ZKL-1R5+) and the output is taken from one of the power divider (M/A-COM T-1000) terminals. To close the loop, the other terminal is connected to the phase shifter (ATM P1213)

B. Phase Noise Experiments

The experiments are carried out by setting the DC bias of the RF amplifier to 6V, therefore ensuring enough gain to both sustain oscillations and drive the resonator nonlinearly. The phase shifter is manually tuned in steps of 5° to increase the circuit delay and, hence, lock the oscillator into different oscillation frequencies (f_{osc}) along the nonlinear resonance curve of the 222 MHz AlN CMR. Table I summaries the output power (P_{out}) and the f_{osc} recorded on the Signal Source Analyzer (SSA) for each phase delay ($\Delta\theta$). Assuming that the only element in the circuit that changes the response with frequency is the resonator, we can also identify its f_r by looking at the maximum P_{out} recorded (the higher is the admittance the lower are the losses in the loop). Consequently, we find that f_r=222.434MHz and this value corresponds to $\Delta\theta$=10° (these values are highlighted by a red box in Table I). Furthermore, we confirm that the P_{in} sent to the resonator is around 4 dBm (this value coincides with P_{out} as the losses in the phase shifter and the cables are approximately the same of those components that connect the power divider with the SSA).

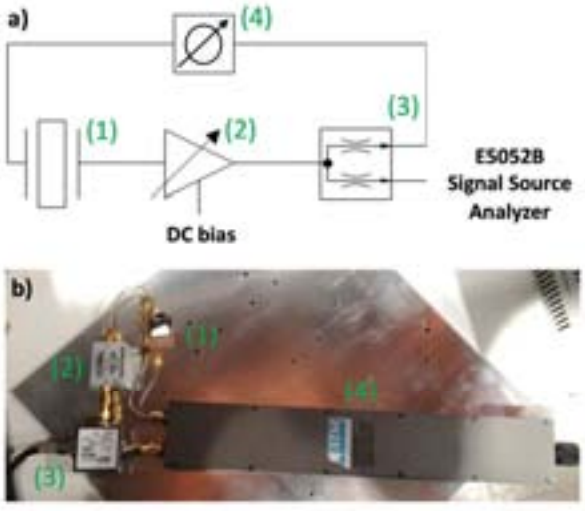

Fig. 6. a) Circuit schematics and b) actual oscillator setup including the (1) AlN CMR mounted on a PCB, (2) RF amplifier, (3) power divider, and (4) phase shifter.

TABLE I. Summary of Output Powers and Oscillation Frequencies corresponding to different Phase Delays in the 222MHz Oscillator.

$\Delta\theta$ (°)	P_{out} (dBm)	f_{osc} (MHz)
0	3.36	222.501
5	3.78	222.470
10	4.04	222.434
15	4.01	222.422
20	3.88	222.413
25	3.79	222.407
30	3.68	222.399
35	3.63	222.393
40	3.62	222.384

Fig. 6 reports the oscillator PN versus the offset frequency (f_{off}) measured for different values of $\Delta\theta$. A dramatic reduction in the PN close-in (f_{off}<1 kHz) is observed when $\Delta\theta \geq 15°$ (this corresponds to $f_{osc}<f_r$ according to Table I). Considering that the power in the AlN CMR is $P_{in} \approx$ 4dBm, we can conclude that for a range of values of the phase shift the resonator is operated in the COS (see Fig. 4). Thus, the effective improvement of PN translates to a change of slope that goes from $1/f^4$ to $1/f^2$ for close-in offsets. Moreover, the experimental results show that the AlN CMR τ_{TH} limits the maximum f_{off} up to which the PN improvement can occur. This confirms the thermal origin of the nonlinearities of the 222MHz AlN CMR. We confirmed that for lower DC biases the power driving the resonator is also lower and no PN improvement is observed.

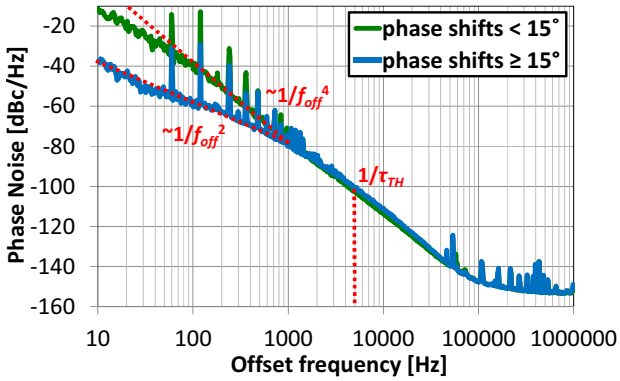

Fig. 7. a) Circuit schematics and b) actual oscillator setup including the (1) AlN CMR mounted on a PCB, (2) RF amplifier, (3) power divider, and (4) phase shifter.

IV. Discussion and Analysis

The previous experimental results show an evident PN slope reduction for close-in offsets that changes from $1/f_{off}^4$ to $1/f_{off}^2$. To provide an intuitive explanation of this phenomenon we resort to a modified version of the Lesson equation that is used to model the PN in closed loop oscillators [7]. Equation (1) describes the oscillator as a first-order filter, which integrates any phase modulations

generated in the circuit (*i.e.* amplifier) when f_{off} is below the Leeson frequency (f_L).

$$S_{\emptyset}(f_{off}) = S_{\theta}(f_{off})\left[1 + {f_L}^2/f_{off}^2\right] \quad (1)$$

where $1/2S_{\emptyset}(f)$ is the single sideband power spectral noise density that is recorded on the SSA, $S_{\theta}(f_{off})$ is the power spectral noise density of the circuit noise. f_L depends on the relaxation time of the resonator (τ) and directly affects the frequency stability of the oscillator with respect to any phase fluctuations generated in the circuit [8].

$$\tau = 1/2\pi f_L = \partial\varphi/\partial\omega \quad (2)$$

where $\partial\varphi/\partial\omega$ is the phase to frequency slope of the resonator admittance at f_{osc}. In the linear regime and when f_{osc}=f_r, (2) becomes $\partial\varphi/\partial\omega = Q/\pi f_r$. In this case, f_L is inversely proportional to Q. For a linear resonator, (1) states that PN lowers if a higher Q resonator is available. When the resonator is locked into the COS region, τ tends to a very large value (ideally infinite), and f_L approaches 0. This non-linear phenomenon effectively lowers the output PN, as if the oscillator was made insensitive to any PN generated externally to the resonator. Under this condition (1) is reduced to:

$$S_{\emptyset}(f_{off}) = S_{\theta}(f_{off}) \quad (3)$$

Comparing (1) and (3), we can observe that the PN in the close-in region goes from ${1/f_{off}}^2 S_{\theta}(f_{off})$ to $S_{\theta}(f_{off})$. This perfectly matches with the case of this study if we assume that the PN produced in our circuit is $S_{\theta}(f_{off}) \propto {1/f_{off}}^2$.

To confirm that the amplifier was the dominant source of noise in the circuit ($S_{\theta}(f)$), we later substituted this amplifier by a lower noise version. Then, we made sure that the power applied to the resonator was enough to drive the device nonlinearly and tuned the phase shifter to reach the COS condition. However, even thought the recorded PN was lower for all f_{off} (-107dBc/Hz @ 1kHz and $1/f_{off}^3$ at the close-in (f_{off}<10kHz)), no change of slope in the close-in region was observed. In this case, the PN was limited by the resonator frequency fluctuations. This confirmed the origin of $S_{\theta}(f_{off}) \propto {1/f_{off}}^2$ as related to the amplifier and proved the concept of amplifier noise evasion by using a nonlinear resonator in the oscillator.

V. CONCLUSION

In this paper we have demonstrated reduction of the close-in phase noise (slope change from $1/f_{off}^4$ to $1/f_{off}^2$) for a 222 MHz oscillator by operating a nonlinearly driven AlN CMR in a particular nonlinear state. To prove the concept, we have built the oscillator by using external coaxial components, which allowed us to separately control the phase and driving power in the circuit. The experimental data also showed the impact of the thermal effect on the resonator nonlinear behavior (PN noise improvement was limited to frequency offsets < τ_{TH}). A simple and intuitive way to explain the experiments was also presented by modifying the conventional Leeson theory.

***Abstract*—This paper investigates a nonlinear amplitude saturation behavior in an electrostatically transduced, silicon MEMS disk resonator operating in its secondary elliptical bulk-mode ($SEBM$) at 3.932 MHz towards its implementation as an all-mechanical automatic gain control (AGC) element. The nonlinear vibration behavior of the $SEBM$ mode is experimentally observed in open-loop testing such that above a threshold small signal drive voltage at a given polarization voltage, the vibration amplitude of the $SEBM$ mode saturates. We also study this nonlinearity in an oscillator circuit designed such that the driving power level at the resonator input can be manually tuned as the circuit operates. The measurements of the voltage amplitudes show a clear transition from the linear to the nonlinear saturation region as the driving power is increased. Short-term frequency stability measurements were also conducted for different v_{ac} and the resulting Allan deviation plots show an improvement in the short-term stability from 1.4 ppb in the linear region to 0.4 ppb in the amplitude saturation region.**

I. Introduction

The demand for high performance and reduced size wireless communication devices has pushed current research interests towards the design and development of low power, small footprint and single chip CMOS integrated wireless-transceivers. The potential of Micro Electro Mechanical Systems (MEMS) technology to meet some of these requirements has led to the recent development and adoption of micro-mechanical resonators for operation as timing references [1]. Such micro-resonators, unlike their traditional quartz crystal counterparts, are manufactured using standard semiconductor manufacturing techniques and offer considerably smaller form factor as well as shorter lead times. Electrostatically transduced MEMS resonators have also been shown to provide high mechanical quality factors (Q) and low static power dissipation, making them attractive alternatives to quartz based timing references. The small size of silicon micro-resonators also comes at a cost of a reduced power handling capacity, which is limited by nonlinear effects of the transduction mechanism and mechanical nonlinearities, affecting the achievable signal-to-noise ratio.

However, these inherent nonlinearities can potentially be engineered to achieve useful properties in certain applications. In this paper, we investigate a nonlinear amplitude saturation behavior in an electrostatically transduced, Si MEMS disk resonator (Fig. 1), operating in its secondary elliptical bulk-mode ($SEBM$) at 3.932 MHz (Fig. 2) towards its implementation as an all-mechanical automatic gain control (AGC) element. The nonlinear vibration behavior of the $SEBM$ is experimentally observed in open-loop testing such that above a threshold small signal driving voltage v_{ac}, the vibration amplitude of the mode saturates. Such nonlinear clamping behaviors have been reported in other MEMS resonators in [2] and [3]. In this work, the amplitude clamping behavior was also studied in a closed-loop configuration where the driving level of the MEMS resonator can be manually adjusted. The performance of this MEMS-based oscillator circuit was then characterized in the linear and nonlinear oscillation region, respectively. We experimentally measure an improvement in the oscillator short-term frequency stability as the resonator is set in the nonlinear region. These results indicate that the amplitude clamping effect in nonlinear micro resonators can potentially be applied in MEMS based oscillator circuits as a mechanical AGC to simplify the circuit configuration as well as retain excellent short term frequency stability.

II. Amplitude Saturation

A. Open-loop characterization

Experiments were performed on Si disk resonators which have a radius of 750 μm, 25 μm thickness and an electro-mechanical transduction air gap of 2 μm (as shown in Fig. 1). The chosen mode of operation is the in-plane $SEBM$ mode at 3.932 MHz. In order to trigger this mode, the body of the device is grounded, while a small signal v_{ac} in combination to a V_{DC} bias voltage is set on the drive electrodes, driving the bulk disk in mechanical vibration. The motional current was sensed through the Sense Electrodes which were biased with the same V_{DC} potential. The BAW micro-resonator was electrostatically addressed using high V_{DC} (typically $>$ 60 V) and v_{ac} ($>$5 dBm output power) and achieved measured quality factor values $Q \approx$ 0.5x10^6 in vacuum (p_0 = 30 mTorr).

Figure 3 shows a series of experimentally measured S_{21} responses of the disk resonator, after a numerical feed-through parasitic cancellation, when operating in the vicinity of the $SEBM$ mode with V_{DC} = 100 V and varying v_{ac} (1.22-2.82 Vp-p). From Fig. 3, when v_{ac} = 1.22 Vp-p, the amplitude response of the resonator is just at the edge of the linear region of operation. However, when we increase the small signal power further, keeping V_{DC} constant, the curves begin to level off indicating an amplitude saturation effect of the generated motional current (i.e. the amplitude of vibration). Furthermore, there is a frequency broadening of the clamping region as the ac component is further increased from 1.35 Vp-p to 2.82 Vp-p. The precise mechanism behind this particular amplitude saturation behavior is yet to be determined. Possible explanations include the parametric [2] or amplitude-dependent nonlinear excitation [3] of a coupled mode of oscillation.

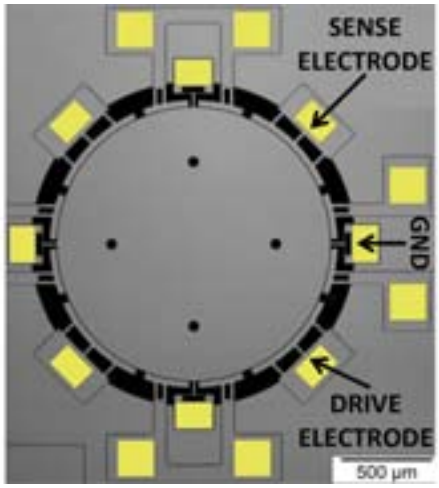

Fig. 1. Micrograph of the electrostatically transduced 3.932 MHz silicon disk resonator.

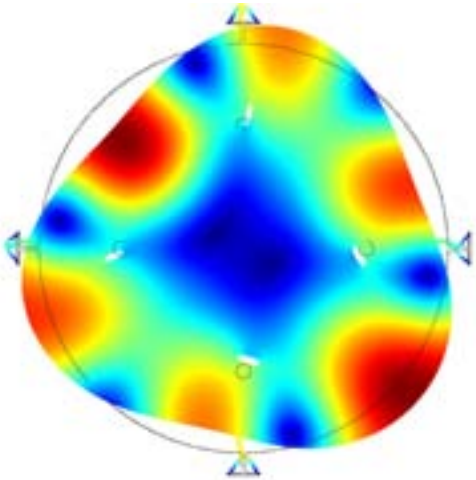

Fig. 2. FEM mode shape analysis of the micro-resonator at 3.932 MHz.

Further experiments are underway to ascertain the origin of the clamping mechanism when the in-plane $SEBM$ is driven into the nonlinear region.

This nonlinear amplitude saturation effect recorded during open-loop characterization can be used as a soft-voltage limiter / all-mechanical AGC, when implemented in an oscillator closed-loop circuit topology.

III. Amplitude and Frequency Stabilization

A. Oscillator Test Circuit

In order to experimentally verify that this particular nonlinear behavior can be used in an oscillator circuit as a soft limiter, we developed a closed loop oscillator topology where the oscillations are self sustained at the $SEBM$ mode. The schematic of this oscillator circuit is shown in Fig. 4. The MEMS resonator is implemented in a feedback loop where the Driving Amplitude Control unit is used to manually tune the value of the driving v_{ac} voltage which is fed to the resonator. For each value of v_{ac}, the Oscillation Amplitude unit measures the amplitude of the signal after the Gain Stage v_{output} (which

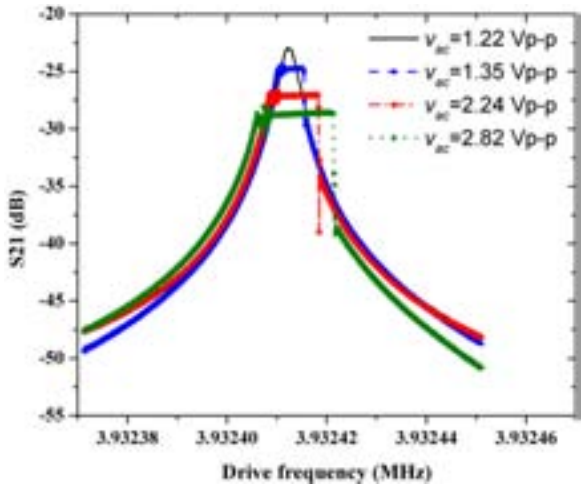

Fig. 3. Measured S_{21} parameter of the disk resonator at the $SEBM$ mode for different drive v_{ac} and V_{DC} = 100 V. The transmission characteristics demonstrate an amplitude saturation behavior when $v_{ac} > 1.35$ Vp-p.

corresponds to the resonator's amplitude of vibration), while a frequency counter (Agilent 53230A) simultaneously records the frequency stability of the oscillator. The Driving Amplitude Control unit is implemented using an AD8611 comparator circuit, driving the MEMS resonator with a square-wave signal of peak-to-peak voltage v_{ac}.

B. Amplitude stabilization

Figure 5 plots the measured Mean Output Amplitude v_{output} as a function of the Driving amplitude control voltage v_{ac} in the range of 0.75-2.8 Vp-p with a fixed polarization voltages V_{DC} at 60 V, 100 V and 120 V respectively. The circuit configuration of Fig. 4 can successfully lock itself into the $SEBM$ mode as we vary the values of v_{ac} and V_{DC}. Fig. 5 shows a clear transition of the oscillator amplitude from the linear to the nonlinear saturation region as the driving power increases for large V_{DC} = 100 V and 120 V. This transition point is consistent with the behavior measured in open-loop testing. From the open-loop measurements of Fig. 3 for a bias voltage of 100 V, the amplitude clamping behavior starts to appear at a $v_{ac} > 1.22$ Vp-p. In the closed-loop circuit, this transition occurs for a driving $v_{ac} > 1.25$ Vp-p. The threshold v_{ac} marking the transition between the linear / nonlinear regime is observed at lower driving voltages as the DC-bias is increased: v_{ac} = 1.25 Vp-p for V_{DC} = 100 V, v_{ac} = 1.15 Vp-p for V_{DC} = 120 V. This suggests that the nonlinear transition point is dependent on the product $v_{ac}V_{DC}$ which is proportional to the applied force on the resonator.

The slope of the output amplitude curve is not completely flat as a function of v_{ac} as we see from Fig. 3 and Fig. 5. This may be due to the unavoidable presence of the feed-trough parasitic capacitance between the input and output stages of the resonator. However, the benefit of this nonlinear amplitude saturation behavior is that the resonator amplitude will saturate before the circuit nonlinearities start becoming dominant.

C. Short-term frequency stability

The short-term frequency stability of an oscillator is a critical figure-of-merit. Nonlinear operation of a resonator as

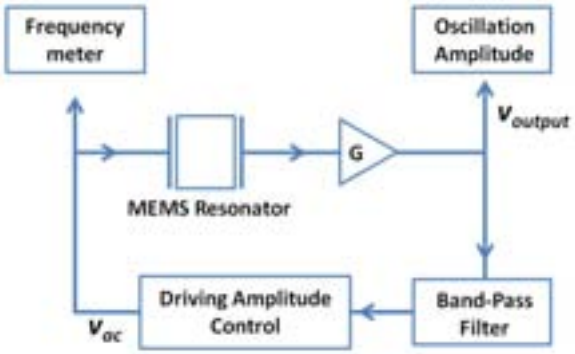

Fig. 4. Schematic of the closed-loop configuration implemented with the disk resonator and used to lock into the $SEBM$ mode.

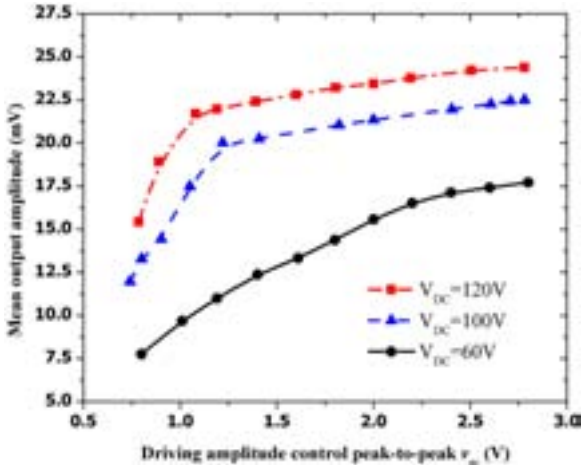

Fig. 5. Oscillation amplitude v_{output} for different drive v_{ac} in the closed loop configuration of Fig. 4.

opposed to the linear-regime is usually avoided because of the amplitude-frequency (a-f) correlation. This has been known to impact the frequency stability of the oscillator due to mixing and up-conversion of low frequency noise onto the carrier and the interaction between amplitude noise and phase noise [4]. However, it has been reported in [5] that driving a double-ended-tuning fork MEMS resonator into the nonlinear regime can result in improved frequency stability due to amplitude and frequency stabilization resulting from internal resonance of a coupled higher order mode. Since the disk resonator presented in this paper operates in a strongly nonlinear regime where amplitude clamping occurs, the question arises as to whether this impacts on the frequency stability.

To experimentally assess the short-term frequency stability of the oscillator as v_{ac} is varied, we produced two-point modified Allan deviation plots using the measurements obtained from the frequency counter. The Allan deviation $\sigma_y(\tau)$ measures the fractional frequency fluctuations of the oscillator for different averaging periods τ and can be expressed as

$$\sigma_y(\tau) = \sqrt{\frac{1}{2(N-1)} \sum_{i=1}^{N-1} \left(y_{i+1}^{\tau} - y_i^{\tau}\right)^2} \qquad (1)$$

where y_i^{τ} is the average normalized frequency fluctuation $(\delta f_i / f_0)$ over the ith interval of length τ.

The resulting Allan deviation plots (Fig. 6) as a function of the drive v_{ac}, show an improvement in the short-term stability (at τ = 0.5s averaging time) from 1.4 ppb in the linear region (v_{ac} = 1.2 Vp-p) to 0.4 ppb for operation in the amplitude saturation region (v_{ac} = 1.6-2.4 Vp-p) at a polarization voltage of V_{DC} = 100 V.

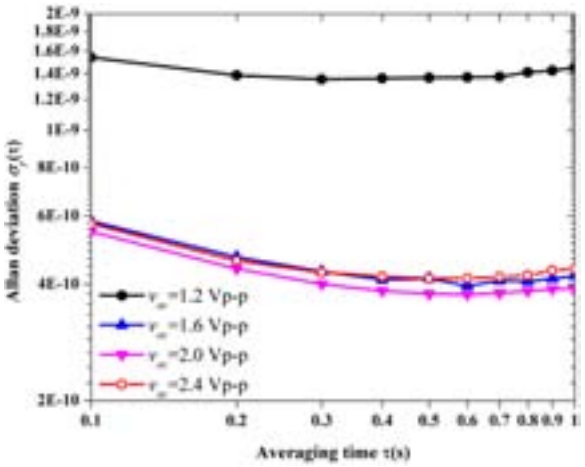

Fig. 6. Allan deviation plots for different drive v_{ac} and V_{DC} = 120 V

IV. Conclusion

A 3.932 MHz disk resonator with nonlinear amplitude clamping behavior was demonstrated in this work. This nonlinear clamping was experimentally demonstrated in open-loop characterization measurements and shows a threshold driving power v_{ac} value for which the amplitude of vibration of the resonator in the $SEBM$ mode saturates. This effect was used to produce an all-mechanical amplitude gain control mechanism where the closed-loop voltage amplitude saturates at similar levels to the ones measured in open-loop testing. Furthermore, the MEMS-based oscillator retains excellent short-term frequency stability measures even though the micro resonator is driven into a complex nonlinear region. There is a 3.5X improvement in the short term frequency stability between the linear region and the nonlinear saturation region. These results show the potential of utilizing such amplitude clamping effects in micro-resonators to produce oscillator circuits where the AGC element can be implemented by the MEMS resonator itself. Such a passive implementation enables a simpler oscillator circuit topology and allows for lowering the power dissipation of such circuits.

Abstract— **GaN is an attractive material for the fabrication of various integrated devices combining several physical effects (semi-conductors, piezoelectric and optic parts, etc.). This work is dedicated to the investigation of GaN for the fabrication of surface acoustic wave oscillators. The first functional two-port resonators have been designed and built on 1.8 µm thick GaN epitaxial layers grown on (111) Silicon. An analysis of the obtained results has been achieved and a set of elastic constants has been fitted to meet the best possible agreement between theory and experiments. Comparison between experimental and theoretical transfer functions has been also exploited to refine the estimation of the wave characteristics. An oscillator has been finally built using the obtained resonators to assess the interest of this material for this kind of application and to prepare future development on this basis.**

Keywords- RF Oscillator; SAW Resonator; Epitaxial GaN; Silicon (111); Layered substrate

I. INTRODUCTION

SAW-resonator based oscillators are fabricated for embedded applications such as Radar and local oscillators for space missions requiring frequency transposition for telecommunications. Although rather compact, these discrete devices contribute to on-board charge and are currently poorly suited to co-integration. The possibility for providing ultimately compact sources able to operate on the same board than most radio-frequency circuits would yield a major advance for integrated time-frequency systems.

Previously on GaN, SAW transducers has already been demonstrated [1,2], as well as actuators and other resonant devices based on the 2-DEG [2-5]. In this paper, we focused the use of Gallium Nitride (GaN) on Silicon Si(111) epitaxial layers for the fabrication of SAW resonators with low losses and good resonance peak dynamic range, a prerequisite for the design of oscillators. Devices have been designed on a 1.8 µm thick GaN. Exploiting the analysis of the obtained results, a set of elastic constants has been fitted. Double-port SAW resonators have been designed and fabricated using this data base. Comparison between experimental and theoretical transfer functions has allowed for refining the estimation of the wave characteristics. An oscillator has been finally built using the obtained resonators to assess the interest of this material for this kind of application.

SAW resonators have been processed using E-beam lithography with a 2 µm period, yielding resonators operating near 1 GHz with Q factor close to 2000 and insertion losses better than 12 dB. Two port resonators were inserted in a feed-back loop oscillator based on a low-noise HX2400 amplifier, enabling short term measurements as well as phase noise extraction. A short term stability of 10^{-7} per second has been measured, clearly penalized by the temperature sensitivity of the SAW (about -30 ppm.K^{-1}). A phase noise figure of -115 dBc/Hz was found at 10 kHz from the carrier and a floor level of -165 dBc/Hz was finally measured. Although these figures are not the best achievable using this material, they are really promising as High Electron Mobility Transistors (HEMTs) are currently manufactured on the same substrate, allowing for future development of co-integrated SAW oscillators.

II. UPDATING THE WAVEGUIDE PROPERTIES

The first step of the presented development did consist in the fabrication of a single-port SAW resonator to adjust the physical constants representative of the substrate (and more particularly the GaN layer). The S_{11} response of the resonator was measured and compared to the predicted device response using a mixed matrix model. The simulation parameters then have been updated to refine the theoretical description of the guided mode properties on such a compound substrate. As shown by the comparison between Figure 1 and Figure 2, the theory/experiment agreement has been optimized considering the S_{11} base line (representative of the resistive losses and other sources of quasi-static damping), the phase velocity (across the resonance frequency), the stop band width (reflection coefficient on a single obstacle) and the magnitude of S_{11} (representative of propagation losses). Only the secondary lobes are poorly predicted from a spectral point of

view (which may be explained by the lack of knowledge of the actual layered substrate structure).

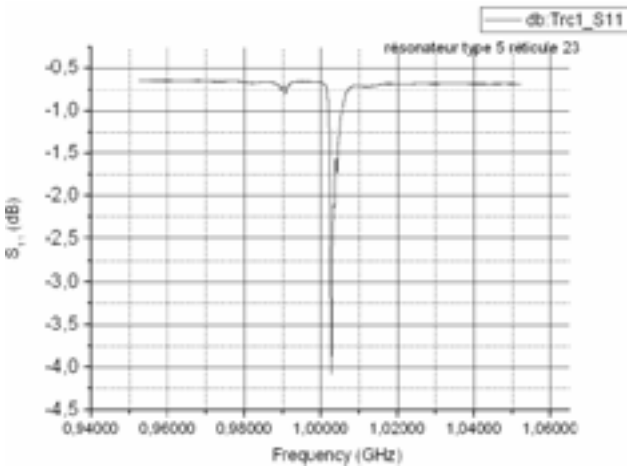

Figure 1 Experimental S_{11} response of the first single-port resonator built on the GaN/Si substrate

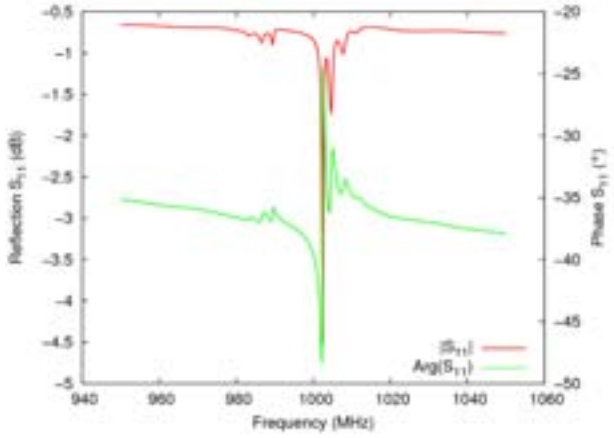

Figure 2 Theoretical prediction of the single-port resonator reflection coefficient S_{11} corresponding to the configuration of after model updating

The simulation of Figure 2 has been achieved considering material coefficients already used in **Error! Reference source not found.**. Some parameters however had to be updated to fit the experimental results of Figure 1. Particularly, the reflection coefficient on a single obstacle has been increased by 20% (yielding a value of 1.8%), the attenuation has been set to 7.5×10^{-3} dB/λ (initially equal to 10^{-3}), the conductance was significantly increased and the phase velocity adjusted to 4050 $m.s^{-1}$. Finally, a 20Ω contact resistance has been accounted for to fit the experimental base line and magnitude, which is a pretty high value that could be explained by the presence of the two dimensional electron gas (2DEG) near the SAW propagation region, or by residual conductivity at the material surface. These updated parameters did allow for a re-computation of the dispersion properties of the GaN/Si(111) waveguide as shown in . The main changes considering the initial predicted dispersion is the slight increase of velocity and decrease of coupling factor, the shape of the curve is kept identical. The use of a 1.8 µm GaN reveals optimal for promoting the coupling coefficient when operating at 1 GHz, allowing for values in excess of 0.2%. Therefore, the double-port resonator dedicated to the oscillator application has been fabricated considering this condition.

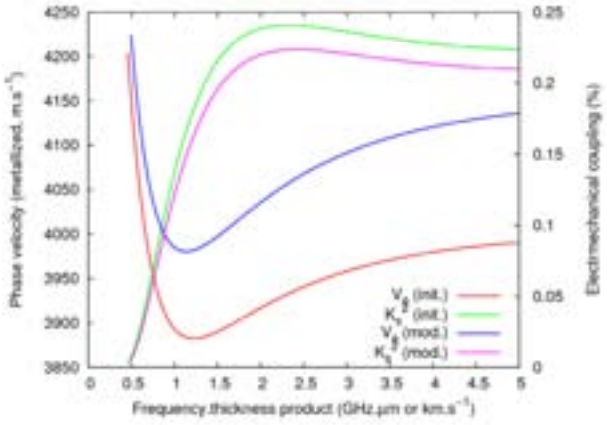

Figure 3 Dispersion curve of the Rayleigh-like wave propagating atop GaN/Si(111): phase velocity and coupling factor versus frequency-thickness product relative to the GaN – 1.8 µm thick GaN is optimal at 1 GHz for maximizing the coupling factor and at 2 GHz for frequency reproducibility

III. FABRICATION OF THE RESONATORS

The fabrication process starts from a GaN epitaxial layer grown by MOCVD on a (111) high resistivity silicon substrate. The structure is the standard one in HEMT processing, including a 1900 nm nucleation layer and buffer, followed by a 25nm Aluminum-Gallium Nitride (AlGaN) barrier. The first step consists in opening large areas in a positive optical resist that will include the whole SAW design. Then, the etching of the entire AlGaN barrier and of 100nm of GaN is performed using a Cl_2/BCl_3 plasma in order to remove the 2DEG and ensure enough electrical insulation under the transducers.

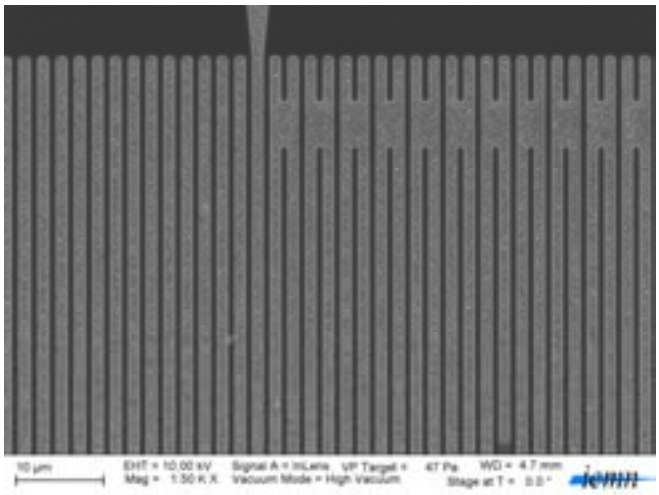

Figure 4 SEM view of a detail of the double-port resonator built on GaN/Si(111) - one can note Al residues after etching which pollute the device surface and hence may be a reason of the observed limited Q factors

As a second step, we deposited a 200 nm thick Al by evaporation. This layer was then patterned using e-beam lithography with PMMA resist in order to define the inter-digitated transducers as well as reflectors of the SAW resonator. Careful attention was paid to the proximity correction by taking information account the whole epitaxial stack and the design. Al was then etched using a Cl_2/BCl_3 plasma, followed by resist stripping in an O_2 plasma. The designed transfer function is shown in Figure 5 and the corresponding experimental measurements are reported in Figure 6 and Figure 7.

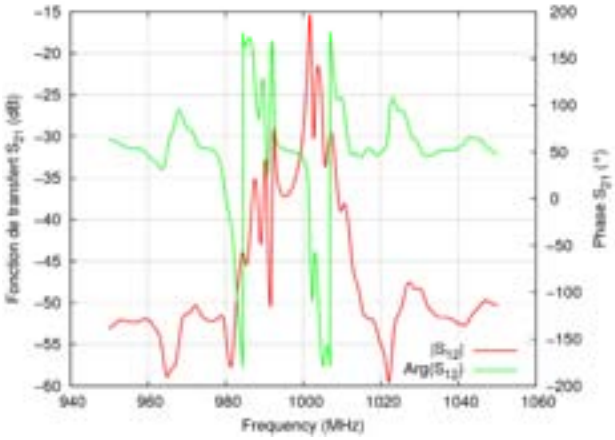

Figure 5 Transfer function of the double-port SAW resonator computed considering the updated parameter of section II

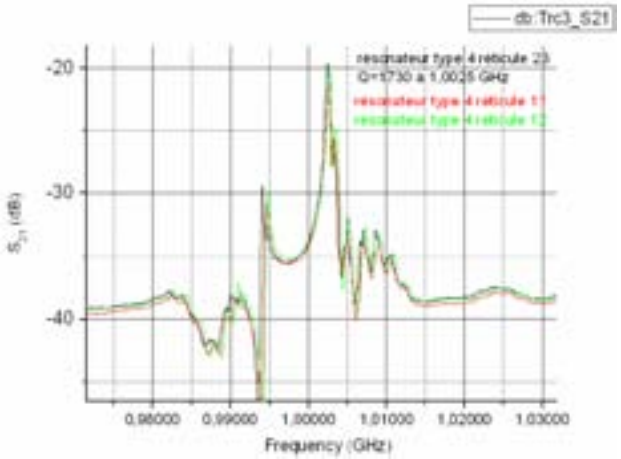

Figure 6 Experimental tranfer function of a first set of double-port resontaors with Insertion losses slightly below 20 dB and Q factor above 1700

Although the overall shape of the transfer function is correctly predicted (resonance at the end of the stop band near 1.002 GHz and a stop band width of about 8 MHz), the side lobes are not reliably predicted which tends to indicate that the structure operation has to be better understood. As shown, two sets of devices have been fabricated to provide resonators for the oscillator tests. The first devices exhibited insertion losses imposing two amplifier stages to reach a loop gain large enough to meet Barkhausen conditions. Therefore, a second run was managed to allow for improving the quality of the devices (mainly reducing surface pollution as shown in Figure 4), yielding a spectacular improvement of insertion loss with experimental values below 10 dB. In that later case, a single amplifier stage is enough to operate the oscillator.

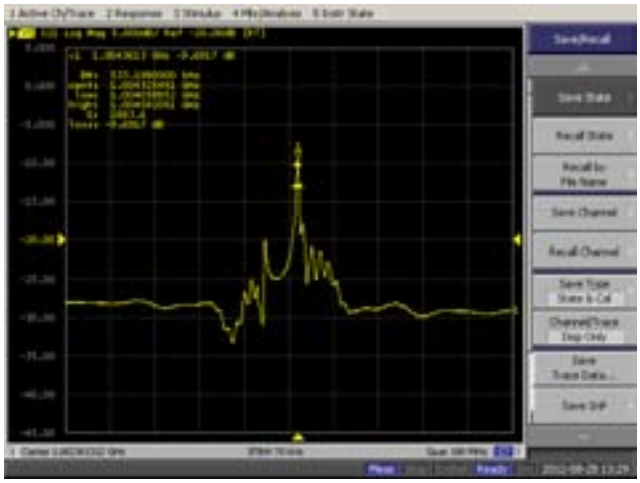

Figure 7 Experimental transfer function of the second set of double port resonators, with improve insertion losses and Q factor close to 1900

IV. Oscillator Fabrication and Characterization

As explained in Introduction, a feedback loop oscillator has been manufactured to allow for testing the quality of the developed GaN/Si resonator frequency stabilization. The resonators were encapsulated in a TO-8 package compatible with vacuum sealing and bonded onto a test board allowing for an easy implementation of the oscillator (in laboratory conditions, as shown in Figure 8). Although the resonator did actually filter the frequency efficiently, a SAW filter was added in the loop to suppress high frequency level feedback mainly introduced by the TO-8 package. Due to the fact that only small parts of GaN/Si were available and not suited to saw-dicing techniques, the use of such a package was inescapable.

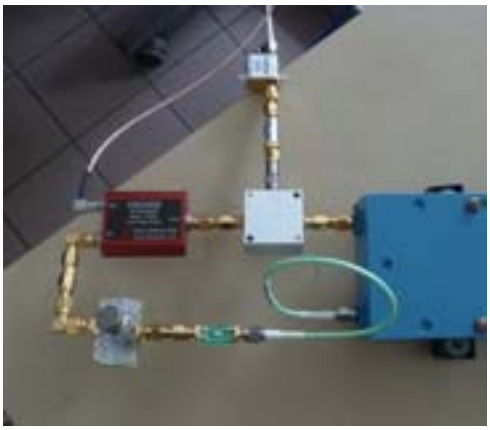

Figure 8 Experimental oscillator setup including the To-8 packaged resonator, a low noise HX2400 holtzworth integrated amplifier, a phase-shifter and a coupler allowing for collecting the signal to be characterized – a 1 GHz SAW filter is inserted to suppress high frequency level feedback

As already mentioned, a single stage of amplification was required using resonators exhibiting IL less than 10 dB. A low-noise HX2400 amplifier was then selected, enabling short term measurements as well as phase noise extraction. A short term stability of 10^{-7} per second has been measured, clearly penalized by the temperature sensitivity of the SAW (about -30 ppm.K^{-1}). Note that this stability was recently improved using a 500 MHz GaN/Si resonator stabilized oscillator, yielding a short term stability of 3.10^{-9} per second (Figure 9).

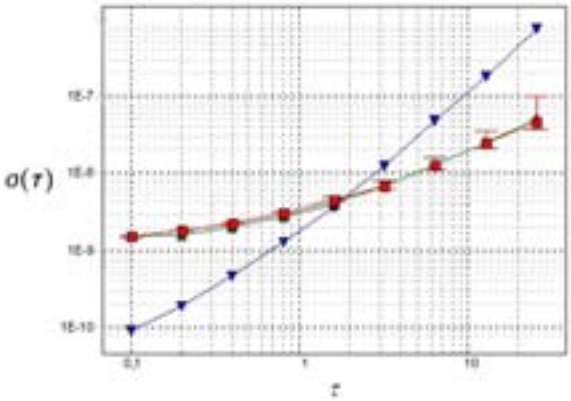

Figure 9 Short term stability of a 500 MHz oscillator stabilized with a GaN/Si SAW resonator based on a material composition similar to the 1GHz device

A phase noise figure of -115 dBc/Hz was found at 10 kHz from the carrier and a floor level of -165 dBc/Hz was finally measured. One can note that the phase noise level passes below -160 dBc/Hz at 500 kHz from the carrier. It is clear that any possibilities to improve the Q factor of the resonator will impact this figure of merit. It has been shown in the paper that routes can be followed in that purpose, by improving the device overall quality but also by a better understanding of its operation, allowing for an optimized design of the SAW device and an improved

VI Conclusion

In this paper, we have shown the possibility to stabilized a feedback loop oscillator with double port SAW resonators built using E-beam lithography on epitaxial GaN grown on (111) Silicon. The devices have been analyzed to try and optimized the next generation of resonators built on such substrates. Although the first results are not meeting the state-of-the-art characteristics of SAW resonators on single crystal, the quality was good enough to obtain phase noise figure better than -160 dBc/Hz at 1 MHz from the carrier. Several tracks are currently considered to improve the Q factor of the resonator and hence this figure of merit.

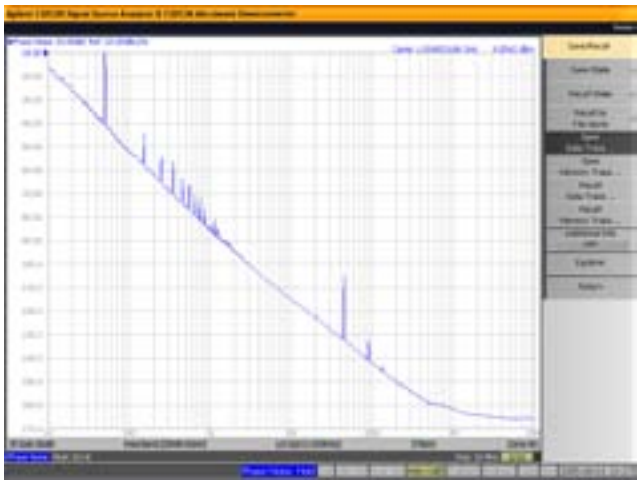

Figure 10 Phase noise of the 1 GHz oscillator of with a noise floor in the vicinity of -165dBc/Hz at 1 MHz from the carrier

The results demonstrate that a GaN-based SAW can be fabricated with acceptable performances on a wafer where the 2DEG can be kept at chosen areas and removed under the SAW. This allows preserving the epitaxial wafer surface for the definition of ohmic contacts and gates. As a consequence, simple process flows can be envisaged in order to co-integrate an amplifier, the next step toward monolithic oscillators.

***Abstract*—We study both theoretically and experimentally an RF photonic frequency source featuring low phase noise, low power consumption, compact size, and wideband tunability. Performance parameters of the oscillator are superior to existing tunable electronic oscillators and synthesizers operating in the 2-35 GHz band, with the close-in phase noise at least 20 dB lower than what is currently achieved with free running tunable RF oscillators.**

***Index Terms*—Optical whispering gallery mode resonator, opto-electronic oscillator, phase noise, voltage controlled oscillator**

I. Introduction

Conventional approaches serving multioctave electronic devices typically employ several fixed frequency sources along with phase lock loops (PLLs) to cover the entire spectral range. This approach is complex and results in limited spectral purity of the generated signal, and leads to an overall increase in the size weight and power (SWaP). For example, existing electronic phase locked dielectric resonator oscillators (PLDROs) are on the order of 2x2.5 inch in footprint with 1–2 Watts of DC power consumption. These devices do not have multi-octave tunability. Their phase noise degrades at high RF frequencies because of reduction of the quality factor of the dielectric resonator. These oscillators also have high acceleration sensitivity. In this paper we describe a novel photonic oscillator based on optical whispering gallery mode (WGM) microresonator that removes all the mentioned PLDRO shortfalls. A major feature of the proposed oscillator architecture is the inherently low acceleration sensitivity, a parameter of significance for all mobile platforms. The successful fabrication of the device supports the development of novel ultra-wideband receivers for communications and radar. The oscillators are also suitable for radar and communication systems supporting small platforms, such as Unmanned Vehicle Systems.

II. Schematic of the Oscillator

The oscillator described below takes advantage of the technology of opto-electronic oscillator (OEO). The OEO is based on an opto-electronic feedback loop that directly converts light energy to spectrally pure microwave or RF oscillation, and has been described in detail in the literature. The oscillator is driven with a continuous wave laser that acts as the source of energy. An important feature of the OEO architecture is that the phase noise does not degrade with increasing oscillation frequency, in contrast to electronic oscillators.

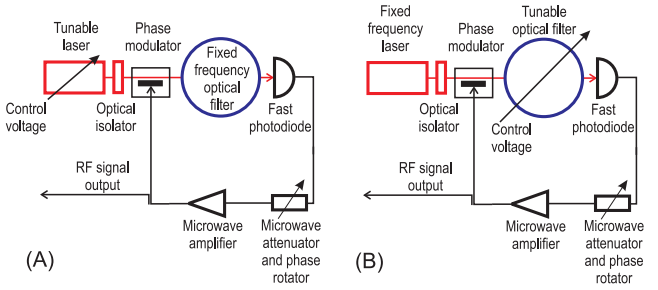

Fig. 1. Schematic of the tunable opto-electronic oscillator. (A) Tunability is achieved due to tunability of the laser frequency. (B) Tunability is achieved due to tunability of the optical resonator frequency. The resonator can be tuned much faster than the laser.

The novel tunable OEO configuration described here is shown in Fig. 1a. Light from an agile tunable semiconductor laser is fed into a broadband phase modulator, then to an ultra-high-Q optical microresonator, and then to a fast photodiode, to produce an electric signal. The signal from the photodiode is amplified before being fed back to the phase modulator to complete the OEO loop. Self-sustained oscillation starts when amplification in this feedback loop exceeds the loss. The narrow optical bandwidth of the resonator (less than 10 kHz) provides the filter function required for the loop. The change in the laser frequency provides the tunability of the oscillator. The spectral purity depends on the Q of the circuit ensured by the optical microresonator. This configuration eliminates supermodes in the noise spectra associated with fiber OEOs.

The device does not require the laser light to pass through the ultra-high-Q optical resonator, as was required in all previous implementations of resonator-based OEOs. Only one modulation sideband passes the resonator mode. Aside from simplification of the architecture, this feature allows improving the linearity of the optical part of the opto-electronic loop. Moreover, it allows reducing the resonator size leading to reduction of the vibration sensitivity of the system. It was noted previously that a phase modulator can be used in a microresonator-based OEO loop [1]; however the realization that the free spectral range of the resonator can significantly exceed the oscillation frequency, if the oscillator configuration shown in Fig. 1 is utilized, is novel.

It was also shown previously that tunable OEOs can be realized using an optical phase modulator and a phase-shifted

fiber Bragg grating (PS-FBG) [2]. The tunability is achieved using a tunable laser source in the OEO loop. The system described here is novel in the sense that it involves a high-Q microresonator that has narrower bandwidth and lower acceleration sensitivity compared to the Bragg grating. It is possible to reduce the phase noise of the OEO due to narrow bandwidth of the resonator modes; while a stable passively mode-locked fiber laser was used to stabilize the OEO in [2]. In addition, agile tunability of the microresonator-based OEO can be achieved by tuning the frequency of the microresonator-based filter, Fig. 1b, if the microresonator is made of an electro-optical material.

The oscillator can be locked to an external frequency reference using a standard PLL. The same loop can be used to tune the oscillator to a desirable frequency Fig. 2. The tuning speed and phase noise of such an oscillator depends upon the bandwidth of the PLL loop. If the bandwidth exceeds 1 MHz, the oscillator will tune to a desired frequency in less than a microsecond. However, within the locking bandwidth, its phase noise will be limited to the phase noise of the PLL oscillator. To achieve the intrinsic low phase noise performance of the oscillator, the bandwidth of the PLL should be much narrower, e.g. 100 Hz. Such a bandwidth will restrict the settling time for the low phase noise of the device to 10 ms.

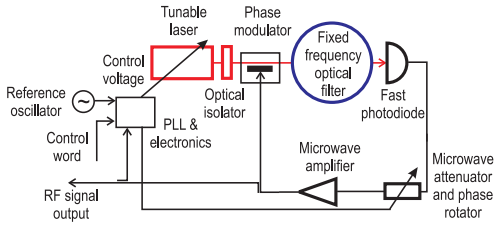

Fig. 2. A phase lock configuration for the tunable opto-electronic oscillator.

A major feature of the oscillator is that the packaged device will have extremely low acceleration sensitivity. The acceleration sensitivity of high performance microwave oscillators primarily results from coupling of vibration disturbances to the high-Q element of the device. The acceleration coupling is increased by resonances corresponding to the actual size of the cavity, which typically range from one to a few inches. This effect severely degrades the performance of the oscillator and diminishes its usefulness. The only remedy currently available is to isolate the oscillator from sources of vibration, which adds to the size and complexity, and reduces the range of applications of high performance microwave oscillators to the laboratory environment. By contrast, crystalline WGM microresonators have mm-scale dimensions, very high mechanical frequencies, and high mechanical Q and, thus, experience a small acceleration for a given applied force. Previous studies indicate that with microresonators the acceleration sensitivity along the resonator plane (x-y plane) is less than 10^{-12}/g, and is basically negligible. In the z-direction, the acceleration sensitivity of a 25-micron thick WGM resonator was calculated to be in range of 10^{-12}/g.

A feature of the WGM resonator is that light is coupled in via the evanescent wave. Fixing the amount of light coupling in a vibration environment can appear a major challenge for the stability of the oscillator, it has, however, been demonstrated that the proposed design for the widely tunable OEO architecture is highly stable in frequency below the level of 10^{-11}/g. This is significantly smaller than the acceleration sensitivity of synthesizers and PLLs used for generation of microwave signals over frequency bands much smaller than the target of the present task.

Finally, an advantage of the proposed oscillator is that its operational frequency can, fundamentally, reach W-band and higher without degradation of the spectral purity of the generated signal. This happens because the quality factor of the oscillator feedback loop does not degrade with the oscillation frequency.

III. Theory

The use of phase modulators in OEOs is unusual since phase modulated light does not produce RF signal on a photodiode. The OEO described here oscillates since the WGM resonator transforms phase modulation to amplitude modulation. In what follows we show that the transformation occurs because of both microresonator-based phase rotation and absorption of the light. Surprisingly, the absorption is not essential here. The microresonator can be overloaded significantly to operate as lossless reflective filter and still enable OEO operation.

Let us consider an OEO shown in Fig. (2). Light emitted by a tunable laser is phase modulated, filtered with a fixed frequency optical filter, and demodulated on a fast photodiode. The photocurrent is phase shifted, amplified, and fed back to the phase modulator. The basic idea of the device operation is that the change of the laser frequency with respect to the frequency of the optical filter results in tuning of the RF transfer function of the opto-electronic loop.

An amplitude transfer function of a fixed frequency optical resonator is

$$F(\omega) = \frac{E_{out}}{E_{in}} = \frac{\gamma_1 - \gamma_2 + i(\omega_0 - \omega)}{\gamma_1 + \gamma_2 + i(\omega_0 - \omega)}, \qquad (1)$$

where ω is the spectral frequency, ω_0 is the frequency of the resonance, E_{in} and E_{out} are the complex amplitudes of the electric field of the input and output light waves, γ_1 and γ_2 are the parameters of the resonance determining the contrast, $1 \geq C \geq 0$, $C = 1 - (|E_{out}|^2/|E_{in}|^2)|_{\omega=\omega_0} = 4\gamma_1\gamma_2/(\gamma_1 + \gamma_2)^2$, and bandwidth $\Gamma = \gamma_1 + \gamma_2$ of the resonance. It is worth noting, that the model describes a WGM resonator with a single coupler, if γ_1 is the intrinsic and γ_2 is the loading-related bandwidths. In the case of significant overloading of the resonator mode, $\gamma_2 \gg \gamma_1$, the contrast of the resonance is nearly zero, $C \to 0$, while phase shift introduced by the mode is not zero.

Let us assume that the input light is both amplitude and phase modulated and that the modulation depth is small, so

the amplitude of the electric field can be presented as

$$E_{in} = E_0\left(1 + a\cos\Omega t\right)e^{-i(\omega t + b\sin\Omega t)} \approx \quad (2)$$
$$E_0 e^{-i\omega t}\left[1 + \left(\frac{a}{2} - \frac{b}{2}\right)e^{i\Omega t} + \left(\frac{a}{2} + \frac{b}{2}\right)e^{-i\Omega t}\right],$$

where a and b are the amplitude and phase modulation coefficients, respectively.

For the amplitude of the light exiting the resonator we find

$$E_{out} = E_0 e^{-i\omega t}\left[F(\omega) + \left(\frac{a}{2} - \frac{b}{2}\right)F(\omega-\Omega)e^{i\Omega t} + \left(\frac{a}{2} + \frac{b}{2}\right)F(\omega+\Omega)e^{-i\Omega t}\right]. \quad (3)$$

The modulated light is sent to a photodiode with resistance ρ and responsivity R, so the photocurrent i_{PD} is equal to $i_{PD} = RP_{out}$, where P_{out} is the optical power at the photodiode (PD). We are interested in the first modulation harmonic of the exiting power (other harmonics are present as well). The photo current is given by

$$\left.\frac{i_{PD}}{RP_0}\right|_{\exp(\pm i\Omega t)} = \frac{1}{2}\left[(a-b)F(\omega)F^*(\omega-\Omega) + (a+b)F^*(\omega)F(\omega+\Omega)\right]e^{-i\Omega t} + c.c. \quad (4)$$

The power of the RF signal from the PD is

$$P_{RF} = \frac{1}{4}\rho R^2 P_0^2\left|(a-b)F(\omega)F^*(\omega-\Omega) + (a+b)F^*(\omega)F(\omega+\Omega)\right|^2 \quad (5)$$

Therefore, the corresponding normalized RF transfer function is given by

$$G_{ph} = \left|F(\omega)F^*(\omega-\Omega) - F^*(\omega)F(\omega+\Omega)\right|^2, \quad (6)$$
$$G_a = \left|F(\omega)F^*(\omega-\Omega) + F^*(\omega)F(\omega+\Omega)\right|^2. \quad (7)$$

for the cases of pure phase and amplitude modulation, respectively. Function G_a always has a minimum at $\Omega = \pm(\omega_0 - \omega)$, so the amplitude modulation is not suitable for the OEO operation. Spectral dependence of G_{ph} on the modulation frequency Ω is shown in Fig. 3.

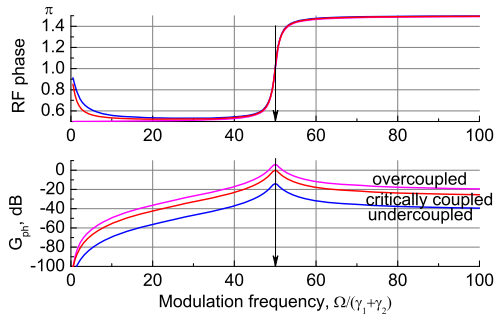

Fig. 3. RF power transfer function and phase shift found using Eq. (6) for various parameters of the resonator. Overcoupled regime corresponds to $\gamma_1 = 0.1$ and $\gamma_2 = 0.9$; undercoupled – $\gamma_1 = 0.9$ and $\gamma_2 = 0.1$; and critically coupled – $\gamma_1 = 0.5$ and $\gamma_2 = 0.5$.

The maximal RF transfer occurs in the case of the overcoupled resonator, when the modulation sidebands are not absorbed. Therefore, the absorption of a modulation sideband does not play any role in the device operation. The RF frequency of the maximum transmission is equal to the frequency detuning between the laser frequency and the frequency of the resonator mode. It means that all slow drifts of the laser frequency will be imprinted at the RF signal. A stable laser is needed to achieve good RF phase noise at low offsets. The modulation sidebands enter the filter, while the carrier does not. This process determines the spectral width of the RF transfer function.

The performance of the oscillator can be improved if one uses an optical fiber delay line along with the resonator. A complex optical transfer function of the resonator with a single optical coupler and the fiber delay line is

$$F(\omega) = \frac{\gamma_1 - \gamma_2 + i(\omega_0 - \omega)}{\gamma_1 + \gamma_2 + i(\omega_0 - \omega)}e^{i\omega\tau}, \quad (8)$$

where τ is the fiber delay time.

The amplitude of the electric field after the phase modulator is

$$E_{in} \simeq E_0 e^{-i\omega t}\left[1 - \frac{b}{2}e^{i\Omega t} + \frac{b}{2}e^{-i\Omega t}\right], \quad (9)$$

where b is the (small) phase modulation coefficient, E_0 is the complex amplitude of the input light, and Ω is the yet unknown RF oscillation frequency. It is easy to find from Eq. (8) and Eq. (9) that the normalized frequency transfer function of the RF photonic loop is

$$H(\Omega) \simeq \frac{\gamma_1 + \gamma_2}{\gamma_1 + \gamma_2 - i(\Omega - \omega_0 + \omega)}e^{i\Omega\tau}. \quad (10)$$

The oscillation frequency is given by

$$\arg[H(\Omega)] = -\psi_0, \quad (11)$$

where ψ_0 is the RF phase shift introduced by the electronic part of the loop. Assuming

$$\Omega\tau = (\Omega - \Omega_f)\tau + 2\pi N, \quad (12)$$

where N is integer, $\Omega_f\tau = 2\pi N$, $(\Omega - \Omega_f)\tau < 2\pi$, $\gamma_1 + \gamma_2 \gg |\Omega - \omega_0 + \omega|$, and $\psi_0 = 0$, we arrive at the conventional frequency puling condition for the oscillation frequency

$$\Omega_0 = \frac{\omega_0 - \omega}{1 + \tau(\gamma_1 + \gamma_2)} + \frac{\Omega_f\tau(\gamma_1 + \gamma_2)}{1 + \tau(\gamma_1 + \gamma_2)}. \quad (13)$$

The oscillator can be continuously tuned by changing the frequency of the microresonator without a fiber delay line in the loop. The tuning is also possible if a fiber delay line is introduced. However, the addition of the delay line requires tuning not only the microresonator optical filter, but also the RF phase shifter. Without a phase shifter the oscillator can be tuned quasi-continuously by hopping from one frequency to another as determined by the delay of the fiber link.

The phase noise of the oscillator is found from

$$\mathcal{L}(f) = \left|\frac{1}{1-H(\Omega_0+2\pi f)}\right|^2 \left[\frac{2q\mathcal{R}P\rho + Fk_BT}{P_{RF}} + \frac{\kappa}{f} + \frac{(2\pi f)^2}{(\gamma_1+\gamma_2)^2+(2\pi f)^2}(\mathcal{L}_{laser}+\mathcal{L}_{WGMR})\right]. \quad (14)$$

where P_{RF} is the demodulated averaged RF power at the photodiode output, q is the charge of an electron, $\mathcal{R}$ is the responsivity of the photodiode, ρ is the resistance of the photodiode, P is the overall DC optical power at the photodiode, F is the noise factor of the amplifiers placed after the oscillator, k_B is Boltzmann constant, T is the ambient temperature, κ is the flicker noise parameter, $\mathcal{L}_{laser}$ and $\mathcal{L}_{WGMR}$ are the phase noise values for the laser and the WGMR, respectively. Phase noise $\mathcal{L}_{WGMR}$ results from interaction of the resonator with the environment as well as with the voltage source used for TOEO tuning. Both the laser and resonator phase noise penetrate to the oscillator phase noise due to strong dispersion introduced by the WGM the modulation sideband interacts with.

The phase noise of the generated RF signal includes thermal noise, shot noise, and flicker noise on one hand, and by the phase noise of the laser as well as the microresonator, on the other. Without the microresonator the laser phase noise is cancelled at the photodiode since both the carrier and the modulation sidebands equally depend on the noise. The resonator de-correlates the noise in a modulation sideband resulting in increase of the noise of the generated RF signal. The phase noise of the laser determines the phase noise of the TOEO if there is no fiber loop. Introduction of the fiber loop results in suppression of the overall phase noise.

IV. Experiment

We assembled the OEO shown in Fig. 1b. The measured transfer function of the open OEO loop (proportional to G_{ph}) is shown in Fig. 4a. The measured RF signal of the oscillating OEO is shown in Fig. 4b.

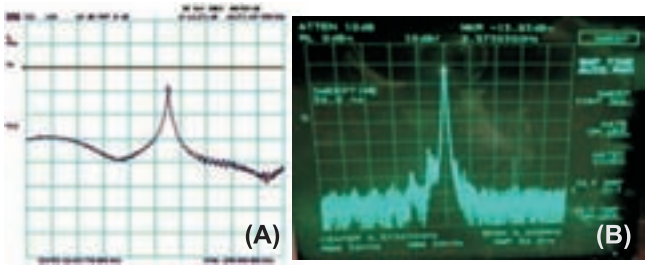

Fig. 4. (A) Transfer function of the open OEO loop as seen at the screen of network analyzer. (B) RF spectrum of the operating OEO as seen at the screen of RF spectrum analyzer.

We used a Koheras Adjustik laser operating at 1549.75 nm with output power of 9.4 mW to pump the oscillator; a phase EOM (EOspace, 16 GHz 3dB bandwidth); a 40 GHz u2t photodiode; a Hittite RF amplifier; and 220 m of SMF-28 optical fiber. These components were mounted on an optical breadboard for demonstration of the TOEO operation and for its characterization.

The tunable optical filter was based on a packaged lithium tantalate WGMR. The resonator was fabricated by mechanical polishing of a cylindrical Z-cut $LiTaO_3$ preform. It had 650 μm in diameter and 100 μm in thickness (69.62 GHz FSR). The unloaded bandwidth was around 1 MHz, the loaded bandwidth was 11 MHz. Modes with horizontal polarization were exited by the laser, and the mode contrast was at about 90-95%. The resonator was packaged with a TEC and a thermistor and pigtailed with PM fibers. Two optical isolators (one at the input and one at the output of the resonator) were also installed. The resonator pads were traced and wire-bonded to a K connector on the package. The microresonator had gold electrodes mounted on its top and bottom surfaces. The frequency tuning was achieved by applying DC voltage to the electrodes.

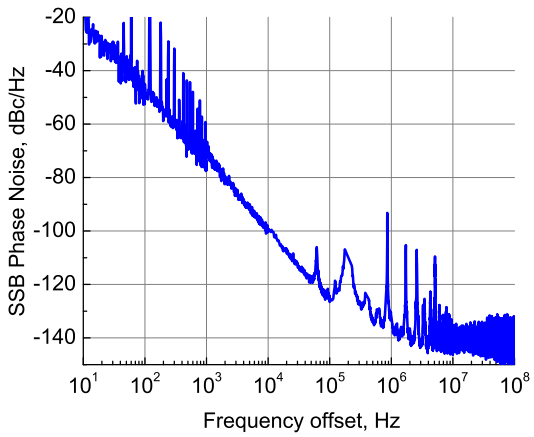

Fig. 5. Measured single sideband phase noise of the TOEO with 220 m of single mode fiber link added between the resonator and the photodiode (offset from 8.44 GHz).

We studied the phase noise of the oscillator (Fig. 5) with an OEwaves phase noise measurement system. As expected, the phase noise was determined by the phase noise of the pump laser. The contribution of the high frequency phase noise resulting from the resonator is estimated to be negligible compared with the contribution from the laser noise.

V. Conclusion

We have introduced and studied a novel tunable opto-electronic oscillator based on a high-Q optical microresonator and a phase modulator.

***Abstract*—We report on the realization of a packaged RF photonic oscillator based on Kerr optical frequency comb generated in an ultra-high Q crystalline whispering gallery mode (WGM) resonator. The oscillator produces spectrally pure RF signals in K_a frequency band, characterized with single sideband phase noise of -110 dBc/Hz at 10 kHz. The stability of the free running oscillator is characterized with Allan deviation of 10^{-10} at 1 s. We also argue that usage of hyperparametric gain based on cubic nonlinearity of the host material of an optical microresonator as part of an Opto-Electronic Oscillator (OEO) loop allows achieving generation of low noise RF signals in microrezonator-based OEOs.**

***Index Terms*—Optical whispering gallery mode resonator, opto-electronic oscillator, phase noise**

I. Introduction

An Opto-Electronic Oscillator (OEO) [1], [2] is used to produce low noise RF signals by optical means. A conventional OEO includes a laser, an electro-optical modulator (EOM), one or multiple optical delay lines, a fast photodiode, an RF filter, and an RF amplifier. The continuous wave (cw) light of the laser is modulated by the EOM. The modulated signal passes the optical delay line(s) and is transformed to an RF signal with the photodiode. The RF signal is filtered, amplified and fed back to the modulator. As a result, a closed RF circuit is created. The oscillation starts when the RF amplification exceeds the integral loss in the circuit. Some elements of the circuit can be merged or replaced, e.g. a directly modulatable laser can be used, and an optical bandpass filter can be utilized instead of the RF filter.

An OEO has an advantage over electronic oscillators due to the optical delay line which becomes an effective ultra-narrow-band filter for the RF signal. The Leeson frequency [3] of the OEO, determined by the length of the delay line, can be very small, at a level that is unattainable in conventional microwave and mm-wave frequency RF oscillators. As a result, an OEO can produce high frequency RF signals with extremely low phase noise. For instance, an OEO generating a stable 10 GHz signal with phase noise of -163 dBc/Hz at 6 kHz offset from the carrier was demonstrated [4].

The long optical delay line used in the fiber-based OEOs results in peaks in the power spectral density of phase noise of the oscillator. The peaks appear at frequencies corresponding to the free spectral range of the opto-electronic loop. This is an undesirable feature in certain applications where the phase noise noise at higher Fourier frequencies can fold back to increase the noise at lower frequencies. The use of the long fiber also restricts the reduction in the size of the packaged oscillator and requires isolation from the external environment. A high-Q optical resonator or an atomic transition instead of the fiber delay line can be used to eliminate these undesirable features [5]. The application of high-Q optical resonators adds value to the system if resonators are not only used for buffering the RF signal and cleaning the supermode spectrum, but also to replace the EOM. Electro-optic modulators based on high-

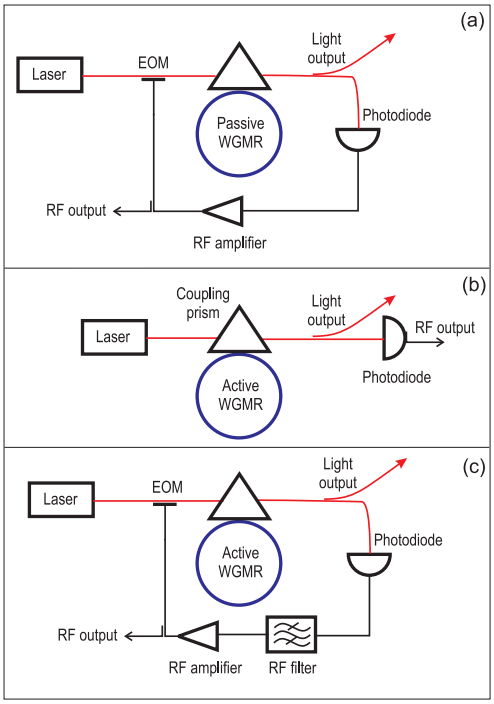

Fig. 1. Possible schemes of opto-electronic oscillators based on microresonators. Here EOM stands for electro-optical modulator, and WGMR – for a whispering gallery mode resonator.(a) A scheme of conventional microresonator-based OEO. The microresonator works as an energy storage element and RF filter. The oscillation occurs at the frequency proportional to the free spectral range (FSR) of the resonator. (b) A scheme of a self-oscillating microresonator-based OEO, e.g. a hyper-parametric RF photonic oscillator or Kerr frequency comb based RF photonic oscillator. The resonator is pumped with continuous wave light. Optical harmonics are generated in the microresonator due to a nonlinear optical process, e.g. four-wave mixing. The oscillation occurs at the frequencies proportional to the resonator FSR. (c) A schematic of the Kerr comb based oscillator. Both nonlinearity of the resonator and an electronic loop are involved.

Q crystalline whispering gallery mode (WGM) resonators combine all the above mentioned functions making an extra-compact OEO feasible [6]. Moreover, the resonant tunable single sideband (SSB) modulator [7] makes fabrication of tunable, compact OEOs possible [8].

It is known that Coupled Opto-Electronic Oscillators (COEO) allow achieving phase noise much lower compared with phase noise of conventional OEOs having the same length of optical fiber involved [9]–[13]. A COEO is a regenerative device that involves both optical and RF gain (active optical and RF loop), while OEO has a passive optical loop and active RF loop. The COEO is more efficient since its effective RF quality (Q-) factor depends on the width of the optical spectrum generated in the active optical loop and is much larger compared with the effective Q-factor of the passive optical fiber loop of the same length usually used in an OEO.

It was shown recently that RF photonic oscillators can be created without usage of an RF feedback loop. These oscillators are based on nonlinear processes within the optical microresonator. Examples include a hyper-parametric [14] as well as Kerr frequency comb [15] based RF photonic oscillators [16], a mode-locked (Raman) laser [17], an opto-mechanical oscillator [18]–[21], a strongly-nondegenerate RF-optical parametric oscillator [22], etc. The devices generate optical harmonics with frequencies slightly different from the frequency of the optical pump taking energy from the optical pump. No RF amplification is involved. The demodulated optical signal becomes a source of stable RF signal.

The optical hyper-parametric oscillator as well as a Kerr frequency comb generator is a product of cubic optical nonlinearity of the material of which the resonator is made, and is generated by pumping one of the resonator modes with a continuous wave coherent light. Kerr frequency comb generation is a unitary process, and can occur in a resonator where the only losses are related to coupling to the external world. In such a case the repetition frequency of the comb does not depend on either frequency or power of the pump light, and the comb becomes an ideal oscillator that does not require any stabilization. The phase noise of the repetition rate of such a comb is given by Leeson formula with oscillator bandwidth coinciding with the bandwidth of the optical modes of the nonlinear resonator and the phase noise has only f^{-2} and f^{0} spectral frequency components.

In practice, contact of the resonator with the environment as well as finite absorption in the resonator host material spoils the stability conditions, and the repetition rate of the comb becomes dependent on parameters of the pump light. We demonstrate a packaged Kerr frequency comb based oscillator producing spectrally pure RF signals in K_a frequency band, characterized with single sideband phase noise of -110 dBc/Hz at 10 kHz. The stability of the free running oscillator is characterized with Allan deviation of 10^{-10} at 1 s. This kind of performance is one of the best ever demonstrated with small volume K_a band oscillators, however the measured noise is much larger than one would expect in an ideal system.

To regain the stability, locking the laser to the resonator mode becomes necessary. An important feature of the Kerr comb is that it is enough to stabilize only a single point in its frequency spectrum to obtain its stable operation. Since the frequency of one comb line coincides with the frequency of the pump laser, and the comb repetition rate is fixed by the properties of the monolithic resonator generating the comb, the entire Kerr comb is stabilized once the frequency of the pump laser is stabilized to an external reference. There is no need to generate an octave spanning Kerr comb to stabilize it. We discuss our progress in experimental realization of the frequency stabilization scheme.

We also show theoretically that usage of optical hyper-parametric gain based on cubic optical nonlinearity of the nonlinear optical microresonator being a part of an Opto-Electronic Oscillator (OEO) loop allows achieving generation of low noise RF signals in microrezonator-based OEOs. Spectral purity of those signals is better compared with the spectral purity of signals generated in similar RF photonic oscillators that have linear optical microrezonators in their loops (Fig. 1a); and, spectral purity of the Kerr frequency comb based RF photonic oscillators based on the self-oscillating nonlinear optical microresonators (Fig. 1b). We suggest a scheme of the RF photonic oscillators relying on the active optical microresonators (Fig. 1c) and explain its principle of operation.

II. Phase Noise of a Packaged K_a-band RF Photonic Oscillator

We fabricated and studied a free running K_a Kerr comb RF photonic oscillator. We fabricated a WGM resonator with 35 GHz free spectral range (FSR) from a commercially available z-cut MgF_2 optical window and pumped the resonator with light from a 1550 nm distributed feedback (DFB) laser. The Kerr comb generation was observed when the cw pump power exceeded 0.1 mW. We pumped the resonator with 5 mW of light and collected 2.8 mW of light exiting the resonator on a fast photodiode characterized with responsivity of 0.55 A/W. The comb generated a 35 GHz RF signal with -22 dBm power at the output of the photodiode.

We used an Agilent signal analyzer and a 40 GHz frequency counter, both locked to a reference Rb clock, to measure the Allan deviation of the K_a-band signal. In addition, we used an OEwaves phase noise measurement system to measure phase noise of the RF signal generated by the comb oscillator. The resultant phase noise and Allan deviation are shown in Fig. (2a) and (2b), respectively.

Theoretically, the shot noise limited floor of the single sideband phase noise is given by equation

$$\mathcal{L}(f) = \frac{2q\rho_{pd}\mathcal{R}P + Fk_BT}{2P_{RF}}\left[1 + \left(\frac{\delta\nu_{S21}}{2f}\right)^2\right], \qquad (1)$$

where P is the optical DC power absorbed at the photodiode, P_{RF} is the demodulated RF power at the photodiode, q is the charge of an electron, F is the integral noise figure of the photodiode and RF amplifier inserted after the photodiode, k_B is the Boltzmann constant, T is the room temperature,

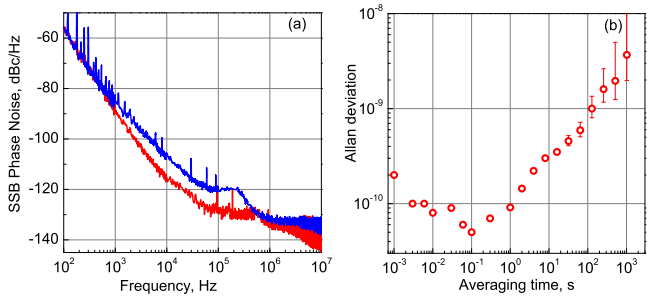

Fig. 2. Characteristics of a free running Kerr comb. Single sideband (SSB) phase noise, (a), of the 35 GHz RF signals generated by free running optical Kerr frequency combs on a fast photodiode. The blue curve is taken using $x4$ frequency divider and OEwaves phase noise test system. The red curve is taken by the measurement of the frequency beat between two nearly identical comb oscillators. The Allan deviation for the 35 GHz comb is shown in panel (b). The WGM resonator temperature is stabilized using a thermistor and a TEC.

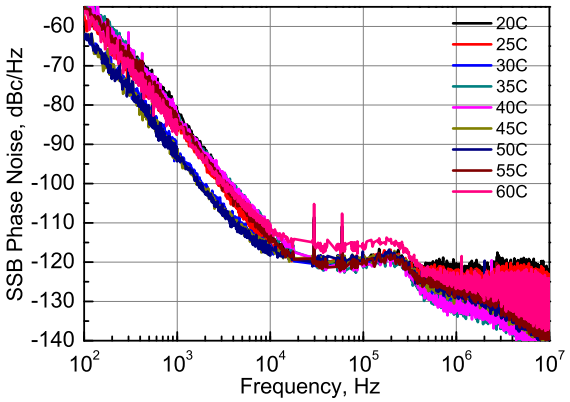

Fig. 3. Characteristics of a free running Kerr comb at different temperatures of the oscillator package. Single sideband (SSB) phase noise of the 35 GHz RF signals generated by free running optical Kerr frequency comb on a fast photodiode. The WGM resonator temperature is stabilized using a thermistor and a TEC.

$\delta\nu_{S21}$ is the full width at the half maximum (FWHM) of the S_{21} of the photonic system (usually coinciding with the FWHM of the mode), and f is the linear spectral frequency. Assuming that $\rho_{pd} = 50$ Ohm, $\mathcal{R} = 0.55$ A/W, $P \approx 5$ mW, $P_{RF} \approx 6$ μW, $F = 3$, $T = 295$ K, and $\delta\nu_{S21} = 10^5$ Hz we find $\mathcal{L}$(f=10 kHz)$\simeq -124$ dBc/Hz. The noise floor approaches -144 dBc/Hz. This is more than 10 dB smaller compared with the observed noise. The difference can result from additional noise introduced by the pump laser.

We also measured thermal dependence of the oscillator phase noise. The temperature of the oscillator package was varied from 20^{o}C to 60^{o}C. Change of the phase noise is shown in Fig. (3). In accordance with the measurement, the phase noise stays below -110 dBc/Hz at 10 kHz for the entire frequency range.

III. Correlation between carrier frequency and repetition rate of the Kerr comb oscillator

We studied the behavior of a free running Kerr frequency comb oscillator to illustrate the correlations between frequency

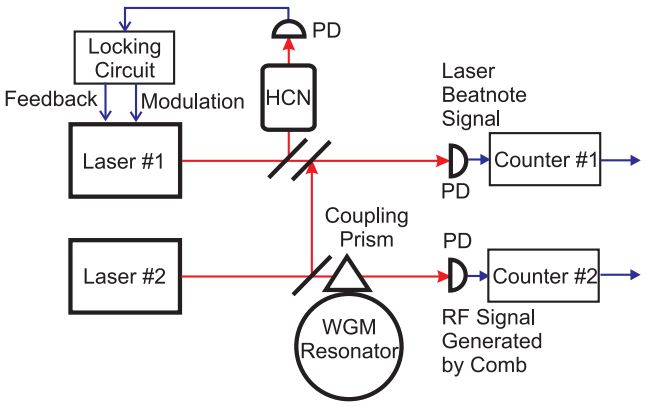

Fig. 4. Schematic of the experimental setup used to observe correlation between the drift of the optical comb harmonics and the Kerr comb repetition rate. The comb repetition rate is measured directly via the RF signal generated at the output of a fast photodiode (PD). A separate laser locked to an HCN transition using PDH technique is utilized to measure the optical frequency. The beat frequency between two lasers is set to be approximately 50 MHz.

of the optical pump locked to a mode of a nonlinear resonator and comb repetition rate. The measurement setup is shown in Fig. (4). This correlation enables the stabilization method of the comb suggested above: it is enough to stabilize only a single point in its frequency spectrum to obtain stable clock operation. The second stabilization point corresponds to locking of the laser to the mode of the resonator. In this system the frequency of one comb line coincides with the frequency of the pump laser, while the comb repetition rate is fixed by the properties of the monolithic resonator generating the comb. Thus, the entire Kerr comb is stabilized once the frequency of the pump laser is stabilized to an external reference and the same time locked to a mode of the resonator; there is no need to generate an octave spanning Kerr comb to stabilize it. In this respect, it is in principle enough to have only two harmonics in the comb (a.k.a. a hyper-parametric oscillator [14]) to realize a stabilized clock. It is even advantageous to use a narrower comb for the stabilization purpose since the narrow comb is not impacted by the variations of the group velocity dispersion and the quality factors of the resonator modes, which may cause undesirable correlation between the comb repetition rate and the pump laser noise.

To establish that a stabilized oscillator could indeed be realized with this scheme, we must verify that the change in the RF frequency, ω_{RF}, corresponds to the change of the optical frequency, ω_0. The stabilization would only be possible if the optical drift is related to the RF drift by their frequency ratio ω_0/ω_{RF} at any instant of time. To examine this, we simultaneously measured both the optical frequency of the pump light and the RF frequency generated by the comb.

We locked a 1550 nm DFB laser to the P9 molecular line of HCN vapor in a sealed cell and used the laser as a reference oscillator (Fig. 4) to measure the frequency of the pump laser involved in comb generation. The laser locked to the cell had stability (Allan deviation) of 3×10^{-11} at 50 s averaging time (τ), beyond which the Allan deviation drifted as $\tau^{1/2}$. This

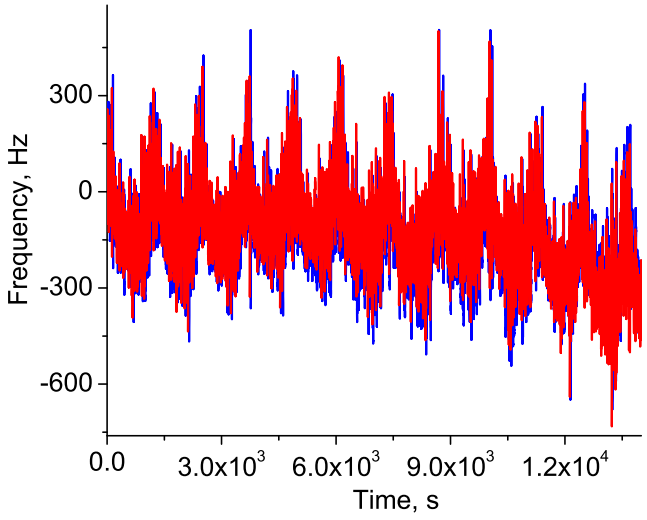

Fig. 5. Experimental observation of correlation between the Kerr frequency comb repetition rate (RF frequency) and the pump frequency using setup shown in Fig. 4. Simultaneously measured drift of the optical pump frequency (blue) and RF frequency (red). The optical frequency is shifted by a constant value and scaled by a constant ratio: $(\omega_0 - 6.4918 \times 10^7)\omega_{RF}/\omega_0$ Hz. The RF frequency is shifted by a constant value: $-(\omega_{RF} - 2297)$ Hz.

reference stability was adequate to observe any drift of the laser that was locked to the resonator mode up to 10^3 s.

We then switched off direct temperature stabilization of the resonator (only the temperature of the platform was stabilized) and observed simultaneous drift of the pump laser frequency and comb repetition rate (RF frequency), with the magnitudes of the shifts following the frequency ratio ω_0/ω_{RF}. RF and optical frequencies were simultaneously recorded for one day and then compared. The result of this measurement is shown in (Fig. 5). Again, the optical and RF frequencies drifted together and the ratio of their drift was ω_0/ω_{RF}. This experiment confirmed that by reducing the drift of the optical frequency and locking it to an atomic transition, the RF frequency produced by the comb could be stabilized. We were unable to measure the degree of correlation quantitatively since our frequency counters had relative frequency drift.

IV. Conclusion

We report on packaging of K_a band Kerr frequency comb RF photonic oscillators and also discuss possible ways of frequency stabilization of the oscillators. Our preliminary measurements show that the frequency of the pump light and the repetition rate of the Kerr frequency comb produced by a nonlinear optical microresonator are correlated if the frequency of the pump light is locked to the corresponding mode of the microresonator.

***Abstract*—The design of ultra high Q factor fiber ring resonators is described. The resonators are characterized with a microwave frequency modulation technique, which allows a precise measurement of their performance. Optoelectronic oscillators are then realized. The phase noise performance is compared to the results obtained with lower Q factor resonators, and the relatively high intra-cavity bandwidth noise is discussed.**

Keywords—Microwave-optics; optoelectronic oscillator; optical resonator; optical fiber; phase noise

I. INTRODUCTION

In the field of low phase noise microwave sources, the opto-electronic oscillator (OEO) is now very popular. Since the first delay line feedback OEOs in the 1990s [1,2], based on optical fiber spools of a few kilometers, the design of these systems has evolved towards more compact oscillators based on optical resonators. These resonators can be whispering gallery mode resonators, such as mini disk monocrystaline resonators [3-5], passive fiber loop resonators [6,7] or active fiber loops resonators, i.e. coupled optical and electronic oscillator (COEO) [8,9].

Recent work [7] has shown the capability of fiber ring resonators (FRRs) of featuring very high optical quality factors (Q_{opt}). These FRRs are compact and easy to use. However, their high quality factor, combined with significant intra-cavity power enhancement factor, lead to the generation of nonlinear optical effects inside the resonator, especially Rayleigh and Brillouin scattering [10]. When the FRR is used to stabilize the frequency of an optoelectronic oscillator (OEO), these nonlinear optical effects degrade the OEO phase noise. In order to eliminate a great part of these effects, an optical isolator has been inserted inside a 100 m long FRR that featured a Q_{opt} of $2\ 10^9$. The use of this FRR to stabilize the frequency of a 10 GHz OEO has resulted in a phase noise level as low as -52 dBc/Hz at 10 Hz offset frequency [7]. The investigations described in this paper tried to extend the performance of such a system to higher Q factors, in order to reach a lower phase noise level for the OEO. However, even if we have been successful in increasing the Q factor of our resonators above 10^{10}, the resulting phase noise is higher than the one obtained with the resonator with Q_{opt} of $2\ 10^9$. This problem is discussed and some hypothesis on the origin of this noise are given.

II. OEO BASED ON FIBER RING RESONATORS

The fiber ring resonator structure is depicted in Figure 1. It uses one or two optical couplers, preferably two if a filtered output is needed (resonator used in transmission mode). The parameters which can be optimized to get the desired Q factor and insertion losses values are the coupling coefficients (and couplers residual losses), the residual losses of all the elements of the loop (including fiber splices) and the fiber type. Of course, a trade-off has to be found between high Q factor and low insertion losses.

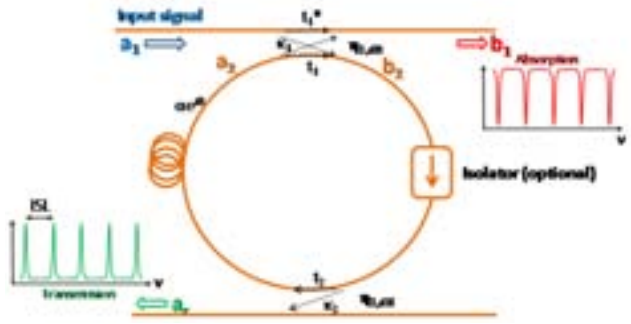

Figure 1 : Fiber ring Resonator topology

The previously realized ring resonators were in the range of 20 m to 100 m length. Because it is the optical resonator bandwidth which is preserved in the microwave application, the microwave Q factor of the OEO is degraded by the ratio of the microwave to optical carrier frequency, which is about 20 000 for a 10 GHz application (optical carrier at 194 THz, or 1550 nm) . Therefore Q_{opt} must be higher than 10^9 in order for this technology to be competitive with the best microwave resonators, which means a fiber ring larger than 10 m and a low coupling factor, or a fiber ring of 100 m if lossy elements are included in the loop. With this approach, most of our designs were based on 20 m fiber rings, featuring Q factors of about $3\ 10^9$, using either SMF fiber or PM fiber. A 100 m ring has also been designed, using PM fiber and including an isolator in order to prevent the growing up of Stimulated Brillouin Scattering (SBS), which appears at relatively low input power because of the large intra cavity power enhancement factor inside the resonant loop.

These resonators have been used to stabilize various OEOs. All the OEOs have the same topology, which is described in previously published papers [7,10] and depicted in Figure 2. The laser is first locked to the resonator frequency thanks to a Pound Drever Hall (PDH) feedback loop ; the oscillation is started thanks to a second loop which is a microwave loop including one or two amplifiers, a phase shifter and a dielectric resonator filter centered at 10.2 GHz.

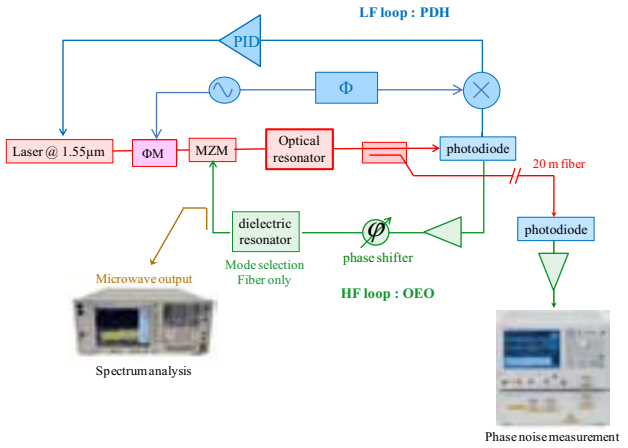

Figure 2 : OEO topology, including a PDH laser stabilization loop and an microwave oscillation loop.

The phase noise results obtained on 10.2 GHz OEOs realized using this system are depicted in Figure 3. In each case, the oscillator system is the same and only the optical resonator is removed and replaced by another. Three types of resonators are used in the OEOs described in this Figure : a mini-disk of CaF_2, a 20 m ring resonator (two spectra plotted, for different optical input power in the resonator) and the 100 m ring resonator which includes an isolator.

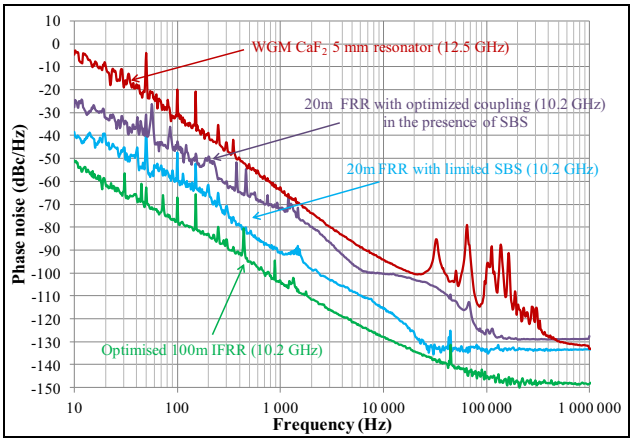

Figure 3 : Phase noise of previously realized OEOs, stabilized with the same PDH circuit, including one OEO based on a CaF_2 mini-disk ($Q = 10^8$), one OEO realized with a 20 m FRR ($Q = 3.5\ 10^9$) and one OEO stabilized with a 100 m FRR which includes an isolator ($Q = 2\ 10^9$).

The best result is obtained with the 100 m FRR OEO, featuring -52 dBc/Hz at 10 Hz offset, and -128 dBc/Hz at 10 kHz. With this resonator, we have been able to remove the main nonlinear optical effects limiting the performance of the 20 m FRR OEO. The phase noise of this oscillator is only limited by the RF amplifiers phase noise, and the measured spectrum can be described by a Leeson type approach.

III. Ultra High Q Resonators Design

Our goal was then to increase again the Q factor of our FRR, above 10^{10} (which means an equivalent Q factor at 10 GHz above 500 000). To this purpose, two ways can be followed : realizing a 100 m long FRR without isolator in the loop, or realizing a much longer FRR, such as a 1000 m FRR, and keeping the isolator which prevents some of the optical nonlinear effects (particularly the growing up of SBS).

In such a design, a trade-off has to be found between Q factor enhancement and the optical losses through the resonator (high Q means low coupling, which induces losses). Optical losses higher than 5 dB means RF losses higher than 10 dB, which are added to the losses of the microwave to optical and optical to microwave conversion which are generally high. We have thus chosen to limit optical IL to about 5 dB. The resonator is modeled either using an equivalent circuit approach on ADS software, or using a dedicated Matlab approach (both give the same results). The resonator performance is simulated varying the coupling factors of the optical couplers (the other parameters being the residual losses of the optical devices provided by the devices manufacturers).

For the 100 m resonator without isolator, a coupling factor close to 1 % meets our requirements in Q and insertion losses (IL). In the case of the 1000 m resonator, a coupling factor of about 10 % is necessary to maintain relatively low IL. This coupling factor also corresponds to the maximum intra cavity power enhancement factor.

The resonators have then been realized, and included in metallic boxes with passive thermal isolation. The devices characterization is performed still using the PDH stabilization loop : the laser is stabilized on one resonance, and the lateral resonances are measured using a microwave vector network analyser (VNA), i.e. the green loop in Figure 2 is replaced by the VNA.

Figure 4 depicts the transmission curve (S_{21}) obtained on the 100 m resonator (actually, more precisely, it is a 120 m resonator). A Q_{opt} of $1.25\ 10^{10}$ has been measured, with optical IL of 7.5 dB (a bit degraded compared to our simulation).

Figure 5 depicts the same measurement performed on the 1000 m resonator. In this case, a Q_{opt} of $1.7\ 10^{10}$ has been reached, with optical IL of 4.1 dB, which was perfectly in agreement with our simulated data. The measured S_{21} phase curve is also depicted in this figure (it is this parameter which stabilizes the oscillator), and the high slope looks very clean and can be easily measured using our microwave modulation technique.

IV. OEOs with Q in Excess of 10^{10}

These two resonators have then been included in the OEO system described in Figure 2. A 10.2 GHz oscillation has been obtained, and its phase noise has been measured.

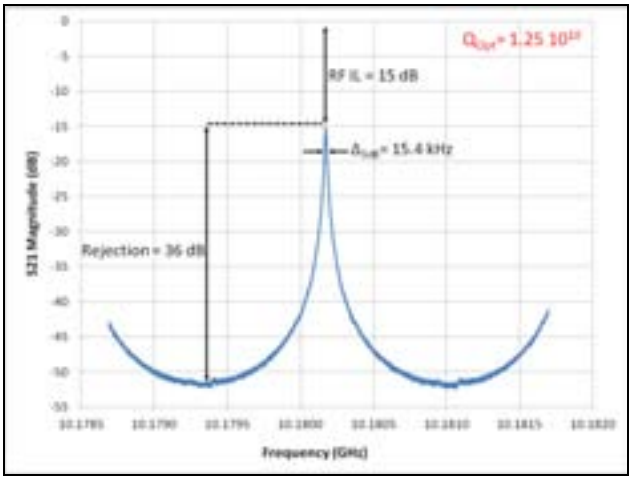

Figure 4 : Measurement of the transmission response near 10.2 GHz of the 120 m resonator, using the PDH lock and a frequency modulation approach (microwave network analyser).

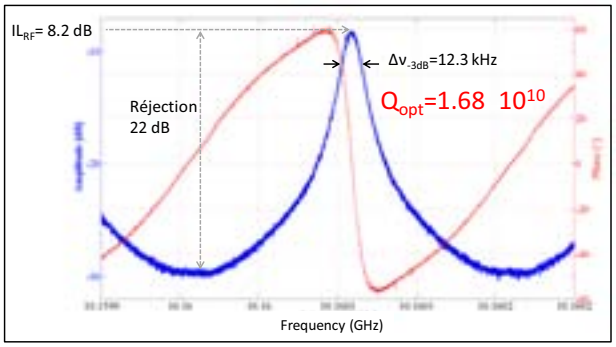

Figure 5 : Measurement of the transmission response of the 1000 m resonator, using the PDH lock and a frequency modulation approach (vector network analyser). The measured Q factor and IL are in this case identical to the ones simulated. The S_{21} phase response is also depicted in this figure.

The phase noise of the 120 FRR OEO is depicted in Figure 6. As shown in the figure, a sudden increase of the noise is observed inside the resonator half bandwidth. We were expecting such a phenomenon, because this resonator is not protected against optical nonlinear effects, and the intra cavity power enhancement factor is huge. We have attempted to reduce its influence by reducing the resonator optical input power, but the best phase noise level we could get with the PDH locking still going on was -40 dBc/Hz @ 10 Hz, which has to be compared to the -52 dBc/Hz @ 10 Hz obtained with the preceding 100 m FRR with a Q factor 6 times lower (but made of PM fiber and including an isolator).

We were more confident in the 1000 m FRR OEO, because of the isolator in the loop, but once again a sudden increase of the noise is observed inside the resonator half bandwidth, has shown in Figure 7. Also shown in this figure is the effect of a reduction of the resonator input power : the changes observed in the carrier to noise ratio outside the resonator bandwidth are proportional to this power, but the phase noise improvement inside the cavity is not (but there is effectively an improvement at low power). The FSR for this resonator is also very small : 200 kHz, which means that the dielectric resonator filter is no more sufficient to filter only one resonant mode. However, at low optical power, we still were able to get a single oscillation, even if the lateral modes can be seen on the spectra every 200 kHz offset.

For this 1000 m FRR OEO, the best phase noise results is -27 dBc/Hz @ 10 Hz and -105 dBc/Hz @ 10 kHz, which is still far from the best result described in section II. The reason may lie in two points : either the 1000 m section between two isolators is too large to prevent the built up of Rayleigh scattering noise, or a polarization noise is predominant because conventional SMF fiber has been used in this design instead of PM fiber (because of the cost of 1000 m PM fiber).

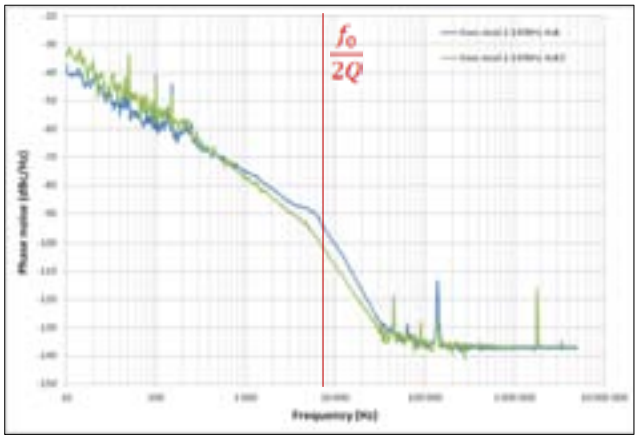

Figure 6 : Phase noise of the 10.2 GHz OEO based on the 120 m resonator ($Q = 1.25\ 10^{10}$). The two curves correspond to two different loop parameters. A large increase of the noise is clearly seen inside the resonator half bandwidth.

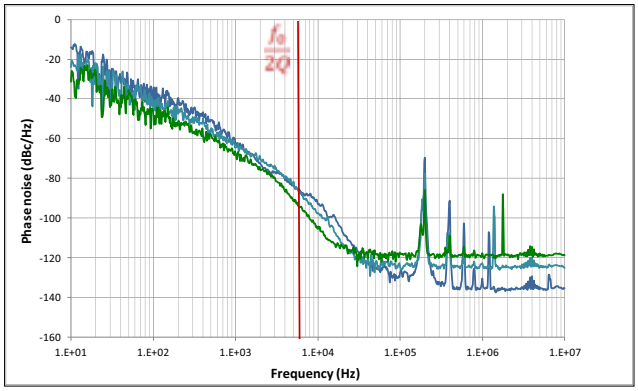

Figure 7 : Phase noise of the 10.2 GHz OEO based on the 1000 m resonator ($Q = 1.7\ 10^{10}$). Again, a large increase of the noise is clearly seen inside the resonator half bandwidth, in spite of an attempt of reducing the intra cavity power (the three spectra presented correspond to different optical power levels at the resonator input).

V. CONCLUSION

Optical resonators with Q factor in excess of 10^{10} have been successfully designed and realized using the fiber ring resonator approach. The stabilization of a laser on one resonance has been demonstrated, using the Pound Drever Hall

technique. The measurement of the resonators characteristics have thus been performed thanks to a microwave modulation and a vector network analyser. The measured data (Q factor, insertion losses, out of band rejection…) are very close to the simulated data for these ultra high Q resonators.

OEOs have then been realized with these two resonators and an approach based on the PDH laser stabilization on the resonator. The measured phase noise spectra show a sudden increase of the noise inside the resonator half bandwidth, which is the signature of a noise induced by the resonator itself.

Further studies will try to cancel this parasitic noise contribution, and also to improve the performance of the best OEO realized up to now, which was based on a 2 10^9 Q factor resonator.

***Abstract*—The fabrication process of whispering gallery mode disk resonators is presented with different characterization techniques in order to monitor roughness and optical quality factor. This type of resonators is then used as the reference frequency element to stabilize the oscillation frequency of an optoelectronic oscillator. Experimental results are provided and demonstrate the efficiency of the method.**

Keywords-component; Optoelectronic oscillator, phase noise, delay line, optical resonator

I. INTRODUCTION

We develop an optoelectronic oscillator [1] (OEO) based on intensity modulation and a high-Q disk resonator. In this OEO, the resonant element is a 5 mm diameter crystalline whispering-gallery-mode resonator [2] (WGM). It selects the microwave oscillating frequency as an optical storage energy element. This resonator also filters the microwave modulation signal. The generated oscillating frequency corresponds to the free spectral range (FSR) of the mini-resonator (in the range 10–11 GHz) [3]. Therefore no delay-induced spurious peaks are present in the spectrum, in contrast with the classical optoelectronic oscillator where the storage element consists of an optical fiber delay line [4, 5]. This resonator features a high quality factor which has been characterized using the cavity ring-down method (CRD) [6]. Another advantage of our system resides in its compactness allowing for efficient control of the temperature. We present experimental results related to the temporal dynamics and phase noise performance of WGM-based OEO. The analysis proceeds by matching the theoretical and experimental results [7]. Power spectrum is given and the generated microwave signal stands 50 dB above the filtered noise of the RF amplifier. We hereafter provide a discussion relatively to its main features.

II. MANUFACTURING THE OPTICAL MINI-RESONATOR

A. Choice of the resonator

In Whispering Gallery Mode (WGM), the light confinement is achieved by total internal reflection on air crystalline interface. The photon life time in WGM cavity – and therefore the delay of the oscillator loop – allows to determine the Q factor. This parameter is defined by the absorption of the disk and the surface losses. To achieve very low absorption losses, the use of a crystalline-resonator is a good choice. The laser light wave is efficiently coupled into and out of the resonator by evanescent field through two tapered optical fibers in an add-drop configuration. Such coupling method offers accurate performance, a good mechanical stability and the coupling efficiency can be easily controlled.

Such high Q-factor resonator is then used to achieve a low phase noise of the OEO. The resonator can be a micro-sphere [9] but we rather prefer disk-resonators. MgF_2 [10], CaF_2 [11], Quartz and fused silica [3] resonators have been studied and each of them provides its own advantages and limitations. In order to prepare the optical resonator, we use a dedicated process and instrumentation, and give the adequate shape to the resonator by polishing and performing several treatments as illustrated on Figure 1. The resonator smoothness is then characterized. Tapered optical fibers are also fabricated in the laboratory. When the laser light wave is coupled into the resonator and the laser wavelength is scanned, resonance peaks are detected and can be then characterized via the CRD technique as reported in reference [6].

Figure 1. Polishing a mini-resonator

B. Manufacturing process

The diameter of the resonator is chosen in the range 5-6 mm in order to get a FSR in the range of 10 GHz. The manufacturing process is divided in two steps: the grinding and the polishing. The grinding generates the geometry of an optical guide: a rim of 50 micrometer on the circumference of the disk. It is realized using silicon carbide and on a very stable support to minimize the geometry default and increase the speed of grinding. The polishing represents the decreasing in the optical guide roughness. It is realized with a sub-micron diamond powder on felt. The hardness of the disk increases the time of each step. This process allows obtaining a very low roughness, 2 nm, and thus a very high Q factor.

Typical roughness obtained is given in Figure 2.

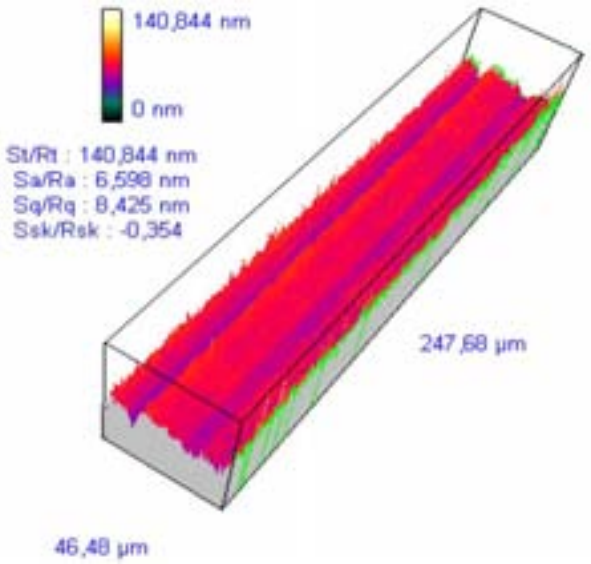

Figure 2. Average surface roughness is 6.5nm

III. Experimental study of the OEO

In order to evaluate the OEO performances if the above resonator is included, the setup given in Figure 3 is used [12]. The optical path is in thin red, while the electric path is in thick black. Inserts show the spectra of the optical fields E(t), F(t) and G(t) at the input, interior and output of the WGM resonator, respectively. The spectral lines are separated by the frequency Ω_M which corresponds to the FSR of the resonator. The through port of the coupling fibers is used to monitor the optical spectra with the OSA, in both the transient and stationary regimes. In the open-loop configuration (no oscillations), this through port is also used to perform the CRD measurement using an oscilloscope, thereby enabling the determination of the intrinsic and in-coupling quality factors. In the electric branch, a fast oscilloscope enables to resolve the temporal dynamics of the microwave V (t), whose complex envelope is V(t) (or A(t) in the dimension form). An ESA also enables to monitor the corresponding RF spectrum.

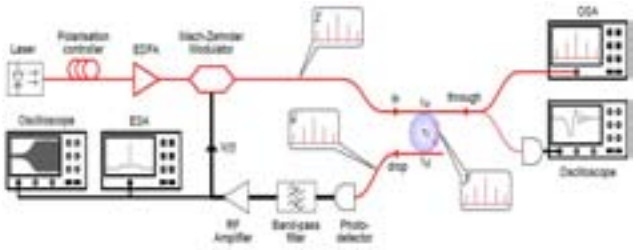

Figure 3. Experimental setup for characterizing the disk-resonator and the realized OEO. EDFA: Erbium-doped amplifier; ESA: Electrical spectrum analyzer; OSA: Optical spectrum analyzer.

We show on figure 4 the coupling of a laser lightwave into the resonator through a tapered fiber.

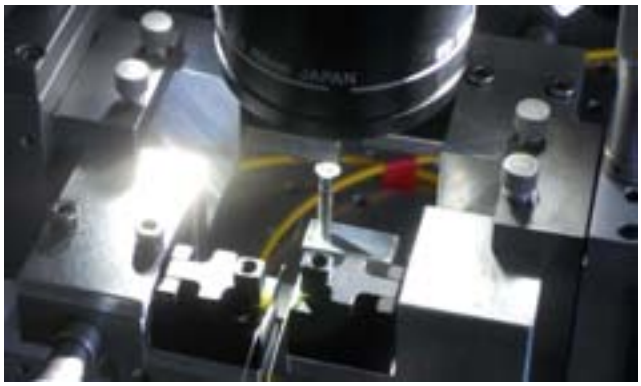

Figure 4. A 5.5 mm diameter disk-resonator coupled in transmission mode to two tapered fibers. The resonator acts like a band-pass filter with a high quality factor

The high Q resonator is then characterized by the CRD technique. Figure 5 presents an example of the ringing diagrams that can be obtained.

It has to be underlined that the key parameters are determined by fitting the measured trace to an adequate simulated trace corresponding to the researched Q-factor for the resonator characterized at 1550 nm.

Figure 6 shows the power spectrum of the OEO. The 10.41 GHz oscillation frequency corresponds to the FSR of the resonator [12]. This microwave signal is strong, and stands 50 dB above the filtered noise of the microwave amplifier.

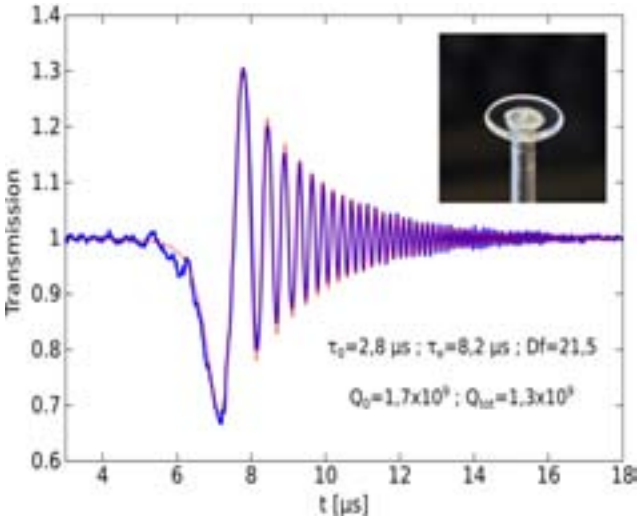

Figure 5. Characterization of a resonator designed and manufactured at the laboratory

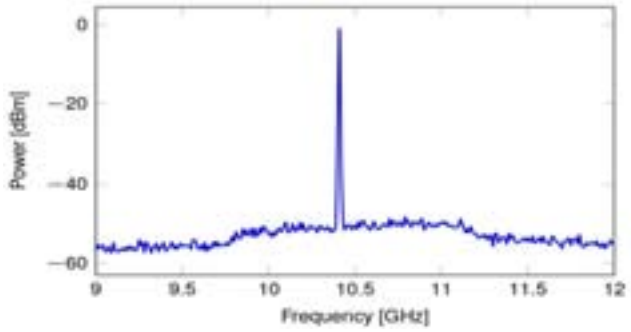

Figure 6. Characterization of a resonator designed and manufactured at the laboratory

On the other hand, the laser wavelength must be stabilized onto one of the resonator's resonances to be able to maintain a stable performance of the oscillator. Different stabilization techniques are possible [13], and we are currently setting up a Pound-Drever-Hall laser stabilization loop [14,15]. The next step will be therefore the characterization of the OEO in terms of phase noise.

IV. Conclusion

We presented here the different fabrication steps of WGM resonators and their characterization. The first experimental results of an optoelectronic oscillator (OEO) based on a high-Q disk resonator are also presented. We are currently working on the stabilization of the system, especially on the laser stabilization onto the resonator, in order to be able to characterize the phase noise performance of this OEO.

***Abstract*— We report on the design of an ultra stable microwave/THz oscillator and on the realization and the characterization of its laser source. The tunable oscillator is expected to show below -150 dB rad^2/Hz phase instability at an offset frequency of 10 kHz for a 30 GHz carrier frequency, as well as 18 GHz, 100 GHz, 400 GHz and 1 THz carrier frequencies.**

Keywords: millimeter and sub-millimiter wave oscillator, frequency stabilization, optical to microwave conversion, THz, ultra low phase noise.

I. INTRODUCTION

The OSMOTUS project (2012-2014) consists into the realization of two microwave/THz oscillators with a very low phase instability, below -150dB rad^2/Hz at an offset frequency of 10 kHz for a 20 GHz carrier frequency. We use the photomixing of two optical frequencies generated by a two-axis dual frequency dual polarization laser. The two laser frequencies will be stabilized on an ultra-low-expansion (ULE) cavity since they are the best resonators in the optical range [1]-[2]. This setup will transfer the exceptional stability from the optical domain to the microwave and terahertz one. Two identical setups will measure the submillimeter phase spectral purity.

II. DUAL-FREQUENCY TUNABLE LASER SYSTEM

A. Two-Axis Dual Frequency Laser

The dual-axis 1550 nm laser is pumped by a polarized and single mode 800 mW diode at 980 nm. This pump, polarized at 45° with respect to horizontal and vertical axes, is spatially split thanks to a birefringent YVO_4 crystal, so that the active medium is pumped by two 2-mm spaced beams. The plano/concave dual axis cavity includes an active medium, one etalon and one electro-optical element per axis, and an YVO_4 crystal recombining the two orthogonal polarization eigenstates (see Fig. 1). The active medium is a 1.5-mm-long phosphate glass co-doped Er/Yb. The high reflectivity coating on the external face of the active medium is the input coupler M1; the internal face of the active medium has a high reflectivity coating at 980 nm. The resonator is closed by the output coupler M2, whose curvature had been chosen in order to facilitate the single mode operation: a good compromise is obtained with a 4 cm radius. The 0.5% transmission of this coupler enables the laser to operate far from the threshold, reducing favorably noises; the laser delivers a with few mW output power per axis. The single mode operation is obtained and controlled on each axis by 40-µm thick etalons with 30% reflection on each side. The rough tunability of each optical frequency is realized by tilting the etalon. We are thus able to sweep each optical frequency by steps of the 1.7 GHz of the free spectral range of the laser cavity; this allows the beat note to be tunable from DC to about 900 GHz [3]-[4].

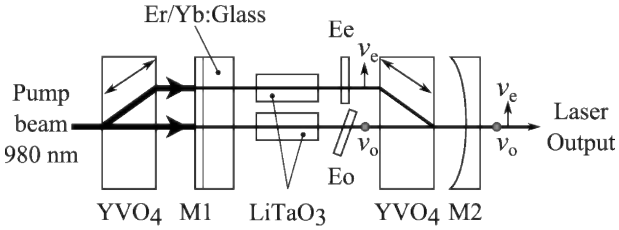

Figure 1. Two-axis dual frequency laser

The frequency of each polarization, with a measured (10^4/f) Hz/Hz$^{1/2}$ frequency noise spectral density, will be further stabilized on one of the resonances of a Fabry Perot cavity. The frequencies are both continuously and independently tunable thanks to the lithium tantalate ($LiTaO_3$) electro-optic crystals, using both thermo-optic (600 MHz/°C) and electro-optic (1.1 MHz/V) effects. The measured relative intensity noise spectral density of one optical axis is displayed on the blue curve on figure 2.

B. Amplifier System

The OSMOTUS performance requires tens of mW for the frequency stabilization, the amplitude stabilization and the beat note generation. The power fluctuations have to be stabilized in order to reduce the AM/PM couplings in the cavity and in the electronic components. Each polarization is independently amplified by a fiber system. Our amplifier system is composed of an erbium doped fiber amplifier (EDFA) and a semiconductor optical amplifier (SOA) per polarization axis (see Fig. 2).

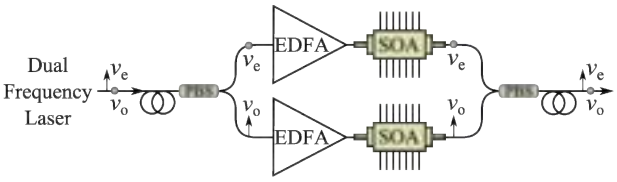

Figure 2. Amplifier system; PBS: polarization beam splitter; EDFA:Erbium doped fiber amplifier; SOA: Semiconductor optical amplifier

Since the EDFA is operated in deep saturation, it provides a constant 10 mW output power into the SOA, which is then also saturated. In that condition, the SOAs deliver a constant output power of 60 mW per polarization axis, with an amplifier system noise factor of 6 dB. Furthermore, a gain-saturated SOA decreases the intensity noise of a laser [5]. As shown on the Figure 2. the output relative intensity noise (RIN) of one axis of the dual frequency laser is reduced by 20 dB, including at the relaxation oscillation of the laser at 100 kHz, without stabilization electronics. The SOA driving currents will permit to independently stabilize the polarization amplitudes with a few hundred kilohertz bandwidth. We have checked that the amplifier system does not add any noticeable frequency noise.

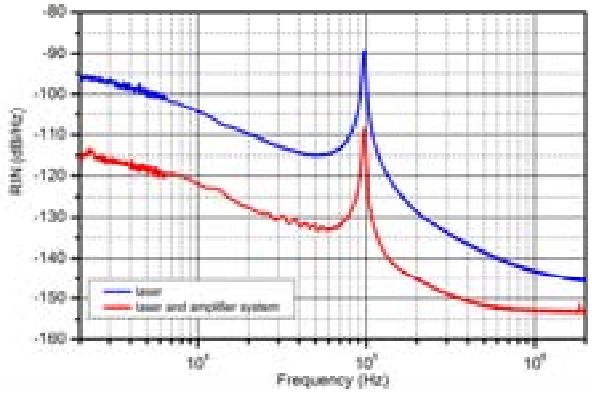

Figure 3. RIN of laser and laser with amplifier

III. Stabilization And Microwave/THz Generation

The two optical frequencies of the laser described above will be stabilized onto two resonances of one Fabry-Perot cavity with the Pound-Drever-Hall scheme. The cavity spacer is made with an ultra-low expansion ceramic (ULE). The cavity is placed in vacuum. This is today the best relative dimensional stability compact resonator, limited by the thermal fluctuations of the spacer and of the mirrors [6]-[9]. The two laser frequencies sense the same cavity length fluctuations so that the best possible relative frequency stability of the beat note is limited by the relative dimensional stability and by the shot noise of each polarization. For a 10 GHz beat note, the beat note frequency noise should be limited by the optical shot noise. For a 1 THz beat note, the cavity stability should limit the beat noise phase noise at 10 Hz offset frequency to –90 dB rad²/Hz.

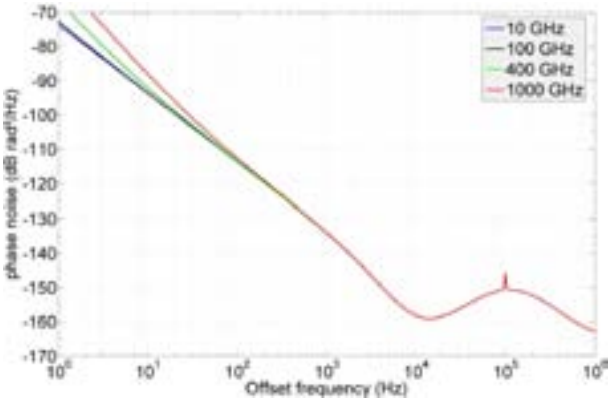

Figure 4. Expected phase noise of ultra stable oscillator

A 75% fraction of the beam transmitted by the cavity is used to stabilize the amplitude of the laser, and a 25% fraction is sent on a polarizer and a photomixer for optical to millimeter wave conversion. In the submillimeter frequency range the photomixer is an optimized UTC photodiode. The AM/PM conversion is a known limiting factor to the

stability of some optical resonators [10]. A first coupling is the opto-thermal conversion in the cavity: the power fluctuations are absorbed by the mirrors and thus induce fluctuations of the cavity length by dilation of the mirrors and by index modification with temperature. In our setup, this effect will be made negligible at a 1 Hz frequency offset by stabilization of the optical carrier at the 8.10^{-9}/sqrtHz level, already demonstrated out of loop. Static biases on the frequency stabilization error signal could give AM/PM couplings: we predict to correct for these by tuning the offsets of the error signals. Photodiodes and amplifiers also give AM/PM couplings at levels of about 10 rad/W; these couplings should be negligible with our level of amplitude stability.

IV. Conclusion

The system will be tunable from DC to THz by steps of 1.5 GHz, which is the free spectral range of the ULE cavity. Two laser/cavity systems are on development. Their phase noise performance will be evaluated by beat note of the two millimetre or THz outputs. At a 10 GHz beat note frequency, our system should have state of the art phase noise performance both at 1 Hz and 10 kHz offset frequencies. Furthermore, the phase noise of the sub millimetre carrier is relatively independent of its carrier frequency: at 18 GHz, 100 GHz, 400 GHz, 1 THz, we hope to exceed the state of the art. At 400 GHz, we use uni-travelling-carrier photodiode (UTC-PD). At 30 GHz, we expect to obtain -80 dB rad^2/Hz at 1 Hz offset frequency, and below -150 dB rad^2/Hz at 10 kHz offset frequency.

Abstract—**External vibrations induce phase noise in low noise oscillators such as the OEO (opto-electronic oscillator). The *g*-sensitivity quantifies the efficiency of this process. In fiber-based OEOs, vibrations of the fiber spool dominate the generation of phase noise. In this case, we observe decreasing *g*-sensitivity with increasing *Q*-factor (i.e., fiber length). This result indicates the interplay of two effects. First, only a portion of the optical fiber is affected by vibrations of the spool, even though the entire spool is subjected to vibrations. For the spools that we studied, the effective length is less than 500 m. Second, as the *Q*-factor increases, an OEO "filtering" effect reduces the phase noise that is induced by a constant magnitude perturbation. These results can be used to optimize the *g*-sensitivity of fiber-based OEOs by either reducing it for low phase noise RF generation or increasing it for sensing applications.**

Keywords-Microwave oscillator, vibration sensitivity, opto-electronic oscillator,

I. INTRODUCTION

The OEO is a delay line oscillator that exploits the advantages of the optical transfer of microwave signals [1]. It is a cost-efficient and frequency-agile source of low phase noise microwave signals whose noise level is comparable at frequencies below 50 kHz to what the best dielectric resonant oscillators can produce [2]. However, as with any high-quality oscillator, environmentally-induced noise from sources such as vibrations can be detrimental to the phase noise of the microwave signal. The transduction gain relating the strength of the external vibration to the phase noise it induces is called the vibration (or *g*-) sensitivity.

In fiber-based OEOs, high *Q*-factor cavities can be achieved using long fiber paths—up to several kilometers. Such a length of fiber is commonly managed by winding the fiber to a spool. In this case, external vibrations affect the phase noise primarily through perturbations of the fiber spool, rather than through direct perturbations of the fiber [3]. Consequently, it is important to characterize the effects of the fiber spool on the OEO *g*-sensitivity.

We present evidence that the *g*-sensitivity of a fiber-based OEO decreases as the fiber length wound to a single spool increases. This decrease is the result of two effects. First, the coupling between the fiber and spool diminishes as more fiber is wound to the spool. Consequently, only a portion of the fiber effectively experiences the vibration, and the magnitude of the vibration-induced perturbation remains constant with increasing fiber length. In the spools that we tested, the length that corresponds to this perturbation—the effective length of the fiber—is less than 500 meters. Second, the power of the phase noise induced by a constant magnitude perturbation decreases as the *Q*-factor (i.e., the fiber length) of the cavity increases. As a consequence, the OEO filters the phase noise.

We can exploit these effects to alter the *g*-sensitivity of fiber-based OEOs. For applications requiring high purity microwave signals, we can decrease the *g*-sensitivity by both lowering the coupling between the spool and the fiber (e.g. by adding padding [4] or by altering the spool geometry) and by increasing the total fiber length. Alternatively, as reported in [5], OEOs can also be used as sensors. In this application, we must increase the *g*-sensitivity while maintaining low phase noise floor levels. In this case, it is necessary to increase the spool-to-fiber coupling, while optimizing the total fiber length.

II. VIBRATIONS IN A FIBER SPOOL

External vibrations induce stresses and strains in the fiber spool that couple into the fiber. The stresses and strains interact with the fiber, altering the round-trip time of the RF signal in an OEO, which causes phase noise. In this section, we are concerned with the scaling of changes in the round-trip time, $\Delta\tau$, as the total fiber length of the OEO, l, increases.

Vibration-induced stresses and strains affect light traveling through the fiber via three mechanisms [6]: physical length changes of the fiber, perturbations of the material index of refraction via the strain-optic effect, and perturbations of the waveguide index of refraction via deformation of the fiber core. Each of these processes will induce $\Delta\tau$ in the OEO that will scale similarly with fiber length.

If the coupling between the fiber and spool is everywhere equal, the perturbation of the round-trip time, $\Delta\tau_{\text{nom}}$, referred to here as the nominal round-trip time, will be proportional to the total length of fiber, l. Hence, we write

$$\Delta\tau_{\text{nom}} \propto l. \tag{1}$$

We found experimentally that the perturbations to the round-trip time are almost constant for the lengths measured, indicating that the spool-to-fiber coupling is not the same at every point in the fiber. For this reason, it is useful to define an effective fiber length that experiences the vibration.

$$l_v \equiv l\,(\Delta\tau/\Delta\tau_{\mathrm{nom}}), \tag{2}$$

where $\Delta\tau$ is the actual perturbation in the fiber delay. From (1), we infer

$$\Delta\tau \propto l_v. \tag{3}$$

We will use (3) to characterize the phase noise.

III. Vibration-Induced Phase Noise

We briefly review the effect of a sinusoidal vibration on the phase noise of an OEO [7].

A sinusoidal frequency change with a peak-to-peak amplitude, Δf, and frequency, f_v, manifests itself in the oscillator phase noise as a sideband at f_v. The single sideband phase noise, $L(f_v)$, at this frequency is

$$L(f_v) = (f_{\mathrm{osc}}/2f_v)^2\,(\Delta f/f_{\mathrm{osc}})^2. \tag{4}$$

We consider an OEO with round-trip time τ and fiber delay length l. The round-trip time determines the oscillating frequency of the OEO via the relation $f_{\mathrm{osc}} = m/\tau$, where m is an integer that denotes the cavity mode that is oscillating. Consequently, we can represent a fractional change in the round-trip time as a fractional frequency change. Hence:

$$\Delta f/f_{\mathrm{osc}} = -\Delta\tau/\tau. \tag{5}$$

We may combine this result with (4) to relate the single sideband phase noise, $L(f_v)$, to the vibration-induced change in the round-trip time. We obtain

$$L(f_v) = (f_{\mathrm{osc}}/2f_v)^2\,(\Delta\tau/\tau)^2. \tag{6}$$

To determine how $L(f_v)$ scales with length, we first note that the round-trip time of an OEO is dominated by the propagation time of the signal within the optical fiber. Hence, we can replace the total round-trip time with $\tau = nl/c$, where n is the optical fiber's index of refraction and c is the speed of light in the vacuum. Using this relation with (3), we find

$$L(f_v) \propto (l_v/l)^2. \tag{7}$$

Thus, a sinusoidal vibration induces a sideband in the OEO phase noise at the vibration frequency. The sideband's power spectral density (PSD) is proportional to the square of the effective fraction of the fiber that is coupled to the spool vibrations.

IV. Results

Our physical model predicts that the effective length of fiber affected by spool vibrations will be constant for long fiber lengths. To demonstrate this result experimentally, we expose only a portion, l_s, of the fiber delay of an OEO to a sinusoidal vibration. We then increase the portion of the fiber that is exposed to the vibration, while keeping the total fiber length constant. By varying the length of fiber exposed to the vibration, we can determine whether the perturbation to the fiber delay depends on the total length of fiber exposed to the vibration.

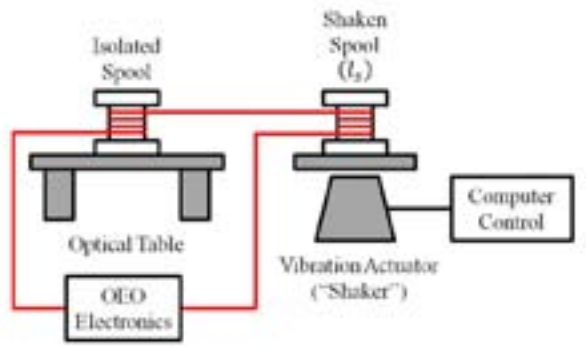

Figure 1. Schematic of experimental apparatus used to measure the effective round-trip time perturbation. Total fiber length is held constant while the length on the shaker is increased.

The setup for this experiment is shown in Fig. 1. We concatenate two fiber spools to form the entire OEO delay, but affix only one of the spools to a shaker. We apply a sinusoidal vibration to the spool on the shaker, while passively isolating the other spool from acoustics and vibration. We measure the phase noise of the microwave signal, and we record the peak that appears at the frequency of the vibration tone. We then repeat the measurement, increasing l_s while keeping the total fiber length constant. Equation (7) indicates that the phase noise sideband will be proportional to l_v^2. Because of diminishing coupling between the fiber and spool, we expect l_v to be constant.

Fig. 2 shows the experimental results. Fitting the log of the data to a linear regression yields a slope of approximately –0.3. The shallow slope indicates that for the lengths tested, the phase noise sideband is constant to within our experimental error. This result is consistent with the hypothesis that the mechanical coupling between the fiber and spool has effectively saturated. In the spools tested here, this saturation occurs at a length shorter than 500 meters.

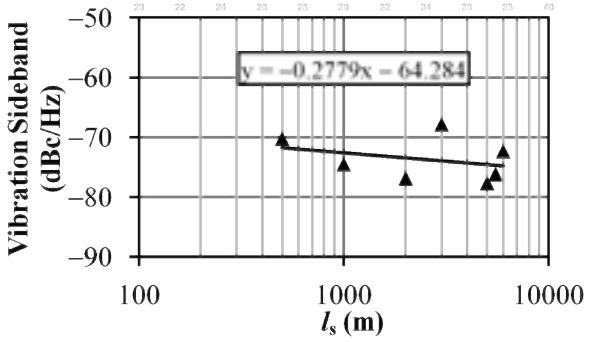

Figure 2. PSD of the vibration-induced phase noise peak for a fixed length OEO. The independent variable is the length of fiber that is exposed to vibration.

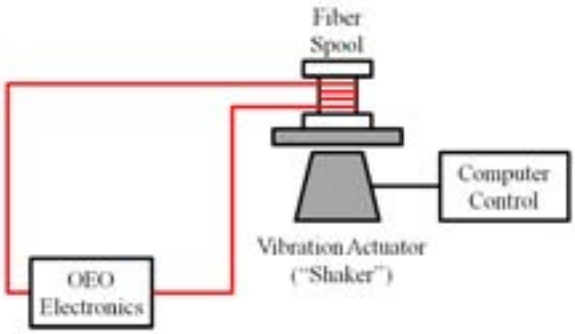

Figure 3. Schematic of experimental apparatus used to measure the length dependence of *g*-sensitivity. Total fiber length is varied.

Because we have shown that l_v is approximately constant, Eq. (7) predicts that the *g*-sensitivity of the OEO will decrease as the total fiber length increases. To test this hypothesis, we expose the entire fiber delay of an OEO to a sinusoidal vibration and measure the phase noise of the microwave signal. Fig. 3 shows the experimental setup. Again, we record the magnitude of the vibration sideband. We repeat the measurement for OEOs of different lengths of fiber. The fiber spools used in this experiment are the same as the earlier experiment.

Fig. 4 shows the experimentally measured values for the PSD of the vibration-induced microwave phase noise peak for OEOs of different delay length. These results demonstrate that as the OEO fiber delay increases, the magnitude of the vibration-induced peak decreases. When the data are converted to a logarithmic scale and fit to a linear regression, the resulting slope is approximately −2.2, so the PSD is proportional to $l^{-2.2}$. This result is consistent with (7) to within the accuracy of our experiments.

In conclusion, we have demonstrated two features of the OEO *g*-sensitivity. First, although mechanical coupling between the fiber and spool dominates the vibration-induced phase noise, the interaction is approximately independent of fiber length for the lengths measured. This result implies that the mechanical coupling diminishes when the fiber wound to the spool rises above a critical value. For the spools tested, this value is less than 500 meters. Second, as implied by the first result, the *g*-sensitivity of the OEO decreases with increasing fiber delay. These results can be used to decrease the *g*-sensitivity of fiber-based OEOs used for low phase noise RF generation or to increase the *g*-sensitivity of OEOs that are used for sensing applications.

Scattering of Cold Atom Coherences by Hot Atoms: Background Gas Collision Shifts of Primary Fountain Clocks

Kurt Gibble
Department of Physics
The Pennsylvania State University
University Park, USA

***Abstract*—We theoretically analyze frequency shifts of cold-atom clocks due to background gas collisions. Because nearly all collisions with room-temperature background gases that transfer momentum eject cold atoms from a clock, the frequency shifts for cold atoms are significantly different than those of room-temperature clocks. From general arguments, measurements of the loss of Ramsey fringe amplitude can usefully bound this source of systematic error.**

Keywords—atomic clock, background gas collision, frequency shift

I. SUMMARY

This paper briefly summarizes a recent theoretical analysis [1] of the frequency due to background gas collisions with ultracold clock atoms. Several primary cesium fountain frequency standards report an uncertainty of 1×10^{-16} for the frequency shift due to background gas collisions [2-4]. It contributes noticeably to a number of overall uncertainty budgets, as low as 2.1×10^{-16} [4], and can be the largest single contribution in the uncertainty budget. These uncertainties are estimated using the measured pressure shift for H_2 in room-temperature Cs cell clocks [5]. Because any momentum transferred to a cold atom almost always prevents it from being detected (Fig. 1), room-temperature measurements do not describe the frequency shifts of ultracold atoms.

We analyze the quantum scattering and show that the interference scattering in the forward direction, with no change in momentum, dominates the background gas shift of cold atoms [1]. For H_2, the frequency shift of a room-temperature clock has the opposite sign as that of a cold atom clock, and is about an order of magnitude larger. Highly polarizable gases, including background Cs vapor, produce similar shifts for cold atoms as H_2. We show that the frequency shift and the loss of Ramsey fringe amplitude due to background gas collisions with cold clock atoms scale in the same way, allowing the background gas shift to be bounded to $\approx\pm4\times10^{-17}$. Measuring the loss of Ramsey fringe amplitude or using calculated shifts [1] can reduce the background gas shift in uncertainty budgets so that it no longer contributes significantly.

Financial support from NASA, NSF, and Penn State.

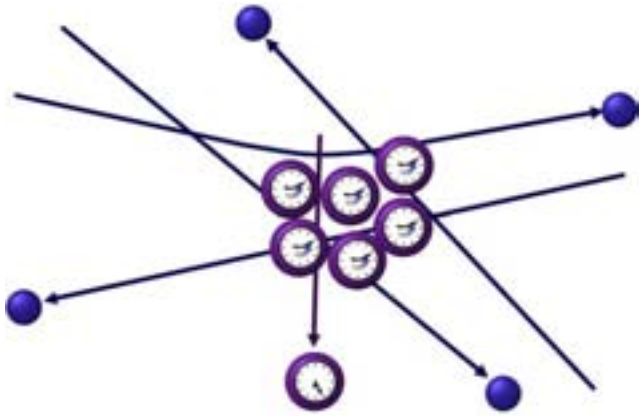

Fig. 1. Background gas collisions with cold clock atoms eject clock atoms so that they are not detected. Nonetheless, undeflected cold atom coherences experience a phase shift due to the scattering. The frequency shifts of undeflected cold clock-atoms are due to long-range collisions with polarizable background gases.

Nanoscale Resonant Sensors with 1D Carbon Nanostructures

A Review of Carbon Nanotube Based NEMS Devices

Zenghui Wang
Electrical Engineering
Case Western Reserve University
Cleveland, OH 44106, USA

***Abstract*— Carbon-based low-dimensional nanostructures, such as graphene and carbon nanotubes, have outstanding mechanical properties and can be implemented as novel nanomechanical devices. Such devices, owing to their miniature sizes and the unique physical properties of the materials, make excellent candidates for physical sensors. In this paper, we will focus on the state-of-the-art nanomechanical resonators made of carbon nanotubes, and evaluate their potential as ultra-sensitive sensors. Specifically, we will describe nanotube resonator mass sensors with the best ones achieving single-proton mass sensitivity, and a nanotube resonant sensor for detecting surface processes such as adsorption and phase transition.**

Keywords—nanoelectromechanical systems (NEMS); carbon nanotube; resonator; sensor; surface adsorption

I. Introduction to Carbon Nanostructures

Carbon nanostructures have been under intensive study for the last two decades. The three most commonly studied forms, graphene (2D), carbon nanotube (1D), and fullerene (0D) can all be viewed as derivatives from the 3D form, graphite (Fig. 1(a)).

The 1D form, carbon nanotube, can be either single-walled or multi-walled, depending on the number of cylindrical layers (Fig. 1(b)). Single-walled nanotube (SWNT) typically have diameter around 1nm, and its length can range from tens of nm to a few cm. The high aspect ratio, nanoscale size, and outstanding physical properties make it a unique choice for building resonant NEMS devices.

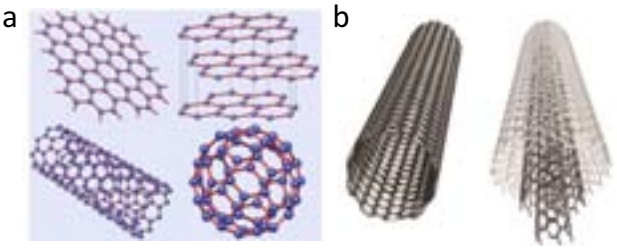

Fig. 1. Schematic of different forms of carbon nanostructures. (a) Graphite (upper right) and its derivatives (counter-clockwise): graphene, carbon nanotube, and fullerene. (b) Single-walled (left) and multi-walled (right) nanotubes.

II. Unique Properties of NEMS Based on Carbon Nanostructures

A. Ultra-Low Mass in Motion

The low mass of the carbon nanostructures make them particularly attractive for various sensing applications such as mass spectroscopy and ultra-low force detection. NEMS devices fabricated with conventional top-down approaches, on the other hand, are limited by the capability of the available lithography techniques and are therefore unlikely to surpass the chemically derived nanostructures. For example, a graphene resonator, made of just a single sheet of carbon atoms, is practically the thinnest resonator one can achieve, and has the lowest possible areal mass density. Similarly, a SWNT resonator is made of a single carbon molecule that is typically 1 nm in diameter and hollow inside. In the near future it is not expected that lithography technique can produce miniature devices comparable with a SWNT resonator in size and mass.

B. Pristine Resonator Surfaces

Carbon nanostructures used in the NEMS devices can have pristine surfaces free from harsh chemical processing. For example, mechanically exfoliated single layer graphene is a single crystal with its both surfaces (note that it has only two surfaces) well defined with the hexagonal honeycomb lattice. Similarly, chemically grown carbon nanotube is a graphene-rolled-up tube and its curved surface well resembles that of graphene. In contrast, top-down fabricated NEMS devices experience processing steps such as Reactive Ion Etch (RIE) and the resulting surfaces can be much rougher, with side walls being very different in surface morphology than the top/bottom sides. Therefore, NEMS based on bottom-up derived nanostructures are particularly suitable for studying surfaced-related phenomena thanks to their pristine surfaces.

III. Sensing Applications

In this section we survey the studies on sensing applications (with a focus on mass sensing) of NEMS based on carbon nanotubes, and compare their performance (mainly mass sensitivity) with conventional top-down fabricated (with lithography technique) NEMS devices to illustrate the unique advantages of carbon nanostructures.

A. Mass Sensing with NEMS Devices

Mass sensing with resonant devices are based on the frequency downshift of a resonator upon the loading of additional masses. A unique advantage of this technique is that it doesn't require the measured particle to be charged (and thus can resolve neutral species), in contrast to conventional mass spectrometry.

To the first order, the mass of the add-particle (the mass to be measured, which is added to the moving part of the resonator during measurement) can be related to the change in resonance frequency f via

$$\frac{\Delta m}{m_0} \approx \frac{\Delta f}{f_0} \tag{1}$$

where f_0 is the initial resonance frequency, Δf is the frequency downshift upon mass loading, m_0 is the initial mass of the resonator, and Δm is the mass of the add-particle. Note that Eq. (1) only gives an order-of-magnitude estimate; the detailed relation depends on many factors such as the resonance mode shape and attachment position of the add-particle.

From this simple relationship it is clear that a smaller m_0 is desirable for achieving a smaller Δm. Therefore, for improved mass sensitivity it is natural to use resonators with small m_0. As technology advances, NEMS devices with smaller sizes continue to be realized, along with continued improvements in achieved Δm.

Doubly clamped beam resonator (see Fig. 2 for illustration) is a commonly used geometry for NEMS devices. One of the main advantages is that the ability to pass an electrical current through the resonator allows direct electrical readout of the mechanical motion, making such devices widely used in different sensing applications.

In 2004, a Caltech group realized attogram (10^{-18}g) mass sensing with a lithography-defined doubly clamped SiC resonator (14μm×670nm×260nm) at T≈17K [1]. This sensitivity corresponds to a few thousands of Au atoms. In 2006 the same group achieved zeptogram (10^{-21}g) mass sensitivity (tens of Xe atoms) by employing a further miniaturized SiC resonator (2.3μm×150nm×70nm) [2]. Similar devices are also used in bio-sensing experiments, demonstrating single-molecule sensitivity [3], [4].

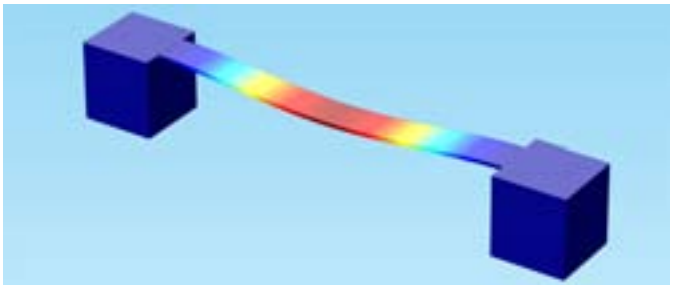

Fig. 2. Schematic of a doubly clamped resonator (in its fundamental resonace mode). For top-down fabricated devices, the suspended part is typically a rectangular beam.

B. Carbon-Nanotube Resonators

The first electrically-tunable SWNT resonator was realized in 2004 by a Cornell group [5]. The device was fabricated by mechanically clamping (and thus electrically contacting) both ends of a SWNT and then suspending the middle segment of it. The resulting doubly clamped device (Fig. 3(a)) is a field-effect transistor (FET), whose conductance between source and drain can be modulated by the voltage on the gate.

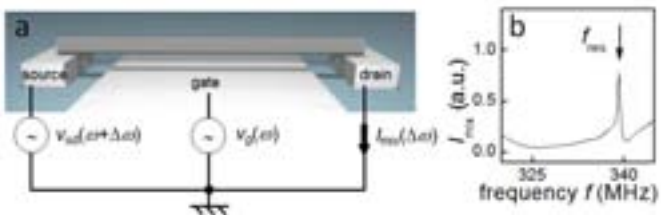

Fig. 3. SWNT resonator. (a) Schematic of a device. (b) An example of mechanical resonance signal in the mixing current.

Mechanical resonance of the suspended carbon nanotube is actuated and detected electrically. An AC signal with angular frequency ω, $V_g(\omega)$, is applied between the SWNT and the underlying gate, generating an AC force at the same frequency and drives the mechanical vibration.

Due to the much smaller capacitance between the SWNT and the gate (compared with the parasitic capacitance between the source/drain contacts and gate electrode), it is difficult to directly read out the mechanical motion signal at frequency ω. Therefore a down-mixing technique is used. In short, a bias signal at a slightly-offset frequency $\omega+\Delta\omega$, $V_{sd}(\omega+\Delta\omega)$, is applied between the source and drain electrodes. The conductance of the SWNT FET is modulated by its mechanical motion at frequency ω. The current through the SWNT is the product of the bias and the conductance, resulting in a term at the intermediate frequency $\Delta\omega$ in the current, $I_{mix}(\Delta\omega)$, which can be detected with a lock-in amplifier. At mechanical resonance, the large motion amplitude leads to large modulation of the device conductance and consequently large modulation in the mixing current. A typical resonance signal in I_{mix} is shown in Fig. 3b. The resonance frequency of the SWNT resonator can be tuned by applying a DC gate voltage, which changes the tension of the SWNT.

C. SWNT Resonator Mass Sensing

In 2008, two research groups independently performed mass sensing experiments with doubly-clamped nanotube resonators. The Caltech group built a SWNT resonator (500nm in length and 1nm in diameter) to detect adsorption of individual Xe and Ar atoms. By fitting measured time-dependent adsorption curve to a statistic model, the researchers are able to weigh the mass of individual Ar atoms, corresponding to a mass sensitivity better than 0.085zg (their measured mass of an Ar atom) [6]. The CIN2 group used a similar structure (900nm long SWNT resonator with 1.2nm diameter) to detect mass loading from evaporated Cr atoms. Resolution of 1.4zg is achieved at low temperature [7]. Atomic mass sensitivity based on singly-clamped nanotube resonator is also demonstrated [8].

As shown in Eq. (1), to further improve mass sensitivity (decrease Δm), one needs to use a smaller device (decrease m_0) and increase the quality factor Q of the resonator (to get better resolution in $\Delta f/f_0$). Accordingly, in 2012 the same CIN2 group built an ultra-short (150nm) nanotube resonator with Q up to 2000, and achieved mass sensitivity of 1.7yg (a single proton) after annealing the device with electrical current [9]. It is worth note that the same group also built a very long (4μm) SWNT resonator with very low spring constant, and achieved force sensitivity of 12zN/Hz$^{1/2}$ [10].

D. Discussion on NEMS Resonator Mass Sensing

Table 1 lists the NEMS mass sensing experimental work discussed above. For SiC devices the dimension is listed as length×width×thickness, and for nanotube resonators it is length×diameter.

TABLE I. NEMS RESONATOR MASS SENSING

Ref	*Device Dimension*	m_0(g)	f_0 (MHz)	Q	Δm(g)
[1]	14μm×670nm×260nm	9.9×10^{-12}	32.8	3000	2.53×10^{-18}
[2]	2.3μm×150nm×70nm	7.3×10^{-14}	190	5000	7×10^{-21}
[3]	1.7μm×120nm×100nm	9.2×10^{-14}	450	2000	1.7×10^{-20}
[6]	500nm×ϕ1nm	1×10^{-18}	300	200	8.5×10^{-23}
[7]	900nm×ϕ1.2nm	2.5×10^{-18}	167	1665	1.4×10^{-21}
[8]	254nm×ϕ2.09nm	2.33×10^{-18}	328.5	1000	3×10^{-22}
[9]	150nm×ϕ1.7nm	6×10^{-19}	2000	1000	1.7×10^{-24}

Clearly both smaller m_0 and higher Q are both important for achieving high mass sensitivity. Top-down fabricated NEMS resonators generally have higher Q, but to further decrease the device size it requires advancement in fabrication technology, such that smaller devices with well-defined surfaces (to retain the high Q) can be made. On the other hand, NEMS devices based on carbon nanostructures (such as SWNT) naturally has ultimately small m_0 which is ideal for sensing applications.

Figure 4 plots the relationship between Δm and m_0 for all the work listed in Table 1. From (1) one can see that, under similar experimental techniques/settings (e.g. measurement bandwidth, equipment resolution, statistical technique, etc.), $\Delta m \propto m_0$ for devices with similar Qs. One such trend line is shown in Fig. 4, and the overall behavior of the data points agree well with this expected trend. Devices with higher Qs have better mass sensitivity (smaller Δm) and appear lower on the plot, and vice versa. This is also apparent from Fig. 4: all the top-down fabricated SiC NEMS have higher Qs and appear below the overall trend line, while most nanotube resonators have lower Qs and are on the other side of the line.

On the other hand, from Eq. (1) one can also see that $\Delta m \propto 1/Q$ if all the other experimental parameters remain the same. We plot in Fig. 5 Δm *versus* Q for all the work listed in Table 1, together with a trend line of $\Delta m \sim 1/Q$. It clearly shows that all the SiC resonators are above the line (has larger Δm) due to their larger m_0 values, while the SWNT devices appear well below the line. Indeed, the effect from m_0 is so dominant such that the dependence of Δm on Q cannot be seen at all from this plot.

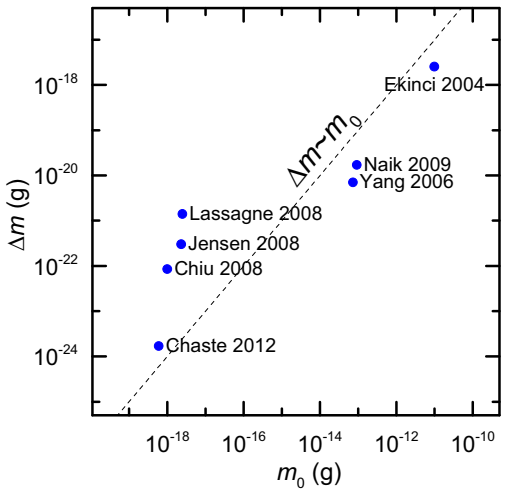

Fig. 4. Mass sensitivity Δm versus resonator intrinsic mass m_0 for all the work listed in Table 1. The dashed line represents linear dependence between Δm and m_0.

The observations imply that under the current technology, in order to improve the sensitivity of these resonant mass sensors, it is much more effective to build NEMS devices based on carbon nanostructures and utilize their ultralow mass. The milestone of achieving yoctogram sensitivity with SWNT resonator clearly demonstrates this fact.

For future work towards improved NEMS mass sensing, there are two main approaches. The first one is to continue improving the Q for NEMS devices based on carbon nanostructures. The first tunable SWNT resonator has a Q of 80[5]; over the years this number has been well improved, and devices with Q up to 10^4 has been reported [11]. Among SWNT mass sensing works, the recent yoctogram sensitivity device has a Q of ~2000 [9]. On the other hand, making SWNT devices compatible with large scale fabrication processes would greatly enhanced the feasibility of these ultra-sensitive devices in realistic applications. This may take significant effort. The other pathway is to further downsize top-down fabricated NEMS devices while maintaining their high Q. This requires novel lithography techniques and advancement in etching processes. In addition, multimode sensing can be used to detect the mass and position of the add-particle in real time, offering new possibilities [4].

IV. SURFACE SCIENCE STUDIES

In this section we describe the surface science studies (focusing on surface adsorption) with NEMS resonators based on 1D carbon nanostructures, and demonstrate its uniqueness (mainly detecting phase transition in the adsorbed layer) compared to conventional top-down fabricated (with lithography technique) NEMS devices.

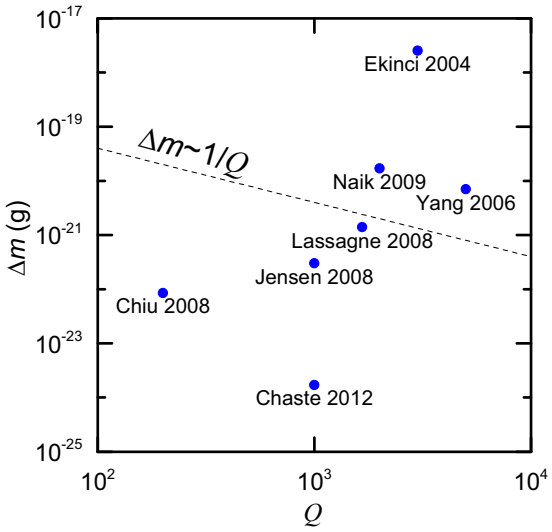

Fig. 5. Mass sensitivity Δm versus resonator quality factor Q for all the work listed in Table 1. The dashed line represents linear dependence between Δm and $1/Q$.

A. *Surface Adsorption Processes*

The study of surface adsorption typically involves answering the following question: under a given condition, when a surface is exposed to a vapor of a different material, what happens on the surface? The detailed answer depends on various parameters such as temperature, pressure, the type of materials involved, the morphology of the surface, etc. Further complications can come from non-equilibrium conditions (e.g. the temperature of the surface is different from that of the vapor) or co-adsorption (different types of adsorbates exist concurrently).

Surface adsorption involves many different physical processes. When a gas atom/molecule impinges on a surface, it may or may not adsorb. The probability is described by the sticking coefficient. Upon adsorption, the atom/molecule can still leave the surface if it has sufficient thermal energy, and the process can be characterized by the desorption rate. The adsorbates can also diffuse alone the surface.

Besides these dynamic processes, the equilibrium states are also extensively studied. A common measure of such equilibrium states is the surface coverage, which provides information about the phase of the adsorbed surface layer. In many adsorption systems, various phases and phase transitions have been identified and studied, revealing a plethora of physics phenomena in these 2-Dimensional (2D) systems.

A common way to describe phase behavior in adsorption system is by using isotherm, which plots the coverage of adsorbates (corresponding to the density of the adsorbed layer) versus 3D gas pressure under a given temperature. From such plots one can derive the entire phase diagram. The relationship between an isotherm plot and a phase diagram is illustrated in Fig. 6.

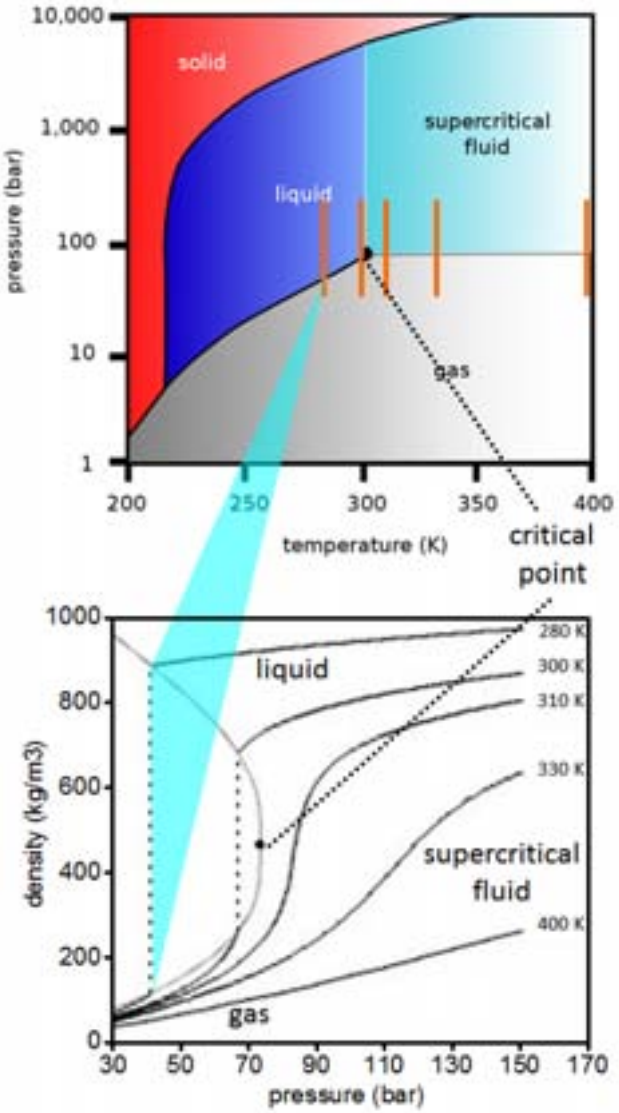

Fig. 6. Phase Diagram (top) and isotherm (bottom) of CO_2 in 3D space. The phase diagram delineates the phase boundaries. Taking vertical (constant temperature) slices (orange lines) in the phase diagram and plotting the order parameter of the system (density) versus temperature for each of these slices, one obtains the isotherm plot. Each isotherm curve represents a vertical slice in the phase diagram. First order phase transitions are represented by vertical steps in the isotherm (highlighted triangle), and the profile of these steps outlines the vapor-liquid phase-coexistence region, with its tip being the critical point.

B. *Surface Adsorption Studies with NEMS Devices*

Lithography-fabricated NEMS devices have been used to study surface adsorption. The mass sensing studies[1], [2] are essentially adsorption experiments at the low coverage limit. Indeed, these devices are well-suited for studying the dynamic processes: the high resonance frequency leads to high operation speed, and the high Qs provide high resolution for detecting small frequency shift. Indeed, the same Caltech group has studied the diffusion process of Xe atoms adsorbed on the surface of a SiC resonator, by monitoring the frequency

noise in the resonance signal arise from the adsorbate fluctuation [12].

C. Adsorption on SWNT Resonator Surface

In addition to the above mentioned advantages of NEMS devices, SWNT resonators further benefit from the pristine surface that comes with the as-grown carbon nanotube, which offer additional opportunities for surface adsorption study. The pristine nanotube surface provides an ideally homogeneous substrate for studying phase behaviors. This is important for observing well-defined phase transitions, as inhomogeneity in the substrate leads to difference in adsorbate-substrate interaction, and thus breaks the simultaneity of phase transition among different adsorption sites.

SWNT resonators with as-grown pristine surfaces have been used to map out the phase behavior of Ar, Kr, and ^{4}He adsorbed layers on nanotube surfaces for different temperature ranges[13], [14]. Multiple low-dimensional phases and phase transitions are observed.

Such adsorption experiments are to certain extent similar to the mass sensing experiments, except they probe a wide range of surface coverage: from the 0 coverage limit (as in mass sensing experiments) to more than one complete monolayer. Most studies are conducted between 0 and 1 layer to reveal the phase transition within the first monolayer. Experiments at higher coverage usually show layer-to-layer condensation instead of phase transition.

In order to reach one complete monolayer, the adsorption experiments are setup up differently than the mass sensing studies (where an oriented nozzle directs the atomic/molecular beam towards the NEMS device resonating in high vacuum). To study the equilibrium states, a stable 3D vapor pressure is necessary to maintain the adsorbed layer on the surface. Therefore, in adsorption experiments, the entire device chamber is gradually pressurized with the adsorbate gas, and resonance of the NEMS device is recorded for each pressure.

An example of adsorption experimental data is shown in Fig. 7. At the low pressure limit (left side) the resonance frequency f_{res} (altitude of the dark curve) slowly decreases, as in the mass sensing experiments. As pressure continues to increase, the decrease in resonance frequency accelerates, until at a certain point it suddenly takes a huge leap to a much lower value. This suggests a large, sudden change in the density of the adsorbed layer (and thus the mass of the resonator) over a very small pressure range, signifying a strong 1$^{\text{st}}$ order phase transition, like the vapor-liquid condensation in the case of 3D matter.

The frequency shift can be converted to the adsorbates coverage on the nanotube surface by assuming that f_{res} varies as $\rho^{-1/2}$ (ρ being the overall density of the resonator). Therefore, the value

$$\phi = \frac{\Delta\rho/m_{ads}}{\rho_0/m_C} = \frac{m_C}{m_{ads}}\left[\left(\frac{f_0}{f_{res}}\right)^2 - 1\right] \qquad (2)$$

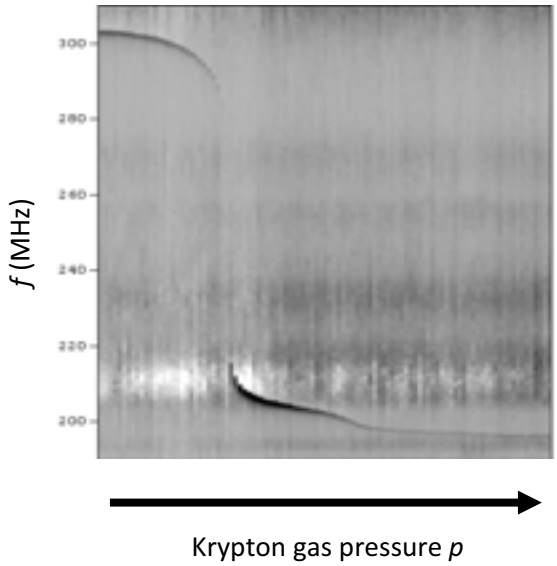

Fig. 7. Example of an experimental adsorption data set. The data is taken with a SWNT resonator exposing to Kr gas with gradually increasing pressure at 77K. The verticle axis is frequency f, the horizontal axis is time (with pressure linearly increasing), and the grey scale represents the measured mixing current. The mechanical resonance shows up as the a sharp (dark) feature at a paticular frequency (the resonance frequency f_{res}) for each verticle data column. Sudden jump in f_{res} represents sudden change in the total density of the resonator, indicating strong phase transition in the adsorbed layer.

gives the ratio of the number of adsorbed atoms to carbon atoms in the layer. Here m_C and m_{ads} are the masses of the carbon atom and adsorbate atom, respectively.

Using Eq. (2) the experimental data in Fig. 7 can be converted to the coverage-pressure isotherm, as shown in Fig. 8. By examining a family of such isotherms under different temperatures, various phases and phases transitions are identified and studied[13], [14].

D. Discussion on NEMS Resonator Surface Adsorption

The small mass and high surface-to-volume ratio make NEMS devices highly sensitive to surface adsorptions, providing an ideal platform for studying both the dynamic processes and equilibrium states.

Furthermore, NEMS resonators based on carbon nanostructures benefit from their pristine surfaces and are capable of resolving various phase transitions within the first adsorbed monolayer, generating new knowledge about this low-dimensional system. Furthermore, the pristine nanotube resonator surface allow exotic phases specific to adsorption systems (unavailable in 3D matters) to be observed. The so-called "Commensurate Solid" (CS) provides an example.

Figure 9 illustrate the CS phase of Kr monolayer adsorbed on a graphitic surface, where the adsorbate atoms are registered with specific locations on the substrate. In this arrangement there is 1 Kr atom per 6 C atoms, and the coverage of CS is fixed at 1/6, which has been observed with SWNT resonators[13]. More interestingly, the fact that SWNT is a seamless roll-up of a graphene sheet imposes additional requirement for a seamless CS coverage: the adsorbate atoms

must also fold onto themselves upon rolling (see Fig. 9 for comparison). This requires that the roll-up vector of the nanotube (*N*,*M*) is a lattice vector in the CS lattice: $N\boldsymbol{a}_1+M\boldsymbol{a}_2.=X\boldsymbol{b}_1+Y\boldsymbol{b}_2$, where *X* and *Y* are both integers.

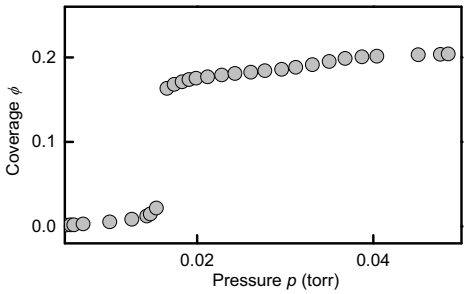

Fig. 8. Coverage isotherm generated using Eq. (2) with the data in Fig. 7. The vertical axis is the numerical coverage (number of adsorbed Kr atom per C atom), and the horizontal axis is 3D Kr pressure. Phase transition appears as vertical step in the isotherm (sudden density increase).

Simple math show that this can occur only when (*N*–*M*)/3 is an integer, where (*N*,*M*) is the nanotube's roll-up vector. This coincides the requirement for an SWNT to be metallic[15]. This also implies that only 1/3 of the SWNT may have a seamless coverage of CS phase of adsorbed Kr atoms. These unique properties suggest opportunities for studying new adsorption phenomena on nanotube surfaces.

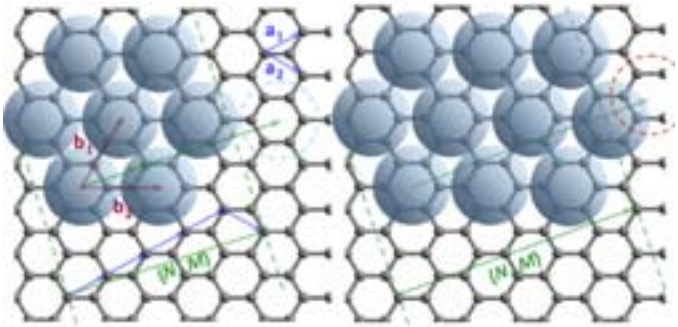

Fig. 9. Schematic of commensurate solid (CS) phase on nanotube surfaces. Large translucent circles represent Kr atoms, and the honeycomb structure underneath represents the graphitic surface of SWNT. $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$ are the basis vectors of the SWNT hexagonal lattice, while $\boldsymbol{b}_1$ and $\boldsymbol{b}_2$ are the basis vectors for the Kr CS lattice. (*N*,*M*) is the roll-up vector of the nanotube: it determines how a graphene sheet is rolled-up into a nanotube, with a given C atom fold seamlessly onto its counterpart $N\boldsymbol{a}_1+M\boldsymbol{a}_2$ away. In order for a SWNT to have a seamless CS coverage, $N\boldsymbol{a}_1+M\boldsymbol{a}_2$ must also be a lattice vector in the $\boldsymbol{b}_1$ $\boldsymbol{b}_2$ basis such that a Kr atom can also fold perfectly into another Kr atom (left), instead of landing in the wrong position after folding (right).

V. Conclusion

Carbon nanostructure-based NEMS resonators have demonstrated unique capabilities in addition to all the benefits offered by a conventional NEMS resonator. Specifically, the ultra-low mass of carbon nanotube facilitates ultra-sensitive mass sensing with SWNT resonators, achieving yoctogram mass sensitivity. The pristine surface of as-grown SWNT enables detailed study of surface adsorption on the resonator, revealing exotic phases and phase transitions in this low-dimensional system. Future development in large-scale fabrication of such resonant devices can lead to practical use of carbon nanostructure in applications such as mass spectroscopy, force detection, and gas sensing.

***Abstract*—This paper reports a high-resolution frequency-output MEMS tilt sensor based on resonant sensing principles. The tilt sensor measures orientation by sensing the component of gravitational acceleration along a specified input axis. A combination of design enhancements enables significantly higher sensitivity for this device as compared to previously reported prototype sensors. The MEMS tilt sensor is calibrated on a manual tilt table over tilt angles ranging over 0-90 degrees with a relatively linear response measured in the range of ±20°(linearity error <2.3%) with a scale factor of approximately 50.06 Hz/degree. The noise-limited resolution of the sensor is found to be approximately 250 nano-radians for an integration time of 0.8 s, which is over an order of magnitude better than previously reported results [1].**

Keywords—MEMS, resonant sensors, tilt sensing.

I. INTRODUCTION

Tilt sensors or inclinometers are widely utilized in many fields such as alignment of machinery, attitude control systems, user interfaces in smart phones, slope monitoring in tunnels and embankments and in wearable devices. Many of these applications require small size, low power and in some cases high performance. Recently, a number of MEMS tilt sensors based on various principles such as thermal convection, piezo-resistance, optical or capacitive sensing [2-6] have been reported providing advantages of reduced size, weight and power and batch manufacturability. However, these solutions are often limited in terms of sensitivity and resolution particularly for low bandwidth applications.

In this paper, we report on a resonant MEMS tilt sensor design for enhanced sensitivity. The mechanical element of the tilt sensor is fabricated in a silicon-on-insulator MEMS (SOI-MEMS) foundry process. The device is vacuum packaged using a custom process following wirebonding to a standard leadless chip carrier. The tilt sensor is then calibrated on a manual tilt table over tilt angles varying from 0-90 degrees demonstrating a relatively linear scale factor of 50.06 Hz/degree in the range of ±20°. This result demonstrates approximately a factor of 6 sensitivity enhancement on a similar device reported by our group last year [1]. A low-noise DC polarization voltage source is used to bias the resonant element. The vacuum packaged sensor chip is then co-integrated together with an oscillator circuit on a single PCB to provide frequency output readout with a noise-limited resolution of approximately 250 nano-radians for an integration time of 0.8 s – an order of magnitude improvement in device resolution over previously reported results.

II. SENSOR DESIGN

We have previously reported on a prototype resonant MEMS tilt sensor [1] demonstrating a scale factor of 8.08 Hz/degree for tilt angles in the range of ±20°. The topology (Fig.1) and operation principle (Fig.2) of the sensor remains similar to the previous device and is briefly introduced below. The mechanical design of the tilt sensor consists of a proof mass suspended by an arrangement of four identically designed flexural beams. A force leverage mechanism couples (and amplifies) the inertial force on the proof mass onto two double-ended tuning fork resonant strain gauges located on either side of the mass. When the sensor is subjected to an angular tilt about the sensing axis, the change in the gravitational force displaces the suspended proof-mass inducing independent axial tensile and compressive stresses on the two DETFs, the magnitudes of which are proportional to the sine of tilt angle. The output of the device is measured by recording the resonant frequency shift of the DETFs which is proportional to the axial force acting on the tines. The differential measurement of frequency enables a first-order cancellation of common-mode effects such as temperature.

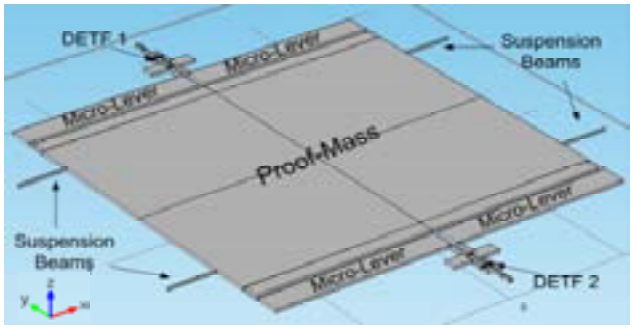

Fig. 1. Topology of the resonant tilt sensor.

The sensitivity of MEM resonant tilt sensor can be estimated from:

$$\Delta f_{out}(\theta) = S_{\mathrm{Re}s} \times EA_{Lvr} \times M_{proof} \times g \times \sin\theta \qquad (1)$$

where S_{Res} is the scale factor of DETF resonant sensing element in unit of '*Hz/N*', EA_{Lvr} is the effective force amplification factor provided by the micro-levers, M_{Proof} is the proof-mass, θ is the tilt angle and g is the magnitude of the gravity acceleration. Δf_{out} is the differential frequency shift output of the tilt sensor. In order to enhance the sensitivity of the tilt sensor, several design modifications were made to the design reported previously [1] to increase the S_{Res}, EA_{Lvr} and M_{Proof}, respectively.

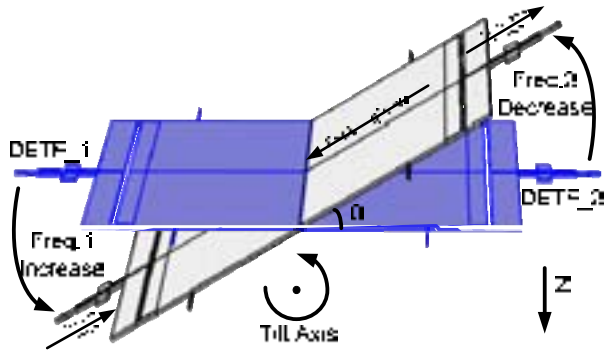

Fig. 2. Schematic illustrating the operation of the tilt sensor.

A. DETF sensing element

Two DETFs form the sensing elements of this device. The scale factor of DETFs sensing element is given by:

$$S_{Res} = \frac{\Delta f}{F_{Axial}} \approx \frac{1}{2\pi} \cdot 0.293 \left(\frac{L_T^2}{E t_T w_T^3} \right) \cdot \sqrt{E \left(\frac{w_T}{L_T} \right)^3 \cdot \frac{1}{\rho \left(A_{Ele} + 0.375 \cdot L_T w_T \right)}} \quad (2)$$

Where F_{Axial} is the axial force load on the free end of DETF sensing element, E is the modulus of elasticity of the material, ρ is the density of the material, L_T, w_T and t_T are the length, width and thickness of the DETF tine beam and A_{Ele} is the area of attached parallel-plate driving/sensing electrodes. As shown in Eq. 2, the scale factor is determined by material properties and device geometry. For single-crystal silicon devices, the relationship between the scale factor and device dimensions may be written as:

$$S_{Res} \propto \frac{L_T^{7/2}}{t_T w_T^{3/2} \left(A_{Ele} + C_2 \cdot L_T w_T \right)^{1/2}} \quad (3)$$

The thickness of the device layer is specified by the manufacturing process. The scale factor enhancement reported in this work arises from in the new tilt sensor was realized by narrowing the beam width and reducing the size of electrodes.

B. Micro-levers

The micro-lever is a mechanical force amplifier that couples the inertial force on the proof mass axially onto the DETFs. The effective amplification factor of micro-lever (EA_{Lvr}) is defined by Eq. 4:

$$EA_{Lvr} = \frac{F_{Axial}}{M_{proof} g \cdot \sin\theta} \quad (4)$$

The effective amplification factor of micro-lever is not only determined by the design of micro-lever but also influenced by the mechanical suspension and DETF design, and can be estimated as:

$$EA_{Lvr}\left(A_{Lvr}\right) \approx \frac{k_{vt} A_{Lvr}}{k_{sus} A_{Lvr}^2 + k_{vt}} \quad (5)$$

The maximum value of the effective amplification provided by the lever is:

$$Max(EA_{Lvr}) = \frac{A_{Lvr}}{2}, \text{ when } A_{Lvr} = \sqrt{\frac{k_{vt}}{k_{sus}}} \quad (6)$$

Here the A_{Lvr} is the lever amplification factor, which is determined by the geometry of the micro-lever, k_{sus} is the flexure stiffness of the proof mass suspension along the sensing axis and k_{vt} is the axial stiffness of the DETFs. As shown in Eq. 5 and Eq.6, for a specific design of the DETF sensing element and suspension, where k_{sus} and k_{vt} are fixed, there is an optimum lever geometry to maximize the effective amplification factor as implemented in device presented in this work. Moreover, as the maximum EA_{Lvr} is determined by the ratio between the axial stiffness of the DETFs and the flexure stiffness of the suspension, a more flexible suspension is designed to further increase the sensitivity to tilt angle.

C. Proof-mass

Increasing the proof-mass is the most straight forward method to enhance the sensitivity. Limits on the proof-mass dimensions are imposed by the fabrication process, material properties and the design area as well as considerations of sensor robustness (e.g. response under sudden shock). The dimensions of the designs presented here were largely restricted by constraints imposed by the foundry process.

III. Scale Factor Calibration

The device is fabricated in a SOI-MEMS foundry process (MEMSCAP Inc., USA) with a device layer thickness of 25 µm. The micro-fabricated chips are mounted onto standard chip carriers and then vacuum packaged using a custom process. The optical micrograph for a packaged sensor chip with wire-bond is shown in Fig. 3.

The vacuum packaged sensor chip is co-integrated with frequency tracking oscillator circuits (Fig.4) on a single PCB and mounted on a manual tilt table to calibrate the scale factor. As shown in Fig. 5, the tilt sensor and manual tilt table were placed on a suspended platform which is adjusted parallel to the ground. The frequency of oscillator output signal was

measured and recorded using a frequency counter (Agilent 53230A).

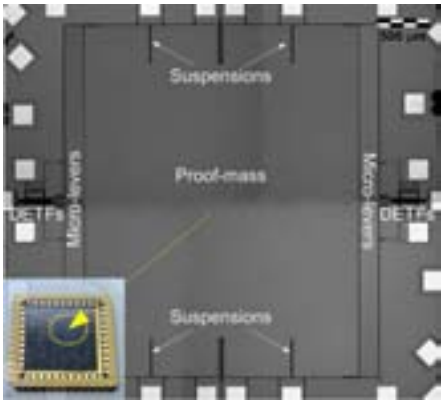

Fig. 3. Optical micrograph of the MEMS sensor element (inset: wire-bonded vacuum packaged chip).

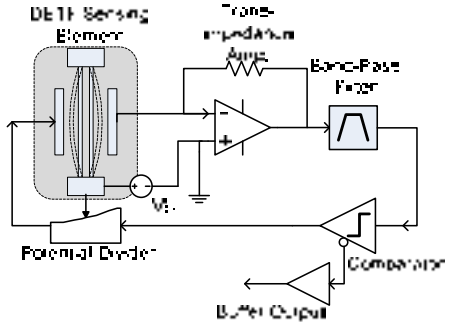

Fig. 4. Electro-mechanical frequency tracking oscillator circuit schematic.

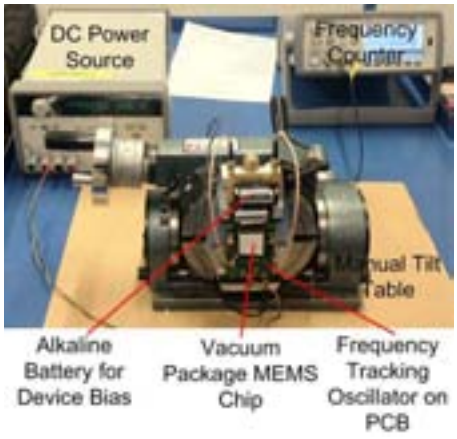

Fig. 5. Experimental calibration set- up.

Fig. 6 shows the output frequency variation of DETF_1 (see Fig. 2) observed in a 0^o-90^o tilt test with 10^o increment for each step. The dashed line is the fitting curve for the mean frequency shift of the tilt sensor for each calibration point. The output frequency shift of the oscillator is seen to vary as a sinusoidal function of the tilt angle and is in agreement with the analytical model presented in Eq. 1. The tilt test results also indicate that the new sensor provides a relatively linear response in the range of $\pm 20^o$ with a differential scale factor of approximately 50.06 Hz/degree, compared to the value of 8.08Hz/degree reported previously [1].

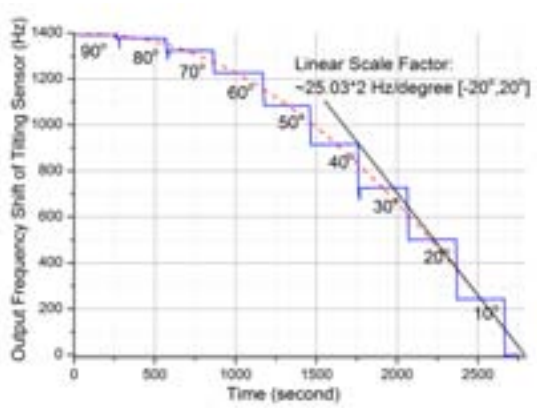

Fig. 6. Output frequency shift response versus tilt angle.

IV. Resolution Analysis

Improving the resolution of the resonant tilt sensor not only requires increasing the scale factor but also optimizing the noise floor. As the frequency shift of the DETFs induced by tilt angle change is tracked by an oscillator circuit, the noise floor of resonant tilt sensor can be derived from the frequency stability of the oscillator output. The noise-limited tilt angle resolution of MEM resonant tilt sensor within the linear tilt angle range is defined as:

$$\theta_{\min} = \left(\frac{\Delta f_n}{f_0}\right) \cdot \frac{\bar{f}_0}{S_{Tilt}} \tag{7}$$

Where the $(\Delta f_n/f_0)$ is the frequency stability of the output signal of frequency tracking oscillator with invariant acceleration input, normally represented in units of ppm (part per million) or ppb (part per billion), $\bar{f}_0$ is the average output frequency of the oscillator over the period of measurement and S_{Tilt} is the scale factor of the tilt sensor.

A. Voltage-Frequency Noise Conversion

The frequency stability of the electro-mechanical oscillator can be influenced by several factors. In this section, we consider limitations arising from voltage-to-frequency (V-F) noise conversion impacting on the frequency stability of the oscillator. V-F noise conversion may arise from the nonlinearities in the mechanics and the electrostatic transduction of the DETF sensing element. The mechanical nonlinearity of DETF converts the noise and drift of the AC driving signal into a corresponding frequency shift [7]. In the oscillator implementation described here, a comparator is employed to limit the amplitude of the drive signal (see Fig.4) and the impact of the AC V-F noise conversion is expected to be small. The parallel-plate electrostatic actuation in the DETF sensing element introduces a frequency pulling effect that is

dependent on the magnitude of DC polarization voltage [8]. Due to the non-linear electrostatic actuation, low-frequency voltage noise and drift in the DC polarization voltage can result in a shift in the oscillator output frequency. If the fluctuation in the DC polarization voltage is defined as $V_P(t)=V_{P0}+\Delta V_P(t)$, the frequency shift induced by the polarization voltage may be expressed as

$$\Delta f_{0\_DC}^2(t) \approx G_{DC}(f_0, V_{P0}, g_{Elc}, t_{Elc}) \cdot \Delta V_P^2(t) \qquad (8)$$

where G_{DC} is a coefficient determined by the resonant frequency of DETF, the geometry of the parallel-plate actuator and the level of DC polarization voltage. The DC polarization voltage limited resolution of MEM resonant tilt sensor can then be estimated as:

$$\theta_{\min\_DC}^2(B) = \left(\frac{f_0^2}{S_{Tilt}^2}\right) \int_{1/\tau_d}^{B} \left(\frac{1}{f_0^2}\right) G_{DC} S_{DC}(f)\, df \qquad (9)$$

where $S_{DC}(f)$ is the power spectral density of the DC polarization voltage noise, B is the measurement bandwidth which is related to the reciprocal of the counter gate time, τ_d is the time-scale over which drift starts to impact the output frequency and f is the Fourier Frequency in the integral of Eq. 10.

B. Experimental Results

To study the influence of DC polarization voltage on the frequency stability of the sensor output, two successive measurements were made on a tilt sensor with the sensitive axis oriented normal to the gravity field. In the first measurement, the DC polarization voltage was supplied by an alkaline battery. In the second measurement, the DC polarization voltage was supplied from a conventional low-noise regulated DC power supply (Agilent E3631A). The magnitude of the polarization voltage was set to be identical in both cases. The oscillator output was logged on a frequency counter and modified Allan deviation calculations were carried out. The results of this calculation are plotted in Fig. 7. When the DETF sensing element was polarized by the regulated DC power source, the short-term frequency stability floor of the oscillator is found to be approximately 19.5 ppb for an averaging time of 1.6 seconds. When the DETF sensing element was polarized using a battery, the short-term frequency stability floor of the oscillator is found to be about 6.7 ppb for an averaging time of 0.8 seconds. It is known that batteries normally has lower noise level than the conventional DC power source [9], so this experiment demonstrates that the influence of DC polarization voltage noise on the frequency stability of the oscillator. For the tilt sensor using batteries as DC polarization source, the equivalent angle resolution is approximately 250 nano-radian, which is over an order of magnitude better than previously reported results [1].

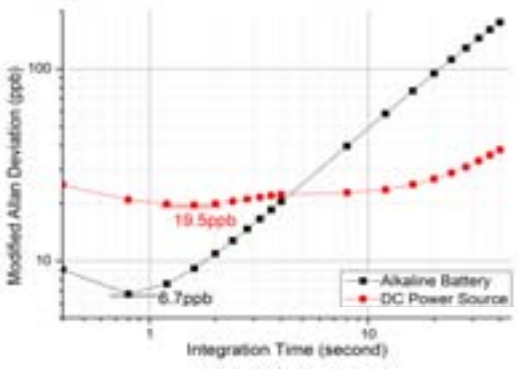

Fig. 7. Modified Allan deviation results for the freqency tracking oscillator with different DC polarization sources.

However, it should also be noted that the output frequency of the tilt sensor polarized by batteries shows larger long-term drift comparing to the tilt sensor polarized by a regulated DC power supply.

V. CONCLUSION

This paper demonstrates an improved high-resolution resonant MEMS tilt sensor with a measured scale factor of 50.06 Hz/Degree for a ± 20 degree tilt angle range. The noise-limited resolution of the device is found to be 250 nano-radian for a 0.8 second averaging time employing a battery-based DC polarization source, demonstrating over an order of magnitude improvement in resolution over previous prototypes.

Case Western Reserve University, Cleveland, OH 44106, USA
*Email: jaesung.lee@case.edu, philip.feng@case.edu

***Abstract*—Molybdenum disulfide (MoS_2) is a layered material that has attractive potential for enabling ultrascaled two-dimensional (2D) nanostructures and nanosystems for future electronics, optoelectronics, and sensors applications. It also has superb mechanical properties, being ~30 times stronger than steel and has intrinsic strain limit up to ~10–20%. These make MoS_2 a particularly interesting material for building novel 2D nanoelectromechanical systems (NEMS). Here we demonstrate ultrathin 2D NEMS resonators based on drumhead-structured MoS_2 diaphragms suspended on circular microtrenches, vibrating at high and very high frequencies (HF & VHF). We show that the resonance frequency can be tuned by adjusting parameters such as built-in tension and dimensions of the MoS_2 devices. In combination with analytical and computational modeling, we identify in these devices the elastic transition regime between the membrane and plate limits, which leads to a clear roadmap for frequency scaling of MoS_2 NEMS resonators.**

Keywords—nanoelectromechanical systems (NEMS); two-dimenstional (2D) crystal; molybdenum disulfide (MoS_2); resonator; thermomechancial noise, frequency scaling

I. Introduction

Nanoelectromechanical devices and systems (NEMS) made of atomically-thin layers of crystalline materials have unique properties and advantages that come from the ultra-low mass and great flexibility of the motional parts of the devices. Graphene NEMS, for example, have been extensively studied and demonstrated great potential. Meanwhile, building NEMS devices by using different 2D materials that have unique electronic and optical properties [1-4] can lead to novel devices suitable for different applications. For most of the last decade, however, graphene has been the only 2D material under significant attention. The recently emerging 2D material MoS_2 is particularly attractive for its compelling physical properties. For example, MoS_2 has a layer-number-tunable band-gap: it evolves from an indirect-gap semiconductor in bulk to a direct-gap semiconductor in monolayer [2]. To date, extensive efforts have mainly been focused on studying the electronic and optical properties of 2D MoS_2 structures [1-4]. Recently, initial experiments have demonstrated that 2D MoS_2 also has excellent mechanical properties [5], which make it one of the strongest and most stretchable and flexible 2D semiconducting materials. In this work, we demonstrate high frequency and very high frequency (HF/VHF) nanomechanical resonators based on very thin suspended MoS_2 diaphragms. In addition, by combining measurement results with theoretical modeling, we present a roadmap that describes the frequency scaling capability of drumhead resonators based 2D MoS_2.

II. Device Fabrication and Measurement

Drumhead-shaped 2D MoS_2 resonators are fabricated using photolithography and mechanical exfoliation. Circular microtrenches of different dimensions are patterned onto wafers with ~290nm-thick thermally-grown SiO_2 on Si with photolithography followed by buffered oxide etch (BOE). We peel off bulk MoS_2 by mechanical exfoliation to achieve devices of different thicknesses. After exfoliation, MoS_2 flakes covering predefined microtrenches form drumhead-structured nanomechanical resonators. We use optical microscope to search and identify suspended MoS_2 structures and later (after measurements of resonances) perform atomic force microscopy (AFM) studies to measure the thicknesses of MoS_2 flakes.

Thermomechanical motions of the MoS_2 nanomechanical drumhead resonators are carefully measured by employing an ultra-sensitive laser interferometry system (Fig. 1). We use a 50× microscope objective to produce a ~1μm laser spot on the device, which enable us to measure the mechanical motion of the devices with a displacement sensitivity at the level of ~30fm/$Hz^{1/2}$. All the measurements are performed at room temperature (T~300K) and in moderate vacuum (p~6mTorr). We use a 632.8nm He-Ne laser, and we control the laser power on the device to be below ~0.7mW to minimize heating effect. This laser power level yields good responsivity in the motion transduction, and does not generate noticeable heating.

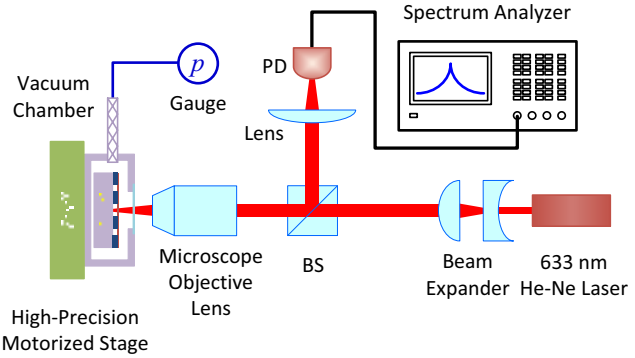

Fig. 1. Schematic of the laser interferometry motion detection system, with thermomechanical resonances spectra analysis. All measurements are performed in moderate vacuum (~6mTorr), and at room temperature (~300K).

III. Experimental Results and Discussions

We investigate the intrinsic thermomechanical resonances of the devices arising from the Brownian motions. Without any external drive, we measure the thermomechanical noise spectrum of the devices using this specially engineered, highly sensitive optical interferometry system. We then fit the measured results to a damped harmonic resonator model to estimate measured quality (Q) factor and the frequency-domain displacement spectral density [6]

$$S_{x,th}^{1/2}(\omega)=\left(\frac{4k_BT\omega_0}{M_{eff}Q}\cdot\frac{1}{\left(\omega^2-\omega_0^2\right)^2+\left(\omega\omega_0/Q\right)^2}\right)^{1/2}. \quad (1)$$

Here, k_B is the Boltzmann constant, M_{eff}, ω_0, and Q are the effective mass, angular resonance frequency, and measured quality factor of the resonance mode, respectively.

To calculate the thermomechanical motion amplitude using Eq. (1), it is necessary to determine M_{eff}, which depends on the mode shape of the resonance. Here we calculate effective masses of circular plate and membrane resonators for their out-of-plane vibrations. For fully clamped circular plate, the mode shape of fundamental mode (m=0, n=1) as a function of normalized radius (0<r<1) can be written as

$$Z_{01}(r)=J_0(\beta_{01}\cdot r)-\frac{J_0(\beta_{01})}{I_0(\beta_{01})}\cdot I_0(\beta_{01}\cdot r), \quad (2)$$

where J_0 is the 0th order Bessel function J, and I_0 is the 0th order extended Bessel function I. For the fundamental mode, $\beta_{01}^2=10.216$. The normalize displacement is defined as

$$u_{01}(r)=\frac{Z_{01}(r)}{\max(Z_{01})}, \quad (3)$$

and the effective mass can be calculated by using

$$M_{eff,01}=M\cdot\frac{1}{\pi}\int_0^1 2\pi r\cdot\left[u_{01}(r)\right]^2 dr. \quad (4)$$

Here M is the total mass of the resonator. Using Eq. (4) we calculate the effective mass of a circular plate to be $M_{eff,01}=0.1828M$ for the fundamental out-of-plane mode.

Similarly, for a circular membrane, the mode shape is

$$Z_{01}(r)=J_0(\beta_{01}\cdot r), \quad (5)$$

where $\beta_{01}=2.405$. The calculated an effective mass for its fundamental mode is $M_{eff,01}=0.2695M$. Using Eqs. (1)–(5) we are able to estimate the thermomechanical resonant noise spectral density of the devices and thus determine the signal transduction responsivity and displacement sensitivity.

Figure 2 shows examples of measured thermomechanical resonance spectra from relatively larger devices (diameter d~6μm) with different thicknesses (t~10–50nm). The measured thermomechanical resonance of device #1 (Fig. 2 (a)–(c), with diameter d≈5.7μm and thickness t≈13nm) has resonance frequency f≈11.54MHz in the HF band, with Q≈105. Another device, device #2 (Fig. 2(d)–(f), with d≈6.2μm and t≈48.8nm), exhibits thermomechanical resonance at f≈16.76 MHz with Q≈180. We have tested devices of a wide range of thickness (t~2–68nm, corresponding to ~3–97 layers).

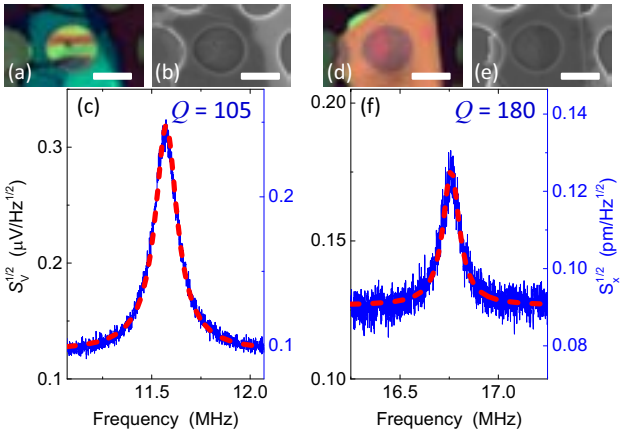

Fig. 2. HF MoS_2 nanomechanical resonators – device images & measured thermomechanical resonances. For each device, optical microscope image, SEM image, and resonance characteristics are shown. (a)–(c) Device #1 (d≈5.7μm and t≈13nm). (d)–(f) Device #2 (d≈6.2μm and t≈48.8nm). From the color and contrast in the optical images, approximate device thicknesses can be estimated (we have verified with AFM). All scale bars are 5μm.

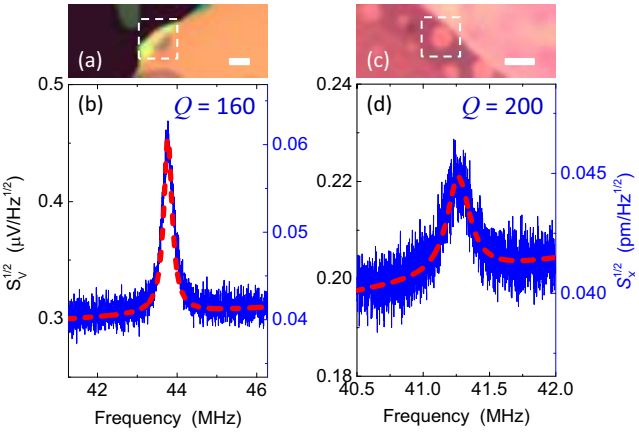

Fig. 3. VHF MoS_2 nanomechanical resonators based on MoS_2 drumheads with smaller diameters. Optical image and mechanical resonance are shown for both devices. (a)–(b) Device #3 (d≈2.5μm and t≈57.5nm). (c)–(d) Device #4 (d≈1.6 μm and t≈2.8nm). All scale bars are 2μm.

We have also measured thermomechanical resonances from relatively smaller devices (Fig. 3). Device #3 (d≈2.5μm and t≈57.5nm) shows resonance in the VHF (30–300MHz) band with f≈43.77MHz and Q≈160. Device #4 (d≈1.6 μm and t≈2.8nm) also displays resonance in the VHF band with f≈41.27MHz and Q≈200. In measurements of both devices, a displacement sensitivity of $S_x^{1/2}$≈42fm/Hz$^{1/2}$ is achieved.

IV. Frequency Scaling

We further investigate the frequency scaling capability of these HF and VHF MoS_2 2D nanomechanical resonators. We

theoretically calculate the fundamental resonance frequencies for circular drumhead resonators and compare with measured results. For a tensioned circular drumhead resonator (clamped on perimeter edge) with finite flexural rigidity D, the resonance frequency can be calculated with the expression [7, 8]

$$\omega_{mn} = \left(k_2^{mn}\frac{d}{2}\right)\sqrt{\frac{16D}{\rho d^4}\left[\left(k_2^{mn}\frac{d}{2}\right)^2 + \frac{\gamma d^2}{4D}\right]}. \quad (6)$$

Here, ω_{mn} is the angular frequency for the resonance for a specific mode (m,n) (with m and n being the numbers of nodal diameters and nodal circles), d is diameter of the diaphragm, ρ is the areal (2D) mass density (kg/m^2), and γ is the built-in tension (force per unit length, in N/m, as in surface tension) of MoS_2 resonator. $D=E_Y t^3/[12(1-\nu^2)]$ is the flexure rigidity, with E_Y being the Young's modulus, t the thickness of the MoS_2, and ν the Poisson's ratio. k_2^{mn} is a mode-dependent parameter which can only be precisely determined numerically.

In the limit of an ideal membrane, the built-in tension dominates, and $\gamma d^2/D \to \infty$. Eq. (6) then simplifies into

$$\omega_{mn} = \frac{\left(k_2^{mn} d\right)}{d}\sqrt{\frac{\gamma}{\rho}}. \quad (7)$$

Eq. (7) gives the 'membrane limit' of a drumhead resonator, which shows dependence on both the built-in tension and dimensions of the device. Here, we use 2D surface tension γ (force per unit length, N/m), which is suitable to 2D material-based resonator, instead of the other form of tension (force, in N) or stress (force per unit cross-sectional area, in Pa or N/m^2) which are more suitable for 3D structures. In addition, we used ρ, the 2D mass density, for the same reason.

In the other limit of an ideal plate, the bending rigidity dominates, and $\gamma d^2/D \to 0$. Eq. (6) then becomes

$$\omega_{mn} = \frac{\left(k_2^{mn} d\right)^2}{d^2}\sqrt{\frac{D}{\rho}}. \quad (8)$$

This is the well-known expression for circular plate resonators. Both limits are plotted as dashed lines in Fig. 4 for d=6μm devices. In the transition regime between the membrane and plate limits, ($k_2^{mn}d/2$) can be approximated with a double exponential expression.

$$\left(k_2^{mn} d/2\right) = \alpha + (\beta - \alpha)e^{\left[-\eta e^{\delta \ln(x)}\right]}, \quad (9)$$

where $x=\gamma d^2/(4D)$. For the fundamental resonance mode (m=0, n=1), the numerical parameters are α=5.7832, β=10.215, η=0.1148, and δ=0.4868 [8]. Compared to the numerical solution, the error from using this approximation (Eq. (9)) is below 3.8% in the entire range of x for the fundamental mode.

Using Eqs. (6) and (9), we calculate resonance frequency of the fundamental mode for MoS_2 drumhead resonators with different diameters and thicknesses. To calculate the areal mass density of MoS_2 resonators, we use 5.06g/cm^3 for the 3D mass density and 0.7nm as the monolayer thickness [2, 4]. In literature there are a number of different Poisson ratios reported for MoS_2, from 0.125 [9] to 0.25 [10] and 0.27 [11]. Here we use Poisson's ratio ν=0.165 [12], same as that for graphene. Indeed, in our estimation, ν very little affects the resonance frequency. This is because when the device is in the ideal membrane limit, resonance frequency does not depend on Poisson's ratio. In the ideal plate limit, ν only affects the flexure rigidity D, and the variation in resonance frequency due to different ν values is always below 2.5%. We use Young's modulus of E_Y=0.2TPa [5,9,13], and the resulting frequency values are consistent with our experimental data. In Fig. 3, we display calculated resonance frequency using built-in tension values γ=0.1–0.5N/m (except for d=0.5μm), as typically observed in mechanically exfoliated flakes [5]. For d=0.5μm devices, we show an additional curve with a tension γ=4.2N/m, which can lead to GHz resonators if the MoS_2 diaphragm is thinner than 3 layers. This tension level corresponds to a strain of only 3% in monolayer and 1.5% in bilayer, still far below the intrinsic strain limit of this material [5,13]. The calculation results are plotted in Fig. 4 together with the experimental results from more than 20 measured devices.

From Fig. 4 we observe that, when the device is sufficiently thin, the resonator is operating in the membrane regime, and can have great frequency tunability through the built-in tension of MoS_2. On the other hand, thick devices mostly operate in the plate regime. In our measurements, data from the larger-diameter (d~6μm) devices agree well with the 6μm curves, and data from the smaller-diameter (d~2μm) devices match the 2μm curves. Data points from some incomplete diaphragms are below the curves for the d~2μm devices. For devices with d=2~6μm and thickness of t=10–20 layers of MoS_2, even with very small tension (γ=0.1–0.5N/m), they are already in the 'crossover' transition regime from plate to membrane.

Besides thickness and tension, lateral device size also has strong effect on the resonance frequency. In Fig. 4 the smaller devices (red circles) clearly have much higher frequencies (note the log scale) than the larger ones. Indeed, all these devices operate in a higher radio frequency band (VHF versus HF). This signifies that reducing the lateral dimension is also an effective means for achieving higher frequencies in MoS_2 nanomechanical resonators. In Fig. 4 we also plot the calculation results for d=0.5 μm devices (the green curve family at the top). It shows that given this small size, 1GHz devices can be achieved for devices thicker than 20 layers.

To further appreciate the strong effect from lateral device size, we plot resonance frequency versus device diameter in Fig. 5. The log-log plot again clearly demonstrates the different power law dependences on diameter in the ideal membrane and plate limits (dashed lines). As expected, part of the 10 layer curve (thin solid line) lies in the transition region between the two limits, while the 100 layer curve (thick line) is mostly in the ideal plate limit. The strong and monotonic dependence of resonance frequency on device diameter signified in this plot, regardless device thickness and the regime it operates in, again suggests that smaller diameters are effective to attaining resonance frequencies in the UHF band.

The results in Fig. 4 and Fig. 5 demonstrate frequency scaling of MoS_2 resonators through dimension engineering. Designing smaller-diameter devices and engineering higher

built-in tension for thinner devices can both lead to higher resonance frequencies. For instance, for a 0.5μm diameter device, a moderate built-in tension level of 4.2N/m (strain $\varepsilon \approx 1.5\%$ for bilayer and $\varepsilon \approx 3\%$ for monolayer) can realize GHz flexural mode MoS_2 resonators for devices less than 3 layers.

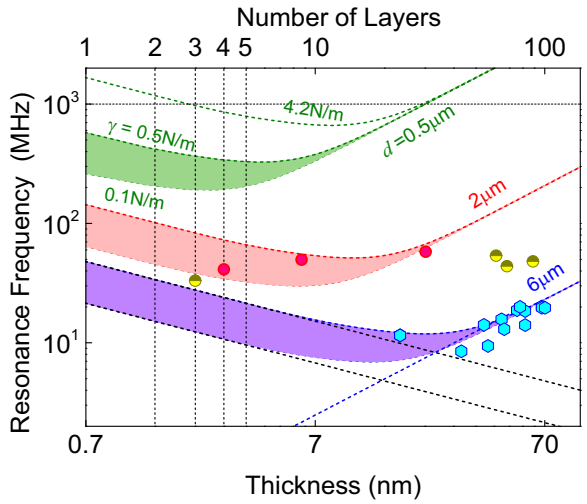

Fig. 4. Frequency scaling and elastic regimes for drumhead MoS_2 2D nanomechanical resonators. Blue, red, and green lines represent calculated fundamental flexural-mode resonance frequencies for devices with d=6μm, 2μm, and 0.5 μm, respectively. The regions with filled colors represent the γ=0.1–0.5N/m built-in tension range for each device size. Black and blue dashed lines respectively show the membrane and plate limits for d=6μm devices. Blue hexagons represent measured devices with larger diameters (~6μm). Red circles represent devices with smaller diameter (~2μm). Half-covered yellow circles denote d~2μm devices with incomplete drumheads.

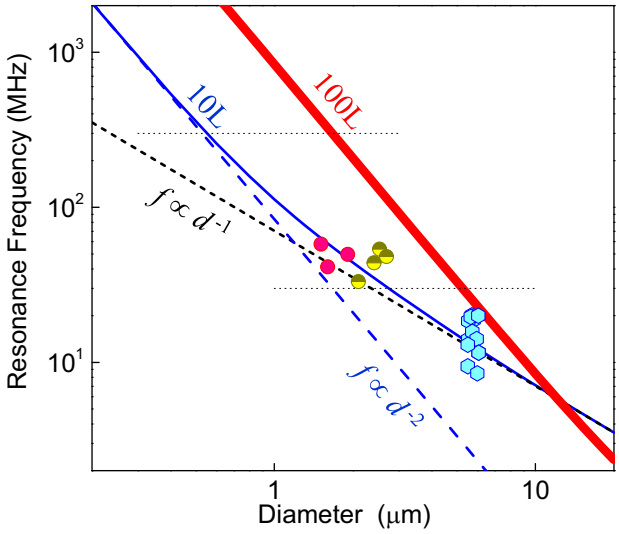

Fig. 5. Frequency scaling of drumhead-shaped MoS_2 2D nanomechanical resonators. Resonance frequency versus device diameter for devices with different thickness (in units of MoS_2 monolayer) are plotted. The red and blue solid lines represent devices of 100 layers and 10 layers, respectively. The blue and black dashed lines stand for ideal plate and membrane (with 0.3N/m built-in tension) limits, respectively. Horizontal dotted lines mark the onsets of VHF and UHF bands. Experimental data are the same as shown in Fig. 4.

V. Conclusions

In summary, we have demonstrated drumhead-structured HF/VHF 2D nanomechanical resonators based on suspended MoS_2 nanosheets with different sizes and thicknesses. Using an ultrasensitive optical interferometric readout technique with exceptional displacement sensitivity as good as ~30fm/Hz$^{1/2}$, we have measured thermomechanical resonances arising from the undriven intrinsic Brownian motions of resonators, the smallest motions from the devices. We also systematically investigate frequency scaling of the MoS_2 resonators and elucidate the membrane and plate limits, as well as the elastic transition regime in between. Combining analysis with experimental results, we identify the built-in tension levels in these exfoliated MoS_2 structures. These results offer guidelines for engineering 2D nanomechanical resonators with desired resonance frequencies, via size scaling and tension control.

Abstract—This paper presents, for the first time, a fast (thermal time constant of 1.3 ms) and sensitive (responsivity of 310 Hz/μW) Infrared detector consisting of an Aluminum Nitride (AlN) nano-plate resonator (NPR) connected to a compact and low power CMOS self-sustained oscillator (fabricated in the AMIS 0.5 μm CMOS process) as a direct frequency readout. A high performance (quality factor Q = 1283 and electromechanical coupling coefficient k_t^2 = 1.56%) MEMS resonant structure based on a thin AlN (250 nm thick) NPR coated with Si_3N_4 (100 nm thick) as IR absorber was fabricated and tested, showing a measured temperature coefficient of frequency (TCF) of -35 ppm/K and FEM simulated temperature rise factor of 72.5 mK/μW. Thanks to the high electromechanical performance of the MEMS resonator, a compact and low power (2.3 mW) self-sustained CMOS oscillator circuit was used as a direct frequency readout, enabling the demonstration of a novel uncooled IR detector with a low Noise Equivalent Power (NEP) of 3.5 nW/Hz$^{1/2}$.

Keywords—Aluminum Nitride; MEMS Resonators; Infrared Sensor; MEMS-CMOS Oscillator.

I. INTRODUCTION

With the recent advance in Micro/Nano-Electro-Mechanical Systems (MEMS/NEMS) technologies, miniaturized sensors with high sensitivity and low detection limit have been developed. In particular, MEMS resonators have been successfully used in detecting mass [1], gas flow [2] and specific chemical agents [3], showing extremely high sensitivity. The exclusive advantage of MEMS/NEMS resonant detectors is the combination of high sensitivity to external perturbation (extremely reduced overall volume) and low noise performance (intrinsically high quality factor Q). MEMS resonant IR detectors based on gallium nitride [4] and quartz [5] resonators have been recently demonstrated showing promising performance. However, complex, cumbersome, power hungry and expensive electronic readouts, based on open-loop measurements involving the use of a network analyzer, have been employed so far to measure the resonance frequency or impedance change of such resonant MEMS IR detectors, which has prevented these technologies to meet the stringent miniaturization, cost and power requirements typical of commercial and military IR imaging and sensing applications.

In this work, a step stone towards the development of MEMS resonant IR thermal detectors characterized by high sensitivity, low detection limit, fast response and compact readout was set by demonstrating an Aluminum Nitride (AlN) piezoelectric MEMS-CMOS oscillator. For the first time, an ultra-thin (250 nm thick) AlN piezoelectric resonator (differently from gallium nitride and quartz, ultra-thin and high quality AlN film can be deposited directly on Silicon substrates by low-temperature sputtering process) working at a higher order lateral-extensional mode [6], whose resonance frequency is highly sensitive to external temperature fluctuation, was integrated with a thin Si_3N_4 film (100 nm thick) as an effective long wavelength IR absorber [7]. The high electromechanical performance (quality factor Q = 1283 and electromechanical coupling coefficient k_t^2 = 1.56%) of the AlN NPR, enabled the direct connection of the resonant device to a compact and low power self-sustained CMOS oscillator circuit as direct frequency readout. This first prototype shows an IR responsivity of 310 Hz/μW, thermal time constant of 1.3 ms, noise equivalent power (NEP) of 3.5 nW/Hz$^{1/2}$ and a power consumption of 2.3 mW , indicating the great potential of the AlN MEMS resonant IR detector technology for un-cooled IR imaging and sensing.

II. DESIGN AND SIMULATION

The core element of the IR detector proposed in this work is an AlN nano-plate resonator, working at a higher order lateral-extensional mode of vibration. The resonance frequency of the AlN NPR, f_0, is determined by the pitch of the interdigital electrode, W_0 (Fig. 1), defined as:

$$f_0 = \frac{1}{W_0}\sqrt{\frac{E_{eq}}{\rho_{eq}}} \quad (1)$$

where E_{eq} and ρ_{eq} are the equivalent Young's modulus and density of the material stack of the resonator. The temperature sensitivity of the resonator arises from the temperature dependence of the equivalent Young's modulus (E_{eq}) of the material stack forming the resonator [8]. For AlN nano-plate contour-mode resonators, the typical value of temperature coefficient of frequency (TCF) is in the range of -30 ~ -50 ppm/K.

This work was supported by DARPA Young Faculty Award contract No. N66001-12-1-4221.

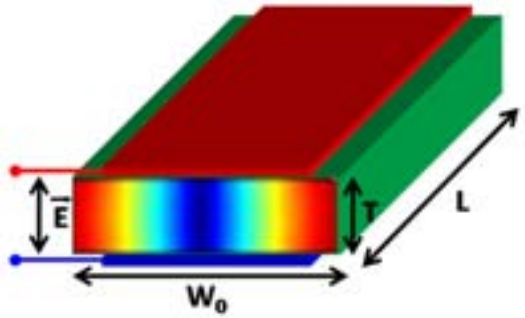

Fig. 1. 3D schematic of the AlN nano-plate resonator. 2D FEM simulated displacement of AlN plate under vertical electric field was superimposed to the AlN film.

IR detectors are typically characterized by two key parameters: noise equivalent power (NEP), and thermal time constant τ, and they can be defined as

$$NEP = \frac{\Delta f_n}{R} \tag{2}$$

$$\tau = R_{th} \cdot C_{th} \tag{3}$$

where Δf_n is the noise induced frequency fluctuation, R is the responsivity, R_{th} is the thermal resistance and C_{th} is the thermal capacitance. For high performance IR detectors, the noise equivalent power and thermal time constant need to be as small as possible. Therefore, the product of NEP and τ can be considered as a device figure of merit for device design and optimization, and can be expressed as

$$NEP \cdot \tau \propto \frac{c \cdot \rho_{eq}}{\eta \cdot TCF} \frac{T^2}{Q \cdot \sqrt{P_c}} \tag{4}$$

where c is the thermal capacity, η is the IR absorption coefficient, P_c is the input power to the resonator. Besides the material properties, (4) clearly shows that fast and low detection limit thermal detectors can be implemented using high quality factor AlN nano-plate resonators with thickness, T<1 μm.

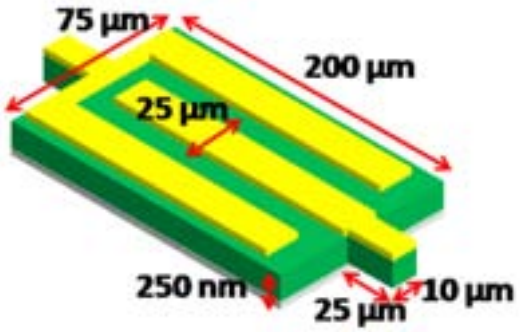

Fig. 2. Optimized dimensions of the AlN nano-plate resonator (the bottom interdigital electrode is shown on top here for clarity).

Based on the aforementioned analysis, an optimized design of an AlN nano-plate resonant structure was proposed (Fig. 2). The thermal time constant and the temperature rise factor (thermal resistance) of the proposed AlN NPR IR detector were estimated by 3D Finite Element Method (FEM) simulation using COMSOL Multiphysics. The thermal conductivity and the heat capacity of AlN were set to be 80 W/(m·K) and 740 J/(Kg·K), respectively. The 3D FEM simulation results are shown in Fig. 3. A thermal time constant as small as 1.3 ms was achieved, thanks to the overall reduced volume of the resonant structure (reduced thermal mass). The temperature rise factor (thermal resistance) of the AlN NPR was found to be 72.5 mK/μW, which guarantees high sensitivity of the device to absorbed IR power.

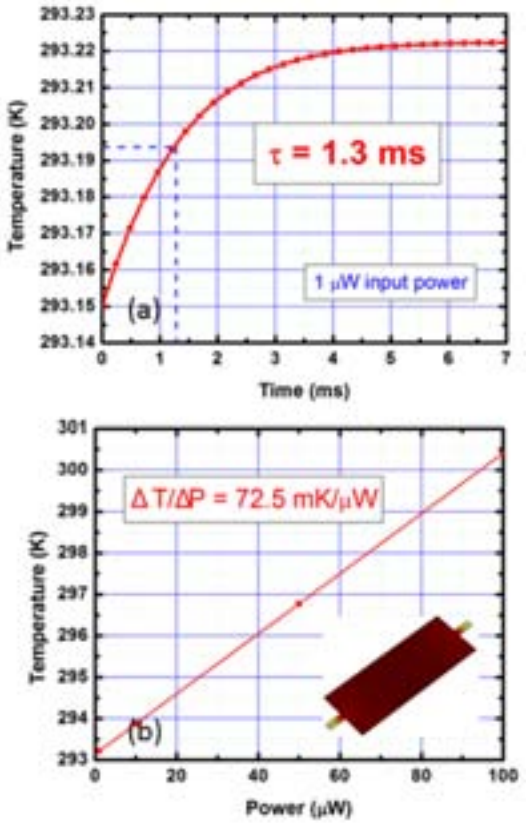

Fig. 3. 3D FEM simulation of the AlN NPR: (a) thermal time constant and (b) temperature rise factor. The inset in (b) shows the uniform temperature distribution across the AlN NPR.

III. EXPERIMENTAL RESULTS

The AlN nano-plate resonator was fabricated using a five-mask microfabrication process, and the detail can be found in [9]. The CMOS integrated circuit (IC) in this work was fabricated in the AMIS 0.5 μm CMOS process. The fabricated AlN NPR was wire bonded to the CMOS IC using a K&S 4523 wedge bonder. The fabricated and wire-bonded MEMS and CMOS dies are shown in Fig. 4.

The electrical performance of the fabricated AlN NPR integrated with thin Si_3N_4 IR absorber was tested by an Agilent E5071C network analyzer after a short-open-load calibration on a standard substrate. The measured admittance amplitude and phase versus frequency and Butterworth-Van Dyke (BVD) model fitting are shown in Fig. 5. The extracted mechanical quality factor Q and electromechanical coupling coefficient k_t^2 are 1283 and 1.56%, respectively. Such high electromechanical performance of the device enabled the capability to connect the MEMS resonator to a compact and low power CMOS oscillator as direct frequency readout. The

temperature coefficient of frequency of the fabricated AlN NPR was measured by a temperature controlled RF probe-station. The measured TCF was found to be -35 ppm/K. Based on the measured TCF and simulated thermal resistance (72.5 mK/μW), the responsivity of the IR detector was estimated to be ~310 Hz/μW.

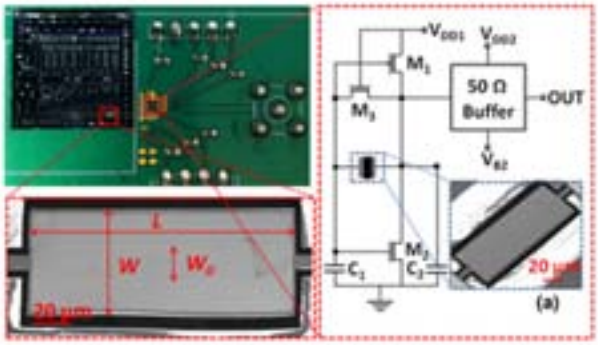

Fig. 4. (a) The fabricated AlN NPR MEMS chip wire bonded to the CMOS die (fabricated in the AMIS 0.5 μm CMOS process). (b) Scanning Electron Microscope (SEM) image of the fabricated AlN NPR; (c) Schematic of the CMOS integrated circuit (IC) as the frequency readout.

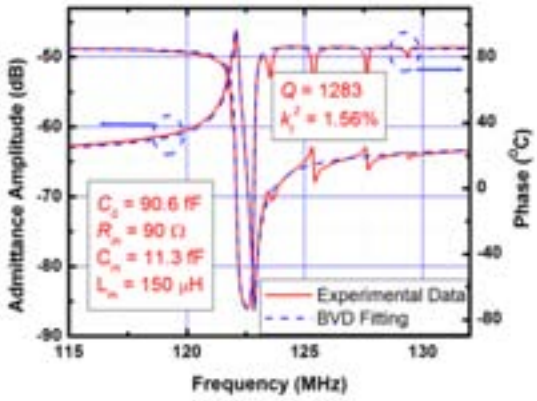

Fig 5. Measured admittance curve and BVD fitting of the fabricated AlN nano-plate resonator.

To evaluate the performance of the fabricated AlN NPR MEMS-CMOS oscillator, the Allan Deviation and phase noise of the device were measured by an Agilent 53230A frequency counter and Agilent N9010A spectral analyzer, respectively. The measured Allan Deviation versus measurement time is shown in Fig. 6 (a). A minimum Allan Deviation of 3.5 Hz was measured at a measurement time of 100 ms, indicating a noise spectral density in 1 Hz measurement time of 1.1 $Hz/Hz^{1/2}$. The phase noise was measured to be -81.1 dBc/Hz at 1 KHz offset and phase noise floor -133.5 dBc/Hz, which are comparable to what is typically achieved with conventional AlN contour-mode resonator based MEMS oscillators [10]. The Noise Equivalent Power (NEP) of the IR detector was estimated to be ~3.5 $nW/Hz^{1/2}$ by dividing the measured noise spectral density by the responsivity of the device (310 Hz/μW).

The IR radiation reflection *R* of the 100 nm Si_3N_4 thin film was measured by a Bruker HYPERION series FTIR microscope. Since the Si_3N_4 was deposited directly on top of a 100 nm thick Au layer, the transmission through the resonant structure was assumed to be ~0. The IR absorption *A* was thus calculated by 1-*R*. A broadband IR absorption higher than 25% from 8 μm to 16 μm with a peak absorption of ~38% at 14 μm was recorded for the 100 nm Si_3N_4 incorporated in the resonant body of the device. .

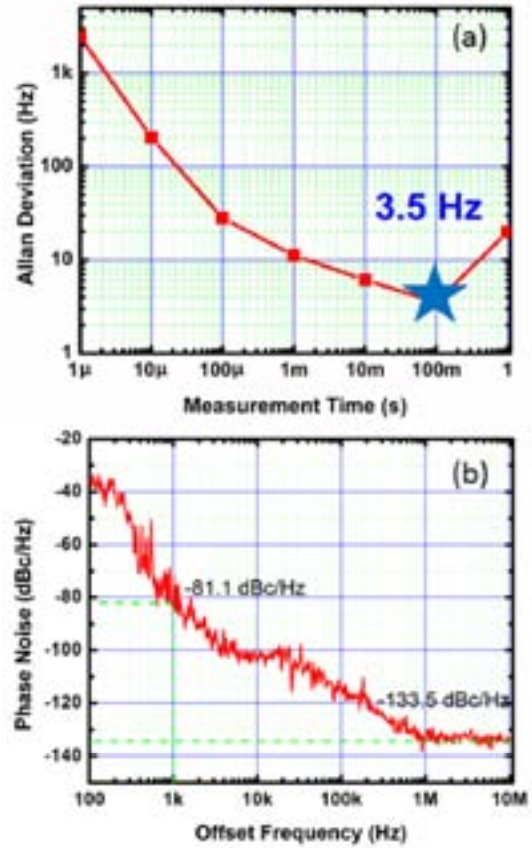

Fig. 6. Measured (a) Allan Deviation and (b) phase noise of the fabricated AlN NPR MEMS-CMOS oscillator.

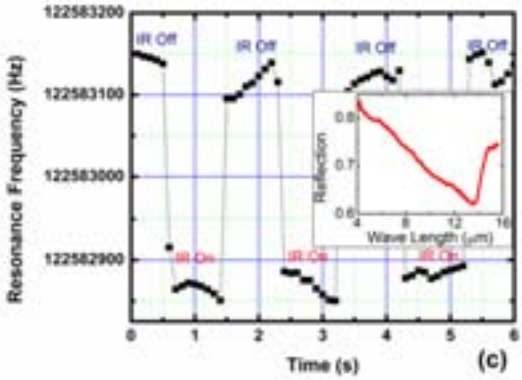

Fig. 7. IR response of the fabricated IR detector to a broad-band IR source (500nm – 25 μm radiation range). The inset shows the measured reflection of the thin Si_3N_4 film.

The IR response of the fabricated device was measured using a Cool Red Infrared light source from Ocean Optics, with a radiation spectrum from 0.5 μm to 25 μm. A ZnSe IR focusing lens was used to focus the modulated IR radiation from the IR source to the AlN NPR. The measured IR response of the device (output frequency of the oscillator versus time) is shown in Fig. 7. The resonance frequency

decreases by ~ 300 Hz when the device is exposed to IR radiation, which corresponds to an absorbed IR radiation power of ~ 1 μW.

IV. CONCLUSION

In this paper, a high performance IR detector based on an AlN nano-plate resonant MEMS-CMOS oscillator was designed, fabricated and tested. For the first time, a high electromechanical performance (quality factor Q = 1283 and electromechanical coupling coefficient k_t^2 = 1.56%) AlN nano-plate resonator integrated with Si_3N_4 thin film IR absorber was connected to a CMOS oscillator, as a low-power and compact frequency readout. The fabricated first prototype showed an IR responsivity of 310 Hz/μW, thermal time constant of 1.3 ms, noise equivalent power (NEP) of 3.5 $nW/Hz^{1/2}$, and power consumption of ~2.3 mW, demonstrating the great potential of the AlN nano-plate resonant IR detector technology for un-cooled IR imaging and sensing applications.

***Abstract*—The optoelectronic oscillator (OEO) is a radio-frequency (RF) source that utilizes lengths of optical fiber in a ring resonator to create low-phase-noise signals. In this work, we demonstrate a novel fiber-optic acoustic sensor by measuring the modulation sidebands induced on the OEO's RF signal by an acoustic tone impinging on the fiber spool in the OEO. The narrow linewidth and high oscillating frequency of the OEO results in a sensor with both high signal-to-noise ratios and high spectral resolution.**

Keywords-Optoelectronic oscillators, acoustic sensing

I. INTRODUCTION

The optoelectronic oscillator (OEO) is a radio-frequency (RF) source that utilizes the low loss-per-unit-length of optical fibers to create a ring-resonator that can generate low-phase-noise RF signals at frequencies greater than 10 GHz [1]. Fig. 1 shows a schematic diagram of an OEO. A continuous wave (CW) laser beam is passed through an optical modulator. The output from the modulator is passed through a fiber spool and then into a photodetector. The output from the photodetector is then amplified and passed through an RF bandpass filter, the output of which is connected to the RF-modulation port of the optical modulator. This configuration constitutes an optoelectronic ring-resonator in which RF signals build up from noise in the amplifiers, photodetector, and laser. Signals at frequencies that experience an integer multiple of a 2π phase rotation in one round-trip experience constructive interference and hence build up faster from one round-trip to the next than signals at other frequencies. At steady-state, the power spectral density of the OEO is given by

$$P_{\mathrm{RF}}(f)=\frac{N(f)}{1+\left|g(f)\right|^{2}-2g(f)\cos\left[2\pi f\tau+\phi(f)\right]}, \quad (1)$$

where, f is the RF frequency, τ is the round-trip time, $N(f)$ is the spectrum of the noise injected in each round-trip, $g(f)$ is the steady-state round-trip gain spectrum, and $\phi(f)$is the sum of any frequency-dependent phase fluctuations in excess of the phase delay induced by the nominal round-trip time τ. Eq. 1 shows that, at steady-state, the OEO's signal power is concentrated at frequencies that satisfy the condition:

$$f_{\mathrm{OSC}}=\frac{m}{\tau}, \quad (2)$$

where m is an integer. Low-phase-noise OEOs utilize fiber spools as long as 10 km. Hence, the round-trip time is determined almost entirely by the transmit time of the laser light through the optical fiber spool

$$\tau=\frac{nl}{c}, \quad (3)$$

where n is the effective index of refraction of the optical fiber, l is the length of the optical fiber, and c is the speed of light in vacuum. From Eq. 2 and 3 we see that the transit time through the fiber spool determines the steady-state oscillating frequency of the OEO. Therefore, external perturbations that alter the transmit time through the optical fiber will alter the oscillating frequency of the OEO.

Sound waves incident on the spools — around which the optical fiber is wound — will induce stresses that alter the round trip time in the OEO. A time-varying sound wave will result in a time-varying fluctuation of the OEO oscillating frequency. In this work, we show that we can create an acoustic sensor by measuring this acoustically-induced frequency modulation of the OEO signal. In addition, because the linewidths of our OEOs are less than 1 Hz, the resulting acoustic sensor has sub-Hertz spectral resolution.

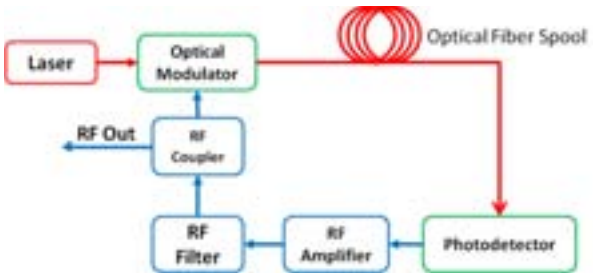

Figure 1. A schematic diagram of the optoelectronic oscillator.

II. PRESSURE WAVES IN OPTICAL FIBERS

Sound waves incident on the spools - around which the optical fiber is wound – induce stresses in the spools. These stresses

deform the spool thereby inducing strain in the optical fiber wound around the spool [2]. Strains in optical fibers can alter the transit time of light through the fiber in two ways: by either altering the physical length of the fiber; or by changing the speed of light (or the effective index of refraction) in the spool. For small perturbations, the change in transit time may be written as

$$\Delta\tau = \Delta n \frac{l}{c} + \Delta l \frac{n}{c} \tag{4}$$

where Δl is the change in fiber length, and Δn is the change in the refractive index of the fiber. Longitudinal strains induced in the fiber cause the fiber length to change, while transverse strains alter the waveguide properties of the fiber leading to a change in its effective index of refraction [2]. Finally, via the strain-optic effect, all strains lead to changes in the refractive index of the fiber material [3]. All three mechanisms contribute to the acoustic sensitivity of the OEO.

III. PHASE MODULATION

A. Optoelectronic Phase Modulation

As a result of the strain-induced changes in fiber transit time, a time varying sound wave will result in a time varying fluctuation in the OEO frequency. Eq. 1 shows that the frequencies at which the power spectral density of the OEO's RF signal is greatest are determined by the fiber transit time τ. When the fiber spool is exposed to a time varying sound wave, the frequencies at which the RF spectrum is peaked become

$$f_{\mathrm{osc}}^{'} = f_{\mathrm{osc}} + \Delta f(t) = \frac{m}{\tau + \Delta\tau(t)}. \tag{5}$$

If the unperturbed OEO's RF signal is a pure tone oscillating at f_{osc}, then the perturbed RF signal will be

$$A_0 \cos\left[2\pi f_{\mathrm{osc}} t + 2\pi\Delta f t\right], \tag{6}$$

where A_0 is the unperturbed RF signal's amplitude. If the sound wave is also a pure tone oscillating at f_a, then from Eq. 5, we may write the induced frequency shift as

$$\Delta f \approx -\frac{m}{\tau}\frac{\Delta\tau}{\tau} = -f_{\mathrm{osc}}\frac{\Delta\tau}{\tau}\cos(2\pi f_a t). \tag{7}$$

Therefore, the acoustic perturbation results in frequency modulation sidebands at offset frequencies ± f_a from the nominal oscillating frequency. These sidebands have magnitudes that are proportional to the nominal oscillating frequency and the change in transit time through the fiber. Therefore, the high oscillating frequency of the OEO (>10 GHz) improves its acoustic sensitivity.

If instead of a pure tone, the unperturbed OEO's RF signal's power spectral density is given by Eq. 1, but the OEO oscillates at a single frequency, then we may rewrite the power spectral density equation for the unperturbed OEO as

$$P_{\mathrm{RF}}(f') \approx \frac{N(f')}{\left[1 - g(f')\right]^2 - g(f')\left(2\pi f'\tau\right)^2}, \tag{8}$$

where f' is the offset from the nominal oscillating frequency. The nominal oscillating frequency of the OEOs used in this work was 10 GHz. The spectrum in Eq. 7 corresponds to a Lorentzian with a full width at half maximum given by

$$\Delta f = \frac{\sqrt{g_0}}{\pi\tau}, \tag{9}$$

where g_0 is the peak round-trip gain at steady-state. For all the OEOs used in this work, the full width at half maximum was less than 30 mHz. The modulation sidebands induced by the sound waves will also have linewidths proportional to the linewidth of the unperturbed OEO. Therefore, the narrow linewidth of the OEO potentially improves its spectral resolution.

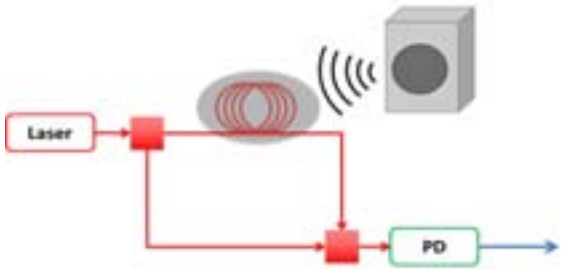

Figure 2. A schematic diagram of an asymmetric Mach-Zehnder modulator used as n acoustic sensor. The sound wave modulates the current from the photodetector "PD."

B. Optical Phase Modulation

So far we have discussed detecting RF frequency modulation induced by sound waves in an OEO. However, an optical beam, even without RF modulation, would experience similar phase modulation when transmitted through an optical fiber spool exposed to sound waves. Fig. 2 shows a schematic diagram of an asymmetric Mach-Zehnder interferometer that includes a fiber spool exposed to sound waves. The optical phase fluctuations induced in the fiber spools result in amplitude fluctuations at the output of the interferometer. Such optical interferometers are the basis of many conventional fiber-optic acoustic sensors [4]. A potential advantage of such optical sensors is that their oscillating frequencies are typically on the order of 100 THz, which may lead to greater acoustic sensitivity than an OEO oscillating at 10 GHz.

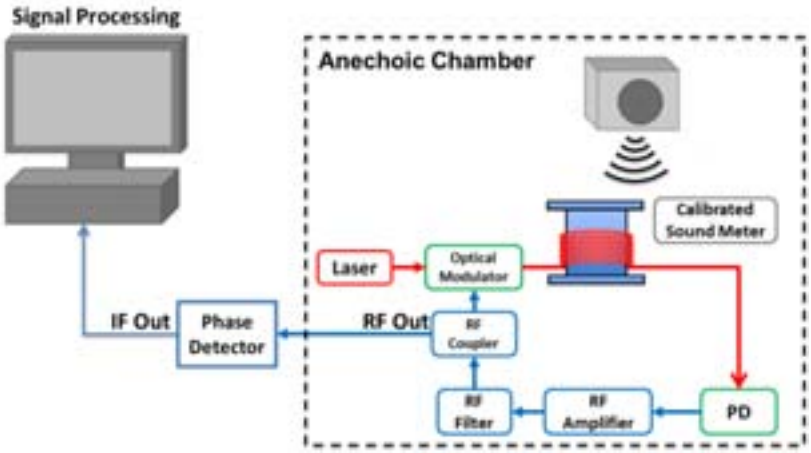

Figure 3. A schematic diagram of our OEO-based acoustic sensor experiment.

However, a potential disadvantage of conventional optical sensors is that the laser linewidths are typically many orders of magnitude greater than the linewidths of low-noise OEO. For instance, the Koheras fiber laser we used in our experiments has a linewidth of approximately 100 Hz. Therefore, conventional fiber-optic acoustic sensors may have worse frequency resolution than the OEO. In the following sections we will describe experiments we performed to test the performance of both types of acoustic sensors.

IV. Experiments

A. Experimental Setup

Fig. 3 shows a schematic diagram of our OEO-based sensor experiment. We placed an OEO in an anechoic chamber. We then played a 1 kHz tone from a speaker approximately 3 m away from the fiber spool in the OEO. We placed a calibrated sound meter next to the spool in order to determine the sound level at the spool. The sound level used in the experiments shown in this wok was 47 dBa,which was the minimum level our calibrated sound meter could detect. To measure the induced phase modulation side bands, we used a delay-line phase-noise measurement system [5]. This measurement system was isolated from the acoustic signal.

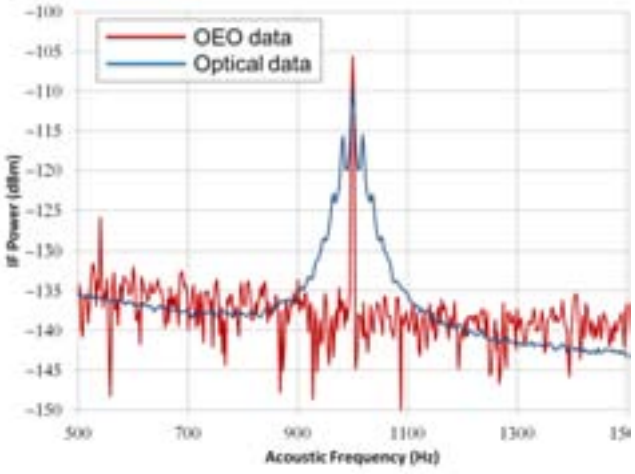

Figure 4. Phase noise plots froman OEO and an a Mach-Zehnder interferometer exposed to a 47 dBa 1 kHz acoustic signal.

We used a similar setup to that in Fig. 3 to test the conventional optical sensor. However, we replaced the OEO with the optical interferometer shown in Fig. 2. In the case of the optical interferometer, we measured the induced modulation directly from the output of the photodetector in the interferometer. In both cases we used the same laser, photodetector, and 6 km spool of Corning SMF-28e+ single-mode optical fiber to detect the acoustic signals.

B. Experimental Results

Fig. 4 shows plots of the phase noise curves of both the OEO and the optical interferometer around 1 kHz. In both cases, the acoustic signal induced a modulation sideband at 1 kHz. In the case of the OEO, the ratio between the peak of the induced sideband and the noise floor of the unperturbed oscillator at 1 kHz is 30 dB; while in the case of the optical interferometer, it was ~26 dB. In addition, the induced sideband in the optical interferometer had a linewidth of approximately 100 Hz, while the linewidth of the induced sideband in the OEO was less than 1 Hz.

V. Conclusion

In this work, we presented experimental data demonstrating the performance of the OEO as an acoustic sensor. We exposed an OEO and a conventional optical interferometer using the same laser, fiber spool, and photodetector, to a 1 kHz 47 dBa acoustic signal. Our results show that the OEO had comparable signal-to-noise ratios to those of the optical interferometer. However, the measured sideband linewidth in the OEO was two orders of magnitude lower than that of the optical interferometer. Our results show that the OEO can potentially be used as a high-spectral-resolution acoustic sensor without sacrificing sensitivity.

***Abstract*—A Surface Acoustic Wave (SAW) sensor platform based on phononic crystals specifically designed for chemical and biosensing will be introduced. The unique feature of this sensor concept is the possibility to determine volumetric properties of analytes at volume as low as 1 nl. The sensor platform has the capability paving the way to study chemical reactions in microreactors or biomaterials directly in their physiological environment without any label.**

Keywords—phononic crystal sensor, surface acoustic wave sensor

I. INTRODUCTION (*Heading 1*)

Acoustic waves at ultrasonic frequencies are applied for sensing purposes as ultrasonic sensors and as microacoustic sensors. The typical operation principle of ultrasonic sensors is that a short ultrasonic burst travels through the medium of interest and probes its acoustic properties. Time of flight is a measure of intrinsic material parameters (density, elastic moduli, speed of sound, …) and kinematic values (acoustic path length, flow rate of the medium, …). The basic principle of operation of acoustic microsensors is based on a standing wave in a confined structure whose frequency is determined jointly by sound velocity and the dimensions of the confinement structure. Besides classical piezoelectric devices a large variety of micromachined resonators have been used as sensor platform. The resonance frequency is a measure of changes of the acoustic properties at the surface of the resonator. It does not play any role in latter context whether these changes are generated by a simple mass or thickness change of a chemically sensitive layer immobilized on the resonator surface, changes in viscoelastic properties of the coating material or viscosity changes of a semi-infinite liquid facing the resonator.

The phononic crystal (PnC) sensor concept merges the principles of operation of ultrasonic and acoustic sensors: an external ultrasonic transducer transmits an ultrasonic wave which passes the phononic crystal on its way to an ultrasonic receiver. The phononic crystal sensor itself provides a resonant feature which can be detected from its transmission behavior. Phononic crystals are periodic composite materials with spatial modulation of parameters relevant for acoustic wave propagation like elasticity, mass density or longitudinal and transverse velocities of elastic waves. The typical structure consists of periodically arranged scattering centers with elastic properties different to a homogeneous matrix surrounding the scatters. As chemical sensor the material of interest is assigned as one component that builds the phononic crystal. The promising feature of phononic crystals when working with liquids confined in a point or line defect structure is the existence of modes which cause characteristic discontinuities in the band gap. Such transmission windows are usually very narrow and easy-to-detect features in a transmission spectrum. At a well selected resonance acoustic energy is localized in the cavity which acts as point of measurement. The frequency of this resonance-based maximum transmission can be exploited for sensing purposes similar to acoustic microsensors. We have shown that the peak frequency is strongly governed by the speed of sound of the liquid and the thickness of the liquid layer. Since speed of sound is a material property secondary values like liquid composition can be deduced if a favorable relation between the primary and the secondary value exists. We recently have proven the sensor concept and have shown an application example [1-3]. The characteristic dimensions involved in phononic crystals like the lattice constant or size of the defect range from meters down to hundreds of nanometers. They are closely related to the frequency one can find the band gaps. For the band gap appearing at frequencies of 1 MHz to several 100 MHz, the required periodicity lies in range of 10 µm to 1 mm dimensions. Phononic crystal sensors can therefore be designed to meet the typical dimensions of microfluidic systems.

Higher probing frequencies are also required to gain competitive sensitivity. The appropriate device to start with the development of a miniaturized phononic crystal sensor is a Surface Acoustic Wave (SAW) delay line. Interdigital Transducers (IDT) launch and receive acoustic waves in the required frequency range. The delay line between the IDTs provides the space to place the phononic crystal. It has been further shown that band gaps exists [4]. Different realizations have been analyzed in [5]. However, these analyzes do not consider liquids as a prerequisite for a (bio)chemical sensor platform. We therefore face challenges in both design (simulation) and fabrication technology.

II. The SAW-PnC Sensor

The scheme of the prospective SAW-PnC Sensor is shown in Fig 1. A typical commercial delay line configuration consists of a set of IDTs to cover the required frequency range the delay line is designed for which is much broader than the frequency range of a single IDT. This feature is favorable for sensing purposes since a sensor must provide a reasonable output span to cover the expected variation of the input, e. g. a certain concentration range. The material is often $LiNbO_3$. A regular phononic crystal is placed between the IDTs. It consists of 8 rows of holes, the hole diameter is *D*, the lattice constant *a* which is close to ½ λ. With respect to fabrication issues the key parameter at the current stage of development is, however, the depth of the hole, *h*.

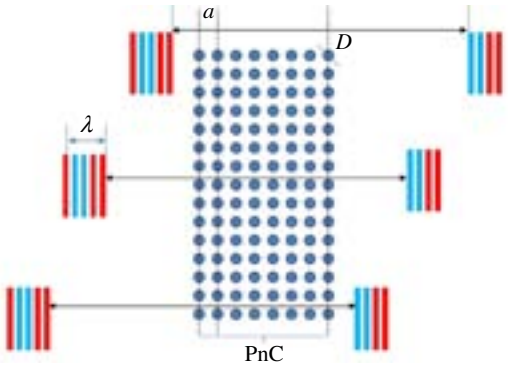

Fig. 1. Scheme of the SAW-PnC (*a* .. lattice constant, *D* .. hole diameter)

III. Simulation

Simulation has been performed with Finite Element Analysis (FEA) using Comsol™Multiphysics both in 2D and in 3D, the latter required for the analysis of the influence of the hole depth. Although the program is very powerful and allows for the implementation of the respective physics, it is not possible do model the complete device. In order to reduce computation efforts and time to an acceptable value, the computation domain does not include the electroacoustic transduction. Instead, the respective actuation has been directly implemented at the particular boundaries. For that reason there is no need for a set of IDTs as shown in Fig. 1. Furthermore, the direct search of resonances through sweeping over a large number of frequencies in the frequency range of interest is inadmissibly time consuming. We ran the sweep with appropriately adjusted sweep steps over the range where one could expect features of interest and have analyzed the displacement pattern at selected frequencies.

Fig. 2 shows the transmission curve in a larger frequency range and less frequency resolution with holes having a depth of only 2 µm (with respect to the fabricated device) and without any structure for reference. As expected, the shallow holes decrease the amplitude of the SAW but do not suppress propagation. The interesting feature is a dip at about 90 MHz which needs further evaluation.

Fig. 3 depicts the results in a smaller frequency range with higher resolution for the 2 µm hole and a hole with a depth of ¼λ. Obviously the deeper holes further decrease the displacement amplitude. A dent is appearing which may suggest the beginning of a band gap.

Fig. 4 shows the computed surface displacement profile at the two very close frequencies marked in Fig. 3. One can see on the left hand side the SAW excitation at the position of the IDTs and in the center the ¼λ holes. We observe a significant increase of surface displacement close the first hole. On the other hand we have to recognize scattering into the volume. This effect is known as Brekhovskikh-attenuation and will lead to an unwanted insertion loss. The strange pattern at the bottom of the device in Fig. 4b seems to be a computational artifact, perhaps from non-optimal boundary conditions. Further improvements in the model are required.

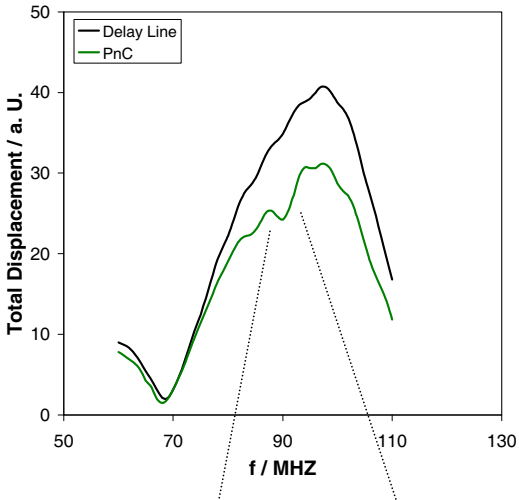

Fig. 2. Simulation of transmission of the delay line (black) and with phononic crystal structure with only shallow holes (green).

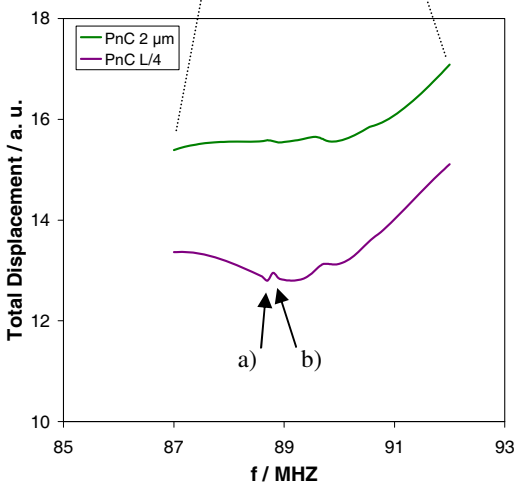

Fig. 3. Transmission analysis in a smaller frequency range with two different depths of the PnC holes (green: 2 µm, pink: ¼ λ).

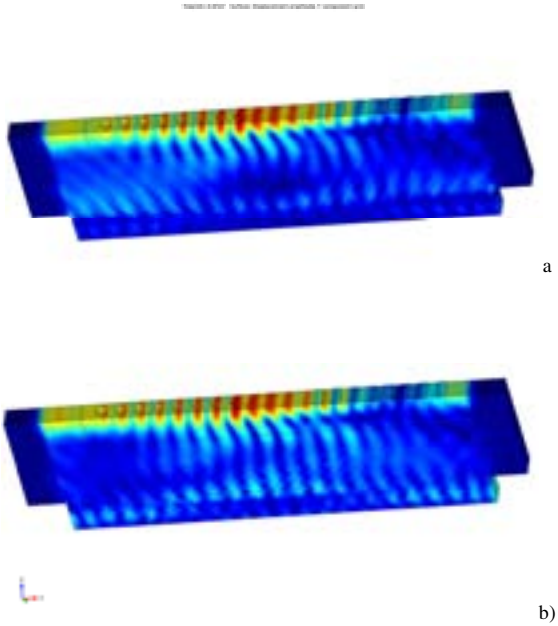

Fig. 4. Displacement at 88.7 MHz a) and 88.8 MHz. The colors illustrate positive (red) and negative (blue) Y-displacement.

IV. Technology Development

Since the preferred design elements of the phononic crystal sensor are holes and slots the development of an etching technology is required. It is far less developed for piezoelectric materials and typically based on reactive ion etching (RIE) [e.g. 6-9]. $LiNbO_3$ is the more appropriate material from the electroacoustic point of view; however, it is more challenging than quartz. We therefore have worked parallel with both substances. We further have considered two routes: etching of holes followed by realization of the IDTs and vice versa. The first variant has been applied to quartz, the second to $LiNbO_3$. The key advantage of the first variant is that hard masks can be applied without major restrictions but requires filling the etched holes for the following lithography whereas the latter one cause problems protecting the IDTs during metal etch.

Fig. 5 shows an array of etched holes as required for different SAW frequencies. A chromium/gold seed layer is deposited by PVD, lithography is based on AZ 15nXT. An Atotech electroplating process creates a nickel hard mask between the developed photoresist elements. The key dry etching process applies a mixture of SF_6/O_2. During the process a backside cooling of helium was necessary to prevent any modifications of the piezoelectric quartz structure. Finally all process residuals, the nickel hard mask and the chromium/gold layer are removed to release the structures. The side walls of the holes are sufficiently smooth and almost perpendicular. An aspect ratio h/D of one is feasible.

The $LiNbO_3$ etch has been performed with a thick photo resist only. It sufficiently protects the IDTs but the maximum etch depth is limited. The side walls are rougher than for quartz and not perpendicular. When overetching the surface of the crystal becomes rough as well. Fig. 6 shows examples.

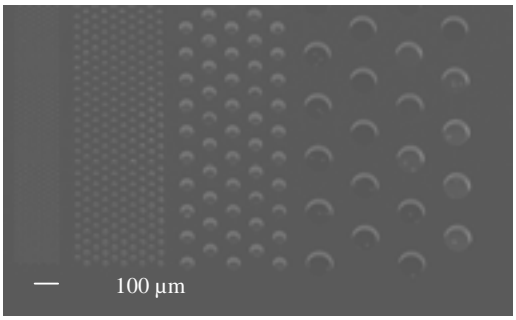

Fig. 5. SEM picture of a set of hole arrays etched into a piezoelectric quartz crystal.

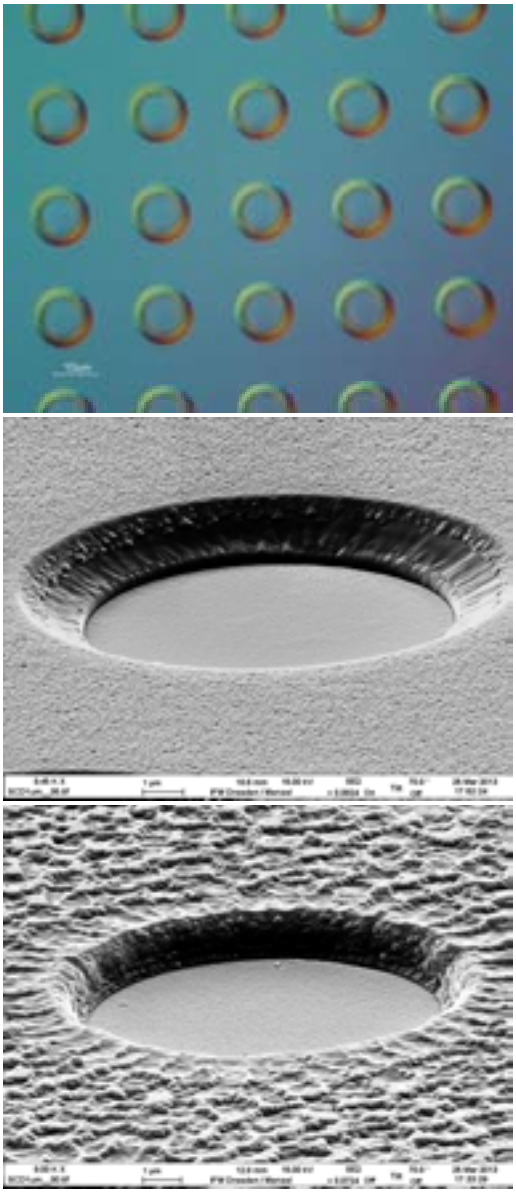

Fig. 6. SEM picture of a hole array etched into a piezoelectric $LiNbO_3$ crystal. The depth of the holes is 2 µm (a). Detail of a single hole and result from overetching are shown in (b) and (c), respectively.

V. EXPERIMENTAL

The $LiNbO_3$ crystal has been analyzed with a network analyzer before and after etching the 2 µm deep holes (Fig. 6b). A tiny but very reproducible dip appears in the transmission plot as shown in Fig. 7. The result agrees well with the simulation results although the frequency of the dip is slightly lower than in simulation. The deviation may be caused by the non-perpendicular side walls.

In conclusion, the preliminary theoretical and experimental results give good reason that a SAW PnC sensor can be realized, however, further work is required to optimize both design and fabrication technology.

***Abstract*—This paper describes the development of a scanning heterodyne interferometer for acoustic wave energy mapping. A robust optical double pass interferometer setup is presented, allowing absolute phase and absolute magnitude measurements of the out-of-plane vibration component witin a 5 to 1200 MHz frequency range, only limited by the photodetector bandwidth. By using a dedicated high frequency demodulator, the system is insensitive to the low-frequency mechanical vibration. The system is here used on single-port Surface Acoustic Wave, allowing for the identification of energy distribution as a function of operating frequency and the acoustic velocity over the Bragg mirrors surrounding the resonator. We envision such an instrument as a tool for assessing acoustic energy confinement allowing for optimizing resonator quality factors aimed at providing improved frequency source stability.**

I. Introduction

Acoustic wave propagation on piezoelectric material is well-known and has led to a thriving use in filters [1], resonators [2] and sensors [3]. While accurate design tools have been developed [4], rising operating frequencies emphasize some of the one dimensional or two-dimensional limitations of the models including the effect of the busses on acoustic energy guiding and more generally of energy confinement. Furthermore, actual manufacturing of high frequency devices reaches the technological limits of lithography and electrode patterning tool, yielding the need for experimental validation of the acoustic energy distribution in the device.

Acoustic energy mapping is a rich analysis method complementary to the classical electrical S-parameters characterization since the latter is insufficient for a good acoustic phenomena understanding. Consequently, several optical setups have been developed in order to measure the surface acoustic vibration, with an emphasis on mapping speed since the faster the characterization, the less prone the measurement is to environmental disturbances and most significantly temperature drift. While magnitude detection is readily achieved by using power measurement of the signal modulated by the acoustic wave in any interferometric strategy, sufficient for energy distribution mapping, the more subtle phase information needed to extract the phase velocity is more challenging due to the slow drift inherent to the high sensitivity to environmental parameters of interferometric setups. Indeed, the challenging aspect of the basic homodyne interferometric approach is its sensitivity to the static phase and hence the slow drift over time of this component which might be suppressed using postprocessing but is best eliminated using extended modulation approaches to get rid of this slowly static phase variation. Some of the classical solutions include the Sagnac interferometer proposed by Tachizaki et al. [5], also used by Hashimoto et al. [6], or another setups by Kokkonnen et al. [7], Martinussen et al. [8], Graebner et al. [9].

In this paper, an alternative approach is proposed, using amplitude splitting heterodyne interferometry. In a first part the theory justifying this concept is proposed, followed by a description of the experimental setup. Finally some results when scanning Surface Acoustic Wave (SAW) resonators operating at 393±1 MHz are presented.

II. Theory and optical setup

A. Amplitude splitting interferometry

Generally and for out-of-plane vibration measurement, amplitude splitting interferometry is used. The Michelson interferometer [10],[11] is the most common configuration. It is based on two arms corresponding to a splitting of a beam of light, with the first acting as a reference arm (fixed path) and the second as the signal arm (movable arm). Both beams are recombined to produce an interference pattern, assuming perfect alignment, resulting in a fringe pattern corresponding to the phase difference between the two waves. This phase difference is, assuming a quadrature condition, locally proportional to the optical path difference. In the case of a monochromatic source (e.g. laser beam), and because the frequency of light waves is too high to be detected by currently available detectors, the resulting intensity is proportional to :

$$I = I_o \left[r_s + r_{ref} + 2\sqrt{r_s r_{ref}} \cos\left(\frac{4\pi \left(\Delta d - \Delta n\right)}{\lambda} \right) \right] \quad (1)$$

where r_s and r_{ref} are the reference mirror and the sample reflectivity, respectively, Δd is the optical path difference due to the object movement, Δ_n is the optical static phase difference between the sample and reference paths and λ is the wavelength of the laser. By assuming a sinusoidal out of plane surface vibration $A\cos\left(\omega t + \varphi\right)$, the resulting intensity is:

$$I(t) = I_c + 2I_o\sqrt{r_s r_{ref}} \cos\left(\frac{4\pi A}{\lambda} \cos\left(\omega t + \varphi\right) - \Phi_n \right) \quad (2)$$

This equation corresponds to a homodyne interferometer and shows that the resulting intensity depends on the sample reflectivity.

When the vibration amplitude is small compared to λ, the Bessel development of the solution of eq. (2) is simplified

[12],[13] into:

$$I'(t) \propto \cos(\Phi_n) + \frac{4\pi A}{\lambda}\cos(\omega t + \varphi)\sin(\Phi_n) \quad (3)$$

Several methods allow to stabilize the interferometer ($\Phi_n = (2n+1)\pi/2$) in order to measure an absolute amplitude and an absolute phase [14] but at the cost of increasing the system complexity. At least one significant issue with the homodyne method concerns the radio frequency leakage. In order to suppress the sample reflectivity problem and diminish radio frequency leakage problems, a frequency shift can be introduced in one of the interferometer arms [7]. This frequency shifting can be achieved by using an Acousto-Optical Modulator (AOM). In this way, the resulting interference intensity, when the vibration amplitude is small compared to λ, is [15]:

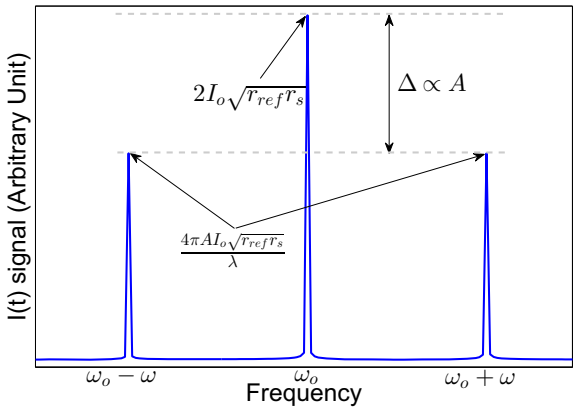

Fig. 1. Fourier Transform of the heterodyne interference signal.

$$\begin{aligned} I(t) &= 2I_o\sqrt{r_{ref}r_s}[\cos(\omega_o t + \Phi_n) \\ &+ \frac{2\pi A}{\lambda}\cos\left((\omega_o+\omega)t + \varphi + \Phi_n - \frac{\pi}{2}\right) \\ &+ \frac{2\pi A}{\lambda}\cos\left((\omega_o-\omega)t - \varphi + \Phi_n - \frac{\pi}{2}\right)] \quad (4) \end{aligned}$$

This equation corresponds to a heterodyne interferometer, where ω_o corresponds to the AOM frequency shift, resulting in a signal of interest observed as a modulation peak (ω_o) and two neighbouring peaks ($\omega_o \pm \omega$). The theoretically absolute value of Fourier Transform of $I(t)$ signal is shown in Fig.1. The absolute amplitude vibration is directly achieved by the modulation/neighbouring peak magnitude ratio (or decibel difference), independent to the sample surface reflectivity. By comparing the phases of the modulation and neighbouring peaks, the absolute phase of the surface vibration is obtained. Thus the static phase Φ_n is suppressed.

Such an approach has been selected and the associated experimental setup is described in the next section.

B. Optical setup description

The optical setup is based on a double-pass heterodyne interferometer [16]. A schematic of the interferometer is shown in Fig.2. The quarter-wave plate's (QWP) fast axis angle is adjusted at $45°$ with respect to the incoming beam linear polarization. After passing through the quarter-wave plate, the laser beam exhibits circular polarization. By passing through the Polarizing Beam Splitter (PBS), the beam is divided into

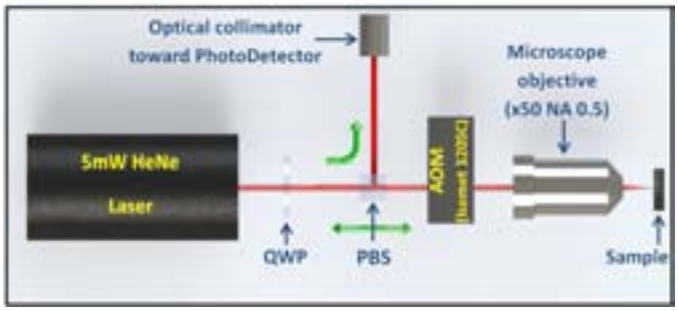

Fig. 2. Optical setup of the double-pass heterodyne interferometer (QWP: quarter-wave, plate PBS: polarizing beamsplitter and AOM: Acousto Optic Modulator)

two beams. The first beam (vertical polarization) is directed towards the optical fiber collimator, acting as the reference arm of the interferometer. The second beam (corresponding to the horizontal polarization) is directed trough the Acoustic Optical Modulator (AOM). The angle between the incident beam and the AOM is set in order to obtain the first diffraction order collinear to the laser beam (the zero order diffraction mode is not used). This beam is the signal arm of the interferometer. After reflection on the sample (by passing trough the microscope lens), the beam is phase modulated by the surface sample vibration and is directed again in the AOM and through the PBS. Due to the quarter-wave plate, the beam has a circular polarization. By using the reflexion on the laser mirror, the signal is directed towards the optical fiber collimator (vertical polarization) and interferes with the reference beam. Use of the mirror of the laser is not problematic (potentially yielding laser instability) in this case due to the frequency shift (AOM double-pass). When the vibration amplitude is small compared to λ, the interference signal of this setup is given by:

$$\begin{aligned} I(t) &= 2I_o\sqrt{r_{ref}r_s}[\cos(2\omega_o t + \Phi_n) \\ &+ \frac{2\pi A}{\lambda}\cos\left((2\omega_o+\omega)t + \varphi + \Phi_n - \frac{\pi}{2}\right) \\ &+ \frac{2\pi A}{\lambda}\cos\left((2\omega_o-\omega)t - \varphi + \Phi_n - \frac{\pi}{2}\right)] \quad (5) \end{aligned}$$

Eq. (5) emphasizes the two passes of the light beam through the AOM, yielding a $2\omega_o$ term which will vanish during the demodulation process described in the next section.

III. Demodulation

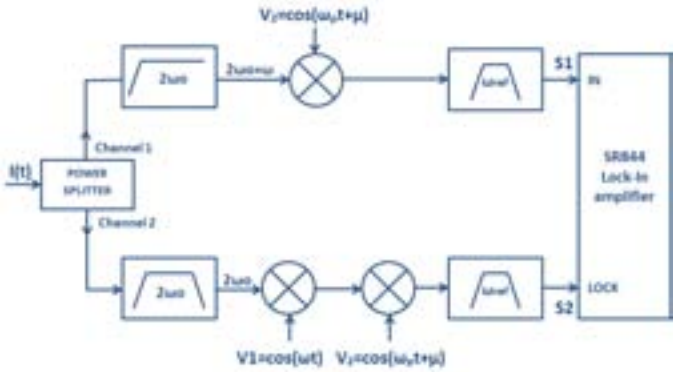

Fig. 3. Demodulation scheme: the recorded signal passing twice through the AOM is centered on a $2\omega_o$ frequency which will be out of the analysis frequency range of S_1 and S_2. ω is the SAW device operating frequency. ω_p is user selected through ω_{ref} as defined in the text.

The setup of the electronic demodulation is schematically shown in Fig.3. S is the interference signal from the interferometer (eq.5), V_1 is the sample drive signal and V_2 is a new user defined signal (from another signal generator, Fig. 3) where μ is the phase difference between V_1 and V_2. With $\omega_p = 2\omega_o + \omega - \omega_{ref}$ and after band-pass filtering at ω_{ref}:

$$S_1 = \frac{I_o\sqrt{r_{ref}r_s}\pi A}{\lambda}\cos\left(\omega_{ref}t + \Phi_n - \mu - \frac{\pi}{2} + \varphi\right) \quad (6)$$

$$S_2 = \frac{I_o\sqrt{r_{ref}r_s}}{4}\cos\left(\omega_{ref}t + \Phi_n - \mu - \frac{\pi}{2}\right) \quad (7)$$

S_1 and S_2 are detected synchronously by a RF lock-in amplifier (SR844 Stanford Research), where S_2 is the lock signal. This setup allows for a maximum detection frequency of 4.5 GHz, limited by the operating bandwidth of the RF components. ω_{ref} is set on the Lock-in frequency range ($0 - 200$ MHz for the SR844). This modulation scheme does not require the clocks of the two signal generators (V_1 driving SAW and V_2) since the drifting phase μ between these two sources is discarded when mixing in the two branches of the demodulation scheme (Fig. 3).

IV. Experiment and results

The objective of the experiments described in this section is to demonstrate the measurement of the acoustic amplitude as well as the acoustic phase of SAW devices, and more specifically a single port SAW resonator. This resonator is obtained by patterning aluminum electrodes using a lift-off process on AT-cut quartz. We select a metallization to period ratio $a/p = 0.5$ and an acoustic period λ of 8 μm. The single port resonator is constituted by one hundred interdigited electrodes in a comb layout, and one hundred Bragg reflectors acting as mirrors on each sides of the transducer. The frequency characterization using a network analyzer exhibits a strong resonance, which is well observed when measuring the acoustic vibration field at one point (Fig.4). In addition to the main resonance at 392.26 MHz, another mode at a nearby frequency is observed at 394.7MHz.

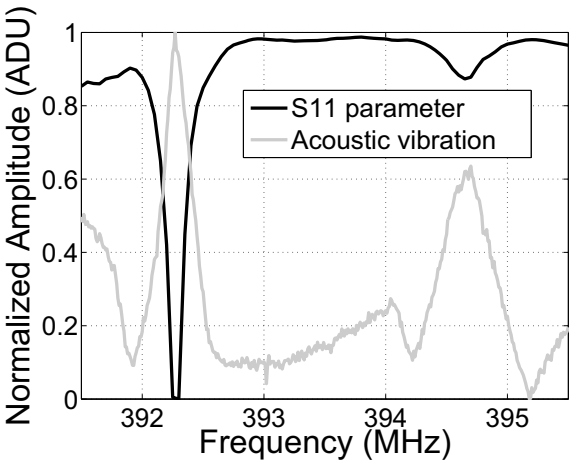

Fig. 4. Electrical reflection coefficient and single-position optical characterisation of the acoustic field magnitude of a single port reflective SAW resonator.

Based on the electrical measurement characteristics of this SAW device, optical mapping of the acoustic field characteristics is performed at both these frequencies. The result of the optical scan characterization on this resonator is shown in Fig. 5 at (a) 392.26 MHz and (b) 394.7 MHz. On the main resonance at 392.26 MHz, the maximum amplitude is well characterized as a light-colored area located over the interdigitated comb transducers. For the second resonance at 394.7 MHz, the maximum amplitude exhibits the parasitic pattern due to the refraction of the acoustic waves under the electrode busses .

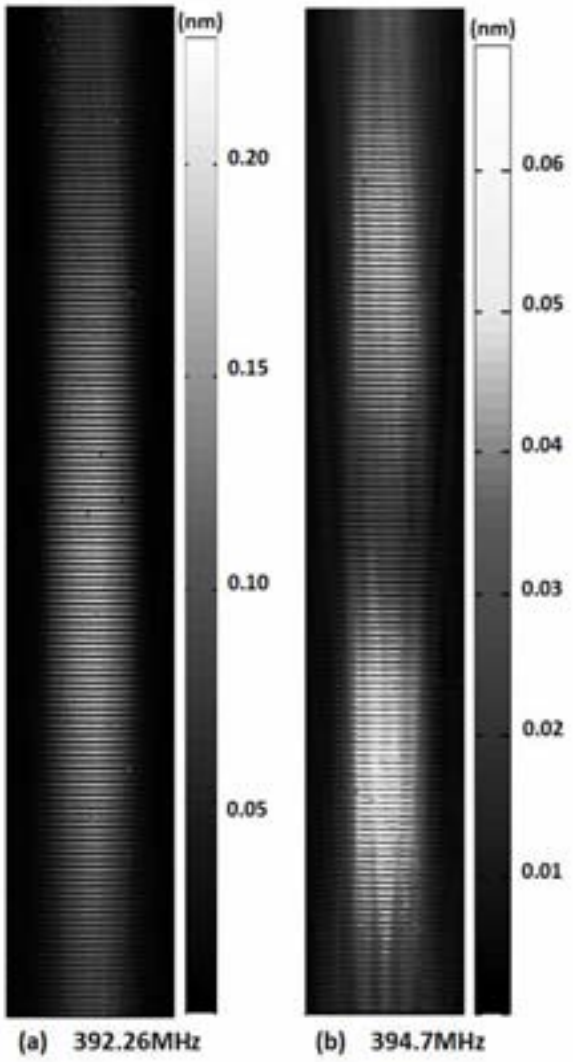

Fig. 5. Optical scan charactization of the acoustic field (out of plane component) amplitude of a single port resonator at (a) 392.26 MHz and (b) 394.7 MHz. Notice that the visual appearance of the stripes, associated with the acoustic nodes and antinodes, is associated due to aliasing of the image.

Following the optical scan characterization, phase information is extracted as shown in Fig.6. A zoom on several periods, which is possible thanks to the large size of the acoustic period and hence wide electrode spacing, exhibits the spatial distribution of the acoustic phase this device, with a 2π rotation over one mechanical period. Unwrapping this acoustic phase information along the acoustic propagation direction provides an estimate of the acoustic velocity. As shown in Fig. 7, the propagating wave over each mirror (positions 0 to 1250 and 1330 to 2400 μm) are characterized by acoustic propagation velocities of equal value but opposite sign (slope of the phase v.s distanc relationship), while the acoustic velocity cancels at the standing wave area over the acoustic cavity (positions 1250 to 1330 μm). The observed acoustic velocity, obtained

by considering that the phase φ to position x slope is given by

$$\frac{d\varphi}{dx} = 2\pi\frac{f}{c} = \frac{2\pi}{\lambda} \Rightarrow c = 2\pi f\left(\frac{d\varphi}{dx}\right)^{-1}$$

of $c = 3138.7 \pm 1$ m/s on both slopes, is consistent with the SAW device operating frequency of $c = \lambda \times f$=8 μm$\times$392.26 MHz=3138 m/s. The scanning probe measurement hence demonstrates the ability to characterize the acoustic propagation and confinement capabilities on a SAW resonator configuration, a requirement for experimentally assessing the main characteristics of a SAW design (acoustic velocity and reflection coefficient on the Bragg mirror electrodes) and understanding the cause for spurious modes or quality factor characterization beyond the basic electrical characteristics. Notice on the zoom of the slopes the ripples associated with the standing wave between adjacent interdigitated fingers. The periodicity of these ripples is 4 μm, consistent with a standing wave pattern between adjacent electrodes.

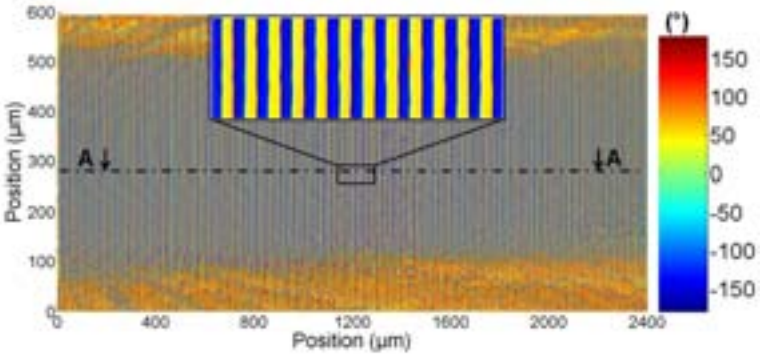

Fig. 6. Optical scan charactization of the acoustic field (out of plane component) phase of a single port resonator at 392.26 MHz.

V. Conclusion

Scanning probe mapping of the acoustic field charateristics, magnitude and most importantly phase, are demonstrated on radiofrequency surface acoustic wave devices using an amplitude splitting heterodyne interferometry approach. This method was selected for its stability and ease of optical alignment, while being insensitive to reflectivity and static phase variations as the scanning takes place. The measurement method, compatible with a use at acoustic device operating frequencies of up to 4.5 GHz, is demonstrated on a 392 MHz SAW resonator. The acoustic velocity of the wave propagating over the Bragg mirrors is observed as the slope of the unwrapped phase *v.s* position map.

***Abstract* — We present here key technologies for an all-optical timing distribution system with sub-femtosecond precision. Timing distribution over a 1.2-km polarization-maintaining, fiber-optic link using balanced optical cross-correlators (BOC) for link stabilization was demonstrated for 16 days with 0.6 fs RMS timing drift and during a 3-day interval only 0.13 fs drift. Jitter characterization of two identical commercial femtosecond lasers using the BOC method verified sub-100-as timing jitter for frequencies above than 1 kHz. Preliminary operation of a fiber-coupled, hybrid-integrated BOC using periodically-poled $KTiOPO_4$ (PPKTP) waveguides indicate great potential for improved BOC timing sensitivities and overall system efficiency and robustness.**

Keywords - timing jitter; ultrafast optics; optical fiber applications; phase locked loops; nonlinear optical devices

I. INTRODUCTION

Modern X-ray free-electron lasers (FELs) [1-3] require timing distribution systems with extremely high timing stability to synchronize RF and optical sources located up to several kilometers apart. Since conventional RF timing systems have already reached a practical limit of about 50-100 fs timing precision for such long distances, next-generation timing systems [4,5] are adopting fiber-optic technology to achieve superior performance with optical signal transport and timing distribution.

Over the past decade, we have been advancing technology for a pulsed optical timing distribution system [5]. Our system consists of a femtosecond mode-locked laser tightly locked to a microwave standard and stabilized fiber links for distributing the pulsed optical timing signal to remote locations. Link stabilization is performed using compact, single-crystal balanced optical cross-correlators (BOC), which are capable of attosecond-level timing resolution. Sub-10-fs system performance over days of operation has been achieved but is limited mainly by polarization mode dispersion (PMD) in standard single-mode fiber.

The authors acknowledge financial support by the United States Department of Energy through contract DE-SC0005262, and the Center for Free-Electron Laser Science at Deutsches Elektronen-Synchrotron, Hamburg, a research center of the Helmholtz Association, Germany. S.V. acknowledges support by Italian National Civil Authority (ENAC) and University of L'Aquila through Giuliana Tamburro and Ferdinando Filauro scholarships, respectively.

In the near future, it is necessary to improve timing distribution down to sub-fs precision since current facilities, such as LCLS at Stanford, can already produce X-ray pulses shorter than 10 fs [6] and concepts for sub-fs X-ray pulse generation are already in place. Improving upon our previous work, we demonstrate here: 1) timing stabilization of a 1.2-km dispersion-compensated, polarization-maintaining (PM) fiber link with sub-fs residual timing drift over 16 days, 2) jitter measurements of two ultralow-noise, commercial femtosecond lasers for sub-100-as timing distribution, and 3) fiber-coupled, hybrid-integrated cross-correlators using periodically-poled $KTiOPO_4$ (PPKTP) waveguides for improved BOC timing sensitivities and overall system efficiency and robustness.

II. TIMING-STABILIZATION OF 1.2 KM PM FIBER LINK

Link stabilization is critical for preserving the timing precision of the pulsed optical timing signal as it propagates through the fiber link over long distances. Environmental disturbances to the fiber link (e.g. thermal fluctuations, acoustic noise, and vibrations) will induce errors in the pulse arrival times at the link output. To stabilize the link, we first measure the round-trip link timing error with high timing resolution using a BOC and then adjust correspondingly a variable delay within the link path to compensate for the detected error.

Our previous results with a 300-m stabilized fiber link using standard single-mode fiber showed that PMD limited the link stability to about 10 fs over few days of operation and caused delay jumps as much as 100 fs when the fiber was significantly perturbed [7]. To eliminate PMD-induced drifts, we collaborated with OFS in designing and fabricating a 1.2-km PM link with 3rd-order dispersion-compensation. The PM link consists of 1088 m of standard PM fiber matched to 190 m of custom dispersion-compensating PM fiber (PM-DCF). The PM-DCF has a PANDA-like geometry containing Boron stress rods with 35-μm diameters, a core index profile similar to conventional DCF, and a dispersion and dispersion slope of -104.1 ps/(nm·km) and -0.34 ps/(nm^2·km), respectively, at 1550 nm.

A. *Experimental Set-up*

The experimental set-up for timing stabilization of the 1.2-km PM link (Fig. 1) begins with a free-running Er-doped fiber laser (Menlo Systems) that outputs 160-fs pulses centered at 1560 nm with +20 dBm average power and 200 MHz repetition rate. The pulse width and repetition rate are selected to keep higher-order dispersion and fiber nonlinearity low. The set-up is divided into two sections: the in-loop, which is responsible for link stabilization, and the out-of-loop, which is for measuring the in-loop performance.

In the in-loop section, the pulses are first divided into a reference and signal path. The reference path serves as a timing reference for the in-loop BOC. The signal path consists of a voltage-controlled free-space delay, polarization optics, 1.2-km PM link, and output coupler. Since the forward and reflected pulses must propagate on the same polarization axis in the PM link, a 45° Faraday rotator is necessary to induce a 90° round-trip polarization rotation so that the reflected pulses will reach the in-loop BOC. The half-wave plate aligns the free-space polarization with the slow axis of the PM fiber. The coupled input power to the PM link was +11 dBm, which is near the onset of fiber nonlinearities. With a 90/10 output coupling ratio, the reflected power was sufficient for in-loop stabilization without the use of an optical amplifier. The timing error is detected with the in-loop BOC, which consists of a single 4-mm PPKTP crystal operated in a double-pass configuration with appropriate dichroic elements [8]. The BOC timing sensitivity was 21 mV/fs. The stabilization feedback loop consists of a PI controller (Menlo, PIC210), high voltage amplifier (Menlo, HVA150) and stacked combination of a 40-µm piezoelectric actuator (Thorlabs, PAS009) and 25-mm motorized delay stage (PI, M-112.12S) for short- and long-term stabilization, respectively. The feedback bandwidth was 20 Hz.

The out-of-loop BOC, which is used to evaluate the in-loop stabilization, monitors the timing error between the link output pulses and new pulses from the laser. The timing sensitivity of the out-of-loop BOC was 2.3 mV/fs. For long-term drift measurements, the out-of-loop voltage is sampled at 1 Hz with an A/D converter (National Instrument, cDAQ-9172). A low-pass RC filter with a 0.5-Hz bandwidth is used to improve signal-to-noise after detection. The time delay of the motor stage was also recorded simultaneously.

Temperature stabilization and vibration isolation are critical for sub-fs-level stability. Separate enclosures were built for the free-space optics and PM link. Each consisted of an external 2" layer of extruded polystyrene insulation foam and an internal Aluminum enclosure, which was temperature-controlled with a resistive heater pad and PID controller.

B. *Long-term Stabilization Results*

Sub-fs timing stabilization of the 1.2-km PM link was achieved for 16 days. Recorded data for the link drift and motor delay are shown in Fig. 2a. Although the data log for the motor delay faulted in day 13, the link stabilization remained unaffected. Overall, the motor delay corrected for over 65 ps of timing fluctuations while the timing drift remaining at the link output showed only a maximum deviation of 2.5 fs and a RMS value of 0.6 fs. This represents a suppression of timing fluctuations by a factor of more than 20,000 over 16 days, indicating that the PM fiber was effective in overcoming the previous 10-fs-level stability limit over few days of operation and eliminating large 100-fs delay jumps caused by PMD upon significant perturbation of the fiber.

Recorded data for relative changes in the internal temperatures of the PM link and free-space enclosures and ambient temperature are plotted in Fig. 2b. The strong correlation between the link drift, free-space enclosure temperature, and ambient temperature confirms that the link drift is limited by environmental fluctuations penetrating into the free-space BOCs or causing drifts in the free-running laser repetition rate. This is reasonable because the free-space

enclosure is large in volume, making it difficult to isolate the enclosed optics from the environment. Resolving these issues should yield 100-as-level stability or even better; this is evident during days 11-14 when ambient fluctuations were fortuitously minimal, resulting in a RMS timing drift of only 0.13 fs.

III. ULTRA-LOW LASER TIMING JITTER MEASUREMENT

In addition to the timing link, we also demonstrate that ultralow-noise lasers for sub-fs timing systems are commercially available today. To measure their timing jitter, however, conventional methods via high-speed photodetectors and RF mixers cannot be used; excess phase noise during photodetection and limited resolution in the mixer prevent jitter characterization below 1 fs. An alternative approach is to use the BOC, which can precisely extract timing information with attosecond-level resolution by avoiding intensity-conversion noise during photodetection [8].

A. *Experimental Set-up*

The jitter measurement set-up using the BOC technique begins with two identical femtosecond lasers (Onefive, ORIGAMI), which produce 170 fs pulses centered at 1554 nm with 170 mW average power. The output pulses trains are aligned with orthogonal polarizations and combined in a polarization beam-splitter before being sent into a BOC. The relative timing jitter between the pulse trains is converted into a voltage signal with a BOC timing sensitivity of 1.3 mV/fs. The error signal is fed back to the piezoelectric tuning port of the local laser to lock its repetition rate to that of the master laser. A "loose" locked loop is implemented so that the high-frequency laser timing jitter can be observed beyond the locking bandwidth. The timing jitter spectral density is measured by directly feeding the output of BOC into a signal source analyzer (Agilent, E5052B). The measured spectrum is divided by two since we assume that the two lasers have identical and uncorrelated jitter.

B. *Results*

The timing jitter spectral density and its corresponding integrated timing jitter are given in Fig. 3. Within the locking bandwidth, the integrated jitter caused by acoustic noise below 200 Hz is suppressed to 100 as. Beyond the locking bandwidth, the integrated jitter from 1 kHz to 1 MHz is less than 70 as and from 10 kHz to 1 MHz is even less than 15 as. This extremely low timing jitter indicate that these lasers are well-suited and immediately available for sub-fs timing distribution systems spanning over kilometer distances.

IV. INTEGRATED BALANCED OPTICAL CROSS-CORRELATOR

To further improve the precision of our timing distribution system, fiber-coupled integrated BOCs are an absolute necessity. One major benefit is that an all-fiber implementation of the timing system will eliminate fs-level drifts caused by free-space beam misalignments. Second, the second-harmonic generation (SHG) conversion efficiency of the integrated BOC will be a significant improvement over that of a bulk-crystal BOC by 1-2 orders of magnitude [9]. In collaboration with AdvR, the fabrication of PPKTP waveguides was optimized by

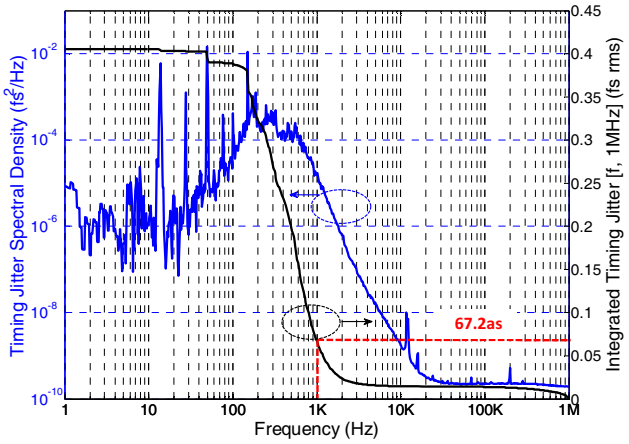

Figure 3. Measured timing jitter spectral density for an individual laser and its integrated timing jitter for the frequency range [f, 1 MHz].

decreasing the mode size and improving the poling quality, and by packaging fiber-coupled, hybrid-integrated BOCs using these waveguides.

A. *SHG Conversion Efficiency in Waveguides*

The waveguides were fabricated by Rb+ ion exchange on a KTP substrate and were diced and polished to a final length of 1 cm. An anti-reflective coating at 1550±50 nm and 775±25 nm was deposited on the front facet of the crystal, and a dichroic coating that is highly-reflective at 1550±50 nm and anti-reflective at 775±25 nm was deposited on the rear facet. Therefore, after forward propagation through the crystal, pulses at the fundamental (FH) wavelength of 1560 nm will be reflected back into the waveguide, generating another second-harmonic (SH) pulse on the return path for balanced operation of the cross-correlator. A peak normalized SH conversion efficiency of 1.76 %/[W-cm^2] was extracted at 1560 nm. The integrated BOC is expected to have a factor of 50 increase in timing sensitivity compared to the bulk-optics BOC, given the same input pulse parameters. This means that the optical power can be decreased by a factor of 50 while achieving the same signal-to-noise ratio as that of bulk-optic BOCs.

B. *Fiber-Coupled Device Operation*

We mounted the coated PPKTP waveguides in a robust fiber-coupled package. The PM fiber at the module input couples FH pulses into the waveguide and couples the reverse-generated SH out. The multi-mode fiber at the other end collects the forward-generated SH. The PPKTP module was tested in a fiber-coupled, cross-correlator configuration. Due to excess coupling loss between the PM fiber and the waveguide for the reverse-generated SH, the SH power collected on the forward path was approximately 10 dB higher than that of the reverse path. Therefore, a 10-dB attenuator was inserted to symmetrize the cross-correlation curve. Preliminary operation of the device yields a timing sensitivity of 4 mV/fs (Fig. 4). A thorough characterization of the device performance as well as packaging optimization is currently in process.

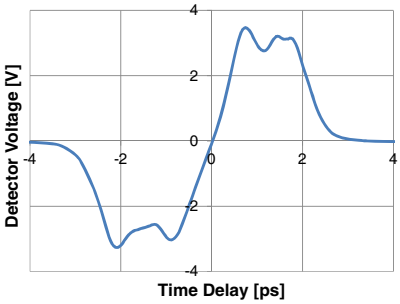

Figure 4. BOC voltage response as a function of relative pulse time delay

V. Summary of Results

In summary, we have presented key technologies towards an all-optical, fiber-based timing distribution system capable of sub-femtosecond precision. Timing distribution over a timing-stabilized 1.2-km PM link using BOCs was demonstrated for 16 days with 0.6 fs RMS timing drift and during a 3-day interval only 0.13 fs drift. Jitter characterization of two identical commercial femtosecond lasers using the BOC method verified sub-100-as timing jitter for frequencies greater than 1 kHz. Lastly, preliminary operation of a fiber-coupled, hybrid-integrated BOC using PPKTP waveguides indicate great potential for improved timing sensitivity and overall system efficiency and robustness.

***Abstract*— In many fundamental physical experiments time plays an important role. The standard way for the comparison of time and frequency is the application of GNSS signals and the Two-Way Satellite Time and Frequency Transfer - TWSTFT. This technique is based on radiofrequency signal transmission. Recently, there was a rapid increase of optical time comparison development, which uses the Satellite Laser Ranging network (SLR). Currently the French project T2L2 is in operation on board of Jason 2 and the European Space Agency project ELT in support of the Atomic Clock Ensemble in Space (ACES) is under development. The goal of both projects is the time synchronization with a precision below 40 ps rms and an absolute error well below 100 ps. Comparing the results of the optical time transfer with the GNSS time comparison requires unprecedented control of the local ties between the different observation techniques. One of the possible methods is the application of the Two Way Time Transfer (TWTT) on a single coaxial cable. Such a system can be implemented using two or more event timers, which are interconnected by a standard coaxial cable. The event timers are exchanging pulses between each other and time tagging them. Out of the measured result one can evaluate the difference of time scale represented by the event timers. It was shown that such a technique can be used for time transfer with a precision of a few picoseconds of rms and an absolute error below 20 ps for distances reaching several hundreds of meters.**

We have implemented this technique for establishing and monitoring the absolute time delays between the SLR system and the time keeping laboratory on the Geodetic Observatory Wettzell. The event timers were developed at the Czech Technical University. The measurement principal is based on SAW filter excitation. The Event Timers were located in different buildings 50 meters apart and with the help of the TWTT technique, the delay between them was measured. The second input sockets of the event timers were used to monitor the respective local timescale.

Keywords—two way time transfer; event timing; time comparison;

I. INTRODUCTION

The precise and accurate time transfer is a prerequisite of a number of experiments in fundamental physics, Earth science, global navigation and many other disciplines. One of the most challenging disciplines is the time transfer ground to space. The standard techniques used recently are based on radio frequencies. They do provide nanosecond accuracies [1]. A significant improvement in time transfer accuracy between ground and space is expected to be achieved by using optical frequencies [2]. The contributors of systematic error to the overall error budget in the optical domain may be reduced to the level of 10 picoseconds.

The laser time transfer (LTT) ground to satellite is an extension of the standard measurement technique of the satellite laser ranging (SLR). A ground SLR station fires laser pulses toward the satellite and records the local times of the laser firings. On board of a satellite the laser pulses are detected and time tagged to the satellite time scale. At the same time the laser pulses are reflected by a system of a retro-reflectors back toward the ground station, which, again, detects the return pulses and time tags them to the ground time scale. The recorded data on board of the satellite is then sent to the ground using a standard telemetry channel.

Combining the laser firing times, propagation and instrumental delays and satellite arrival times, the space and the station clocks may be compared. The error in propagation time ground to space is completely compensated in a laser time transfer when combined with satellite laser ranging data at the same time. The importance of such a method is reflected in a rapid development of the time transfer projects T2L2 (France), ELT (ESA) or LTT (China).

Doing the time transfer using SLR technique requires deep understanding of the individual timing systems of each site. First of all it is important determine from which reference point the optical time transfer is performed. In case of optical time transfer actually the time transfer is realized between the satellite time scale and the time scale which is realized inside the event timer. It requires a very good synchronization of the event timing system relative to the local time scales, which we want to compare.

The simplified diagram of the Wettzell Observatory timing system is shown in Fig. 1. It consists of four buildings separated by several tens of meaters in distance. We are

operating several Cesium atomic standards, where HP1732 is considered as the master clock establishing UTC(IFAG). In addition we are operating several H-Masers which are used for Very Long Baseline Interferometry (VLBI) measurements as well as SLR observations. In each observation point the local time scale is generated out of distributed frequency sources. From a distribution of the generated 1pps signals, 1pps is sent back to the Master Clock (MC) room where the localy generated time scales are compared to the Master Clock time scale (UTC(IFAG)) every 3 hours. For measuring these time delays between the time scales the time interval counter SR620 is used measuring the delays with a resolution of 1 ns.

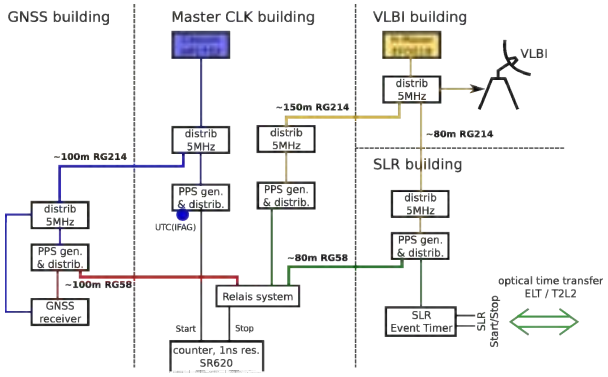

Fig. 1. The simplified block diagram of the timing sytem in Wettzell Observatory. There are several atomic clocks distributing frequency between different building, where the geodetic observation techniques are located. The time scales are generated in each building separately.

For the optical time transfer between ground and space measuring biases between local time scales with an accuracy of 1 ns can be one of the limiting factors of the entire experiment. The problem arises when all timing signals are distributed approximately 90 cm underground using cables RG214 (frequency) and RG58 (1pps) and that the annual temperature variations under ground in the same depth reaches 12 ºC. Considering the temperate dependency of the cables [3] one can conclude, that the timing delays between the local scales must be changing in an uncontrolled fashion over the year by as much as 1 ns. Such changing biases are not captured by the current measurement system.

For monitoring these biases we applied the recently introduced TWTT method, which is based on two or more interconnected event timing systems linked with a single cable [4]. This method allows a time scale comparison with picosecond precision and accuracy. We are now systematically investigating the local biases by applying this technique.

II. The Timing Device

For comparing the time scales we are using Event Timing (ET) devices which were developed at the Czech Technical University [5]-[7]. The ET allows the detection of Times of Arrival (ToA) of input pulses with respect to a local time base. The single shot precision is 700 fs RMS per channel.

Operating the device in a common laboratory environment without temperature stabilization a TDEV better than 4 fs is routinely achieved for averaging times between 300 s to 3000 s [7]. For checking the measurement performance and for experiments such as two way time transfer, a reference time mark generator has been included into the timing device. It generates low jitter pulses synchronously to the local time base. The repetition frequency of these pulses and number of generated pulses are programmable.

III. Two Way Time Transfer Principal

The technique of the Two Way Time Transfer (TWTT) via single coaxial cable was inspired by the comparison of the two event timers using pulses and a signal splitter. The pulse from a signal source is split into two equal pulses and connected to the ET A using cable C_1 and to ET B using cable C_2; The times of arrival (ToA) at both devices are measured and the time difference is computed ($Diff_1$). Then the cables are exchanged (ET A -> C_2 and ET B -> C_1) and time difference ($Diff_2$) is computed again. The time scales difference between both event timers then becomes

$$\hat{\Delta}_c = \frac{1}{2}\left(Diff_1 + Diff_2\right) \quad .$$

The advantage of exchanging the cables is that the time scale differences do not depend on the length of the cables C_1 and C_2.

Inspired by the described method we have implemented the TWTT technique according to the schema displayed in Fig. 2

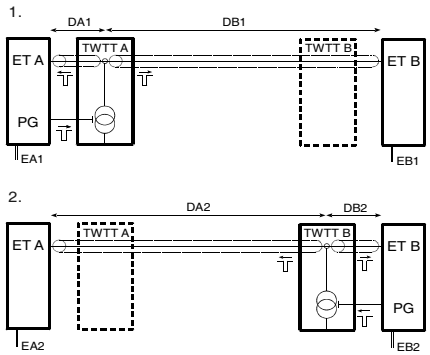

Fig. 2. Block scheme of the Two Way Time Transfer via a single coaxial cable: 1st step when the TWTT module A is generating the test pulse, 2nd step when the TWTT module B is generating the test pulse.

The operating scheme is the following: two Event Timers ET A and ET B are equipped with TWTT modules. These modules are interconnected by a single coaxial cable. The measurement is carried out in two steps. In the first step the ET A generates a pulse, using a current driver the pulse is applied to the interconnecting cable and the ToA of the received pulse is measured by both event timers (ToA_{A1} and ToA_{B1}). In the second step the role of the devices is exchanged. The ET B generates a similar pulse that propagates along the cable in opposite direction. After time tagging at both devices this yields ToA_{A2} and ToA_{B2}. The timescales difference can be then computed according as

$$\hat{\Delta} = \frac{1}{2}\left((ToA_{B1} - ToA_{A1}) + (ToA_{B2} - ToA_{A2})\right).$$

The precision of the resulting time scale difference will depend on the precision of both event timers, the reproducibility of the pulses generated by TWTT modules and on the influence of noise induced on the interconnecting cable. Experimentally it was possible to establish time scale comparisons with a precision and an accuracy of the order of 1 ps [4].

IV. EXPERIMENTS

At the Geodetic Observatory Wettzell we carried out several TWTT experiments with two ET systems. That is why only two scales could be compared at the same time. First of all it is important to note that the operation principle is comparing the time scales held inside the event timers. When a locally generated time scales realized by 1pps signals need to be compared, they must be time-tagged at second input of each of the event timing systems. To reducing systematic errors we have used the following steps to calibrate such a system up to reference point, UTC(IFAG) in our case:

1. We set the trigger levels of the ET devices to be the same in both ETs (IN1(TWTT input)/-0.180 V and IN2/0.7 V). In the same laboratory we used a common clock (frequency reference) for both devices and we measured the difference between the ETs using TWTT (ΔT_{TWTT}). Then we switched the inputs of the ETs from TWTT input to IN2, were we have connected the power spitted 1pps pulses. Exchanging the cables of the 1pps signals we have measured the difference of the event timers in the second input (ΔT_{1pps}). The difference between the ET using IN2 and TWTT input was $\Delta ET = -12.6\ ps$, measured with accuracy 2.6 ps rms.
2. As a second step we have installed the ETs in laboratories whose time scales were to be compared, the simplified scheme is in Fig. 3. The absolute calibration is divided into three steps.
   a. At first the ETs were connected to the reference points for time, namely UTC(IFAG) and $SLR_{ref.}$ with cables of the delays τ_{C1} and τ_{C2}. In this arrangement the time scale difference $SLR_{ref.}$ – UTC(IFAG) was evaluated.
   b. The cables were exchanged and the time scale difference $SLR_{ref.}$ – UTC(IFAG) was evaluated again. Out of those two measurement one can obtain the cable length difference $\Delta\tau_C = \tau_{C2} - \tau_{C1}$.
   c. The cables were connected to another output in the pulse distribution system of the 1pps and the time differences to the reference points were evaluated, ε_{UTC} and ε_{SLR}.

   The measured calibrations are summarized in TABLE I. The Time scale difference from the reference point UTC(IFAG) to $SLR_{ref.}$ can be computed according to

$$SLR_{ref.} - UTC(IFAG) = ppsDiff - \Delta\tau_C - \varepsilon_{SLR} - \varepsilon_{UTC} - \Delta ET,$$

where SLRref. – UTC(IFAG) is the time scale difference from the reference points, ppsDiff is the difference of 1pps pulses in SLR and MC.

TABLE I. SUMMARY OF TWTT CALIBRATION.

Constant name	Mean value	rms
ΔET	-12 ps	2.6 ps
$\Delta\tau_C$	10.085 ns	104 ps
ε_{UTC}	-17 ps	93 ps
ε_{SLR}	0	0

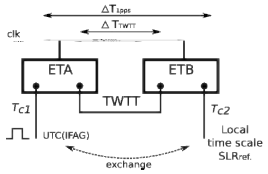

Fig. 3. Calibration of the TWTT method used in experiment, which is comparing two time scales.

The TWTT was implemented after considering several facts and additional measurements. First of all the repetition rate of sending pulses was chosen with respect of the communication speed as 500 Hz. The entire measurement loop was programmed in such a way that between two following 1pps pulses one TWTT measurement was done. To improve the precision of the TWTT measurement 32 pulses were exchanged between each ET. The single shot precision of the TWTT method using a 100 m long interconnecting cable of RG214 quality is 1.4 ps. With averaging a precision of the TWTT method of $1.4\,ps/\sqrt{32} = 0.25\ ps$ was obtained. The most important quantity is the systematic error, which is introduced by such a measurement. It can be measured connecting both devices to the same clock source. With short RF cables one can measure the time difference between the ETs using the TWTT method. In the here reported case the systematic error is negligible [4]. After that the devices were interconnecting using the long RF cable, which was used for the TWTT procedure between the buildings and the ETs offset was measured again. The difference between the measurements with short and long cable is giving the systematic error. Using the 100 m of RG214 (in our case we used this cable for interconnecting the master clock (MC) and the GNSS room) the systematic error was measured to be 7.4 ps. The MC and SLR buildings were interconnected with higher quality cable (LDF4) of a length 93 m. Measuring the systematic error caused by the TWTT signal degradation on this cable is 1.8 ps.

Up to now we have compared two time scales with UTC(IFAG). The first experiment performed was between

MC and GNSS laboratory, where the GPS receiver WTZA (Ashtech Z12T) is located. The experiment lasted several days and is shown in Fig. 4. The sudden rise of the time scales difference during 4th day was caused by an air conditioning failure. The absolute delay was compared to the absolute timing delay from the reference point of the GPS WTZA receiver up to UTC(IFAG) reference point. The delay was measured 3.4 ns higher than the old records. This discrepancy shows the need of better monitoring of the time scales, because there is not yet any plausible explanation for such a difference.

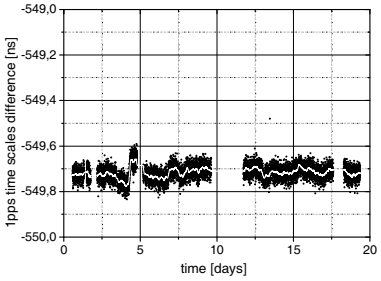

Fig. 4. Time scale comparison between Master Clock room where UTC(IFAG) is located and the GNSS laboratory where the GPS receiver WTZA (Ashtech Z12T) is located.

To show the timing stability, the time deviation of the time difference was computed, see Fig. 5. The single shot jitter of time scale difference was 22 ps rms and the TDEV falls down to 3 ps for averaging intervals $\tau > 200$ s.

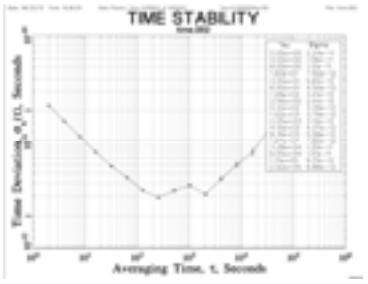

Fig. 5. Timing stability TDEV of compard UTC(IFAG) and GNSS laboratory time scales.

As a second step the entire experiment was moved to perform time comparison between UTC(IFAG) and the SLR time scale, which is important for optical time transfer. For this purpose we have developed a program, which can be used for full implementation of the measured results of time comparison into the entire ranging chain, where the epochs from the SLR measurement can be corrected. Fig. 6 shows the time difference between UTC(IFAG) and the SLR time scale. There is a significant drift of 2.5 ns/day, which is caused by the drift of the main cesium clocks HP1732 versus the H-Maser EFOS18.

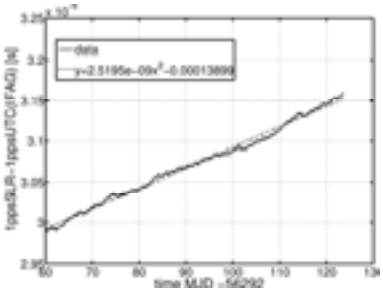

Fig. 6. Time scale comparison between Master Clock room where UTC(IFAG) is located and the SLR techniqu.

V. CONCLUSION

We have implemented the Two Way Time Transfer method in the Geodetic Observatory Wettzell for comparing the locally generated system time scales with our timing reference point UTC(IFAG). Up to now we have made two comparisons between UTC(IFAG) and GNSS laboratory and SLR as well as the absolute calibration of the suggested measuring technique. We have shown that the systematic error of the TWTT method can be kept very low. For high quality RF cables as LDF4 the systematic error can be kept as low as 1.8 ps, which is almost negligible in comparison with the single shot precision of the 1pps generation. The comparison of the time scales between UTC(IFAG) and the GNSS laboratory the time scale shows that both scales are uncorrelated for averaging times up to 200 s and the TDEV levels out at 3 ps for $\tau > 200$ s. Even though both scales are generated from the same source of frequency (Cs, HP1732) the observed drifts were caused by air-conditioning failure in GNSS laboratory.The comparison of the time scales between UTC(IFAG) and SLR shows the difference of two different sources of clocks, which generate the scales. While SLR runs from the H-Maser EFOS18, UTC(IFAG) is generated from cesium standard HP1732. A linear drift between the Cs HP1732 and H-Maser EFOS18 of 2.5 ns/day was obtained.

***Abstract*—We are reporting on a new approach to an optical two-way time transfer based on signals of individual photons. This approach enables to reach extreme timing stabilities and minimal systematic errors using existing electro-optic technologies. In our indoor experiment we have achieved sub-picosecond precison and 3 ps accuracy of a two-way time transfer via free space optical channel. The entire system is compact and simple. It is a perspective technique for space application, where it might provide picosecond accuracies over space distances.**

Keywords—photon counting; two-way time transfer; accuracy; picosecond stability

I. Introduction

The two-way time transfer is an effective way to synchronize two independent time scales with high precision and accuracy independently on the variations of the interconnecting channel [1]. In our previous work we have demonstrated electronic circuits for two-way time transfer via a single coaxial cable with picosecond accuracy and precision [2]. The experiment proved the capability of this technique to maintain picosecond stability over the periods of seconds to days. The systematic errors of the order of units of picoseconds have been achieved [3].

This technique may be effectively applied in configurations, where the sites may be interconnected by a broad bandwidth coaxial cable. Considering the performance of the top quality coaxial cables available, the picosecond performance may be accomplished over distances up to 2 km maximum. For longer distances the optical approach may be considered.

Propagation of optical signal in a free space is suffering of negligible degradation (in atmosphere) or no degradation at all in a vacuum. Photon counting approach to the signal detection is providing several additional key advantages: the reduction of most systematic errors found in commonly used multi-photon detection systems and the capability to operate with ultimately low signals. The repetitive optical signals of an average intensity as low as 1×10^{-4} photon per pulse may be detected and time tagged with sub-picosecond precision and stability.

We have designed and tested the optical analogy of the two-way time transfer using a common optical channel. The photon counting approach has been applied. The pilot experiment has been completed in our lab.

II. Principle of Operation

Optical two way time transfer (OTWTT) is a powerful technique to compare two time scales with sub-picosecond precision and a few picosecond accuracy over long distances. The principle is plotted in Fig. 1.

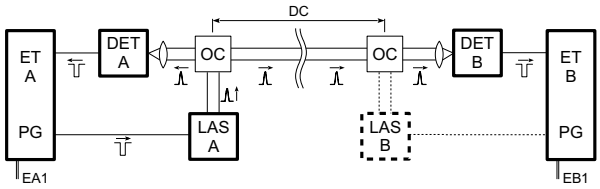

Fig. 1. Experimental scheme of optical two-way time transfer.

The operating scheme is the following: two event timers *ET A* and *ET B* are equipped with identical OTWTT modules. The event timers represent the time scales *A* and *B*. Each OTWTT module consists of an optical signal combiner *OC*, laser diode optical source *LAS* and an optical detector *DET*. These modules are interconnected by an optical channel: free space or an optical fiber. The measurement is carried out in two phases. First the part *A* is activated, as illustrated in Fig. 1. The source of optical pulse – diode laser *LAS A* is generating a ultrashort optical pulse triggered by a pulse generator *PG*. It is split by a signal combiner *OC A* and is propagating in both directions toward parts *A* and *B*. They are detected by the optical detectors and time tagged in the respective time scales *A* and *B*. The corresponding epochs *EA1* and *EB1* are recorded and stored. In the second phase the module *B* is activated, the diode laser *LAS B* is generating ultrashort uniform pulse, which is split and propagating toward both parts *A* and *B*. There they are detected and time tagged in the respective time scales. The corresponding epochs *EA2* and *EB2* are recorded and stored. Using equations

$$DS = ((EB1 - EA1) + (EB2 - EA2)) / 2 \qquad (1)$$

$$DC = ((EB1 - EA1) - (EB2 - EA2)) / 2 \qquad (2)$$

two pairs of epochs $EA\times$ and $EB\times$ can be combined producing the difference *DS* between the two time scales (1) along with the delay of the optical channel *DC* interconnecting the two

OTWTT modules (2). Reference points are defined symmetrically inside each optical signal combiner.

III. Why Single Photon Detection?

The application of single photon detection – photon counting – has a number of key advantages in comparison to a conventional optical detection of "strong" (i.e. multi-photon) optical pulses in this type of measurement:

- The detection process is inherently digital, the detector has only two output stages: photon not detected and photon detected. There is no analog signal processing (amplification, discrimination, etc.) involved. This simplifies the detector itself and reduces the problems of device stability, linearity, drifts, aging etc.
- The photon counting approach to the optical detection is based on an ultimately fast sampling of optical signal, where the sampling itself is provided by a quantum nature of light. This fact is canceling the dependence of detection delay on signal amplitude and maintains a wide dynamical range.
- Photon counting process is capable to detect ultimately low energy optical signals. In a real experiments the optical pulses of an average energy of 1×10^{-4} photons per pulse may be detected.
- Extreme detection sensitivity, high dynamical range and high timing resolution in detection of pulsed signals enable to complete the measurements under very high background photon flux and dark count rate conditions.
- Various signals – photons – from various sources and signal paths may be detected in one setup. The detected signals are identified in data analysis process.

Photon counting approach to detection of optical signals has indeed drawbacks:

The experimental result can not be obtained on the basis of a single measurement. The result may be obtained by a statistical processing of a set of a large number of individual measurements only. That is why the effects suffering of time variations much slower than a useful signal data rate may be measured. Considering the useful data rate of photon counting signals of the order of 100 readings per second, the measured effect time variations of the order of seconds and slower may be registered. Considering a nature of the time transfer experiment, this effect represents no limitation.

IV. Experiment Setup

We have designed and tested the optical two way time transfer in laboratory conditions. The experimental scheme was identical to Fig. 1.

The optical test pulses were generated by a PicoQuant diode laser type LDH-P-FA 530B which is delivering 80 ps long pulses at the wavelength of 531 nm. The epoch timing was accomplished using an in house built epoch timing systems NPET [4], which are providing sub-picosecond resolution and femtosecond timing stability [5]. A common source of frequency and time reference has been used for both epoch timing systems *A* and *B*.

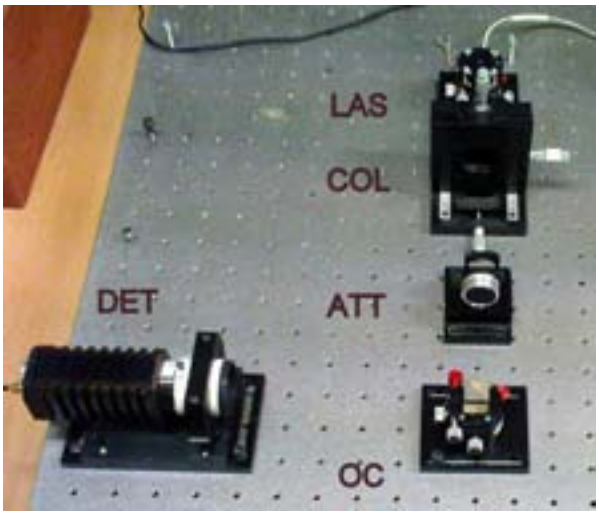

Fig. 2. The realization of experimental setup of part *A*. Optical signal is generated by laser *LAS*, collimated by a collimator *COL*, attenuated by attenuator *ATT*, split by optical signal combiner *OC* to detector *DET* and to the part *B* of experiment setup on a right side, not displayed on photo.

The optical signals were detected by photon counting detectors developed in our labs [6]. These are solid state photon counters based on silicon. They do provide more than 30 % photon detection probability, timing resolution of a single measurement better than 20 ps. Their long term and temperature stability is excellent. The temperature drift is typically 260 fs/K, the timing stability in a sense of time deviation TDEV is better than 150 fs for averaging time of seconds to days [6].

The two-way time transfer optical link was a free space path on an optical bench. The signal combiner has been realized using a modified cube beam splitter and additional neutral density attenuators. The photograph of the experimental setup of part *A* is in Fig. 2. Laser source and its collimating optics is on a top right, in a right center is a set of attenuators, bottom right is the cube beam splitter. The photon counting detector package is on the left. Please note no signal path optical shielding. The photon counting experiment has been performed in full daylight conditions.

The measurements were carried out at the repetition rate of 500 measurements per second. The optical signals intensity on the detectors inputs has been adjusted to get a useful data rate of 5 to 15 %. This optical signal intensity guarantees photon counting regime of operation. The useful data flow was typically 20 to 75 valid readings per second. The average values were evaluated for groups of 70 data points, every 1.5 second. The total background photon flux and dark count rate were rather high of the order of 0.5 Mega counts per second. Nevertheless the photons of interest have been detected, time tagged and identified.

V. Experiment Results

The example of the data acquired in one measurement series lasting 5000 seconds is plotted in Fig. 3. The histogram of mean epochs recorded on detector *A* is plotted. The resulting single shot resolution of the system is 50 ps r.m.s.

The time scales difference *DS* evaluated on the basis of these data sets is plotted in Fig. 4. The two time scales *A* and *B* were represented by a common frequency and time reference. Hence the Fig. 4 illustrates the stability of the measurement setup. The identical data set has been used to evaluate the time deviation TDEV [7]. One can conclude from Fig. 5 that at the measurement repetition rate of 500 measurements per second the time scales difference of 1 ps may be achieved within 100 – 200 seconds. Obviously higher measurement repetition rates (up to 5 kHz) will result in a same precision and accuracy in shorter time.

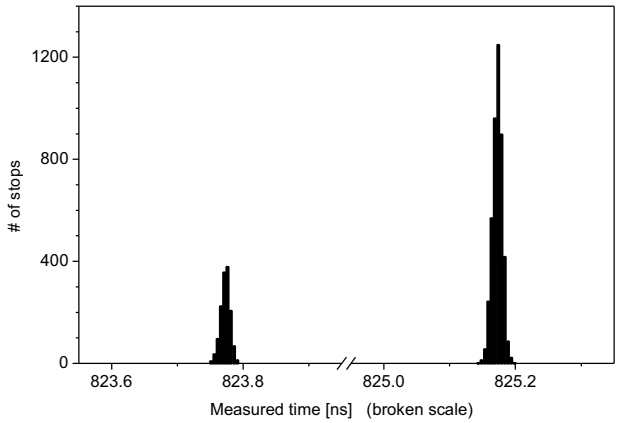

Fig. 3. Example of measured data, the histogram of mean epochs recorded on detector *DET A*.

The two-way time transfer optical path delay *DC* was evaluated to be 540 ps. This value is in an excellent agreement with the geometry of the experiment. The equivalent optical distance of reference points of modules *A* and *B* was determined as 160 ± 1 mm.

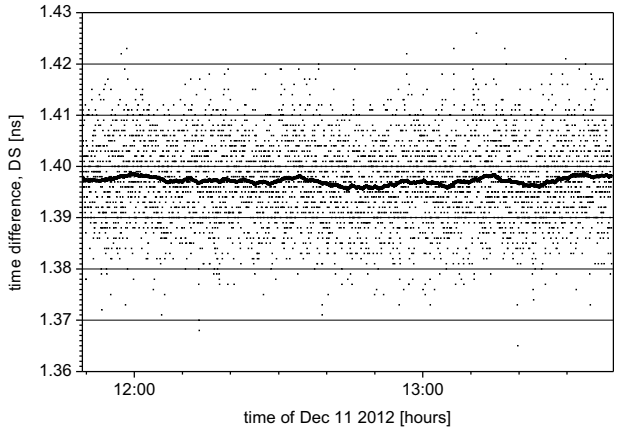

Fig. 4. The time scales difference *DS* evaluated on the basis of data sets plotted in Fig. 3 (points). And its moving average (solid line) evaluated with time window 15 min.

The measurement series were repeated over three days. The series to series data consistency was within statistical errors.

VI. Time Transfer Precision and Accuracy

The precision of the time scales difference will obviously depend on the precision of both event timing systems and on the stability of the photon counting detectors. All of those provide sub-picosecond precision. The time deviation TDEV value obtained from experimental data demonstrates this fact.

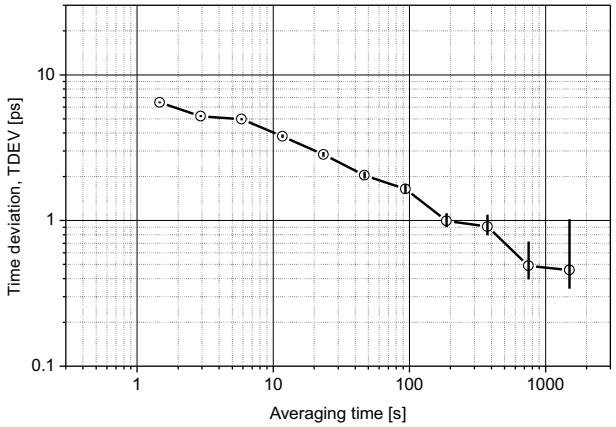

Fig. 5. The time scales difference DS in a sense of time deviation TDEV, the time scales *A* and *B* were represented by a common frequency and time reference, hence it illustrates the stability of the measurement setup

The key question is the accuracy of the time scales difference *DS*. Considering the analogy to the two-way time transfer via single coaxial cable and the detailed error analysis [3] one can conclude that the accuracy is limited by the non-symmetry of the setup, propagation of the test pulses in two directions and non-equality of response of the detectors and event timing devices to the test signals. Applying photon counting approach these non-symmetries may be kept at 1 ps level.

In optical two-way time transfer over a free space the resulting accuracy may be estimated by comparison of evaluated propagation delay *DC* with the real optical path length. According to error analysis [3] the accuracy of time scales difference *DS* is higher in comparison to optical path delay *DC*. Thus the accuracy of *DC* represents the worst case estimate of accuracy of time scales difference *DS*. The measured optical path difference *DC* was equal to the physical length of the optical path with better than 3 ps accuracy. This fact indicates the accuracy of determining *DC* at the level of 3 ps. That is why the accuracy of optical two way time transfer better than 3 ps has been achieved.

VII. Perspective Applications

One of the most promising application of this time transfer technique is an inter-satellite link. The technique described together with the existing technology is capable to provide sub-picosecond precision and a few picosecond accuracy for time scales synchronization over distances in space. Thanks to a photon counting approach miniature laser sources and transmitting and receiving optics may be used. The microchip lasers delivering pulses of micro Joule energies and collecting optics of 20 mm in diameter may accomplish optical two-way time transfer over distances up to 100 thousands kilometers. The photon counting detectors have been qualified for operation in long lasting space missions [6].

The capabilities of the technology available for space applications has been demonstrated in a satellite laser ranging experiment. The measurements have been performed at the

satellite laser ranging station in Graz, Austria [8]. The measurement repetition rate was 2 kHz. The precision of one way propagation delay ground to space to the GPS satellite in a sense of time deviation TDEV is plotted in Fig. 6.

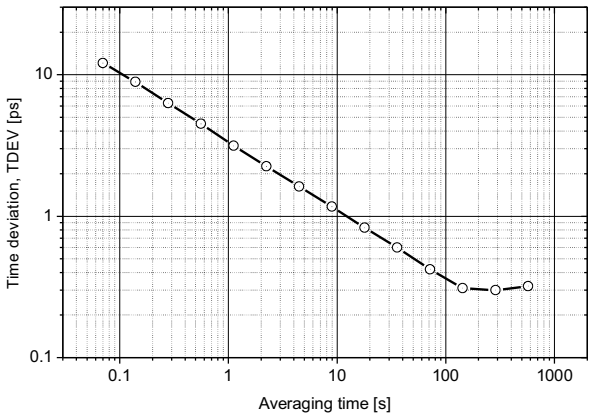

Fig. 6. One way propagation delay ground to space to the GPS satellite in a sense of time deviation, evaluated from outdoor experimental data, photon counting detection, station Graz, Austria, 2 kHz laser repetition rate. Note the values of 200 fs for averaging times of hundreds of seconds.

From Fig. 6 one may conclude that existing electro-optical technologies based on photon counting approach might support laser time transfer in space with sub-picosecond precision.

VIII. Conclusion

We have demonstrated a new approach to an optical two-way time transfer which is based on signals of individual photons. This approach enables to reach extreme timing stabilities and minimal systematic errors using existing electro-optic technologies. In our indoor experiment we have achieved sub-picosecond precision and an accuracy better than 3 ps of a two-way time transfer via free space optical channel. This technique is a perspective for space application, where it might provide picosecond accuracies over long distances. The microchip lasers delivering pulses of micro Joule energies and collecting optics of 20 mm in diameter may accomplish optical two-way time transfer over distances up to 100 thousands kilometers. The entire system is compact, rugged and simple.

Comparsion between Timing Methods in BeiDou Satellite Navigation System

Hai Sha，Pengpeng Li，Jianwei Zhan，Bo Xu，Gang Ou

National University of Defense Technology
Changsha, China
sandhai@163.com

***Abstract*—BeiDou satellite navigation provides the RDSS two-way timing and RNSS timing. In this paper, the basic principles of these two timing methods are illustrated, and the factors which affect the precision for the two methods are analyzed. Compared with the wildly used RNSS timing method, the RDSS timing method can only be used by a limited number of users, due to the limited capacity of the RDSS system, and it cannot meet the requirements of high dynamic users. However, the experimental results indicate that the RDSS two-way timing method provides higher precision than RNSS timing method.**

Keywords—BeiDou; RDSS; RNSS; timing method; error analyses

I. INTRODUCTION

BeiDou satellite navigation system can provide service of positioning, timing and short message communications based on the radio determining of satellite service (RDSS) and the radio navigation of satellite service (RNSS) for the users of China and part of Asia-Pacific region [1]. In 2020, BeiDou system will completely be established with global coverage.

In BeiDou system, there are two timing ways: RDSS two-way timing method and RNSS timing method. Because RDSS payloads were only installed in the GEO orbit satellites [2], RDSS two-way timing can only be used when one or more GEO satellites are visible. For RNSS timing, it demands four or more satellites are visible. Currently the BeiDou timing receiver has been widely utilized in electric power, communications, finance and other industries.

In this paper, the basic principles of these two timing methods are discussed. Then through analyzing the various errors, the precision is drawn in theory. Finally through the equipment test result, two timing methods are validated in respect of accuracy.

II. BASIC PRINCIPLE

A. RDSS two-way timing method

For the RDSS system, in Master Control Center (MCC), the time frame interrogation signal generated under the control of the main atomic clock (BeiDou system Time: BDT) is transmitted from the MCC to satellite via satellite transponder, and finally received by the timing user.

There are two steps in RDSS two-way timing method. In the first step, the forward propagation delay τ_{forward} from the Measure Control Center (MCC) to the user is calculated by the MCC. In the second step, the time clock error Δt is calculated by the user on receiving the forward propagation delay [3-4]. The principle is shown in Fig.1.

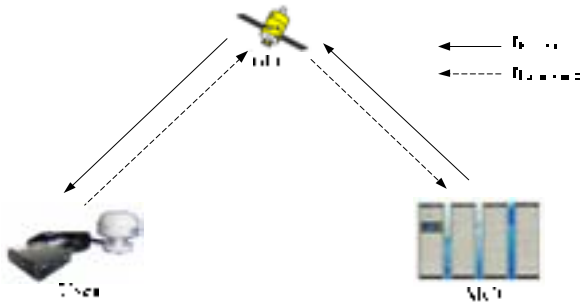

Fig. 1. Principle of RDSS two-way timing method

In the first stage, when receiving the time frame interrogation signal transmitted by the MCC, the user immediately sends the response signal. The round-trip time delay τ_{delay} between sending the interrogation signal and receiving the response signal is measured by the MCC. τ_{delay} can be expressed as follows:

$$\tau_{\text{delay}} = \tau_{\text{forward}} + \tau_{\text{backward}} \tag{1}$$

If the position of satellite and user were unchanged in the two-way transmission, τ_{forward} is equal to τ_{backward}. So the value of τ_{forward} is[3]

$$\tau_{\text{forward}} = \frac{1}{2}\left[\tau_{\text{delay}} + (\tau_{\text{forward}}^{\text{air}} - \tau_{\text{backward}}^{\text{air}}) - \tau_{\text{backward}}^{\text{equip}}\right] + \tau_{\text{forward}}^{\text{equip}} \tag{2}$$

Where $\tau_{\text{forward}}^{\text{air}}$ and $\tau_{\text{backward}}^{\text{air}}$ are respectively troposphere and ionosphere delay in forward and backward propagation process; $\tau_{\text{forward}}^{\text{equip}}$ is the equipment delay in forward propagation process from the MCC to user; $\tau_{\text{backward}}^{\text{equip}}$ is the equipment delay in backward propagation process.

In the second step, the τ_{forward} value is send to the user through the interrogation signal by the MCC. The pseudo-range ρ on receiving this interrogation signal is obtained by the user, the time clock error Δt can be obtained as follow:

$$\Delta t = \frac{\rho}{\mathrm{c}} - \tau_{\text{forward}} \tag{3}$$

B. RNSS timing method

RNSS timing can be achieved by obtaining the clock offset between local time and the BDT, which is realized by receiving RNSS signals [5]. When the position of the RNSS receiver is unknown, four or more satellite observations must be obtained to determine the extra unknown position information and time information . If position of the RNSS receiver is accurately determined, then only one satellite observations is needed to achieve the BDT. The principle of RNSS timing is shown as Fig. 2.

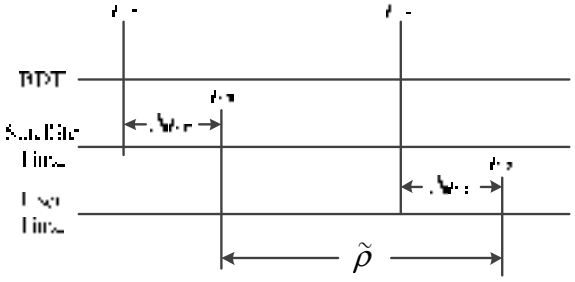

Fig. 2. Principle of RNSS timing method

Suppose the j[th] satellite observation has been obtained, the satellite time and BDT at the time instant of transmission are t_{BT} and t_{ST} respectively, while the receiver time and BDT at the time instant of receiving are t_{BR} and t_{UR} respectively.

Δt_{SB} is time error between the satellite time and BDT at the moment of signal transmission, while Δt_{UB} is time error between the receiver time and BDT at the moment of signal receiving. $\tilde{\rho}$ is the pseudorange measured by the receiver, which can be modeled as

$$\frac{\tilde{\rho}}{\mathrm{c}} = t_{\text{UR}} - t_{\text{ST}} = \frac{\rho^j}{\mathrm{c}} + \Delta t_{\text{SB}} - \Delta\tau - \Delta t_{\text{UB}} \tag{4}$$

Where ρ^j is the true distance between the satellite and the receiver; c is the speed of light. $\Delta\tau$ is time error including the satellite clock error, ionosphere error, tropospheric error, hardware delay and receiver noise. The receiver clock error can be expressed as

$$\Delta t_{\text{UB}} = \frac{\tilde{\rho}}{\mathrm{c}} - \frac{\rho^j}{\mathrm{c}} + \Delta t_{\text{SB}} - \Delta\tau \tag{5}$$

Δt_{UB} represents time error between the receiver time and the BDT, which is needed when computing the time information.

III. Analysis of Timing Precision

A. RDSS two-way timing method

The precision of RDSS two-way timing method is analysis from the formula (3). ρ contains the user measurement error; τ_{delay} contains the MCC measurement error, $\tau_{\text{forward}}^{\text{air}}$ and $\tau_{\text{backward}}^{\text{air}}$ contain the atmospheric error which composed of the troposphere and ionosphere error, $\tau_{\text{forward}}^{\text{equip}}$ and $\tau_{\text{backward}}^{\text{equip}}$ contain the device delay error. Otherwise, the position of the satellite is different on the forward and backward propagation process, which induces the approximation error.

Hence, assume that all errors are independent, the error of RDSS two-way timing method is

$$m_{\Delta t} = \sqrt{m_{\text{user}}^2 + \frac{1}{4}m_{\text{mcc}}^2 + \frac{1}{4}m_{\text{iono}}^2 + \frac{1}{4}m_{\text{trop}}^2 + \frac{1}{4}m_{\text{device}}^2 + m_{\text{app}}^2} \tag{6}$$

Where m_{user} is the user measurement error, m_{mcc} is the MCC measurement error, m_{iono} is the ionosphere delay error, m_{trop} is the troposphere delay error, m_{device} is the device delay error, m_{app} is the approximation error. According to the RDSS system parameters [1,6], the theoretic precision of RDSS two-way timing is:

$$\sqrt{10^2 + \frac{5^2+1^2+0.5^2+0.5^2}{4} + 3^2} = 10.8\text{ns}\cdot$$

B. RNSS timing method

From the formula (5), the factors which mainly affect the precision of the RNSS timing are receiver measurement error, satellite orbit error, satellite clock error, ionosphere error, tropospheric error. Suppose that the UERE value of RNSS standard positioning service is 7.1 m [6], the precision of RNSS timing is about 23.7 ns.

Meanwhile, the clock error is obtained while computing the PVT solution, then the precision of clock error σ_{t} can be expressed as:

$$\sigma_{\text{t}} = \text{TDOP} \times \sigma_{\text{UERE}} \tag{7}$$

IV. Experimental Result

In order to compare the precision of RDSS two-way timing method with that of RNSS timing method, the measurement data of these two timing method are compared.

As to the RDSS two-way method timing, the timing result is shown as Fig. 3. The timing precision is 8.1 ns, which is according to the theory analysis.

The RNSS timing test is carried out in Changsha by the high precise receiver. Because the true BDT is unknown, the variance of clock error is shown as Fig. 4, which is subtract from the frequency drift. The timing precision is equal to the variance of clock error added by system error. Meanwhile the TDOP is Fig.5.

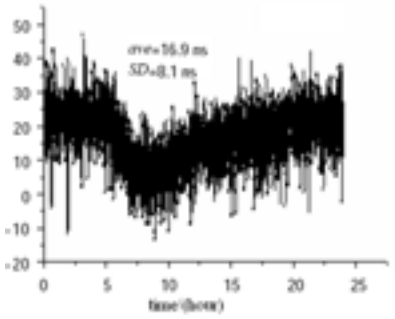

Fig. 3. Result of RDSS two-way timing in Herbin [3,4,7]

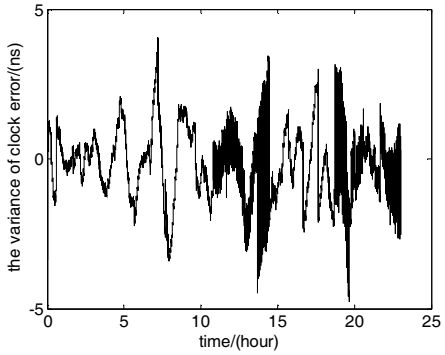

Fig. 4. Result of RNSS timing in Changsha

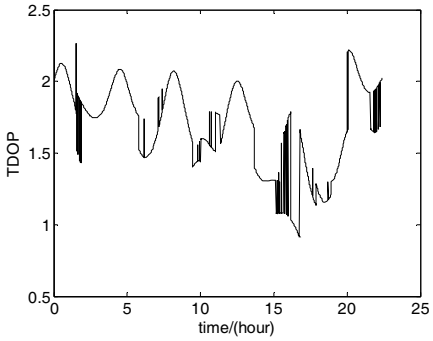

Fig. 5. TDOP value

V. CONCLUSION

The precision of RDSS two-way timing method is mainly influence by the MCC measurement error, ionosphere delay error, troposphere delay error and approximation error. The measurement data and the test result indicate that indicate that the precision of RDSS two-way timing method is about 8.1ns. The variance of clock error in RNSS timing method is about 5 ns. If considering the system error, the precision is larger than that of RDSS two-way method.

Abstract—**EGNOS is the European Satellite Based GPS Augmentation System. It generates its own time scale (ENT) that is steered to GPS time. The time offset between ENT and UTC (actually UTC(OP)) is contained in EGNOS Message Type 12. The aim of this paper is to validate the content of this message and to present the performances of ENT with respect to UTC and GPS time over more than 4 years.**

Keywords-component : EGNOS, ENT, UTC, GPS time.

I. INTRODUCTION

The European Satellite Based Augmentation System, called EGNOS (European Geostationary Navigation Overlay Service), provides to users in Europe an augmentation of three pseudo-GPS signals plus corrections/integrity information about the available GPS constellation [1] enabling to compute a safe and precise position that can be time tagged in a legal time scale (UTC). The EGNOS Open Service was declared operational in October 2009, while the Safety-Of-Life service has been operational since March 2011. EGNOS services are, at the time of writing, broadcast by 3 geostationary (GEO) satellites, whose PRNs are 120, 124 and 126.

EGNOS broadcasts the ephemerides of the GEO satellites (Message Type 9) allowing time and frequency transfer [2], although the GEO-ranging function is currently not supported by the EGNOS system. EGNOS also broadcasts in its navigation message the time difference between EGNOS Network Time (ENT) and UTC (actually UTC(OP)). This is done through an EGNOS ground station set up in Observatoire de Paris and connected to UTC(OP) [3,4].

The time offset between ENT and UTC(OP) is contained in EGNOS Message Type 12. The aim of this paper is to validate the content of this message and to present the performances of ENT with respect to UTC and GPS time. Moreover the recent improvements of UTC(OP) [5] allow to relate ENT to UTC with an unprecedented accuracy without any additional modeling.

II. EGNOS NETWORK TIME

A. ENT generation

The EGNOS Ground Segment consists of Ranging and Integrity Monitoring Stations (RIMS) equipped with Cs or Rb clocks, which are connected to a set of redundant control and processing facilities (CPF), in order to determine the integrity, ephemeris and clock differential corrections for each monitored satellite, to compute the ionosphere delays, and to generate the GEO satellite ephemeris. The GEO satellite downlinks these data on the GPS L1 frequency with a modulation and a coding scheme similar to GPS.

RIMS clock synchronization is performed using the composite clock technique in which ENT is defined as the implicit ensemble mean of a set of RIMS clocks and the synchronization process generates estimates of the time and frequency offsets of each RIMS clock relative to it [6]. ENT is then steered to GPS time using a second order, low-pass digital filter.

B. ENT requirements

All measurements and data are referred to the internal EGNOS Network Time (ENT) whose performance requirements were derived exclusively from navigation accuracy performance requirements. It is required that ENT stay within 50 ns (5σ) of GPS Time (GPST), allowing the user to combine GPS and EGNOS signals in the navigation solution. The EGNOS user shall be aware that applying EGNOS corrections to its GPS measurements will turn its time reference from GPS time into ENT.

GEO Time is the time reference of the EGNOS pseudo ranges. The [ENT - GEO Time] accuracy is specified to be less than 10 ns (3σ), after offset and frequency corrections provided in EGNOS GEO message 9, which might be of interest to realtime users. Table 1 below summarizes the EGNOS time requirements:

TABLE I. EGNOS TIME REQUIREMENTS [7]

1	[ENT - GPS time] offset ≤ 50 ns (5σ)
2	[GEO Time - GPS time] offset ≤ 50 ns (5σ)
3	[GEO Time – ENT] accuracy ≤ 10 ns (3σ)
4	[ENT - UTC(OP)] accuracy ≤ 10 ns (3σ)

C. The Message Type 12

To synchronize ENT and UTC, it was decided to install a special RIMS at Observatoire de Paris, called "RIMS-UTC" or PARA, as part of the EGNOS system. A block diagram of this RIMS can be found in [3]. The time difference [ENT – UTC] can be computed by the CPF using simply :

$$ENT - UTC = [ENT - UTC(OP)] + [UTC(OP) - UTC]$$

where [ENT – UTC(OP)] is determined by the CPF as an output of its ENT composite clock algorithm, and [UTC(OP) – UTC] is computed by CPF using a prediction algorithm. Currently this prediction is not implemented and therefore EGNOS broadcasts in its message 12 the time offset [ENT – UTC(OP)] for the real time synchronization to UTC in compliance to [8].

The Message Type 12 (MT12) contains an estimation of ENT – UTC(OP) expressed in the form of a linear model (offset A0, drift A1 and reference time t_{ot}), assumed to be valid for 86400 s, that can be extrapolated at any current time from its reception to the reception of a new set of such parameters or its validity time. The maximum broadcast interval of MT12 is 300 s [8]. However it has been shown that the accuracy of A1 is limited [9], it is therefore not recommended to use it for more than a couple of minutes beyond the reference time t_{ot}. Possible ways to improve the model are detailed in [9] and an implementation is expected to be carried out with the EGNOS v2.4.2. by 2017.

III. PERFORMANCES OF ENT

A. *UTC-ENT*

In this paragraph, we estimate the time difference UTC – ENT. This computation is carried out by :

UTC–ENT = [UTC–UTC(OP)] – [ENT-UTC(OP)]

where UTC-UTC(OP) comes from the BIPM Circular T and ENT-UTC(OP) is the daily mean coming from MT12. The uncertainty on this estimation is in the range of a few ns (quadratic sum of the uncertainties in our process and in the BIPM Circular T).

Figure 1 shows UTC-ENT from February 2008 to May 2013 as well as a linear fitting:

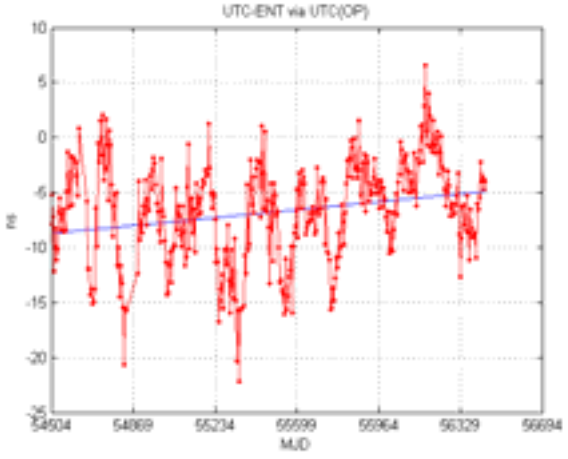

Figure 1. Esimation of UTC - ENT

ENT is therefore a real-time time scale close to UTC. The mean value of UTC-ENT over more than 5 years is -6.7 ns and the standard deviation is 4.5 ns. On top of the fluctuations, we also observe a general trend of about 0.7 ns per year, the origin of which is unclear. The stability of UTC-ENT is given in Figure 2.

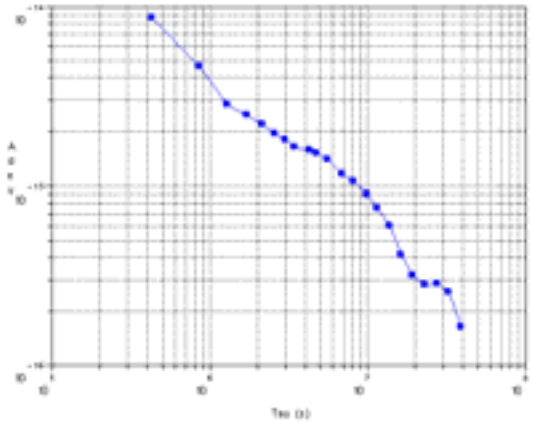

Figure 2. Allan deviation of UTC - ENT

It shall be recalled here that ENT is steered to GPST which is itself steered to UTC(USNO). Figure 3 is the time deviation of UTC-ENT.

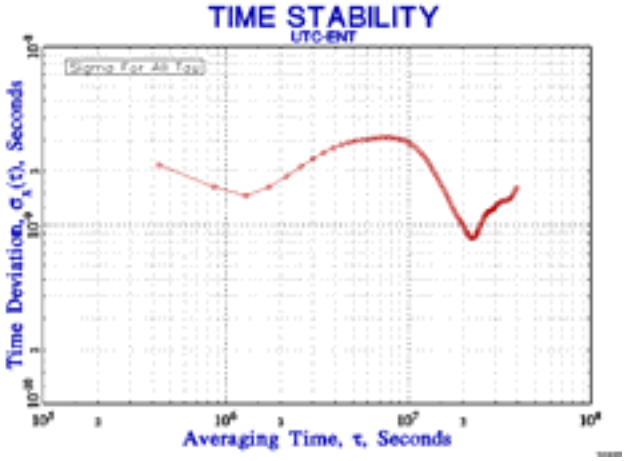

Figure 3. Tdev of UTC - ENT

B. *GPST-ENT*

In this paragraph, we estimate the time difference GPST – ENT. This computation is carried out by:

GPST–ENT = [GPST–UTC] + [UTC-ENT]

Where GPST-UTC comes from the BIPM Circular T and UTC-ENT comes from the previous computation. Figure 4 shows UTC-ENT from February 2008 to May 2013.

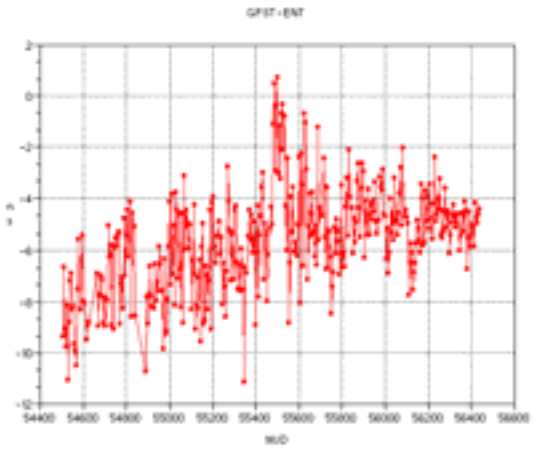

Figure 4. Estimation of GPST - ENT

ENT being steered to GPST, one may expect a zero mean value. This is not what we observe, maybe because of some remaining calibration biases. The mean value of UTC-ENT over more than 5 years is -5.7 ns and the standard deviation is 2.0 ns. According to this estimation, the requirement on the time offset ENT-GPST is met.

IV. Independent Assessment of ENT-UTC(OP)

A. Method

The method consists in an independent estimation of ENT at user level. In this case, we use the GPS measurements of a dual-frequency calibrated receiver called OPMT connected to UTC(OP). We apply EGNOS corrections and station delays on these measurements, so that we get $[ENT_{user} - UTC(OP)]_{OPMT}$ that we can compare to $[ENT - UTC(OP)]_{MT12}$.

The general model for EGNOS measurements uses the C/A pseudo-range observable (C1 observable in the RINEX files). The reference orbit and clocks come from the GPS broadcast ephemeris.

The following formulation is used (one epoch and one GPS):

$$C_1 = D^{EGNOS} + e + \left(h_{rec}^{EGNOS} - h_{GPS}^{EGNOS}\right)$$

- C_1 is the C/A pseudo-range measurement.
- D^{EGNOS} is the geometrical distance between the transmitter and the receiver L_1 centres of phase, including the troposphere delay.
- e is the ionosphere propagation delay on the L1 GPS frequency.
- h_{rec}^{EGNOS} and h_{GPS}^{EGNOS} are respectively the receiver and transmitter clock offsets expressed in the EGNOS reference time.

D^{EGNOS} is computed using the GPS broadcast ephemeris corrected with the data from the EGNOS messages. The tropospheric delay is estimated with a standard mapping function and a fixed zenith troposphere delay of 2.37 m. The receiver centre of phase is obtained using the IGS station log for OPMT station and the ITRF solution for the corresponding marker coordinates. e is estimated using the EGNOS ionosphere message. h_{GPS}^{EGNOS} is computed using the slow and fast corrections obtained from the EGNOS messages applied on the GPS broadcast clock value corresponding to a single frequency user (use of the broadcast TGD values).

Then, at a given epoch and for each GPS in view we obtain an estimation of h_{rec}^{EGNOS} from the above equation. All these estimates are averaged over a 15 minute interval to minimize the pseudo-range measurement noise effects. This produces an estimation of the offset between the receiver clock and the EGNOS time defined by the EGNOS messages.

B. The EPO (EGNOS Performance Observatory) tool

The OPMT receiver is not directly connected to UTC(OP) but to an Hydrogen Maser whose time offset is monitored versus UTC(OP) on an hourly basis. These time offset values are given in so-called LZOP files. These values can be interpolated by a simple linear model over one day for down sampling. The values of the different time propagation delays of OPMT station are extracted from the CGGTTS daily file.

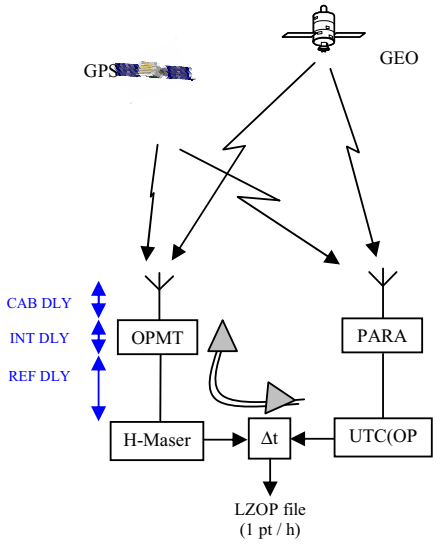

Figure 5. Independent assessment chain (OPMT), EGNOS RIMS (PARA) and their connections to UTC(OP)

Basically, the method implemented in CNES EPO tool is to determine first $[ENT_{user} - UTC(OP)]_{OPMT}$, this time difference being obtained by :

- applying the EGNOS corrections on the GPS measurements collected at OPMT (using the previously described method)

- relating ENT to UTC(OP) using the internal delays of the station OPMT

This time difference is then compared to the broadcast information at each reception time of a new valid model of MT12.

Finally, we obtain $[ENT - UTC(OP)]_{MT12}$ - $[ENT_{user} - UTC(OP)]_{OPMT}$ which is expected to be close to zero if the different calibrations of pieces of equipment and cables in the EGNOS PARA RIMS and in the independent assessment chain are correct. This analysis is automatically performed on a daily and a monthly basis.

C. *Results*

Figure 6 shows the mean daily difference $[ENT - UTC(OP)]_{MT12}$ - $[ENT_{user} - UTC(OP)]_{OPMT}$ computed as explained above from Nov 2008 to May 2013.

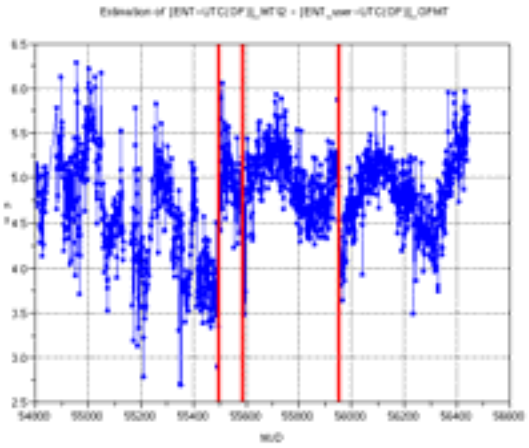

Figure 6. Mean daily difference $ENT - UTC(OP)]_{MT12}$ - $[[ENT_{user} - UTC(OP)]_{OPMT}$

The red vertical bars indicate the changes of Hydrogen Maser in the station OPMT. The stability of this mean daily difference is quite good over such long a period. We observe that the changes of Hydrogen Maser (as well as other events) have an impact at the ns level, consistent with delay calibration uncertainties at Observatoire de Paris.

The overall bias is about 4.7 ns and can be at least partly explained by :

- the uncertainty in the calibration of IGS station OPMT (estimated in the range of 3.3 ns (k=1))
- the uncertainty in the calibration of RIMS PARA and equipment used to connect it to UTC(OP)
- the difference between ENT and $ENT_{user.}$
- the potential code bias [10] between the OPMT receiver (Ashtech Z12T) and the RIMS receiver

This result however validates the requirement on the accuracy of ENT-UTC(OP).

V. UTC(OP) MODERNIZATION

LNE-SYRTE has improved the performances of UTC(OP) since October 2012. UTC(OP) is currently generated from a H-Maser steered on Primary Frequency Standards Cesium fountains [5]. Figure 7 shows the evolution of UTC – UTC(OP) since February 2008 :

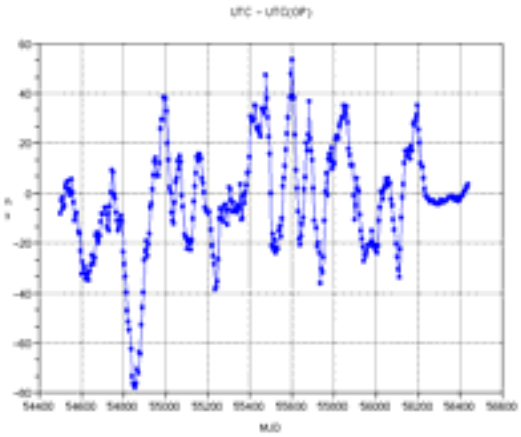

Figure 7. UTC – UTC(OP)

Since Nov 2012, UTC(OP) has been between +/- 5 ns of UTC. It is now an excellent realization of UTC and therefore the EGNOS user can obtain UTC in real-time at the level of a few ns, when applying the MT12.

ACKNOWLEDGMENT

The authors wish to thank the NTMF (CNES Navigation and Time Monitoring Facility) exploitation team for their daily work to compile the database enabling such long term analyses.

Exponential Degrading of NTP Synchronization with Number of Network Hops

Akihiko Machizawa and Tsukasa Iwama
National Institute of Information and Communications Technology
Tokyo, Japan 184–8795
Email: machi@nict.go.jp

***Abstract*—Time synchronization using the Network Time Protocol (NTP) has increased with the growth of the Internet. There are hundreds of public NTP servers in the world. Conventional client software selects a peer/server using packet delay jitter statistics for some manually listed servers, even though it is commonly understood that the nearest NTP server should be used. We demonstrate that NTP synchronization degrades with the number of network hops. The hop count indicates the number of routers on the network path, which is where most jitter and packet loss occur. The accuracy of client time synchronization degrades exponentially with hop count. We propose a round-trip hop-counts-capable NTP server response for the accurate selection of the nearest server.**

I. Introduction

Time synchronization using the Network Time Protocol (NTP) [1] has increased with the growth of the Internet. NTP is a standard for time synchronization in an IP-based network. There are hundreds of public NTP servers across the world. Conventional client software selects a peer/server using packet delay jitter statistics for some manually listed servers, even though it is commonly thought that the nearest NTP server should be used. What is the "nearest?" There are two metrics for network distance [2]. One is delay time and the other is hop count. The hop count indicates the number of routers on the network path. Communication quality is degraded because of the hop count, because most jitter and packet loss occur at routers.

Although it is known that packet delay jitters are proportional to the square root of the hop count [3] [4], how an increasing number of hops affects NTP synchronization has not yet been reported. However, detecting the nearest server can be difficult. An IPv4 header has a Time-to-Live (TTL) field and an IPv6 header has a Hop Limit (HL) field. Since each router subtracts one count from these fields, the hop count can be estimated with the fields. Some Internet Control Message Protocol (ICMP) diagnostic tools, such as traceroute, use ICMP echo reply and ICMP time-exceeded packets to determine initial TTL/HL values as the hop count. However, such tools use a significant number of packets and are often blocked by fire walls. Furthermore, the forward and backward paths may differ. In addition, traceroute measures only the hop counts of the forward path.

In this article, we quantitatively demonstrate that client NTP synchronization accuracy degrades with the hop count. We analyze the pseudo one-way delay between clients and our NTP server (ntp.nict.jp) [5], [6] [1]. This server is a primary (stratum 1) NTP server operated by the national time authority in Japan and is used by more than ten million clients worldwide.

We propose a method to detect the nearest NTP server using round-trip hop counts (RTH). RTH is the total number of hops on the path from a client to a server (forward path) and from the server back to the client (backward path). We propose a TTL/HL reflecting method at servers to measure RTH. This method copies the TTL/HL values of incoming request packets at the servers into the field of the outgoing NTP server response packets. The TTL/HL values successively decrease by the forward and backward paths. Using this method, clients can select the nearest NTP server among the listed servers.

The remainder of this paper is organized as follows. In Section II, we examine the methodology employed to evaluate synchronization error. In Section III, we compare the degradation of NTP synchronization with the hop count and delay time. Then, in Section IV, we propose a simple and effective RTH measurement technique.

II. Methodology

A. One-way Delay and Synchronization Error

In Fig. 1, an NTP request packet from a client contains only the origin timestamp T_1. A server receives the packet at T_2. The server sends an NTP response packet to the client at T_3. The packet now contains T_1, T_2, and T_3. The client receives the packet at T_4. Timestamps T_1 and T_4 are based on the client clock, which has the offset (O) relative to the server. Timestamps T_2 and T_3 are based on the server clock and show the correct time. The network delay from the client to the server is d_1, and the delay from the server to the client is

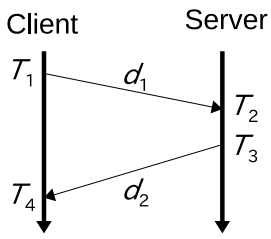

Fig. 1. Four timestamps of NTP and one-way delay

[1] http://www2.nict.go.jp/aeri/sts/tsp/PubNtp/index-e.html

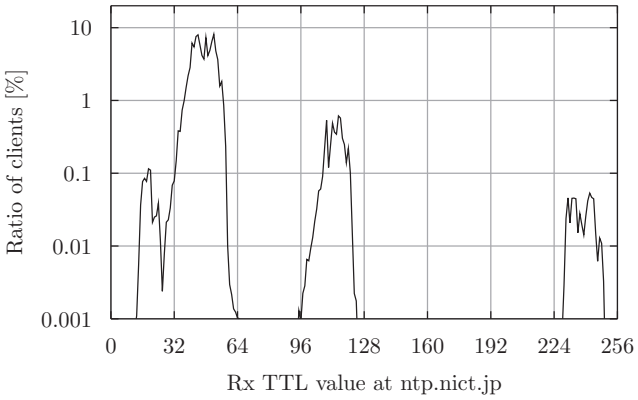

Fig. 2. Histogram of TTL/HL values in packets received by ntp.nict.jp

d_2. These four timestamps and two delays have the following relation ship.

$$T_2 = T_1 + O + d_1, \tag{1}$$

$$T_4 = T_3 - O + d_2. \tag{2}$$

If d_1 and d_2 are known, O can be computed as follows.

$$O = ((T_2 - T_1) + (T_3 - T_4) + (d_2 - d_1))/2. \tag{3}$$

Most NTP clients assume symmetric delay, i.e., $d_1 = d_2$. However, delays are actually asymmetric and dynamic. Therefore, offset estimation error is a function of network delay. The following equation, which is derived from equation (1), represents the synchronization error trend.

$$T_2 - T_1 = O + d_1. \tag{4}$$

B. Round-Trip Hop Counts Estimation

An IPv4 header has a TTL field, while an IPv6 header has a HL field. Since each router subtracts one count from these fields, the hop count can be estimated with the fields. One-way hop counts from a client to a NTP server can be estimated by capturing NTP request packets at the server. The TTL/HL values in the captured packets show the hop counts as they are decreased by one at each hop. Fig. 2 shows the distribution of TTL/HL values received by ntp.nict.jp. RTH is the total number of hops from both the forward and the backward paths. The estimated RTH is equal to two times the estimated one-way client to the server hop count.

Four groups can be seen in Fig. 2. The smallest and second smallest groups overlap. The nmap OS fingerprints database states that initial values of 32, 64, 128, and 255 are used. [2] Each group in Fig. 2 must correspond to each initial value. Hence, hop counts are estimated from the difference between each initial and received TTL/HL values. Then, based on the symmetric path assumption, RTH is estimated as two times the one-way hop count. However, we know that the forward and backward paths may be different. We will propose a real RTH estimation method in Section IV.

[2]http://nmap.org/

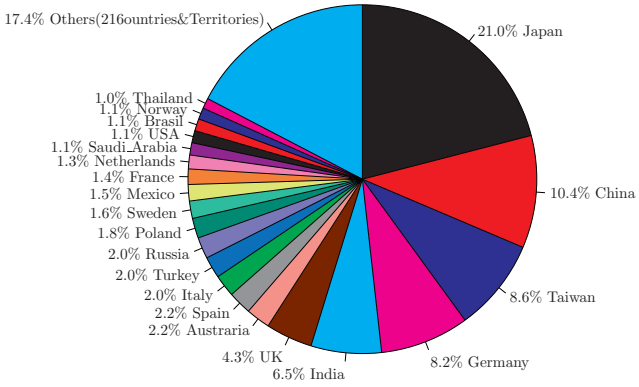

Fig. 4. Geographical distribution of clients using ntp.nict.jp (as of June 2013)

C. One-way Delay Classification

Equation (4) contains the one-way delay d_1 and the offset O. So, $T_2 - T_1$ is called as pseudo one-way delay. Clients are classified into four categories using the pseudo one-way delay, as shown in Fig. 3. Type I is normal, and the others are abnormal. Type IIa is the switching route, Type IIb is time-slotted, and Type IIc is drifted. We use data from the Type I clients.

III. Results

A. Data Collection

We use NTP response packets from ntp.nict.jp. This server receives requests from all over the world (238 countries and territories). This server is a Stratum 1 NTP server operated by the national time authority in Japan. This server has field-programmable-gate array-based high-performance hardware. Fig. 4 shows the geographical distribution of clients that access ntp.nict.jp. More than 10 million clients are distributed around the world. Therefore, the request packets for this server are suitable for analyzing the synchronization error related to the hop count. The pseudo one-way delay represents client synchronization, because it is the sum of the clock offset and network delay, as expressed by equation (4). We capture the server's response packets. The reason we use the server's response packets rather than request packets is that the response packets contains both T_1 and T_2 timestamps.

B. Results Analysis

Fig. 5 plots the standard deviation of the pseudo one-way delay between the server and clients along the estimated RTH on a semi-log scale, and Fig. 6 plots the standard deviation of the pseudo one-way delay between the server and clients along the pseudo one-way delay on a semi-log scale. We can see a stronger correlation in Fig. 5 than Fig. 6. The accuracy of client time synchronization degrades exponentially with the hop count. The regression line is expressed as follows.

$$\sigma = \sigma_0 \times \alpha^H, \tag{5}$$

$$\sigma_0 = 1.1 \times 10^{-}5\ [s], \tag{6}$$

$$\alpha = 1.25. \tag{7}$$

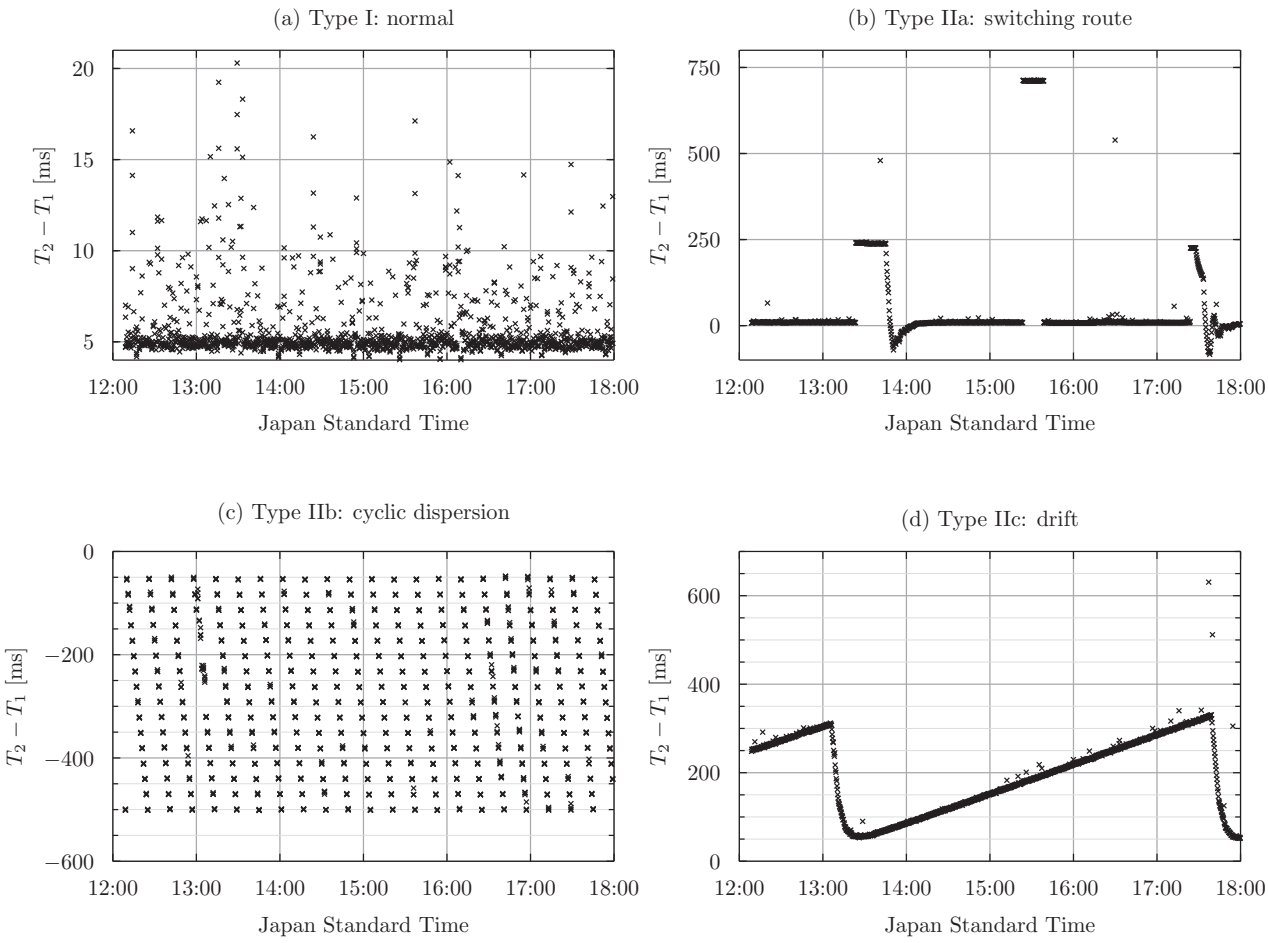

Fig. 3. Typical pseudo one-way delay.

Here σ denotes the standard deviation of the pseudo one-way delay, and H is the estimated round-trip hops.

IV. RTH CAPABLE SERVER RESPONSE

The forward path and backward path between a client and server may be different. We propose a TTL/HL reflecting method at servers to measure the exact RTH. This method copies the TTL/HL values of incoming request packets at the server into fields of the outgoing NTP server response packets. The TTL/HL values successively decrease by the forward and backward paths. Using this method, clients can select the nearest NTP server among available servers.

Fig. 7 illustrates the proposed method.

1) The client sends NTP request packets with TTL/HL values as TTL_1.
2) The server copies the TTL/HL value of the received packets (TTL_2) into the initial TTL/HL values of the response packets (TTL_3).
3) The client extracts TTL/HL values of the received server response packets as TTL_4.
4) Then, RTH can be calculated as follows.

$$RTH = TTL_1 - TTL_4. \tag{8}$$

The current recommended default initial TTL/HL value, which is published in the "IP OPTIONS NUMBERS" at the IANA web site [3], is

$$TTL_{IANA} = 64. \tag{9}$$

The value must be at least sufficiently large for the Internet's "diameter," i.e., the longest possible path. A reasonable value is approximately two times the diameter, which allows for continued Internet growth [7], [8]. If the server receives a packet with a TTL/HL value greater than or equal to TTL_{IANA}, then it recognizes that the packet is a RTH request and copies the value into the response packet. However, if the TTL/HL value of the receiving packet is less than TTL_{IANA}, the server sets the TTL/HL value as TTL_{IANA}.

The ability to select the most appropriate nearest server will lead to (1) improved client accuracy, (2) reduced network traffic, and (3) reduced power consumption. We implemented the TTL/HL reflecting function on servers associated with ntp.nict.jp (this NTP server is a multiple IP address host).

[3] http://www.iana.org/assignments/ip-parameters

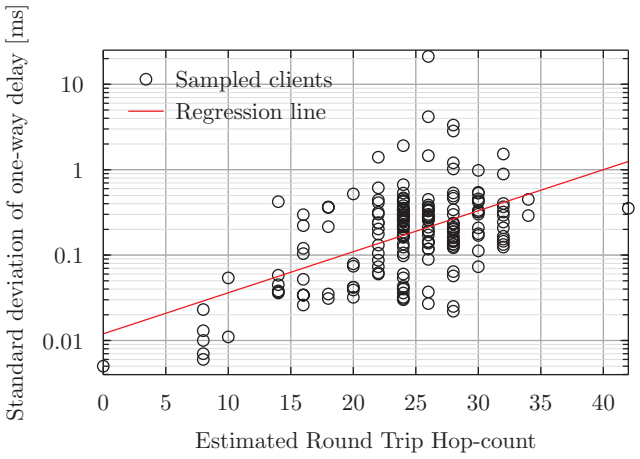

Fig. 5. Degradation of client accuracy with RTH. The standard deviation of the pseudo one-way delay from clients to ntp.nict.jp increases exponentially with increasing network distance (RTH).

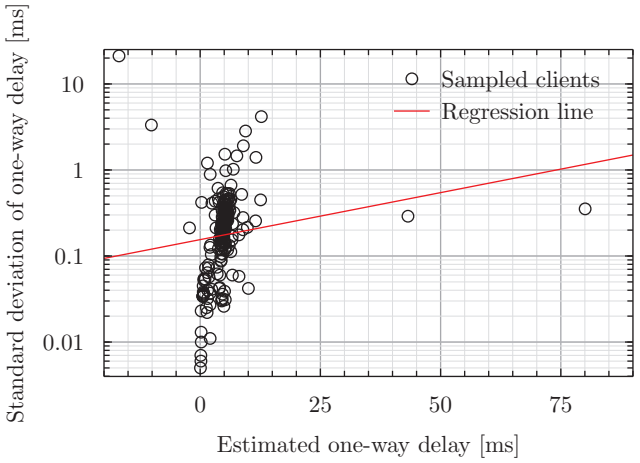

Fig. 6. Degradation of client accuracy with delay.

V. Conclusion

We showed that the accuracy of NTP client synchronization degrades exponentially with the hop count. We also proposed a TTL/HL reflecting method for the selection of the nearest server. RTH is more useful than round-trip time for NTP synchronization. The proposed method is very simple and has been implemented at ntp.nict.jp.

Selecting the nearest server will lead to (1) improved client accuracy, (2) reduced network traffic, and (3) reduced power consumption. We implemented the TTL/HL reflecting function on the servers associated with ntp.nict.jp.

In future, we plan to develop a NTP client that implements both the TTL/HL reflecting method and high-precision time stamping [9].

Abstract—**10^4 magnesium atoms have been trapped in an optical lattice at the predicted magic wavelength of 469 nm. The trap depth of the lattice sites is 16 E_r corresponding to a Lamb-Dicke parameter of $\eta = 0.51$. The temperature of atoms in the lattice is 10 μK. We performed magnetic field-induced spectroscopy on the strongly spin-forbidden clock transition and observed for the first time a 50 kHz broad carrier signal together with a 80 kHz broad red sideband.**

Keywords-Magnesium optical lattice clock; Lamb-Dicke spectroscopy; magic wavelength

I. INTRODUCTION

Magnesium is the 12th element in the periodic table and thus is the lightest species among the candidates for optical atomic clocks. It has three stable isotopes: the bosonic ^{24}Mg and ^{26}Mg, as well as the fermionic ^{25}Mg with a nuclear spin of I = 5/2. Most knowledge has been gained so far on ^{24}Mg which has a natural abundance of 78.99 % in an isotope mixture. Magnesium benefits from a low sensitivity to black body radiation [1] and a relatively simple electronic level structure (see fig. 1).

All relevant transitions for laser cooling and clock spectroscopy in magnesium are in the blue or UV range of the electromagnetic spectrum. Laser cooling at 285 nm in the singlet manifold has been well developed [2]. The broad transition linewidth of 78 MHz limits the final temperature in a magneto-optical trap (S-MOT) to approximately 3 mK. The intercombination line with its linewidth of 36 Hz is not suitable for magneto-optical trapping. Nevertheless, we use this transition to optically pump the pre-cooled singlet atoms into the long-lived triplet manifold. Metastable magnesium thus only occurs by laser excitation of the intercombination line as there is no decay channel from the $^1P_1$ to the triplet manifold via intermediate states like in strontium [3].

Applying a repumping laser to the $^3P_1 \rightarrow {}^3D_2$ transition, atoms are optically pumped to the $^3P_2$ state which is the starting point for our triplet MOT (T-MOT). The $^3P_2 \rightarrow {}^3D_3$ cooling transition further cools the atoms to 1 mK. Since the energy splitting of the ^{3}D states is only marginal, a second repumping laser for the $^3P_0$ state is mandatory to close the MOT cycle. All lasers operate around 383 nm.

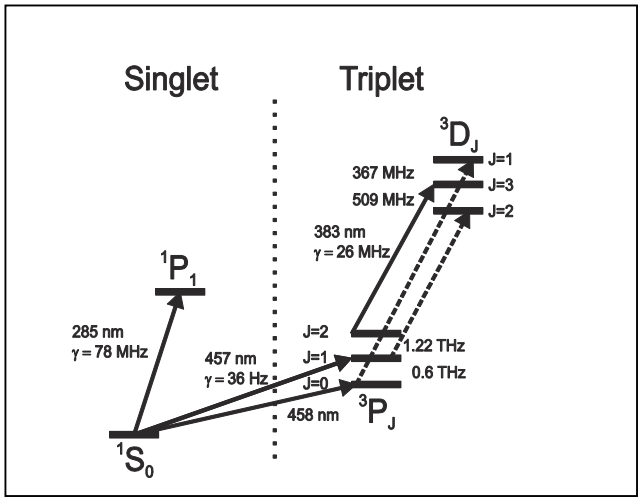

Figure 1. Partial level scheme of ^{24}Mg. The S-MOT is operated on the $^1S_0 \rightarrow {}^1P_1$ transition. The intercombination transition $^1S_0 \rightarrow {}^3P_1$ is used for transferring the atoms to the triplet manifold. Operating the T-MOT envolves three lasers: The cooling laser is acting on the $^3P_2 \rightarrow {}^3D_3$ transition, while two additional repumping lasers re-cycle atoms that have decayed to the $^3P_0$ and $^3P_1$ states. Clock spectroscopy is performed on the $^1S_0 \rightarrow {}^3P_0$ transition.

Concerning optical trapping of magnesium, it turned out that directly applying laser light at 469 nm (which is the predicted magic wavelength) to the atoms while they are in the $^3D_3$ state leads to photo ionisation. Hence, we need a far detuned trap for first trapping before we can load the magic wavelength lattice. Recently, we developed a loading scheme for an optical dipole trap (ODT) at 1064 nm for enhancing the transfer efficiency into the dipole trap, which has earlier been limited by the density of the T-MOT [4]. Atoms are continuously pumped from the singlet manifold into the dark $^3P_0$ state by not applying the relevant repumping laser. The coldest among the $^3P_0$ atoms are accumulated in the dipole trap thus creating a quasi energy filter for metastable atoms.

In this paper we report about the successful transfer of $^3P_0$ atoms into an optical lattice at the predicted magic wavelength of 469 nm and the first spectroscopy of the strongly spin-forbidden clock transition $^1S_0 \rightarrow {}^3P_0$ at 458 nm. This is a key breakthrough in order to realise a magnesium lattice clock

improving our latest frequency measurement on cold free-falling atoms [5].

II. Experimental Setup

Atoms are prepared and manipulated in a vacuum chamber made of stainless steel with a background gas pressure below 10^{-9} mBar. The S-MOT is loaded from a Zeeman-slowed thermal beam of magnesium atoms as described in [5]. In contrary to our previous work, the light at 285 nm is nowadays generated by frequency quadrupling a commercial 5 W fibre amplifier laser at 1141 nm. For long-term stability, the frequency doubled laser at 570 nm is locked to an iodine spectroscopy. The main output of the laser feeds a home-built resonant second harmonic generation (SHG) cavity allowing for the generation of up to 350 mW at 285 nm with a linewidth of 6 MHz. An acousto-optic modulator (AOM) splits the UV light into a resonant beam for Zeeman-slowing the thermal atoms and the light further prepared for magneto-optical trapping.

For pumping the atoms from the singlet to the triplet manifold we perform laser excitation on the narrow $^1S_0 \rightarrow {}^3P_1$ intercombination line. The transfer laser is a commercial laser system consisting of an amplified diode laser at 914 nm feeding a SHG cavity. The output power at 457 nm is typically 120 mW. In order to address this narrow transition, the laser is frequency-stabilised to a high-finesse cavity with F = 39000 providing a laser linewidth of 30 Hz. A detailed description of this laser system can be found in [6].

The T-MOT light at 383 nm is generated by a laser system consisting of three independent lasers for addressing the $^3P_2 \rightarrow {}^3D_3$ cooling transition and the two repumping transitions, respectively. Three master oscillator power amplifiers (MOPA) deliver 1 W optical power at 766 nm each feeding independent home-built SHG cavities (see fig. 2). The output power of each SHG is about 100 mW at 383 nm and the lasers have a linewidth of 1 MHz. For frequency stabilisation of the three MOPAs that are far from any magnesium transition and differ several hundreds of GHz in frequency (see fig. 1), we transfer the stability of a reference laser to the MOPA systems via a common transfer cavity [7,8]. Following a suggestion given by Budker et al. [9], we lift the degeneracy of higher order modes inside the cavity by slightly tilting one of the cavity mirrors thus obtaining a mode spacing of 112.5 MHz which is feasible for locking a laser with respect to an atomic transition (the remaining gap can be bridged with AOMs). The length of the cavity is controlled with a piezo-electric transducer (PZT) to which one of the cavity mirrors is attached. Long-term stability is achieved by stabilising the cavity length to an ECDL locked to the ^{39}K D_2-line at 766 nm via Doppler-free saturation spectroscopy. The MOPAs are stabilised to the transfer cavity using the Pound-Drever-Hall (PDH) method [10]. Frequency modulation sidebands are generated by laser diode current modulation around 20 MHz. Each SHG cavity is then locked to its respective MOPA light using exactly the same modulation sidebands which largely reduces the complexity in electronic stabilisation efforts.

A Ti:Sa laser giving 0.9 W of optical power with a maximum

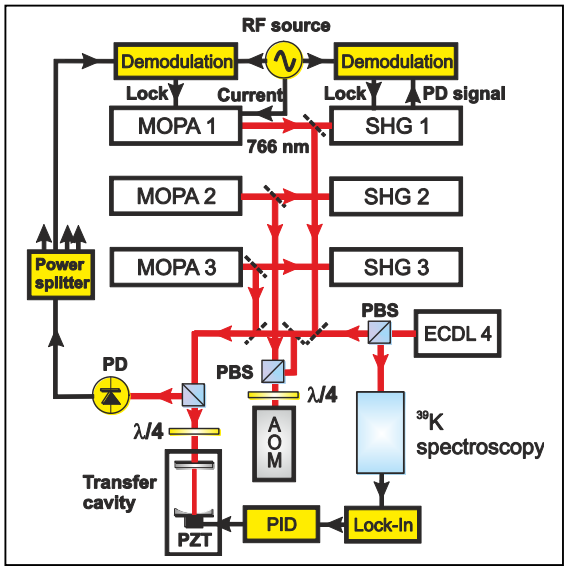

Figure 2. Schematic setup of the laser system used for operation of the T-MOT. The three independent lasers are locked to a common transfer cavity using the PDH scheme. The length of the transfer cavity is stabilised by means of a fourth laser referenced to the D_2-line of ^{39}K via Doppler-free spectroscopy. The locking scheme is shown in detail only for MOPA 1 for clarity. (PZT: piezo-electric transducer, PBS: polarising beam splitter, PD: photo diode)

tuning range of 930 – 960 nm feeds a commercial SHG cavity providing the light for the optical lattice. Long-term frequency stability of the Ti:Sa laser is obtained by stabilising it to the ultra-stable clock laser at 916 nm by means of another transfer cavity. According to the theoretical prediction of the magic wavelength for magnesium, the SHG output delivers 130 mW fibre-guided light at 469 nm to the experiment for generating the optical lattice. In order to fulfil the power requirements on Lamb-Dicke confinement, this light is enhanced in a linear build-up cavity which is set up in the horizontal plane around the vacuum chamber. Fig. 3 shows the schematic setup of the resonator. The cavity has a total length of 850 mm with a beam waist of 65 µm and consists of a curved mirror (R = 500 mm, T = 3 % around 469 nm), a plane mirror being HR-coated for the magic wavelength but AR-coated for the clock laser at 458 nm and a second curved mirror (R = 350 mm) having the same coating as the plane one. We operate with this three-mirror folded design due to two constraints on the cavity: (i) the clock laser has to be spatially overlapped with the lattice light for interrogation without being enhanced inside the cavity and (ii) the transmission of the incoupling mirror has to match the light losses per round trip inside the cavity (impedance matching) to ensure the highest possible enhancement factor. Offering a high transmission for 458 nm at the same time represents a hard-to-fulfil requirement on the mirror coating. Finally, the dipole trap beam at 1064 nm emitted by a Ytterbium fibre laser is overlapped with the lattice light in order to transfer the atoms into the optical lattice.

The maximum build-up factor of the cavity is 15, so we obtain a circulating power of 1.5 W by coupling 100 mW of light into the cavity. The corresponding trap depth is 16 E_r with E_r being

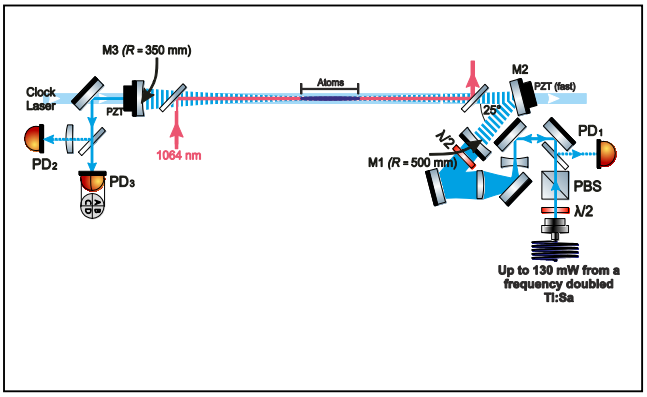

Figure 3. Schematic setup of the enhancement cavity for generation of the optical lattice. The total length of the cavity is 850 mm which is stabilized using the back-reflected light at mirror M1 (photo diode PD1). Using PD2 measuring the light leaking out of the cavity, the intra-cavity power is stabilised while a 4-quadrant photo diode (PD3) stabilises the cavity mode.

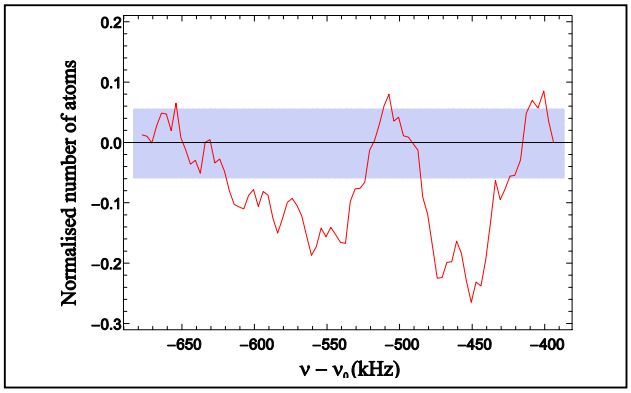

Figure 4. First spectroscopy of the clock transition. The red line is a moving average of five consecutive data points while the blue area indicates the signal standard deviation in absence of the spectroscopy laser. The carrier is observed at a detuning of -460 kHz and the red sideband at a detuning of -550 kHz.

the recoil energy (in temperature units E_r is 1.8 μK). We measured the trap frequencies to be 2π x 150 kHz which results in a Lamb-Dicke parameter of η = 0.51. The enhancement and thus the trap depth may be further increased by exchanging the view ports of the vacuum chamber as there might be a coating damage. A photo diode in front of the cavity is used for cavity length stabilisation (PD1) using the PDH scheme. PD2 is used for stabilising the circulating power inside the cavity while a 4-quadrant photo diode controls the cavity mode by giving feedback to two PZTs acting on Mirror 3 (see fig. 3).

The clock laser at 916 nm is guided via a 30 m long phase-stabilised fibre from a separate room to the magnesium experiment showing a frequency instability of 5 x 10^{-16} in 1 s averaging time. The light is amplified in the magnesium laboratory and frequency doubled to 458 nm in a commercial SHG cavity with an output power of 100 mW. The clock laser light is further fibre-guided to the experimental chamber and is aligned paraxial with the optical lattice.

III. Preparation of Atoms

The procedure of preparing metastable $^3P_0$ atoms in an ODT at 1064 nm is described in detail in [4]. For clarity, the continuous loading scheme we are using is different from stepwise loading of the S-MOT and the T-MOT with subsequent capture in the dipole trap. Instead, during the dipole trap loading, the S-MOT laser, transfer laser, T-MOT lasers and dipole laser are operating continuously, except the repumping laser for the $^3P_0$ state. Since the ODT has a maximum depth of 260 μK, we filter out the coldest $^3P_0$ atoms being captured by the potential. We trap about 10^5 atoms at a temperature of 100 μK.

In order to trap atoms in the optical lattice, the lattice light is applied additionally to the ODT, while the dipole trap and all other lasers are turned off after a period of 100 ms. Transfer of atoms to the lattice is performed with an efficiency of 10 %. The temperature of atoms in the lattice has been measured to be 10 μK.

IV. Spectroscopy of the $^1S_0 \rightarrow {}^3P_0$ Transition

In order to enhance the mHz natural linewidth of the clock transition for spectroscopy, we follow the suggestion of Taichenachev et al. [11] and apply a homogeneous magnetic field during the interrogation pulse thus creating a mixture of the magnetic $^3P_1$ state and the non-magnetic $^3P_0$ state. In order to address the transition for the first time, we apply a strong field (B = 500 G) causing ~ kHz power broadening of the line. Later on, we will require only a weak magnetic field if the transition frequency is well known.

After 1 s of preparation of atoms in the dipole trap, they are transferred to the optical lattice. In parallel, the static magnetic field is created by switching the Anti-Helmholtz MOT coils to Helmholtz configuration. During the 100 ms spectroscopy pulse, atoms in the $^3P_0$ state eventually are de-excited to the $^1S_0$ state depending on the clock laser frequency, so losses in number of atoms would indicate a spectroscopy resonance. For detection the quadrupole field is restored, atoms are released from the lattice and subsequently captured by the T-MOT for fluorescence detection. Detection in the triplet manifold is carried out with a high signal-to-noise ratio since no atoms from the background gas contribute to the signal.

Fig. 4 shows such a recorded spectroscopy sequence. The clock laser frequency was changed in steps of 300 Hz. Each data point is the result of three differential measurements (with and without the clock laser) being averaged. Furthermore, we took a moving average over five such consecutive data points to reduce the signal noise. One can clearly see a carrier signal together with a red sideband. Knowing the frequency of the $^1S_0 \rightarrow {}^3P_0$ clock transition without performing an absolute frequency measurement to be ν_0 = 655 058 646 681 860(47) Hz due to earlier frequency measurements of the $^1S_0 \rightarrow {}^3P_1$ transition [5] and the $^3P_1 \rightarrow {}^3P_0$ transition [12] we observe the carrier with 25 % of atoms being de-excited at a detuning of -460 kHz from the expected signal having a FWHM of 40 kHz. Due to the magnetic field of 500 G, a 2nd order Zeeman shift of -534 kHz is expected for the clock transition which is

in moderate agreement with the measurement. The red sideband could be observed at a frequency detuning of -550 kHz with a FWHM of 80 kHz. The broad carrier linewidth may be due to additional homogeneous broadening effects like fluctuations in the magnetic field. The width of the red sideband is subject to inhomogeneous broadening since the width of the second lattice energy band is 50 kHz. However, we do not observe a blue sideband giving rise to the assumption, that atoms occupy mostly the lowest energy band in the $^3P_0$ lattice potential.

V. Summary & Outlook

We have presented the successful loading of 10^4 metastable atoms in an optical lattice at the predicted magic wavelength of 469 nm. The atoms have a temperature of 10 μK. Performing magnetic-field-induced spectroscopy, we are able to observe the strongly spin-forbidden $^1S_0 \rightarrow {}^3P_0$ clock transition.

In order to increase the signal-to-noise ratio of the spectroscopy signal, we will, as a next step, optically pump the prepared atoms in the $^3P_0$ state back to the $^1S_0$ state, while being held by the dipole trap. Transfer to the optical lattice will thus happen in the singlet manifold and remaining metastable atoms will be blown away with resonant beams. Performing clock spectroscopy starting in the $^1S_0$ state with detection using the T-MOT afterwards promises a significant higher signal-to-noise ratio as no background atoms will contribute to the detection signal.

***Abstract*—Optical frequency combs are key instruments that have revolutionized many fields like frequency metrology and spectroscopy. Traditionally based on fiber lasers or Ti:Sapphire lasers they have been widely studied. Here we demonstrate a 1-micron optical frequency comb based on passively mode-locked diode-pumped solid-state laser technology with low-noise properties and high-reliability.**

Keywords—femtosecond laser; optical frequency comb; carrier-envelope offset frequency; relative intensity noise

I. INTRODUCTION

Optical frequency combs (OFCs) have revolutionized the way optical frequency metrology can be done since more than 10 years and are a key component in optical atomic clocks. Initially demonstrated with Ti:Sapphire lasers [1], optical frequency combs have been generated with several other laser technologies. Fiber laser technology at wavelengths of 1 µm and 1.55 µm has been the object of many efforts for improving their performances and in particular their noise properties [2]. OFCs based on passively mode-locked diode-pumped solid-state lasers (DPSSLs) have been less studied while offering excellent prospects for low-noise high-performance operation due to the low-loss laser cavity and high intra-cavity pulse energy [3]. A 1.55 µm DPSSL has been self-referenced and characterized in [4] while in [5] a self-referenced 1-micron Yb:KYW has demonstrated state-of-the-art low phase-noise microwave generation. Here we present a passively mode-locked diode-pumped Yb:glass laser that has been self-referenced and that demonstrates low-noise properties.

II. EXPERIMENTAL SETUP

The laser is passively mode-locked via a semiconductor saturable absorber mirror (SESAM) and delivers 111 fs transform-limited soliton pulses with an average output power of 205 mW at a repetition rate of 100 MHz. The pump diode is a fiber-coupled single-mode diode and the laser gain material is made of Yb-doped glass. One cavity mirror (the SESAM) is mounted on a piezoelectric transducer (PZT) for repetition rate tuning. After propagation in a 50-cm long photonic crystal highly nonlinear optical fiber (HNLF), the laser pulses generate an octave spanning supercontinuum amounting 110 mW of average power that spans from 650 nm to 1325 nm (see Figure 1). An f-2f nonlinear Michelson interferometer is fed with the supercontinuum for carrier-envelope offset frequency (f_0) detection. In contrast to the system reported in [5] no external optical amplifier is needed. A signal-to-noise ratio of up to 40 dB for f_0 (at an instrument resolution bandwidth of 91 kHz) has been detected. Prior to the injection into the HNLF, a small portion of the laser output is sampled, coupled into a single-mode fiber and detected with a fast photodiode for repetition rate stabilization via the PZT-mounted SESAM. H-maser referenced synthesizers provide the frequency reference for the stabilization of both, the repetition rate and f_0. Figure 2 presents the schematic of the experimental setup.

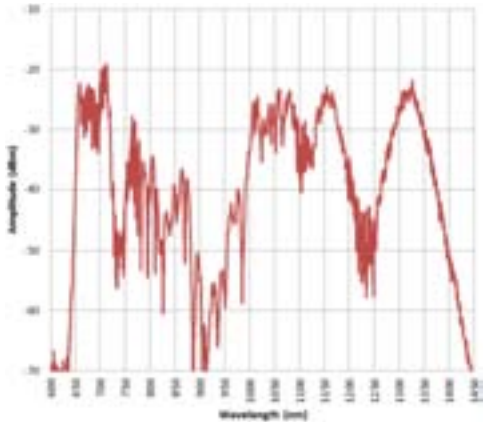

Fig. 1. Typical spectrum of the generated supercontinuum. The total average power was 110 mW.

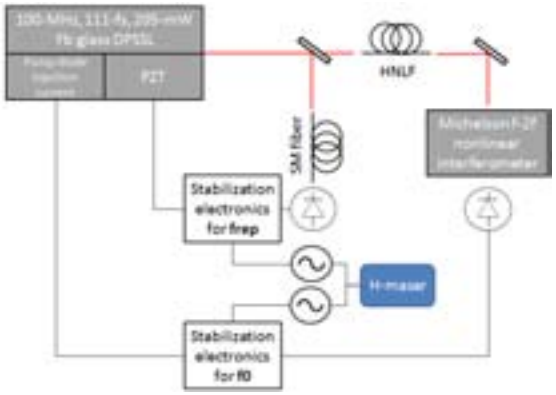

Fig. 2. Schematic of the experimental setup.

III. RESULTS

Using standard locking electronics and feedback to the pump diode injection current, f_0 was phase locked to an H-maser referenced microwave synthesizer. The selected f_0 frequency harmonic was at 274 MHz and was first band-pass filtered and then divided by a factor 16 before being phase-compared to the reference synthesizer signal in a digital phase detector. The in-loop f_0 integrated phase noise amounts 736 mrad when integrated from 1 Hz to 1 MHz for a measured f_0 frequency of 274 MHz (see Fig. 3). The achieved integrated phase noise is comparable to the best fiber lasers. The f_0 phase-locking is very robust and lasts for days. Figure 3 shows an Allan deviation of the stabilized f_0 when compared to the reference synthesizer signal. The anticipated τ^{-1} slope is well observed. The relative intensity noise (RIN) of the laser has been also measured (Figure 4). For a free-running laser, at offset frequencies above the laser pump modulation bandwidth, shot-noise limited RIN is achieved with a level of -154 dBc/Hz. The corner frequency around 4 kHz is directly linked to the long upper-state lifetime of the ytterbium ions in the gain medium that acts as a low-pass filter to pump power fluctuations.

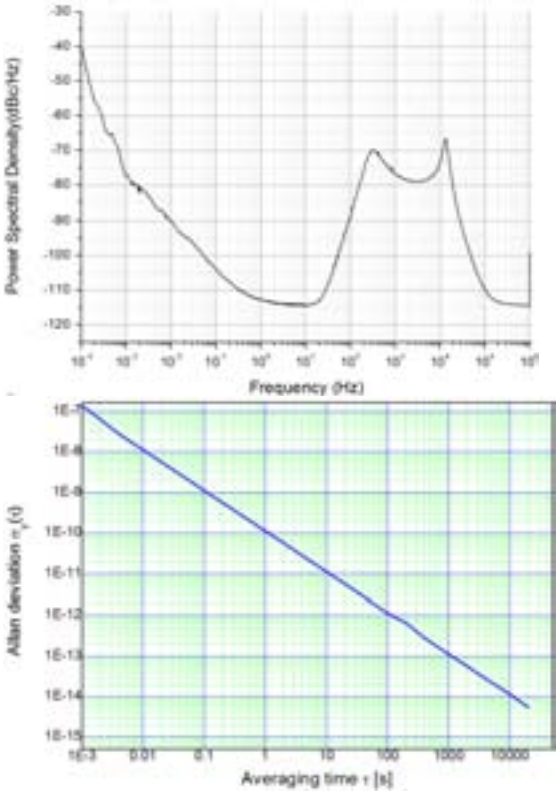

Fig. 3. Top: Phase noise power spectrum density of the divided by 16 274-MHz carrier-envelope offset frequency. The integrated phase noise amounts 736 mrad when integrated from 1 Hz to 1 MHz at a carrier frequency of 274 MHz. Bottom: Allan deviation of the stabilized f_0.

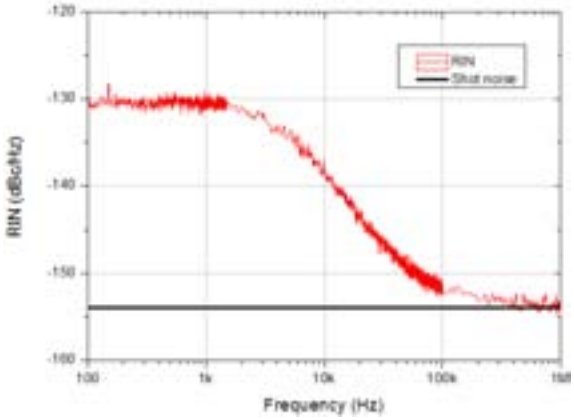

Fig. 4. Relative intensity noise (RIN) of the free running laser.

The repetition rate stabilization on an H-maser referenced synthesizer resulted in a relative frequency instability of $3 \cdot 10^{-12}$ at 1s averaging time. Figure 5 shows the Allan deviation of the free-running and H-maser referenced repetition rate of the mode-locked laser. These measurements were performed with a Symmetricom 5120A instrument based on cross-correlation.

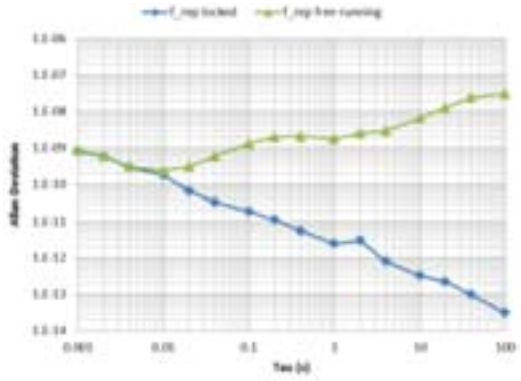

Fig. 5. Allan deviation of the free running and H-maser stabilized repetition rate of the modelocked laser.

IV. CONCLUSIONS

A low-noise 100-MHz diode-pumped Yb:glass solid-state laser has been fully stabilized. An integrated phase noise of 736 mrad has been measured for the carrier envelope offset frequency while the Allan Deviation of the repetition rate amounted to $3 \cdot 10^{-12}$ at 1 s averaging time. The relative intensity noise was limited to the photocurrent shot noise (-154 dBc/Hz) for frequencies above 100 kHz. This system was very reliable with locking periods of several days. Future work will be related to the stabilization on an optical reference and the generation of low-phase noise microwaves.

Abstract— **We present a new method for accurate mid-infrared frequency measurements and stabilization to a near-infrared ultra-stable frequency reference, transmitted with a long-distance fibre link and continuously monitored against state-of-the-art atomic fountain clocks. We demonstrate the frequency stabilization of a mid-infrared laser with fractional stability better than 4×10^{-14} at 1 s averaging. This new stabilization scheme gives us the ability to transfer frequency stability in the range of 10^{-15} or even better, currently accessible in the near-infrared or in the visible, to mid-infrared lasers in a wide frequency range.**

Frequency transfer, high resolution spectroscopy, frequency stabilization.

I. INTRODUCTION

Ultra-high-resolution spectroscopy enables to test fundamental physics with molecules as for instance the non conservation of parity [1] or the stability of the electron-to-proton mass ratio [2]. However many of these tests rely on the availability of ultrastable and accurate laser sources emitting in the mid-infrared (MIR) where molecules exhibit rovibrational transitions. MIR laser frequency stabilization has been performed for a long time using molecular references such as CH_4 or OsO_4 [3]. However the obtained stability is at least one order of magnitude below those of visible or near-infrared (NIR) lasers stabilized to ultra-stable cavity. Moreover only a few molecular lines can be used when ultra-high accuracy is needed. It is thus very challenging to develop a frequency stabilization scheme in the MIR with performances similar to that of the visible and NIR domains.

For that purpose, we have built a frequency chain which enables to coherently transfer the stability and accuracy of an ultrastable laser emitting at 1.54 µm to the MIR spectral region (Fig. 1). This ultrastable signal is generated at LNE-SYRTE where its frequency is measured against a set of primary standards using an optical frequency comb. It is transferred from LNE-SYRTE to LPL through an optical link [4]. A second optical frequency comb is phase-locked to this signal and, using sum-frequency generation in a non-linear crystal [5], the MIR frequency is compared or phase-locked to a high-harmonic of the comb repetition rate.

In this paper, we will describe the principle of coherent frequency stability transfer between near- and mid-infrared frequencies around 10 µm and present the performances obtained with the phase-lock of a CO_2 laser. We will then give the first results of frequency stabilization obtained with a Quantum Cascade Laser (QCL).

II. EXPERIMENTAL SET-UP

The experimental setup is shown in figure 1 (a thorough description can be found in reference [6]). The ultra-stable optical reference located at LNE-SYRTE is a 1.54 µm fiber laser locked to a high finesse cavity. Its fractional frequency instability was measured to be lower than 2×10^{-15} at 1 s and 10^{-14} at 100 s (after a 0.3-Hz/s drift was removed) [7]. Its frequency is measured using a fiber fs laser centered around 1.55 µm. The laser repetition rate is phase-locked to the optical reference frequency after removal of the comb frequency offset f_0. The absolute frequency of the comb repetition rate 36^{th} harmonic (9 GHz) is continuously measured against the primary standards of LNE-SYRTE. It enables real-time correction of the ultra-stable laser frequency drift by acting on the driving frequency of an acousto-optic modulator. This results in an ultra-stable NIR reference, the frequency of which is traceable to primary standards with a 10^{-14} uncertainty after 100 s.

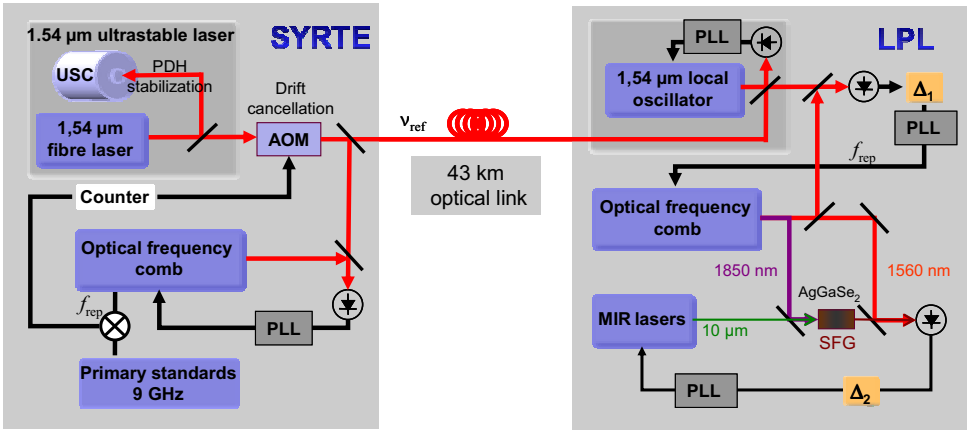

Figure 1. Experimental set-up. The MIR laser frequency can either be controlled with the beat-note Δ_2 or the OsO_4 absorption signal (see text). PLL: phase-lock loop, PDH: Pound-Drever-Hall stabilization, SFG: sum-frequency generation, AOM: acousto-optic modulator, USC: ultra-stable cavity.

This optical reference signal is transmitted to LPL through a 43-km long optical link. The free-running link exhibits a propagation instability of 2×10^{-14} at 1 s and around 10^{-15} between 100 s and 1 day. When compensated, the link instability has been measured to be roughly $10^{-15}\ \tau^{-1}$ and to reach around 10^{-18} after 10^3 s. The frequency stability and accuracy of the reference signal are thus preserved at the LPL optical link end. At LPL, a low-noise laser diode is phase-locked to the incoming signal and constitutes the local optical frequency reference ν_{ref}. The repetition rate f_{rep} of a 1.55 µm fibre fs laser is phase-locked to ν_{ref}. The beat-note Δ_2 (see Fig. 1) then compares the MIR laser frequency ν_{MIR} around 10 µm and the n^{th} harmonic of the repetition rate. This signal is generated using sum-frequency generation (SFG) of the MIR light and an additional comb output centred on 1.85 µm, generated in a non-linear fiber [5]. This comb output and the MIR laser beam are focused in a 10-mm long crystal of AgGaSe2 for type I SFG. The resulting shifted comb, centred on 1.55 µm, is combined with the 1.55 µm fs-laser output. An adjustable delay line enables to control the overlap of the pulses in the time domain. The resulting beat-note Δ_2 shows a signal-to-noise ratio of about 25-30 dB in a 100 kHz bandwidth. This beat-note is then mixed with an RF oscillator to generate the error signal to lock the MIR laser to the optical frequency comb (OFC). Resulting from the frequency difference between two modes of the same comb, Δ_2 is independent of the comb offset f_0. The MIR frequency is thus directly linked to the near-infrared frequency reference.

III. MIR FREQUENCY NOISE AND STABILITY

To characterize the phase-coherent link between the near-infrared frequency reference and the MIR frequency, we

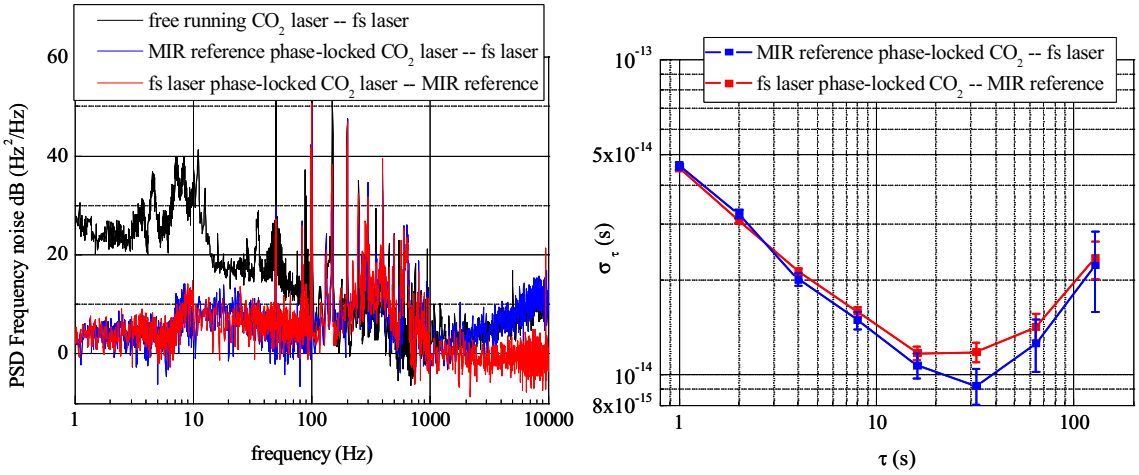

Figure 2. CO_2 laser results. *(Left)* PSD of frequency noise of the free-running CO_2 laser (black), the CO_2 laser phase-locked onto the MIR reference (blue) and onto the fs laser (red). *(Right)* Fractional frequency stability (Allan deviation) with ± 1σ error bars, same colors as the left figure.

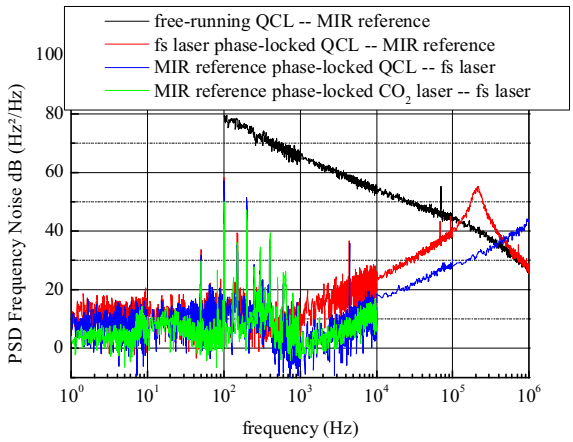

Figure 3. QCL preliminary results in terms of frequency noise. Free running QCL (black), QCL phase-locked onto MIR reference (blue) and onto fs laser (red). CO_2 laser phase-locked onto MIR reference from fig. 2 is added for comparison (green).

used a CO_2 laser stabilized onto an OsO_4 saturated absorption line as a MIR reference. Such a OsO_4-stabilized CO_2 laser constitutes the current state-of-the-art MIR secondary reference standard [3]. Corrections are applied to a PZT controlling the laser cavity length with a stabilization bandwidth of about 400 Hz limited by the PZT actuator. We first phase-lock the MIR laser onto the MIR reference and use the Δ_2 beat-note to evaluate the frequency noise and stability. Then, the MIR laser is phase-locked onto the OFC using Δ_2 and frequency stability is measured by beating with the MIR reference. Two MIR lasers have been successively phase-locked to the optical reference signal. We will first present the performances obtained with a CO_2 laser and then give the preliminary results of the QCL phase-lock.

A. CO_2 laser

Fig. 2 shows the frequency noise and stability of the CO_2 laser either locked onto the MIR reference or onto the OFC. In both cases, the results are very similar. The CO_2 laser frequency noise reaches about 3 Hz²/Hz at 1 Hz and is pretty flat (white frequency noise) until a few hundred hertz. The f slope after 1 kHz observed on the blue data is attributed to the NIR phase-locked loop. It is not observed when the CO_2 laser is locked to the OFC due to its small stabilization bandwidth of ~ 400 Hz. The right figure shows a 1s-stability lower than 5×10^{-14} with a decrease in $\tau^{-1/2}$ until a few tens of seconds. The small difference between the stabilities is due to non-stationary effects.

B. Quantum Cascade Laser (QCL)

Fig. 3 presents preliminary frequency noise results obtained with a QCL. The free-running QCL is much noisier than the CO_2 laser (about 70 dB at 100 Hz). However, the set-up allows a frequency noise reduction of about 60-70 dB at 100 Hz with a lock bandwidth of about 200 kHz when the QCL is phase-locked onto the OFC (bandwidth > 1 MHz when locked onto the MIR reference [8]). There is still some residual noise in the low frequency domain that is not suppressed. The frequency noise is indeed a little higher (less than 10 dB Hz²/Hz) than the one of the stabilized CO_2 laser. We attribute this excess noise to optical feedback in the laser and are now progressing towards its reduction. Nevertheless, these results represent to our knowledge the best ones ever obtained with a QCL.

IV. Conclusion

We have presented a coherent frequency chain able to transfer the frequency stability and accuracy from a remote ultra-stable 1.54 µm frequency reference to a MIR source. State-of-the-art results have been obtained with a CO_2 laser and we are now progressing toward the extension of this experiment to QCLs. Preliminary results give a frequency noise lower than 100 Hz²/Hz from 1 Hz to a few kHz. Moreover, this technique can be easily implemented in any laboratory receiving an ultra-stable signal and adapted to laser sources in a wide wavelength range, from 3 to 20µm.

***Abstract*—In this paper, we demonstrated improvement of frequency uniformity and stability for Temperature Compensated Surface Acoustic Wave (SAW) devices. SiO_2 has been used to obtain low Temperature Coefficient (TempCo) in SAW devices for more than three decades [1]. One of the big issues is that SAW devices have to be processed at temperatures below 300C. When low temperature SiO_2 is exposed to the ambient environment, it interacts with ambient humidity [2], [3], [5], [6]. Such interactions can change frequency of the SAW devices and can make frequency trimming with a focused Ion Beam [7], [8] extremely challenging. UV and steam treatment of SiO_2 improved trimming rate stability on the first trimming [4] and [9], but was not sufficient to provide tight frequency control required for SAW devices after the second trimming. Using silicon nitride (Si_3N_4) capping layer on top of SiO_2 showed some improvement in frequency control after trimming process. Most improvement was obtained using aluminum nitride (AlN) capping layer on top of SiO_2 followed by two trimming steps.**

Keywords-SAW, Temperature, coefficient, trimming. frequency

I. INTRODUCTION

Controlling frequency of temperature compensated devices is critical in obtaining high yielding production process. The use of SiO2 films has been recently used to improve behavior of SAW filters over the required temperature range. Unfortunately, the diffusion of the moisture into SiO2 film during exposure of the wafers to the ambient environment causes the reaction of H20 with strained Si-O bonds and formation of silanol (Si-OH). This has a great effect on the local intrinsic SiO2 film stress and leads to the reduction of compressive residual stress and progressive increase of the tensile residual film stress.

With above mentioned effect, it is impossible to obtain yield above 90% without use of frequency trimming. In this paper we address the issues with obtaining best results through a judicious use of both deposition and trimming techniques.

II. EQUIPMENT

In this research, we used Advanced Modular Systems' (AMSystems) three chamber cluster tool pictured in Figure 1 for deposition of all layers as well as frequency trimming.

SiO2 was deposited using RF diode mode from SiO2 target. We used 12" target at 1kW of RF power and frequency 13.56 MHz. Only Ar process gas had been added during SiO2 deposition.

Si3N4 film was deposited by dual AC magnetron from highly doped - highly conductive Si target. 40kHz AC power at 1kW had been applied between two Si targets. Ar and N2 were added as process gases during deposition. Deposition was done in poisoned nitride mode to get a stable and stoichiometric Si3N4 film.

Standard process for AlN deposition was used with dual AC magnetron. AC power applied between targets in a reactive deposition mode.

Standard Trimming process was performed on the deposited films. Process is established by removing film thickness of the top layer, based on frequency maps using an adjustable focused DC ion source and scanning wafer mechanism. Trimming process was used to get high yield of devices from wafer.

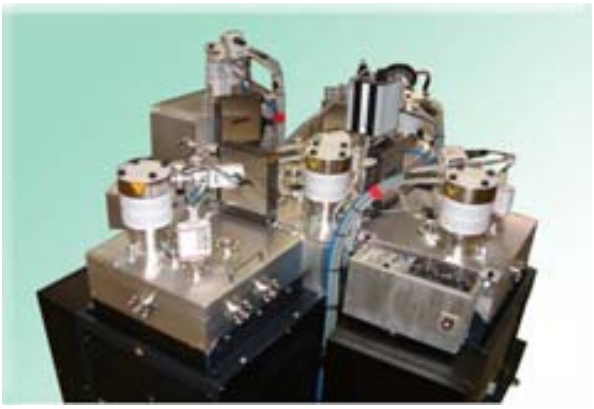

Figure 1: AMSystems Cluster Tool

III. METHODS FOR IMPROVING TEMPCO CONTROL

For several decades SAW device manufacturers attempted to utilize SiO2. Unfortunately, low temperature oxide depositions necessary for the SAW applications, combined with a need for low cost equipment, limited options available to the SAW manufacturers. Over decades many methods have been tried in order to reduce variation of frequency due to the inherent oxide interactions with ambient moisture. In this

paper we have compared few methods of protection and surface modification of the silicon dioxide films in order to prevent the physical adsorption of water vapor molecules on the surface of silicon dioxide film and reaction between Si-O bonds with H2O molecules with Si-OH formation.

To prevent physical adsorption of water vapor on Silicon dioxide film we used two different cap layers: AlN and Si3N4 films. Both films have good passivation properties, stable and have high grain density. 500A of Si3N4 or AlN films were deposited on top of SiO2 films without vacuum break. 500A was chosen to make sure that after trimming process at least 200A of the film is still remaining.

For SiO2 surface modification we used two methods:

1. High power density UV radiation
2. Annealing of SiO2 film in high humidity environment

High power density UV radiation was done by scanning wafer under excimer laser radiation. XeCl excimer laser with wavelength 308nm and power density greater than 10MW/cm2 per pulse was used for SiO2 surface modification. Surface densification under this process conditions prevented diffusion of moisture into SiO2 grain bonds.

Annealing of SiO2 film in high humidity was done at the temperatures between 250…300C in water stem with post annealing and then, drying. This process allows saturating all available Si-O bonds and eliminating further changes under exposure to the ambient.

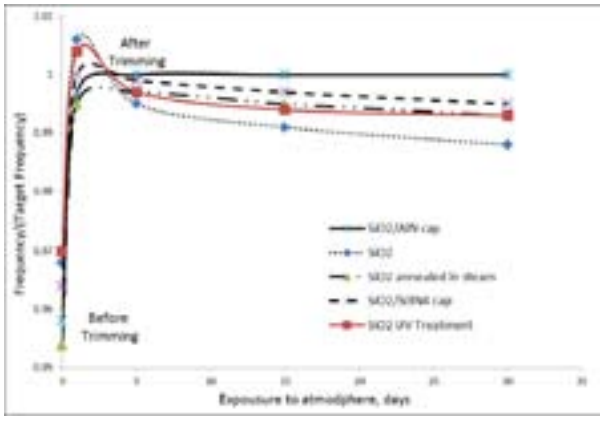

Figure 2: Average Frequency as a function of time exposure to atmosphere for different methods of SiO2 treatments and capping processes

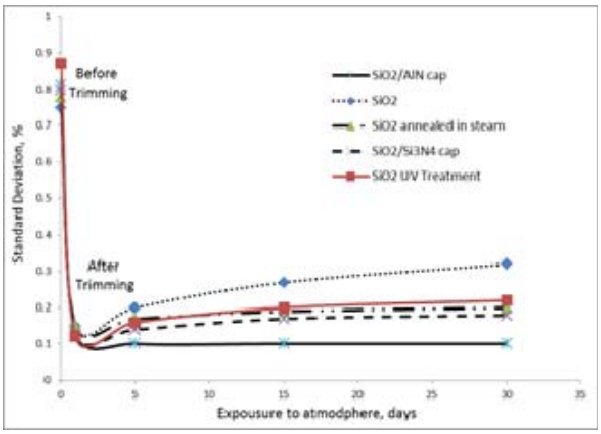

Figure 3: Cross wafer Frequency variation as a function of time exposure to atmosphere for different methods of SiO2 treatments and capping processes

Figures 2 and 3 show improvements obtained using different methods commonly used to improve frequency control in temperature compensated SAW devices.

The most successful method as we observed is to cap SiO2 with AlN without air exposure and trim it with focused ion beam. Even though this technique is adequate for a lot of devices, there is a further benefit in performing a second trim. Figure 4 shows the benefits of the two steps trimming vs. one step trimming.

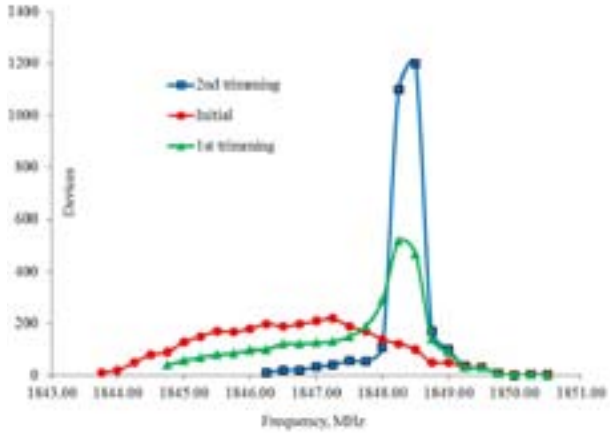

Figure 4: Two step trimming on an AlN capped temperature compensated SAW device

Depending on the initial frequency distribution, the first trim can have 5X improvement. Second trim provides another 4X improvement over the first trim. As the result the total frequency improvement can be as big as 20 times.

IV. SUMMARY

Capping SiO2 temperature compensated layer with AlN film and using two steps trimming can provide high yielding SAW devices for the tough requirements for today's RF filter needs.

***Abstract*—Resonators manufactured on $Ca_3TaGa_3Si_2O_{14}$ single crystals (CTGS) operating in a thickness shear mode were investigated. The frequency temperature characteristics of the rotated Y-cut based resonators were measured. The resonators operated at the crystal elements with angle cut −21°20' have frequency deviation less than 120 ppm in the operating temperature range from −60 up to 85°C. The temperature coefficient of frequency of the second order is close to −0.022 ppm/°C^2. It is shown that maintaining turnover point of the frequency temperature characteristic within the range of ±1 °C requires accuracy of the crystal element manufacturing not worse than ±1.5 angular minutes for resonators with Ag electrodes. The dependence of the Bechmann's number on electrode thickness was calculated. It was discovered that for Ag electrode coating with electrode thickness of 200 nm, the single-response characteristic of the resonator can be obtained if the electrode size (l_x) does not exceed 12 thicknesses of the crystal element. With the limiting value of the relative electrode size equaling l_x/t =12.3, the relative resonance interval is 1%, while the capacitance ratio is 47 units.**

Keywords-$Ca_3TaGa_3Si_2O_{14}$, resonator; single crystal; bulk acoustic waves; temperature coefficient of frequency (TCF)

I. INTRODUCTION

More recently, new piezoelectric crystals that also operate at high temperatures have been introduced for wide bandwidth acoustic wave filters, frequency control, and high-temperature sensor applications. The study, production, and application of the langasite family crystals have been rapidly developing in recent years. Langasite family crystals are promising piezoelectric materials for the new generation of acoustoelectronic devices, as they can successfully replace the traditionally used ceramics and quartz. The crystals have high acoustic Q-factors, zero temperature coefficients of frequency of the first-order (TCF(1)), high coupling coefficients. Moreover, they lack phase transition up to pre-melting temperatures (Tmelt = 1470°C).

The langasite family is a group of crystals isostructural to $Ca_3Ga_2GeO_{14}$ and recently it includes around 100 compounds. The best known crystals with zero TCF(1) of the group are langasite, lanthanum gallium silicate (LGS, $La_3Ga_5SiO_{14}$), langatate, lanthanum gallium tantalate (LGT, $La_3Ta_{0.5}Ga_{5.5}O_{14}$), langanite, lanthanum gallium niobate (LGN, $La_3Nb_5Ga_{5.5}O_{14}$), calcium niobium gallium silicate (CNGS, $Ca_3NbGa_3Si_2O_{14}$), and catangasite, calcium tantalum gallium silicate (CTGS, $Ca_3TaGa_3Si_2O_{14}$). Langasite family crystals belong to the structure type of the trigonal system (space group P321, point group 32).

Temperature frequency characteristic of the temperature compensated langasite cut is a parabola. The value of temperature coefficient of frequency of the second order TCF(2) is equal to −0.058 ppm/°C^2. Frequency deviation in the operating temperature range from −60 to 85 °C is about 300 ppm. For some applications of piezoelectric devices, such frequency deviation value is not satisfactory. As a result of search for a more temperature stable material, the $Ca_3TaGa_3Si_2O_{14}$ (CTGS) single crystal was synthesized.

CTGS possesses a number of unique piezoelectric characteristics that enable its application for the development and manufacture of acoustoelectronic devices. CTGS has a small frequency deviation in the temperature range (temperature frequency coefficient of the second order is about −0.026 ppm/°C^2 [1] and −0.039 ppm/°C^2 [2]).

In this work, the influence of electrode materials and sizes on the frequency temperature characteristics of CTGS resonators operating in a thickness shear mode (TS-mode) was investigated. The Bechmann's number for CTGS resonators was also calculated.

II. EXPERIMENTAL

CTGS single crystals were grown by Czochralski method using an Ir crucible. The growth process was carried out in Ar atmosphere. The crystals were grown along the crystallographic <100> direction. The pulling rate was 0.5 − 1 mm/h and the rotation speed was 11 rpm.

Figure 1. CTGS single crystal

The orientation of CTGS single crystals and the notation system for designation crystalline plates were made according to the IEEE Standard on Piezoelectricity [3]. The plate's cuts are denoted by (YZw) Φ. In this work, we used the plates of six cuts (YZw) –25°, (YZw) –22°20', (YZw) –21°20', (YZw) –21°, (YZw) –20°30', and (YZw) –20°. The obtained crystals and plates were oriented using an X-ray diffraction. The plates were lapped with 10μm Al_2O_3. The roughness of plates was Ra<0.24 μm. We produced the round shape blanks 4.5 mm in diameter and with primary flat oriented parallel to Z′-axes. The plates' thickness was about 120 um. Electrodes of different sizes and from diverse metals (Ag and Au) were deposited. The fundamental frequency of TS-mode was about 10.7 MHz. The measurements of the temperature frequency characteristics were performed by the S&A W2200B Temperature Test System. The attenuation characteristics of the CTGS resonators were measured using Agilent E5061A specter analyzer. For the approximation of the frequency temperature characteristics, a polynomial function was used,

$$(f_r - f_0)/f_o = a + b\cdot(T - T_0) + c\cdot(T - T_0)^2 \qquad (1)$$

where b and c are the temperature coefficients of frequency of the first and second order, respectively. f_0 is resonance frequency at the reference temperature T_0, f_r is resonance frequency at temperature T.

A turnover temperature was obtained by formula,

$$T_e = -b/2c \qquad (2)$$

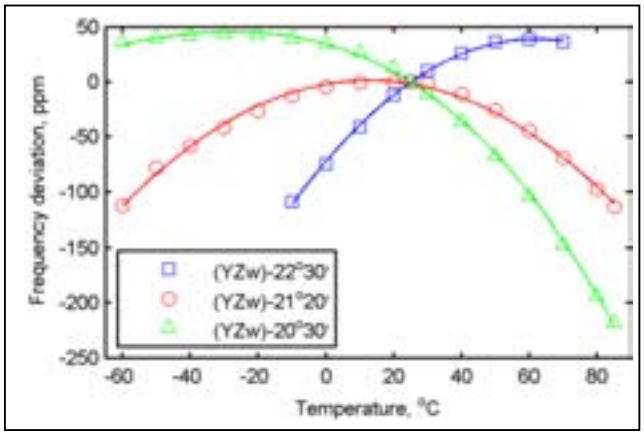

Figure 2. Frequency temperature characteristics of CTGS resonators. Electrode film is Ag, the electrode diameter is 1.75 mm.

III. RESULTS AND DISCUSSION

A. *Study of frequency temperature characteristics of CTGS resonators*

Figure 2 shows a typical frequency deviation as a function of temperature for CTGS resonators. As observed in Fig.2, resonators with Ag electrodes operating at (YZw) –21°20' cut have a frequency deviation less than 120 ppm in the temperature range from –60 up to 85°C. The value of TCF(2) is about −0.022 ppm/°C^2 which is in a good agreement with [1] and [2].

The turnover temperatures for different sizes and electrode materials were calculated by formula (2). As observed in Fig.3, for the electrode of the same size and material with angle cut varying from –25° to –20°, the dependance of frequency temperature characteristic extremum point is represented by a straight line. Inclination of lines for Au electrodes is half times bigger than that of Ag electrodes. It means that for resonators with Ag electrodes, maintaining turnover point of the frequency temperature characteristic within the range of ±1 °C requires crystal element manufacturing accuracy not worse than ±1.5 angular minutes. For resonators with Au electrodes, the accuracy should be ±1.0 angular minutes.

B. *Bechmann's number for CTGS resonators*

In [4], Tiersten applied the equations of three-dimensional linear piezoelectricity in the analysis of trapped energy resonators vibrating in coupled thickness-shear and thickness-twist modes in the vicinity of the fundamental and odd overtone thickness-shear frequencies. Based on his analysis, Tirsten derived the two-dimensional condition that generalizes the Bechmann's number $\lceil l_x/t \rceil$ for one dimension and provides the condition for the existence of only one trapped mode.

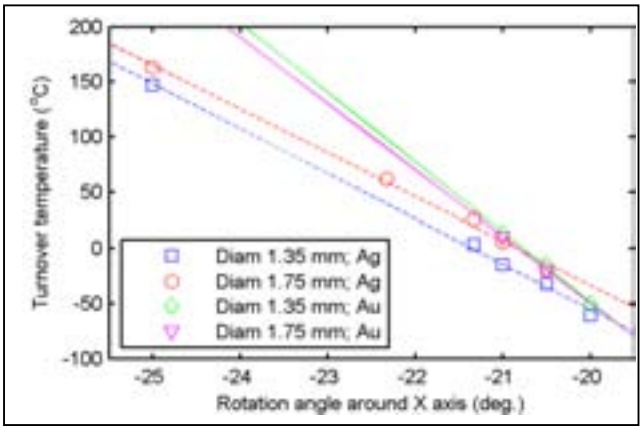

Figure 3. Turneover temperature as a function of rotation angle for resonators with different electrodes

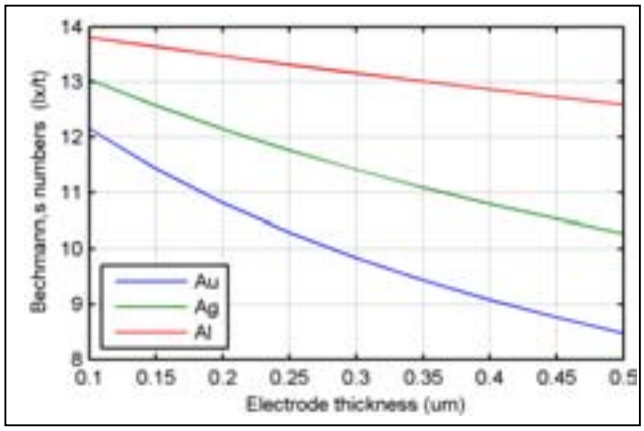

Figure 4. Bechmann's number as a function of the electrode thickness

The latter condition can be written as:

$$\left[\frac{l_x}{t}\right] \le \frac{d_B}{n\sqrt{4k_{26}^2/n^2\pi^2 + R}} \qquad (3)$$

where k_{26}^2 is coupling coefficient for this cut, n – overtone number. In this paper, we considered only the fundamental mode of the thickness shear mode ($n=1$). The dimensionless trapping parameter d_B depends on the material constants of the crystal and the electrode shape.

Loading mass R determines the frequency change after electrode deposition.

$$R = 2\rho' t'/\rho t \,. \qquad (4)$$

where - ρ , ρ' - density of the plate and electrode's material, respectevely.

Using the formulas of paper [4], values of parameters d_B were calculated. The optimum shape of electrode for (YZw) – 21°20' cut is an ellipse elongated along the X-axis. The ratio γ of the electrode size along the X axis to the electrode size along the Z′ axis is equal to 1.84. The parameter d_B value equals to 2.92. For the case $\gamma = 1$, the value of dimensionless parameter d_B is equal to 1.78.

Based on (3) and (4), the values of Bechmann's number as a function of a thickness of Al, Ag end Au electrodes were calculated. As observed in Fig.4 for the Ag electrode with thicknesses of 200 um, the relative electrode size should be less than 12 units. To specify our estimates, CTGS resonators with different electrode sizes were produced. Fig.5 shows amplitude frequency characteristic of CTGS resonators.

As observed from Fig.5, there is not any spurious resonance in the case of relative electrode sizes being less than 12.3 units. On the other hand, there is unwanted response with relative electrode size equalling 15.7 units.

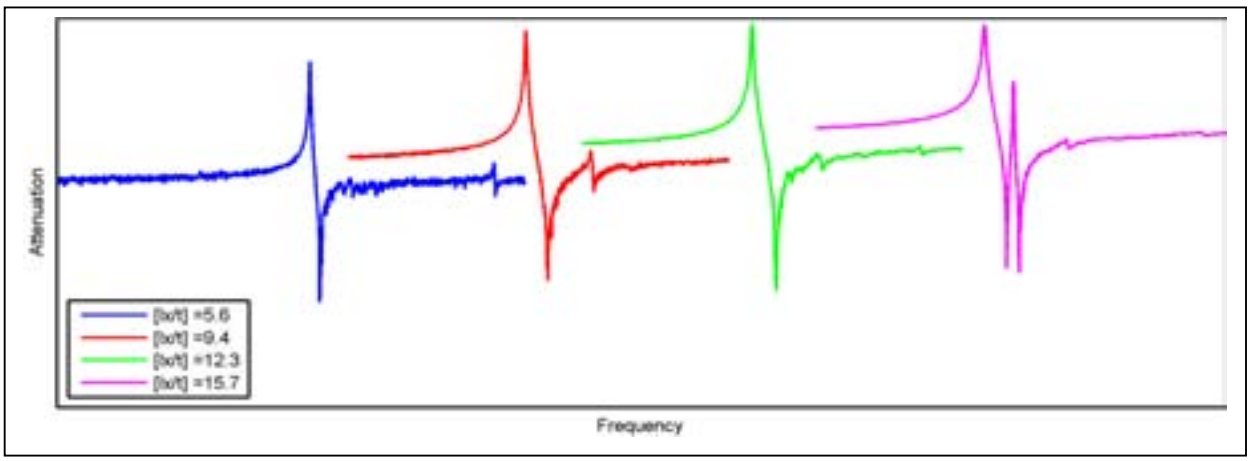

Figure 5. Amplitude frequency characteristic of CTGS resonators with different electrode sizes

TABLE I. PROPERTIES OF CTGS RESONATORS

Ratio of the electrode diameter to the plate thickness	Resonance resistance, R, Ом	Static capacitance, C_0, pF	Resonance spacing, %	Capacitance ratio, r
5.6	252	0.52	0.41	123
9.4	19	1.54	0.91	54
12.3	11	2.5	1.05	47
15.7	14	4.3	1.43	34

The measurement results for CTGS resonators are shown in the Table. The resonance spacing increases from 0.41% to 1.43% with the relative electrode size growing from 5.6 to 15.7 units.

IV. CONCLUSION

Resonators on CTGS single crystals operating in the fundamental mode of thickness shear vibration were investigated. On (YZw) –21°20' cut in operating temperature range from –60 up to 85°C, the resonance frequency deviation of less than 120 ppm was obtained. The TCF(2) is close to –0.022 ppm/°C^2.

It was shown that for resonators with Ag electrodes, maintaining extremum point temperature of the temperature-frequency characteristic within the range of ±1 °C requires crystal element manufacturing accuracy not worse than ±1.5 angular minutes.

The dependence of the Bechmann's number on electrode thickness was calculated. It was discovered that for Ag electrode coating with the thickness of 200 nm, the single response resonator can be obtained if the electrode size (l_x) does not exceed twelve thicknesses (t) of the crystal element. With the limiting value of the relative electrode size equaling l_x/t =12.3, the relative resonance interval is 1%, while the capacitance ratio is 47 units.

***Abstract*— In this paper we propose the use of infrared spectroscopy as an alternative technique to X-ray diffraction for the assessment of the crystal orientation of aluminum nitride thin films. Infrared scans of samples with different tilt angles of the c-axis are measured to accurately determine the structure of the longitudinal optical absorption band, which is found to be the composition of the contributions of three different populations of grains with different angles of tilt of the c-axis. A direct relationship is established between the wavenumber of these contributions and the actual angle of tilt measured through a XRD ψ-scan.**

I. INTRODUCTION

Quartz crystal microbalances (QCM) operating in liquid media have demonstrated the potential of shear acoustic wave resonators for bio-medical applications. Since their relative sensitivity increases with frequency, resonators operating at GHz frequencies are expected to push down detection limits, as already stated in the late fifties [1]. High frequency resonators make use of piezoelectric thin films, which also offers the possibility of integrating them in a multisensory chip. For these reasons, bulk acoustic wave (BAW) resonators based on AlN or ZnO films are being developed as an alternative to QCMs for bio-chemical applications [2].

BAW resonators operating in the shear modes are preferred for sensing applications in liquid environments, because the movement of the material parallel to the surface is not hampered by the surrounding liquid, which overcomes the attenuation suffered by longitudinal modes obliged to displace the adjacent fluid in their movement normal to the surface. AlN and ZnO films deposited by sputtering crystallize in the wurtzite structure and tend to grow with the c-axis normal to the substrate. Shear modes can be excited in several ways. The most straightforward, known as lateral excitation, would be by applying an electric field parallel to the surface to excite the shear wave by virtue of the d_{15} piezoelectric coefficient. In practice, lateral excitation is achieved using coplanar electrodes on top of the c-axis oriented films, which provides an extremely weak electric field between the electrodes and, hence, a hardly noticeable shear excitation [3]. An alternative way to effectively excite shear modes is by normal excitation of films exhibiting the c-axis tilted respect to the surface normal, through the component of the electric field perpendicular to the c-axis and the d_{15} coefficient. According to theoretical studies [4], the largest electromechanical coupling factor (k_S^2) for the shear modes in AlN is achieved for a tilt angle of around 47°. Films with tilted grains are achieved by sputtering on rough substrates displaced from the center of the target so that the growth of the microcrystal along a given direction is encouraged [5]. An effective method to assess the angle of tilt of the c-axis is the XRD polar figure of the (00·2) planes, although this measurement is complex and time-consuming. A more convenient solution is the ψ-scan in a conventional Bragg-Brentano XRD configuration (see figure 1) along the Bragg angle corresponding to <00·2> direction (θ=18°); in this case, an accurate alignment of the sample in the φ orientation is required to guarantee the detection of the x-ray reflected in the tilted grains.

In this communication we propose an alternative method to detect and quantify the angle of tilt of wurtzite AlN films independently of the φ orientation through infrared (IR) measurements in the reflectance mode. The method is based on the analysis of the longitudinal optical (LO) absorption mode, which is sensitive to the angle between the c-axis and the surface of the film.

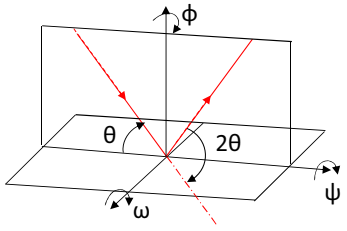

Figure 1. Geometry and nomenclature for the XRD measurements

II. THEORY

The absorption of infrared incident radiation by a polycrystalline thin film depends significantly on the geometry (angle between the incident radiation and the polarization state

and angles between the bonds and the surface) and on the nature of the phonons associated with each vibrational mode. The vibrational modes in a given material can be IR active or not, depending on its ability to absorb IR radiation. Materials with wurtzite structure, like AlN, have two types of bonds: **A1,** parallel to the c-axis, and, **E1,** nearly perpendicular to it. The phonons associated with these two bonds (or branches) split into two IR active vibrational modes: longitudinal optical (LO) and transverse optical (TO), which propagates perpendicular and parallel to the c-axis, respectively. Therefore, there are four characteristic IR active modes: **A1**(LO), **E1**(LO), **A1**(TO), and **E1**(TO), which are sketched in figure 2 together with the direction of the associated electric field (***E***) and the propagating vector (***q***). Figure 2 also shows (third row) the wave vector ***k*** and the electric field $\boldsymbol{E}_v$ of the photons in the AlN for both TO LO energy regions, assuming a horizontal AlN surface. The directions of $\boldsymbol{E}_v$ and ***k*** results from the application of Snell's laws and the actual dispersion of the refractive index in materials exhibiting a wurtzite structure shown in figure 3. The behavior of the refractive index is due to the anisotropy in the macroscopic electric field induced by polar phonons.

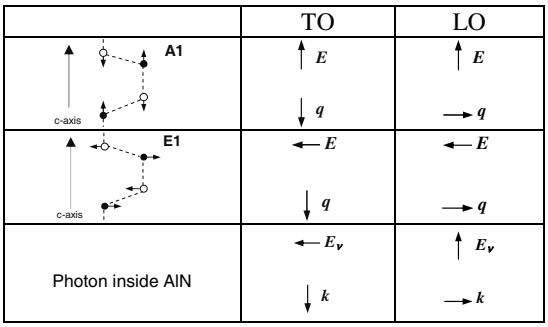

Figure 2. Schematic representation of the magnitudes involved in the absorption for the IR modes TO and LO of the branches A1 and E1. ***E*** is the direction of the electric field induced by the vibration of the polar bonds, ***q*** is the propagation vector of the phonons, $\boldsymbol{E}_v$ is the electric field of the photons and ***k*** is the wave vector of the transmitted light. It is assumed that the AlN surface is horizontal with respect to the figure.

A phonon can absorb a photon with an associated electric field ($\boldsymbol{E}_v$) and a wave vector (***k***) only if the scalar products $\boldsymbol{E}\cdot\boldsymbol{E}_v$ and $\boldsymbol{q}\cdot\boldsymbol{k}$ are different from zero. The resulting absorption bands in the IR transmittance or reflectance spectra of an AlN thin depend on these selection rules. The phonon frequencies corresponding to the LO and TO regions, $\boldsymbol{\Omega}_{LO}$ and $\boldsymbol{\Omega}_{TO}$, and the loss factor $\boldsymbol{\gamma}$ are slightly dependent on the crystal quality of the polycrystalline film and some other material parameters, such as the internal stress or the presence of impurities. The measured IR spectrum of AlN films shows a band of total reflection (*reststrahlen* band) between the TO and LO modes, in which the real part of the refractive index is null (neglecting optical losses). For AlN the wavenumbers associated to these frequencies used in this work are $k_{A1(LO)}$ = 890 cm^{-1}, $k_{EI(LO)}$=916 cm^{-1}, $k_{A1(TO)}$ = 608 cm^{-1}, and $k_{E1(TO)}$ =669 cm^{-1}.

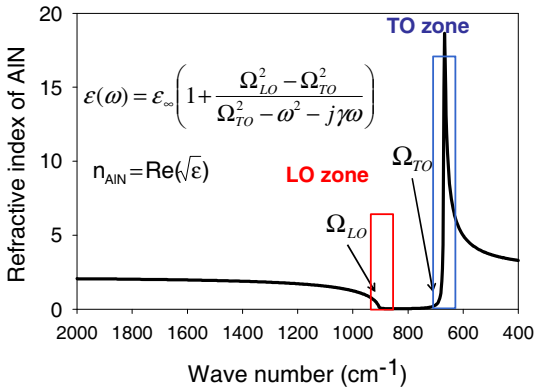

Figure 3. Dispersion of the real part of the refractive index for a wurtzite AlN film.

As shown in figure 3, the refractive index of AlN increases strongly near the TO modes and falls to almost zero around the LO modes. Therefore, according to Snell's laws, for IR light impinging the surface at any angle of incidence (different from normal or grazing), the transmitted light with an energy close to that of the TO modes travels perpendicular to the surface, whereas it moves almost parallel to the surface for energies around the LO modes. Therefore, for a pure c-axis oriented film and under normal incidence, the **A1**(TO) mode cannot absorb a photon, since the associate electric field, $\boldsymbol{E}_{A1TO}$, is perpendicular to $\boldsymbol{E}_v$. In the same way, the **E1**(LO) mode cannot be observed because the associated electric field, $\boldsymbol{E}_{E1LO}$, is perpendicular to $\boldsymbol{E}_v$. Thus, according to the selection rules sketched in figure 2, transmittance spectra can only display the **E1**(TO), whereas reflectance spectra only shows the **A1**(LO) mode; in this last case, although total reflection takes place, the light penetrates into the film to a depth of around a wavelength and can be absorbed by phonons. On the contrary, in the hypothetical scenario of grains lying with the c-axis parallel to the surface, both **A1**(TO) in normal transmittance and **E1**(LO) in normal reflectance would appear in the spectra. Finally, if the c-axis is tilted with respect to the surface normal, a band corresponding to a composition of the two modes in each zone (**A1**(TO) and **E1**(TO) for transmittance and **A1**(LO) and **E1** (LO) for reflectance) with mixed **E1** and **A1** symmetry character will appear. These composed modes, called *quasi-modes*, have vibrational energies that are a composition of those of the pure modes and their direction of propagation forms with the c-axis or the normal to the surface [6-8]. This is described by a relationship between the position of the resulting absorption bands ($\boldsymbol{\Omega}_{Q(LO)}$ and $\boldsymbol{\Omega}_{Q(TO)}$) in the IR spectrum and the angle ψ of the c-axis with respect to the surface normal [6,7]:

$$\Omega_{Q(TO)}^2=\Omega_{E1(TO)}^2\cdot\cos^2(90-\psi)+\Omega_{A1(TO)}^2\cdot\sin^2(90-\psi) \quad (1)$$

$$\Omega_{Q(LO)}^2=\Omega_{A1(LO)}^2\cdot\cos^2(90-\psi)+\Omega_{E1(LO)}^2\cdot\sin^2(90-\psi) \quad (2)$$

According to this model, the tilt angle of the grains associated to each band can be derived by measuring their position in the reflectance spectrum around the LO zone. It is important to highlight that a given tilt angle is associated to a

single absorption band whose energy is a composition of that of A1 and E1 modes in each branch.

III. Experimental

A pure Al target 15-cm in diameter was sputtered in a Von Ardenne-CS 730 pulsed-DC planar magnetron sputtering system. A standard 10-cm diameter (100)-Si substrate covered by a Ni layer was placed on the substrate holder directly under the target. The distance between the substrate and the target was about 5.5 cm. The deposition of the AlN film was carried out in two stages as described in [9]. Initially, during the nucleation stage, the discharge was operated at a pressure of 2.66 Pa for a period of 3 minutes, to grow a 100 nm-thick seed layer. After the first stage the process pressure was decreased to 0.266 Pa, which resulted in an anisotropic deposition flux at the substrate surface (excluding the center area). During this stage, a 2.5 µm-thick layer was grown.

Since the structure contains a metallic underlayer, only reflectance measurements were carried out. Infrared reflection spectra were measured with a Fourier transform infrared (FTIR) Nicolet 5-PC spectrophotometer in the 400 cm^{-1}- 4000 cm^{-1} range with a spectral resolution of 2 cm^{-1}. A spot size of 4 mm in diameter was used to measure each 5 mm along a radius of each wafer.

X ray diffraction (XRD) measurements were performed with a Supratech XPERT-PRO diffractometer using the Kα1,2 doublet of a β-filtered Cu anode. θ/2θ patterns from 10° to 40° and ψ scans from -80° to 80° around the (00·2) reflection at 2θ=36.02º. These measurements were performed along the radius of each wafer in steps of 5 mm.

IV. Results and Discussion

To extract the tilt angle of the c-axis with respect to the normal to the surface (ψ), the IR specular reflection spectra of AlN thin films were measured. Figure 4 shows the reflectance spectra of a representative 2100 nm-thick AlN film deposited on a 10 nm-thick Mo layer, both in the reflectance mode and in absorbance units. Reflectance coefficient (*R*) is related with absorbance (*A*) through: $A=Ln(-R/100)$.

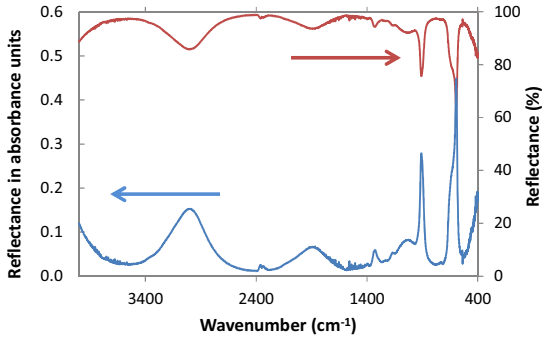

Figure 4. Reflection spectra of AlN films deposited on a Mo metallic layer in % of reflectance and in absorbance units

Interference fringes in the AlN film are clearly visible. The reststrahlen band can also be observed. At the edges of this band, the absorption modes are present as valleys in the reflectance spectrum and as peaks in the absorbance one. For the analysis, we have chosen the reflection spectrum in absorbance units and fitted the bands with Lorentzian curves. Figure 5 shows the reflectance spectra of the film of figure 4 around the reststrahlen band in absorbance units. Absorption bands in both LO and TO zones can be seen. In the TO zone the refractive index is very high and suffers a significant variation with the wavenumber (see figure 3). For this reason the interference fringes are very sharp and close to each other. In the film of the figure, the sharpest peak at 600 cm^{-1} is actually an interference fringe and not an absorption band. For thinner or thicker films, these interference fringes in the TO zone may overlap the TO modes making it difficult to extract accurate information from them. Since the sought information can be found in both TO and LO zones, the LO absorption band is a more convenient choice for a detailed analysis.

The existence of composed peaks in the LO zone suggests the existence of different populations of grains with different orientations, that is, different angles of tilt of the c-axis. It is worth noting that a single grain with a fixed tilt angle ψ yields only one quasi-LO mode at a wavenumber given by equation (2).

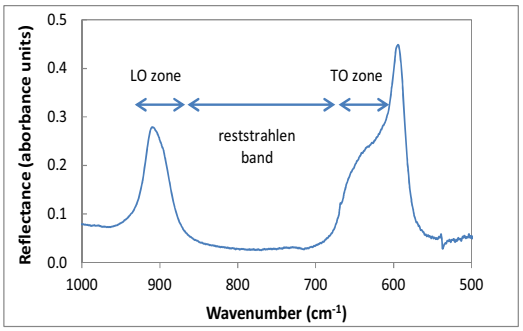

Figure 5. Detail of the reststrahlen band zone of the Ir absorbance spectra for AlN film deposited on a Mo layer.

To analyze the spectral terms of the absorption band, these were fitted using lorentzian functions together with the baseline to account for the background arising from the optical interference fringes and the reststrahlen band edge. The accuracy of the fit is increased by simultaneously fitting the composed absorption band and its second derivative, since this latter is very sensitive to the number and the position of the lorentzian terms. First, we have fitted the spectrum using two lorentzian contributions, which account for two populations of grains having two different c-axis orientations. The fitting is shown in figure 6.

Although Fig. 6(top) suggests that both position and amplitude of the band are accurately fitted, the analysis of the second derivative reveals that the fit is not correct. Fig. 6(bottom) shows the new fit achieved by adding a third lorentzian contribution revealing that, although the accuracy in the fit of the spectrum does not improve, the fit of the second derivative is more precise, which suggests that the sample contains actually three populations of differently tilted grains.

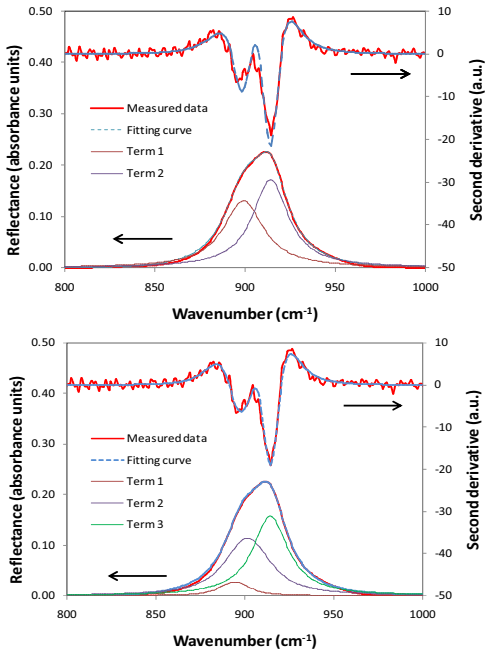

Figure 6. Comparison of the fitting of experimental data with (top) two, and (bottom) three lorentzian terms. The second derivative of the experimental data and fittings are also shown.

The values of the tilt angle for each population are 35º, 0º and 66º, as derived from wavenumbers extracted from the fitting of the spectra using equation (2). To validate these values we have analyzed the XRD-ψ scan of the samples. A typical pattern is shown in figure 7. Three angles of tilt can be observed at ψ=-34°, 0° and 65°, which are in good agreement with the abovementioned IR results.

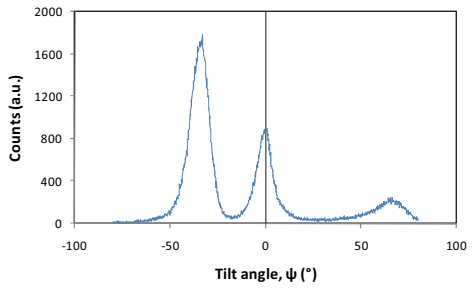

Figure 7. XRD ψ scan of the 00·2 peak of the same sample of figure 6.

To confirm the accuracy of the angle of tilt achieved through the analysis of the IR spectra we have analyzed the XRD-ψ scans of several samples containing differently tilted grains and compared the information with that obtained from the IR absorption analysis. Figure 8 shows in the theoretical relationship between angle of tilt and the position of the IR absorption band derived from eq. 2 along with the experimental data achieved using the two techniques. The excellent agreement confirms that IR spectrophotometry is an adequate technique to assess the c-axis tilt.

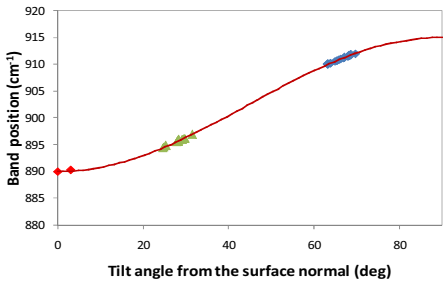

Figure 8. Relationship between the fitted band positions in the LO zone of the reflectance spectra of several AlN films and the tilt angles derived from the XRD measurements. The red line is the relation of equation (2).

V. Conclusions

In this paper we propose an accurate method for determining the structure of AlN films with grains with the c-axis tilted with respect to the normal to the surface. By fitting accurately the position of the IR absorption bands, the fine structure including the different populations of grains with different angles of tilt can be assessed. The method does not require any special experimental arrangement, which makes it a straightforward non-destructive technique to quantify the axis of tilt of non pure c-axis-oriented films.

Abstract— **Independent piezoelectric strain coefficients d_{11} and d_{14} in disordered $La_3Ga_{5.3}Ta_{0.5}Al_{0.2}O_{14}$ (LGTA) and ordered $Ca_3TaGa_3Si_2O_{14}$ (CTGS) crystals of the langasite family were measured by high-resolution X-ray diffraction (HRXRD) under external electric field application which causes changes in the interplanar spacing because of the reverse piezoelectric effect. The experiment showed that the piezoelectric strain coefficients can be precisely determined by measuring changes in the interplanar spacing using the optical scheme of a triple-axis X-ray diffractometer. The measured independent piezoelectric strain coefficients d_{11} and d_{14} for LGTA and CTGS crystals were $d_{11(LGTA)}=6.455\cdot10^{-12}$ C/N, $d_{14(LGTA)}=-5.117\cdot10^{-12}$ C/N; $d_{11(CTGS)}=3.330\cdot10^{-12}$ C/N, $d_{14(CTGS)}=-15.835\cdot10^{-12}$ C/N.**

I. INTRODUCTION

The application of high-resolution X-ray diffraction for measuring piezoelectric strain coefficients is based on that the X-ray radiation is sensitive to changes in the interplanar spacing. The effect of external electric field applied to a crystal on the character of X-ray diffraction was first reported in 1938 [1]. It was shown that the applied electric field causes changes in the shape and angular position of diffraction peaks. The possibility of application of X-ray diffraction to measure piezoelectric constants was theoretically substantiated in 1976 [2]. Some articles present the results of measuring piezoelectric constants of various materials where the values of constants measured by X-ray diffraction differ, as a rule, from those obtained by the conventional method based on measuring the velocity of bulk acoustic waves [3-4].

Piezoelectric strain coefficients measured by HRXRD are characterized by high precision because the constants are calculated on the basis of precisely measured values of a studied crystal thickness and electric voltage applied to it. The present-day experimental facilities permit the determination of X-ray diffraction angle with an accuracy of ~0.0001°. Note, however, that there are some problems which hamper the application of HRXRD. First is the bending of a studied sample under the electric field effect. The bending is caused both by the use of thin single-crystal wafers (<500 mkm) and rigid fastening of these wafers. In double-axis X-ray diffraction this results in the shift of diffraction maxima because of changes in the interplanar spacing and bending deformation of single-crystal wafers. To avoid the bending effect, soft plastic fastening should be used and the optical scheme of a triple-axis X-ray diffractometer should be employed for investigation. When a fixed X-ray wavelength is used, the diffraction angle depends only on the interplanar spacing and can be exactly determined from the angular position of the crystal-analyzer.

The aim of this work is to measure the independent piezoelectric constants in the LGTA and CTGS crystals by high-resolution triple-axis X-ray diffraction.

II. DETERMINATION OF PIEZOELECTRIC COEFFICIENTS BY HRXRD

The equation for the reverse piezoelectric effect describes crystal deformation under external electric field as

$$r_j=d_{ij}\cdot E_i \quad (1)$$

where r_j are the components of the deformation tensor, d_{ij} are the components of the piezoelectric strain coefficients tensor, and E_i are the components of the electric field intensity vector.

According to the definition of the deformation tensor, its diagonal components are quantities which characterize relative changes in the distance between atoms of a unit cell along the three basic directions of the coordinate system [5]. So, the diagonal components of the deformation tensor correspond to a relative change in the interplanar spacing in a crystal along corresponding directions.

The relation between the X-ray diffraction angle and interplanar spacing in a crystal is determined by the Bragg equation [6]

$$2d\cdot\sin(\Theta)=n\cdot\lambda \quad (2)$$

where d is the interplanar spacing, Θ is the diffraction angle, n is the diffraction order and λ is the X-ray wavelength. The

This work was supported by Ministry of education and science of Russian Federation (contract 16.513.12.3027) and Russian Found of Basic Researches (contract 11-02-00659)

relative change in the interplanar spacing $\Delta d/d$ can be described as

$$\Delta d/d = \frac{(d+\Delta d)-(d-\Delta d)}{(d+\Delta d)+(d-\Delta d)}, \quad (3)$$

where Δd is the absolute change in the interplanar spacing d. In the case of increasing of the interplanar spacing ($d + \Delta d$), a decrease in the diffraction angle is observed in accordance with expression (2). Denote this angle as Θ^-. If the interplanar spacing decreases($d - \Delta d$), the diffraction angle would increase. Denote this angle as Θ^+. Express the terms in (3) with the terms from (2) using the designations introduced above, we obtain an expression connecting the relative change in the interplanar spacing with the change in the diffraction angle

$$\Delta d/d = \frac{\sin\Theta^+ - \sin\Theta^-}{\sin\Theta^+ + \sin\Theta^-}. \quad (4)$$

The piezoelectric strain coefficients were measured using thin single-crystal wafers with metallic electrodes formed on their surfaces. The crystallographic orientation of the plates was chosen such that the external voltage applied to the electrodes would cause compressive (tensile) deformation of the wafer in the direction normal to the vector of the electric field intensity. Using the laboratory coordinate system and denoting this direction as the x_1 axis, the electric field intensity would be

$$E_i = E_1 = U/D, \quad (5)$$

where U is the applied electric voltage and D is the single-crystal wafer thickness along x_1. Using expression (1) and taking (4) and (5) into account we obtain an expression for the piezoelectric strain coefficient d_{11}

$$d_{11} = \frac{\sin\Theta^+ - \sin\Theta^-}{\sin\Theta^+ + \sin\Theta^-} \cdot \frac{D}{U}. \quad (6)$$

Note that an applied electric field can also cause shear deformation in the presence of the corresponding components of the piezoelectric strain coefficients, which would also change the position of the Bragg maximum on the rocking curve of the crystal. Therefore, it is necessary to use the optical scheme of a triple-axis X-ray diffractometer and to determine the value of the Bragg angle from the angular position of the crystal-analyzer, which would allow the determination of compressive (tensile) deformation through excluding the effect of shear deformation.

All independent piezoelectric strain coefficients can be determined by using a set of crystal wafers cut in a certain way. However, in some cases only one crystal wafer can be used. This concerns crystals belonging to the space group of symmetry 32. The tensor of the piezoelectric strain coefficients for crystals of this symmetry group is

$$d_{ij} = \begin{pmatrix} d_{11} & -d_{11} & 0 & d_{14} & 0 & 0 \\ 0 & 0 & 0 & 0 & -d_{14} & -2d_{11} \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix},$$

i.e. this tensor has only two independent components d_{11} and d_{14}. If electric field is applied to the plate of the X-cut of a crystal of the symmetry group 32 (planes (110) are parallel to the wafer surface), the crystal wafer would be subject to compressive (tensile) deformation in the x_1 and x_2 directions in accordance with expression (1). The deformation sign would depend on the orientation of the wafer in the laboratory coordinate system and direction of the applied electric field. Therefore, reflection from the planes of (*hh0*) type in the geometry of reflection diffraction and reflection from the (*h00*) planes in the transmission geometry can be used to measure the piezoelectric strain coefficient d_{11}.

To measure the second independent piezoelectric strain coefficient d_{14}, use can be made of the fact that the piezoelectric strain coefficient responsible for the crystal compression along the x_2 direction during rotation of the X-cut wafer of a crystal of symmetry group 32 around the x_1 axis changes as

$$d'_{12} = -\cos^2\alpha \cdot d_{11} + \sin\alpha \cdot \cos\alpha \cdot d_{14}, \quad (7)$$

where d'_{12} is the value of the piezoelectric coefficient in the new coordinate system and α is the angle of the wafer rotation around x_1. If the wafer is rotated at the same angle but in different directions, values of the piezoelectric strain coefficient d'_{12} would be different. This can be explained by the properties of trigonometric functions in expression (7): the **cos** function is even while **sin** is odd. The expression for d_{11} and d_{14} can be obtained from the difference in the values of piezoelectric coefficients in two coordinate systems.

$$d'_{12(+\alpha)} - d'_{12(-\alpha)} = 2\sin\alpha \cdot \cos\alpha \cdot d_{14}, \quad (8a)$$

$$d'_{12(+\alpha)} + d'_{12(-\alpha)} = -2\cos^2\alpha \cdot d_{11}. \quad (8b)$$

Thus, to measure the piezoelectric strain coefficient d_{14} it is appropriate to find the reflections from the planes normal to the (*hh0*) planes and not coinciding with planes of (*h00*) and (*00l*) type.

III. Experimental Set-Up

The independent piezoelectric strain coefficients d_{11} and d_{14} in the LGTA and CTGS crystals were measured on a Bruker D8 DISCOVER X-ray diffractometer in the triple-axis X-ray diffractometer scheme. The experimental scheme is shown in Fig. 1. The X-ray radiation was collimated with a 100 μm entrance slit. The source of radiation was an X-ray tube with a rotating copper anode ($CuK_{\alpha 1}$ radiation, X-ray wavelength $\lambda = 1.54$ Å). Ge(220) crystals with double reflection were used as a crystal-monochromator and a crystal-analyzer.

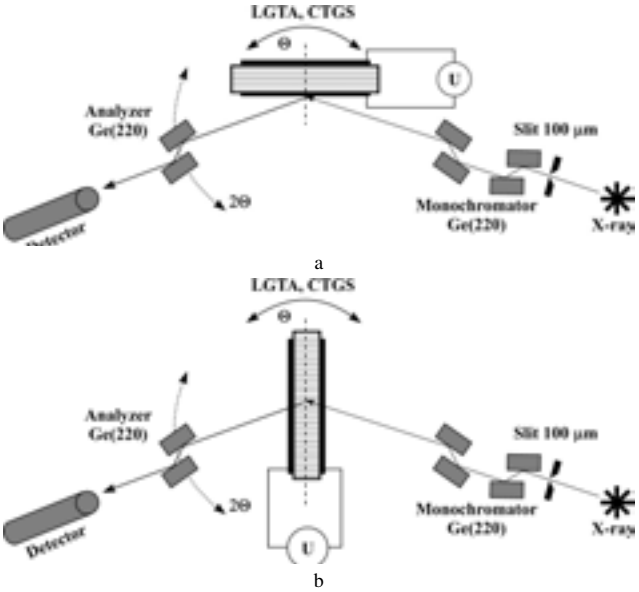

Figure 1. Experimental set-up: (a) bragg diffraction geometry, (b) laue diffraction geometry

Plates of the LGTA and CTGS X-cut (16×8×0.2 mm^3) were used in the measurements. *Al* – electrodes with thickness of 100 nm were deposited on both sides of the single-crystal wafer to apply the external electric field.

The X-ray diffraction angle was determined from the maps of diffracted intensity distribution depending on the rotation of the sample (Θ) and crystal-analyzer (2Θ).

The measurements were performed for different reflections, which radically increased the precision of the measurement results. Table I presents the reflections and corresponding Bragg angles for the studied LGTA and CTGS crystals.

TABLE I. X-RAY BRAGG REFLECTIONS FOR MEASUREMENTS OF PIEZOELECTRIC COEFFICIENTS

Reflection (*hkl*)	**Diffraction geometry**	**2Θ (°)**	
		LGTA	***CTGS***
(110)	Bragg	21.584	21.895
(220)	Bragg	43.974	44.648
(330)	Bragg	68.331	69.464
(440)	Bragg	96.969	98.867
(201)	Laue	30.531	31.119

IV. EXPERIMENTAL RESULTS

In the experiment, maps of the diffracted X-ray intensity in the 2Θ – Θ space coordinates were obtained. Figure 2 displays the maps of the diffracted X-ray intensity distribution for the (400) reflection of LGTA under applying of the external electric voltage of various polarity U= – 1800, 0, +1800 V in the diffraction scheme of Fig. 1(a).

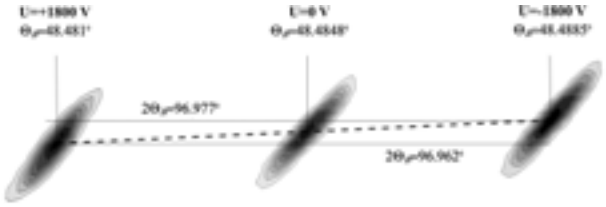

Figure 2. Experimental maps of the diffracted x-ray intensity obtained for reflection (440) and at different values of external electric voltage applied to LGTA wafer in bragg diffraction scheme of Fig. 1(a).

The figure shows that an applied electric field causes changes in the Bragg peak angular position along two coordinate axes (2Θ and Θ). In this case the fastening of the single-crystal wafer maintains its free movement under deformation and the angular movement of the diffracted intensity maximum along the 2Θ axis, corresponding to the scanning by the crystal-analyzer, is equal to the double value of the rotation angle Θ of the studied crystal.

Table II presents the results for the X-ray diffraction angles of various reflections and the values of the piezoelectric strain coefficient d_{11} for the LGTA and CTGS single crystals calculated from expression (6). The average value of the piezoelectric strain coefficient d_{11} from Table II is $d_{11(LGTA)}=6.455\cdot10^{-12}$ C/N for the LGTA crystal and $d_{11(CTGS)}=3.330\cdot10^{-12}$ C/N for the CTGS crystal.

TABLE II. DIFFRACTION ANGLES FOR DIFFERENT REFLECTIONS OF LGTA AND CTGS CRYSTALS AND PIEZOELECTRIC COEFFICIENTS d_{11}.

Reflection (*hkl*)	**LGTA**			**CTGS**		
	$2\Theta^-$ (°)	$2\Theta^+$ (°)	$d_{11}\cdot10^{-12}$ (C/N)	$2\Theta^-$ (°)	$2\Theta^+$ (°)	$d_{11}\cdot10^{-12}$ (C/N)
(110)	21.5855	21.583	6.358	21.8957	21.8943	3.331
(220)	43.9765	43.9715	6.010	44.6474	44.6446	3.312
(330)	68.335	68.326	6.428	69.4664	69.4616	3.350
(440)	96.977	96.962	6.437	98.8711	98.8630	3.330
(201)	21.5855	21.583	6.358	21.8957	21.8943	3.331

The reflection (201) was used to measure the piezoelectric strain coefficient d_{14}. The maps of the diffracted X-ray intensity distribution were obtained in the Laue diffraction geometry schematically presented in Fig. 1(b). To position the (201) plane in the reflecting mode, the single-crystal wafers of the LGTA and CTGS X-cut were rotated around the X axis by the angle α=±34.8° for LGTA and α=±35.6° for CTGS.

Figure 3 shows the maps of the diffracted X-ray intensity obtained in the diffraction scheme of Fig. 1(b) for the reflection (201) of the LGTA single-crystal wafer under electric voltage of various polarity *U*= – 1800, 0, +1800 V. The map in Fig. 3(a) was obtained at the rotation of the single-crystal wafer around the X axis by the angle α=–34.8° and that in Fig.3 (b) at α=+34.8°.

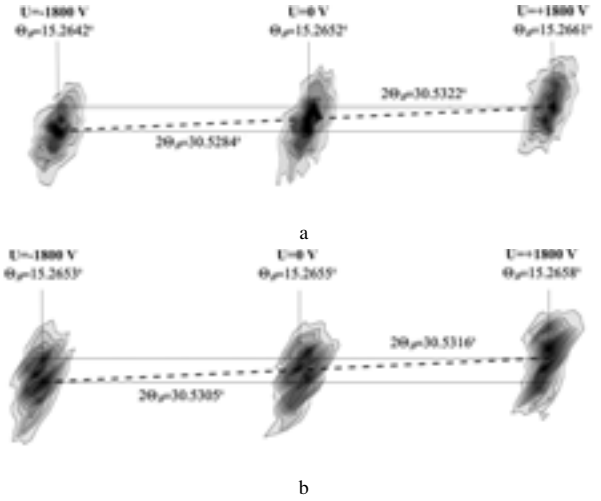

Figure 3. Experimental maps of the diffracted x-ray intensity obtained for reflection (201) and at different values of external electric voltage applied to LGTA wafer in laue diffraction scheme of Fig. 1(b): (a) α=−34.8°, (b) α=+34.8°.

The values of d'_{12} were calculated from expression (6). To calculate the d_{14} coefficient in LGTA and CTGS crystals, expression 8(a) was used, taking the rotation angle α around the X axis into account. Note that the obtained values of the piezoelectric strain coefficients allow for the sample rotation in the laboratory coordinate system. The results of d_{14} measurements in the LGTA and CTGS crystals are presented in Table III.

TABLE III. PIEZOELECTRIC COEFFICIENTS d_{14} IN LGTA AND CTGS CRYSTALS.

LGTA				CTGS			
$d'_{12(+\alpha)}\cdot10^{-12}$ (C/N)	$d'_{12(-\alpha)}\cdot10^{-12}$ (C/N)	α (°)	$d_{14}\cdot10^{-12}$ (C/N)	$d'_{12(+\alpha)}\cdot10^{-12}$ (C/N)$_i$	$d'_{12(-\alpha)}\cdot10^{-12}$ (C/N)	α (°)	$d_{14}\cdot10^{-12}$ (C/N)
1.954	6.750	34.8	-5.117	-9.681	5.229	35.16	-15.835

Comparison of the d_{11} and d_{14} values obtained in this work with those reported in other articles [7-8] shows that the data for LGTA virtually coincide while the values of the coefficients for CTGS radically differ. Note that the difference in the values of d_{11} is smaller than for d_{14} in the CTGS crystal.

V. CONCLUSION

High-resolution X-ray diffraction in the triple-axis diffractometer scheme was used to measure the independent piezoelectric strain coefficients d_{11} and d_{14} in disordered $La_3Ga_{5.3}Ta_{0.5}Al_{0.2}O_{14}$ and ordered $Ca_3TaGa_3Si_2O_{14}$ crystals of the langasite family. To measure the piezoelectric strain coefficients d_{11} and d_{14}, an external electric field was applied to single-crystal wafers, which causes changes in the interplanar spacing due to the reverse piezoelectric effect and, hence, brings about changes in the Bragg peak angular position. This approach is a direct method for measuring piezoelectric strain coefficients.

It is shown that the independent piezoelectric strain coefficients d_{11} and d_{14} in crystals of the langasite family of the space group symmetry 32 can be measured using only one single-crystal wafer of the X-cut. In this case, the piezoelectric strain coefficient d_{11} is measured using the reflection from the planes of (110) type in the Bragg diffraction geometry and the d_{14} coefficient is measured using the reflection from the planes of (201) type in the Laue diffraction geometry.

The measured values of the independent piezoelectric strain coefficients were $d_{11(LGTA)}=6.455\cdot10^{-12}$ C/N, $d_{14(LGTA)}=-5.117\cdot10^{-12}$ C/N in the LGTA crystals and $d_{11(CTGS)}=3.330\cdot10^{-12}$ C/N, $d_{14(CTGS)}=-15.835\cdot10^{-12}$ C/N in the CTGS crystals.

Abstract— **In this paper, we present our studies of the influence of the stress on Aluminum Nitride containing various concentrations Scandium (Sc). Coupling coefficient (kt2) was measured across the wafer and wafer to wafer as a function of stress and Sc content of the film. Previous studies demonstrate a considerable increase in kt2 as a function of Sc content of the film [1], [2], [4], [5]. Unfortunately, when deposited on 200mm wafers we observed that coupling coefficient varies significantly more than that of a standard Aluminum Nitride (AlN). Both stress and concentration of Sc must be controlled across the wafer to achieve uniform coupling coefficient acceptable for production of Bulk Acoustic Resonator (BAW) devices [3], [6], [7]. We were able to control coupling coefficient across the wafer and wafer-to-wafer by adjusting magnetic fields in dual magnetron configuration as well as adjusting concentration of Sc in our two sputtering targets.**

Keywords- component; Aluminum Nitride; Scandium; coupling coefficient; stress

I. INTRODUCTION

Most PVD deposition processes require only average stress measurement on a wafer to provide reasonable device performance. It is not uncommon to have 300MPa to 400MPa variation of stress across wafer on AlN deposition without anyone realizing it. Actually stress has a significant impact on coupling coefficient of AlN film. Local Stress variation across a wafer produces variation of piezoelectric coupling coefficient, and, as the result, dramatically reduces device yield. Similar problem can be addressed to the stress variation of AlScN film. Figure 1 shows effect of stress on AlN and AlScN films.

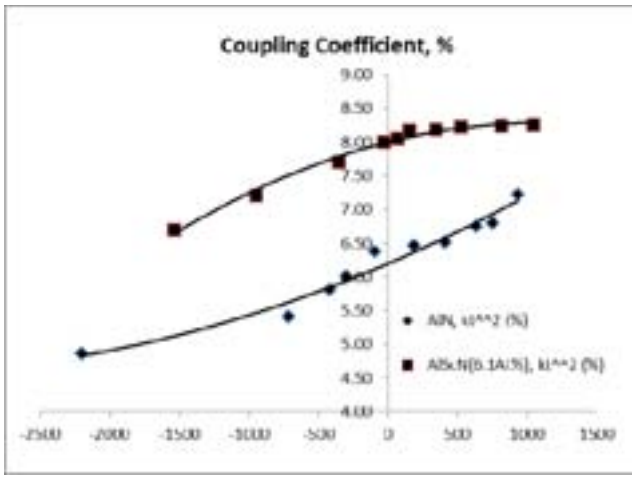

Figure 1: Variation of coupling coefficient as a function of stress for AlN and AlScN films

Tight control of coupling coefficient is essential for producing high quality devices. Using dual target magnetron configuration allows very tight control of stress and coupling coefficient across a wafer.

In this investigation we used different magnetic fields on each magnetron in conjunction with different concentrations of Sc on each target to produce the tightest control on both stress and coupling coefficient.

II. EQUIPMENT

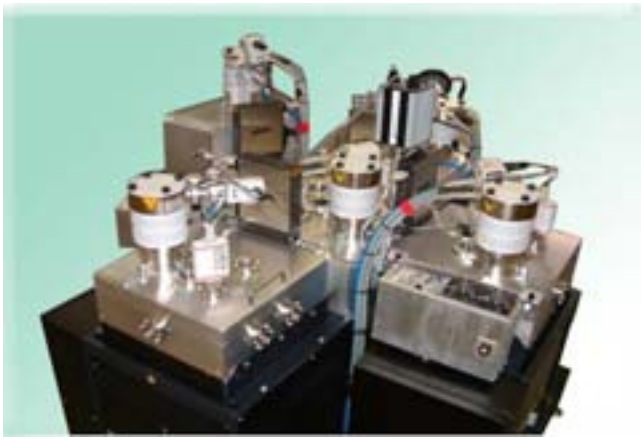
In this investigation we used Advanced Modular Systems cluster tool with AlN and AlScN deposition chambers and ion beam trimming module (shown in Figure 2).

Both AlN and AlScN depositions use a dual magnetron with AC power applied between targets. Frequency of AC power is 40 kHz and power may vary from 3 to 10 kW. It is a reactive deposition process in deep poison mode using two aluminum or composite targets and, argon and nitrogen process gasses.

The trimming module uses DC focused ion source with argon process gas to improve thickness/uniformity of either AlN or AlScN films. Film thickness trimming/tuning is a process based on ion beam scanning across a wafer with power variation based on film thickness map. Utilization of the trimming module opens up a much wider process window for stress control because it allows to avoid spending too much effort on controlling thickness uniformity during deposition.

Simple resonators with three layer's Bragg reflector were manufactured during investigation for piezoelectric coupling coefficient measurements.

Figure 2: AMSystems cluster tool

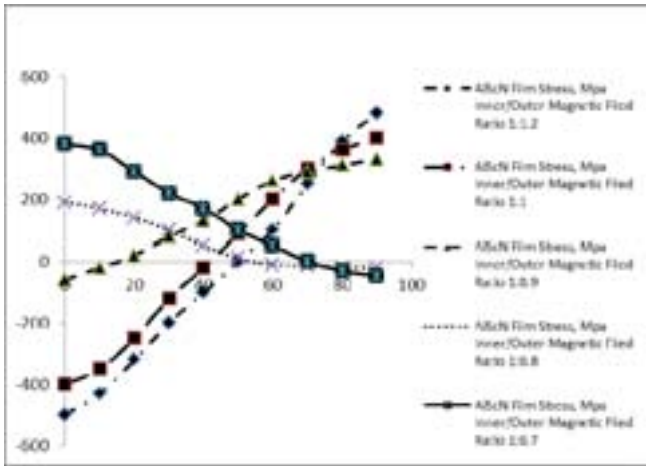


III. STRESS CONTROL

Typical stress control techniques involve either substrate bias or change in gas pressure. Unfortunately, both of these methods are capable of changing average stress on a wafer without having much effect on the local stress across a wafer.

AlN Film stress depends on magnetic field on the surface of the target (7). AlScN film stress also depends on magnetic field on target surface. Since center of the wafer receives more deposited material from the inner target and wafer edge receives more deposition from the outer target, variation of the ratio of the strength of magnetic field between inner and outer targets (magnetrons) allows controlling concentric stress uniformity. We found that in AMS system stress variation has almost perfectly radial distribution that varies with the ratio of magnetic field between inner and outer magnetrons. Figure 3 shows change in stress across a wafer as a function of the ratio of the inner to outer magnetron magnetic fields.

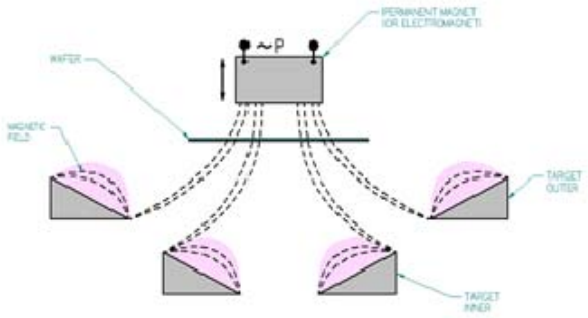
Figure 3: Stress variation across wafer as a function of the ratio of inner to outer target magnetic fields



It is clear that a standard 1:1 ratio of magnetic field that produces the best results for AlN process is unacceptable for AlScN process. We found that the ratio of inner/outer of 1.0/0.8 is the best for stress control.

Placing an additional magnetic field with an adjustable strength behind a wafer as shown in Fig.4 creates a variable unbalance effect of the either inner or outer magnetron (and, as the result, increases or reduces ion bombardment) and provides an additional fine control of the film stress uniformity across a wafer (center to edge) over the target life. This magnetic field can be varied by either an electro-magnet with adjustable electrical current or a permanent magnet with a motor that can adjust the distance between the magnet and the wafer.

Figure 4. Magnetron with the enhanced magnetic field



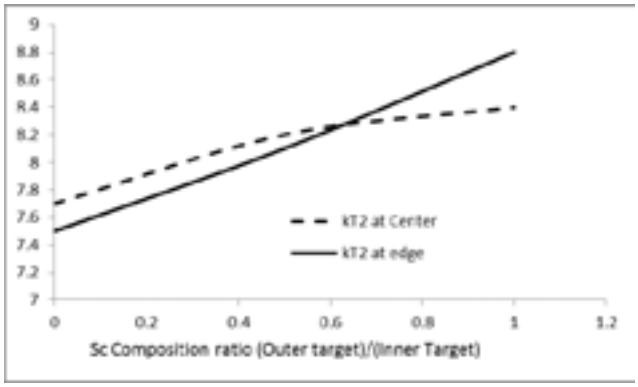
IV. COMPOSITION CONTROL

Another advantage of the dual magnetron is its capability to use targets (inner and outer) with different ratio of Sc/Al. This

method provides an additional control to obtain a uniform coupling coefficient across a wafer.

We started our study by using the same composition on both targets of about 6.1 atomic % Sc with the rest being Al. Analysis showed that deposited on the wafer film contained about 4.2% Sc. In order to achieve desired improvement of coupling coefficient we changed to 8 atomic % Sc on the inner target and varied Sc concentration on the outer targets. Figure 5 shows variation of coupling coefficient across a wafer as the inner target Sc concentration is 8% and outer target Sc concentration is varied between 0 and 8%.

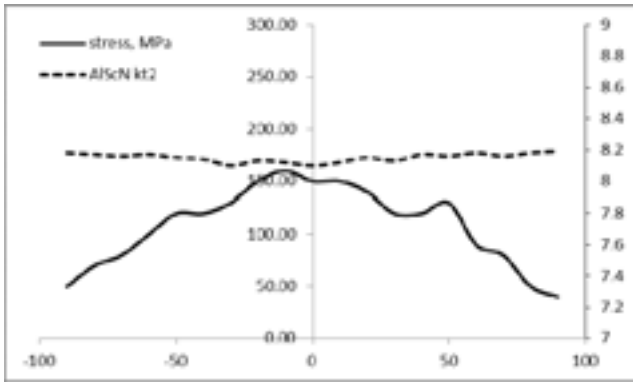
Figure 5: Coupling coefficient across wafer as a function of Sc concentration in two targets



By using the same Sc concentration of inner and outer targets we get slightly higher concentration of scandium on the edge of the wafer. The optimum concentration profile is obtained with concentration of scandium of about 8% on the inner target and 4% on the outer target. It should be noted that most cost efficient method would be to use 8% Sc for inner target and pure outer aluminum target. The Coupling coefficient on the edge is only slightly lower than that in the center, but the cost of the target set is less than half of the target set with equal concentration in the inner and outer targets.

Figure 6 shows excellent control of both local stress and coupling coefficient across a wafer using optimized combination of optimum magnetic field ratio and Sc concentration.

Figure 6: Coupling coefficient and local stress on AlScN wafers



V. SUMMARY

Using dual magnetron design is highly advantageous in controlling stress and coupling coefficient in AlScN films. By adjusting magnetic field and concentration on target, it is fairly easy to obtain highly controlled coupling coefficient and stress in a high volume production environment.

***Abstract*—In this paper, we study the fundamental cause of anchor dissipation in Lamé- or wineglass-mode resonators and show that by carefully optimizing the resonator tether geometry low anchor losses can be achieved, making it possible to reach the intrinsic *fxQ* limit of the resonating material. Through analytical and finite element investigation, we demonstrate that the anchor loss is most significant when the flexural-mode resonance frequency of the tether is in sync with the Lamé-mode frequency of the resonating plate. This has a significant bearing on the design of Lamé-mode resonators with release holes or temperature-compensation trenches, where the modification of the resonator structure requires modification to the tether geometry to maintain a high *Q*. We verify the predicted results through experimental measurements and present an optimized design that exhibits a mechanical *Q* of 408,270 for the fundamental Lamé mode at 41.57 MHz. The *fxQ* for this device is 1.7x10^{13}, one of the highest values reported in silicon.**

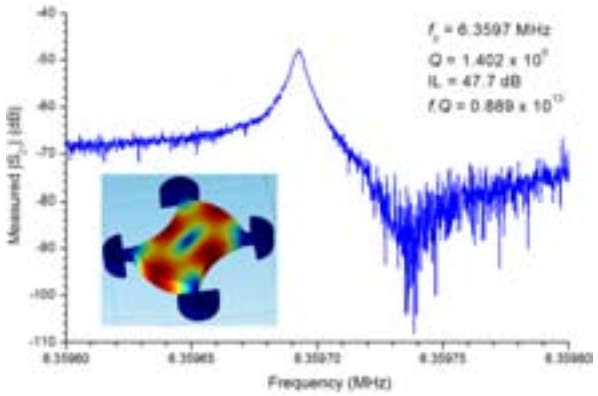

Fig. 1: Measured response of a fundamental Lamé mode at 6.3597 MHz showing a *Q* of 1.4 million.

I. Introduction

Low-loss resonators operating in the low- to mid-frequency range (kHz to few MHz) are critical in the implementation of low-power precision timing references in real time clocks and inertial measurement units (IMUs). At these frequencies, most silicon-based resonator topologies suffer from increased thermoelastic damping (TED) [1]. Due to their isochoric nature, pure Lamé-mode resonators are immune to TED and are ideally suited for such low-frequency timing applications. Straight tether supported Lamé- or wineglass-mode resonators operating in the low MHz frequency range have been shown to exhibit extremely high $f \times Q$ values on the order of 10^{13}, close to the fundamental phonon-phonon loss limit in silicon (see Fig. 1) [2], [3]. However, experimental results suggest increased anchor dissipation exists for certain tether geometries, resulting in *Q* degradation by over an order of magnitude [3]. In light of the utility of these resonators in timing applications, the design of tethers for low anchor loss is critical and merits further investigation.

Anchor loss, also known as clamping loss, has been widely investigated in a variety of resonator geometries due to its significance in the design of high-*Q* resonators. Unlike intrinsic losses which are primarily set by the material of the resonator and its operating frequency [1], [4], anchor loss is design dependent and therefore can be minimized through appropriate design choices. Analytical models estimating the clamping loss in simple beam geometries have been presented in literature [5]. Recently, more exotic ring resonators have also been analyzed for their substrate damping effects [6]. Unfortunately, most of these analytical estimates require precise knowledge of the stress profile at the anchoring area, which is difficult in the case of complex resonator geometries. In addition, the estimation of the exact *Q* may require the use of fitting parameters, which need to be extracted from measured results. Recognizing this limitation, a significant effort has been put towards the estimation of anchor *Q* using finite element methods. Bindel *et al.* applied the method of perfectly matched layers (PML) to the problem of anchor dissipation in stem-supported disk resonators [7], motivated by their utility in electromagnetic analysis [8]. Since then, there has been additional work validating the PML-based approach for anchor *Q* estimation [9]. In both these works, the finite element analysis (FEA) has been implemented using custom built codes, making it difficult to generically adopt. In this work, COMSOL®, a commercial software package, is utilized to model the anchor loss in resonators. The COMSOL

This work is supported by NASA under the Chip-Scale Precision Timing Unit project (Grant #NNX12AQ41G).

simulation parameters are chosen such that the simulated anchor *Q*s match reported analytical estimates of anchor *Q* for different beam resonance modes. This model is then used to predict the anchor loss in Lamé-mode resonators. In the subsequent analysis, it is shown that the anchor *Q* degradation is primarily due to the co-existence of the tether resonance modes near the frequency of the primary Lamé mode. This has important consequences in the design of Lamé-mode resonators with passive compensation or etch holes for wet release compatibility, as such modifications can lead to a reduction in the resonator frequency.

For the purpose of experimental verification, a 100 µm × 100 µm Lamé-mode resonator is analyzed for its tether-dependent anchor loss and a good agreement between the predicted and measured results is shown. An optimized Lamé-mode resonator is presented with a measured mechanical *Q* of 408,270 at a center frequency of 41.57 MHz, attaining an $f \times Q$ of 1.7×10^{23}, which is close to the intrinsic phonon-phonon limit in silicon [4].

II. Estimation of Anchor *Q* using Finite Element Modeling

Fig. 2 shows the finite element model of a beam using a PML to model the substrate as a semi-infinite layer [7]. The material parameters for the PML are same as those for the substrate layer, which usually are the same as those for the beam. It should be noted that the parameters of the PML are critical in achieving accurate anchor *Q* estimates. Similar to the observations in [9], the choice of alpha, *i.e.* the PML scaling factor, determines the magnitude of the simulated anchor *Q* and should be optimized for the specific resonator frequency and geometry. This idea is elaborated in Fig. 3, which shows a large variation in the simulated *Q* as a function of alpha.

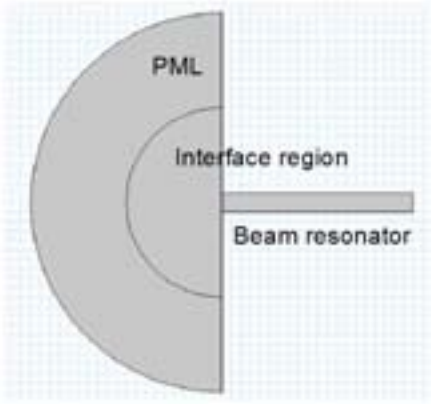

Fig. 2: Model of a beam resonator for anchor loss estimation.

From Fig. 3, we can clearly see that the minimum value of the estimated anchor *Q* converges to the analytical estimate from [5]. A similar study is performed for all the beam geometries and modes analyzed in [5]. The results are summarized in Table 1, demonstrating an excellent agreement between the analytical and the FEM estimates of minimum anchor *Q*.

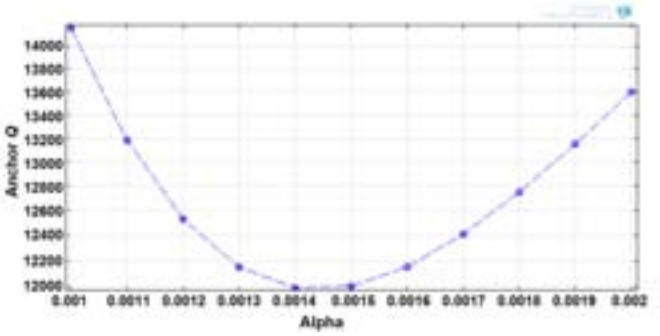

Fig. 3: Simulated anchor *Q* for a silicon beam resonator as a function of alpha. The silicon beam is 500 µm long and 7.2 µm wide. The analytical estimate of anchor *Q* for the third-order flexural mode (clamped-clamped boundary) is calculated to be 11,177 [5].

Table 1: Comparison of the simulated anchor *Q* with analytically calculated estimates for flexural modes of a silicon beam resonator [5].

Length (µm)	Width (µm)	Frequency (kHz)	Anchor *Q*	
			Analytical	*Simulated*
Fixed Free Cantilever (first-order flexure)				
700	6.45	15.94	2.6626×10^6	2.65×10^6

500	7.2	1210	11,177	11,976

III. Resonator Design

Fig. 4 shows a scanning electron microscope (SEM) image and critical tether parameters of a Lamé-mode resonator. The frequency of the fundamental Lamé mode is set by the characteristic plate length L as marked in Fig. 4 and is given as,

$$f_0 = \frac{1}{2L}\sqrt{\frac{G}{\rho}} \quad (1)$$

where G is the shear modulus (Pa) and ρ is the density (kg/m^3). Fig. 5 plots the simulated anchor *Q* loaded with the intrinsic phonon-phonon loss limit in silicon [4] as a function of tether geometry for a 100 µm × 100 µm square plate resonating in the fundamental Lamé mode.

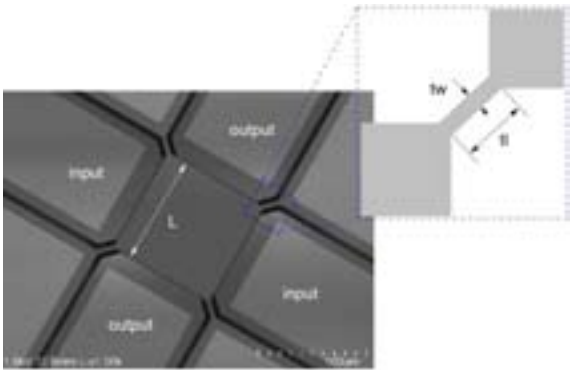

Fig. 4: (Left) A SEM image of a Lamé-mode resonator and (right) the critical tether parameters. The characteristic length L sets the frequency of the fundamental Lamé mode.

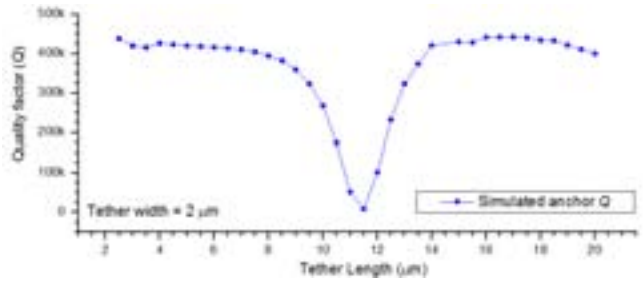

Fig. 5: Simulated anchor Q as a function of tether length for a 100 μm × 100 μm Lamé-mode resonator having a tether width of 2 μm. The simulated Q is loaded with the phonon-phonon loss limit in silicon [4]. Change graph wider

IV. Origin of Anchor Loss in Lamé Resonators

In order to support the Lamé-mode resonance, the tethers are required to undergo forced flexural vibrations. As a consequence, the anchor loss in such resonators is strongly dictated by the flexural resonance frequency of the tether which can be expressed as,

$$f_n = \frac{1}{2\pi}\beta_n^2 \frac{t_w}{t_l^2}\sqrt{\frac{EI}{\rho A}}, \qquad (2)$$

where f_n is the resonance frequency of the nth mode, β_n is the mode constant, t_w is the tether width (μm), t_l is the tether length (μm), E is the Young's modulus (Pa), I is the area moment of inertia for the tether cross-section (m^4) and A is the cross-section area of the tether (m^2). For a cantilever loaded with a mass at its free-end, the resonance frequency is found to be reduced and can be estimated using the formulation in [10]. The effect of mass loading is accounted for by the lowering of the mode constants, β_n, which affects the resonance frequency through (2). Table 2 lists the mode constants and the critical tether length at which the flexural resonance frequency for the tether equals the frequency of the fundamental Lamé-mode of a 100 μm × 100 μm square plate when the tether width is fixed at 2 μm. While the results agree well for longer tether lengths, at shorter tether lengths, the tether aspect ratio is much smaller than 10:1 and the Euler-Bernoulli approximation introduces significant inaccuracies. Inclusion of the effect of rotary inertia can help improve the accuracy of the analytical estimates. Fig. 6 plots the FEA results of the first two tether modes and their critical tether lengths.

Table 2: Analytically estimated critical tether length for a 100 μm × 100 μm Lamé-mode resonator.

	β	Critical tether length (μm)	
		Analytical	Simulated
Mode 1	0.425	1.44	3.5
Mode 2	3.925	13.34	11.5
Mode 3	7.065	24.01	23
Mode 4	10.215	34.72	34

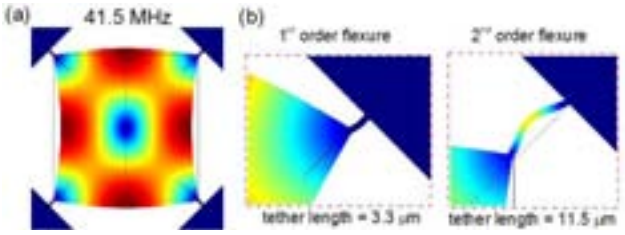

Fig. 6: (a) Fundamental Lamé mode of a 100 μm × 100 μm silicon square plate. (b) First- and second-order flexural modes of the tether. The tether width is 2 μm and the critical tether length is 3.3 μm and 11.5 μm for the first- and second-order mode, respectively. With these critical anchor dimensions, maximum anchor loss of the resonator is found.

From the presented analysis, it is clear that when the tether resonance frequency is near the frequency of the Lamé mode, the resonator Q is degraded due to the additional energy lost from the tether's resonance. In other words, to enable high-Q Lamé-mode resonators, the tether geometry should be set such that the flexural mode of the tethers is far from the fundamental Lamé-mode frequency. While a simple analytical formulation can be used to estimate the critical tether lengths FEM is preferred where accuracy is critical.

V. Experimental Verification

A. Device Fabrication

In order to experimentally investigate the dependence of the Lamé-mode anchor Q on its tether length, devices were fabricated using the process flow shown in Fig. 7. The starting substrate is a silicon-on-insulator (SOI) wafer with a 25 μm thick low resistivity (0.02 Ω.cm) device layer to enable electrostatic actuation. The choice of electrostatic actuation is made to ensure that the resonator Q is not degraded by interface losses [11].

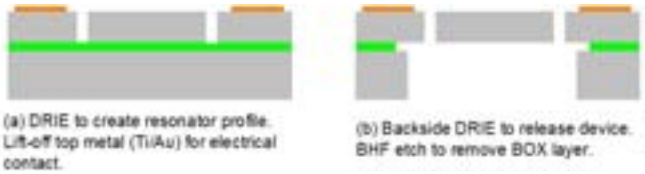

Fig. 7: Fabrication process flow used to experimentally investigate anchor loss in Lamé-mode resonators.

B. Measured Results

The fabricated devices are measured using an Agilent E5061B network analyzer in a vacuum probe station. Multiple dies of resonators were tested and the extracted

mechanical Q as a function of the tether length is plotted in Fig. 8. The data for the simulated anchor Q is overlaid for comparison. In order to obtain the unloaded resonator Q, the series electrical resistance and the resonator motional impedance is estimated using standard extraction techniques [12]. From the analysis, it is estimated that series electrical resistance of the contacts to the resonator is 3.9 kΩ.

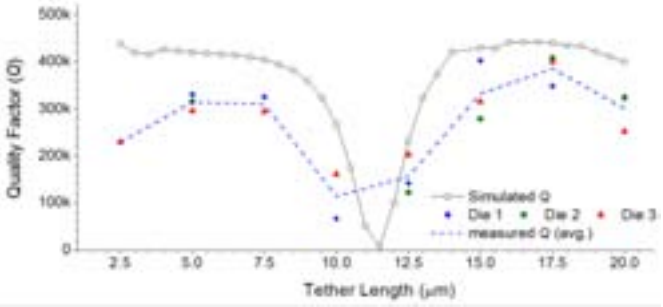

Fig. 8: Extracted unloaded Qs of multiple Lamé-mode resonators as a function of tether length for a tether width of 2 μm. The data for simulated Q is overlaid for comparison.

Fig. 9 plots the measured response of a Lamé-mode resonator with optimized tether geometry: a tether length of 17.5 μm and tether width of 2 μm. The measured Q for this device is 302,120 at 41.57 MHz. Using the extraction method in [12], the unloaded Q of the resonator is extracted to be 408,270 giving an $f \times Q$ of 1.7×10^{13}.

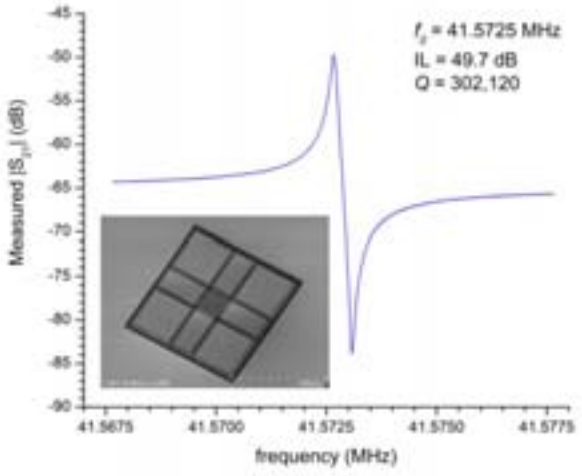

Fig. 9: Measured response of an optimized Lamé-mode resonator with an applied bias of 250 V. (Inset) SEM image of the device. The device has a tether length of 17.5 μm and tether width of 2 μm.

The results in Fig. 8 suggest that for optimum tether geometries the resonator Q is primarily limited by the intrinsic phonon-phonon interactions in silicon. Secondly, we can clearly see the accuracy of prediction using finite element methods. With the validation of the anchor loss model, a similar analysis can be performed for the tether optimization of passively compensated Lamé-mode resonators, and will aid in the development of low-power low-frequency precision timing references.

VI. Conclusion

In this paper we investigated the cause of anchor loss in Lamé-mode resonators and verified the role of the tether resonance modes in degrading the Lamé-mode resonator Q. Finite element analysis was used to estimate the resonator Q and was shown to agree well with both analytical estimates and experimental measurements. An optimized tether design was presented with an unloaded Q of 408,270 for the fundamental Lamé mode at 41.5 MHz attaining an $f \times Q$ of 1.7×10^{13}, which is close to the fundamental phonon-phonon loss limit in silicon.

For low-power low noise timing applications, it is important to design passively compensated resonators to reduce the frequency fluctuation with temperature. From the presented analysis, we can deduce that since the frequency of temperature-compensated Lamé-mode resonators is different from their uncompensated counter-parts, the optimum tether geometry will also be different. The presented tether optimization procedure will be invaluable for the design of low-loss temperature-compensated Lamé-mode resonators.

***Abstract*—In this work, we present the first demonstration of synchronized oscillations in an SOI resonator array with quality factors (Qs) in the order of 10^6 through mechanical coupling. We have fabricated arrays of up to six resonators. Our experimental results indicate that even as the length of the array is expanded, Q is maintained in the order of 10^6 at a resonant frequency of 13MHz. This yields an f•Q product of 1.3×10^{13}, which is close to that of a single Lamé mode resonator. With Q maintained at 10^6, our results show that the motional resistance reduces according to the number of resonators incorporated into the array. These results in turn suggest that mechanical coupling can be extended to even yet longer arrays for reducing motional resistance as well as improve power handling without notably diminishing Q.**

Keywords—array; mechanical coupling; motional resistance; Lamé mode; quality factor

I. INTRODUCTION

Within the field of frequency control and timing devices, micromachined electromechanical resonators have a number of attractive features that help them standout from FBARS, SAW, and quartz resonators. Some of these include the advantage of a small form factor and an easier path towards integration with integrated circuit electronics. Possibilities of where this kind of technology is heading include all-mechanical radio front-ends [1]. Due to their small size and high quality factors (Q) that can be over 10^4, radio-frequency channel selection is now a possibility [2]. Silicon-based (including polysilicon) devices have the advantage of superior mechanical characteristics that allow for high Q even in the millions to be realized [3]. While more efficient electromechanical transduction technologies like piezoelectric AlN provide a pathway to realizing devices with motional resistances approaching targets of 50Ω, the tradeoff that continues to remain is the limited Q typical of this class of devices [4]. Capacitive devices and hybrids thereof continue to exhibit the highest Qs reported in the literature [5-7]. At the same time, the drawback of capacitive transduction lies in the less than satisfactory coupling efficiency even with narrow air gaps, leading to motional resistances that are much larger than is desired [8]. In principle, for contour modes of resonance that have their eigenfrequencies defined by their lateral dimensions, the coupling area reduces when these devices are scaled toward higher operating frequencies, translating to a higher motional resistance. One approach of overcoming this loss in area that comes with designs for higher frequency is to couple multiple copies of the same resonator into an array. By summing up the individual currents from each resonator collectively, the overall motional current increases and thus reduces the net motional resistance. Due to the fabrication tolerances and high Qs, such collective summation is difficult with electrical coupling since the resonances of the each resonator will not perfectly coincide altogether. In order to synchronize their resonances, resonators can be mechanical coupled. Through careful design of the link couplers and phase combinations of the electrodes, the spurious modes can be suppressed so as to yield just a single detectable resonant peak. This has been successfully demonstrated in a polysilicon surface micromachining process based on coupled disk resonators [9]. In fact, this mechanical coupled array approach has been used in combination with more lossy AlN resonators in order to boost Q [10]. While the Qs for these polysilicon arrays are not significantly lower than those of the single disk resonator, the f•Q product of these resonators are notably lower than for single-crystal silicon (SCS) resonators [11]. Possible reasons could lie in the design (e.g. anchor loss in the quasi-nodes of the wine glass disk resonator) or in the material itself possessing greater internal frictional loss [12].

We have previously reported on SCS resonator arrays that were fabricated in SOI based on square-plates [13] and disks [14] that were excited to vibrate in the breathing mode. SCS has the advantage over polysilicon of higher piezoresistive coefficients; hence these resonator arrays could also exploit the benefits of piezoresistance to further enhance transduction. It was found that mechanical coupling did not necessarily result in greater attenuation of Q. However, these breathing mode resonators are limited by anchor losses with Qs that are far less than the highest f•Q products reported for SCS resonators. In this work, we apply the principle of mechanical coupling to the Lamé mode, known for their high Qs and low loss in order to further assess the impact of mechanical coupling on Q. Results of fabricated resonator arrays of up to 6 resonators show that Q can be maintained at a million, with no significant indication that mechanical coupling degrades Q. This allows the motional resistance to be reduced in proportion to the number of devices.

II. Low Loss Features of the Lamé Mode Resonator

The nodes of the Lamé mode of a square-plate resonator are located at the corners of the plate, thus providing a convenient location to clamp the structure. Being able to clamp the plate at the nodes helps reduce anchor loss. In previous studies that compared different kinds of tether designs and their effects on Q, it was found that the choice between a T-shaped and straight tether made no significant difference to the associated Q [15]. It was also shown in a previous study that making variations to the geometry of T-shaped tethers likewise made no difference to Q [16]. These results altogether suggest that anchor loss is unlikely to be the dominant cause that limits Q.

The Lamé mode's unique isochoric mode shape means that the driving factor for thermoelastic damping (TED) is absent. The effects of this unique feature have been observed in our previous studies on the effect of etch holes on Q [17]. Hence by elimination, the observable Q of the Lamé mode is most likely determined by more fundamental dissipation effects such as Akhieser loss. In short, the unique low-loss characteristic of the Lamé mode allows us to more carefully examine the effects of attenuation from mechanical coupling in the limit of low dissipation, whereby these effects should be more obvious.

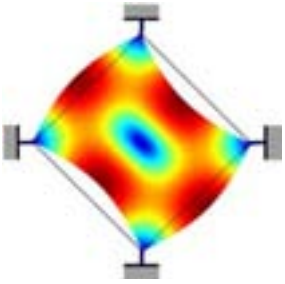

Fig. 1. Mode shape of a Lamé mode resonator simulated by finite elements in COMSOL multiphysics.

III. Lamé Mode Resonator Array

The sides of the Lamé mode square-plate resonators in this work are aligned to the <110> direction in the (100) plane. We have previously shown that this yields Qs that are twice that in the <100> direction [18]. To synchronize two resonators that are to vibrate in phase, we physically link the two resonators by a beam coupler that is half of the wavelength (λ/2) of the Lamé mode resonator. This is defined by:

$$\lambda = L\sqrt{1+\nu} \tag{1}$$

where L is the length of the square-plate and ν is the Poisson's ratio in the <110> direction. As a further measure, as is seen from Fig. 2, the electrical routing of the electrodes has been designed so as to actuate and detect both resonators in phase.

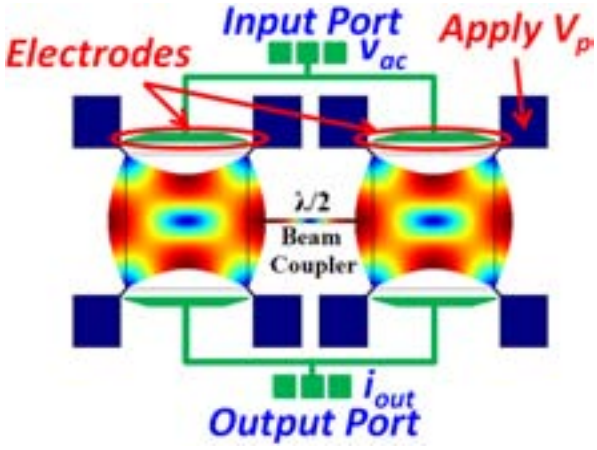

Fig. 3. Simplest configuration of a resonator array containing just two of the same resonators linked via a λ/2 beam coupler. The resonators are designed to be actuated and detected in phase by the routing of the electrodes.

Note that the schematic in Fig. 2 represents a single-ended configuration. To achieve a fully-differential configuration as the array size is doubled, we couple two sets of in-phase twin arrays (illustrated in Fig. 2) with a beam coupler that is a full wavelength (λ). This is depicted in Fig. 3 that shows an array of four resonators, which can be separated into two sections. Within each section the resonators vibrate in phase, linked by λ/2 coupler. Between the two sections, the resonators vibrate in anti-phase through the λ coupler. This phase combination is excited preferentially over other spurious modes by the design of the electrical routing of the electrodes. As shown in Fig. 3, the two sections are actuated and detected out-of-phase via two separate input ports and also two separate output ports.

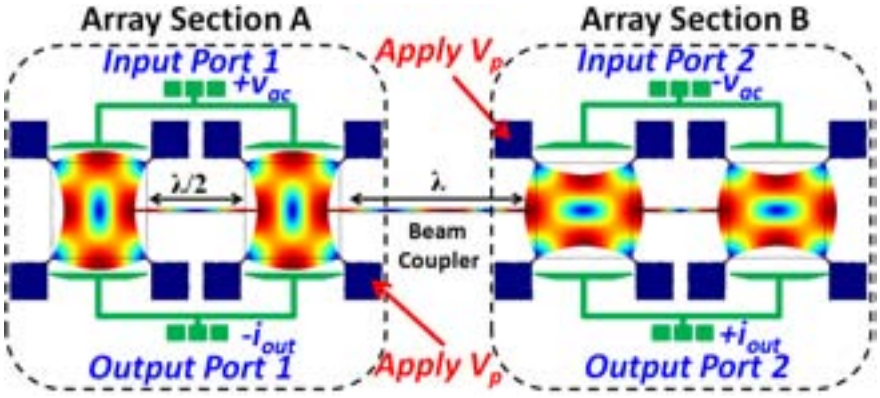

Fig. 2. Phase combination of an array of four resonators split into two sections. Within each section the resonators are in phase but between the sections the resonators are out-of-phase (AABB combination), achieved by the choice of beam coupler lengths and electrical routing of electrodes.

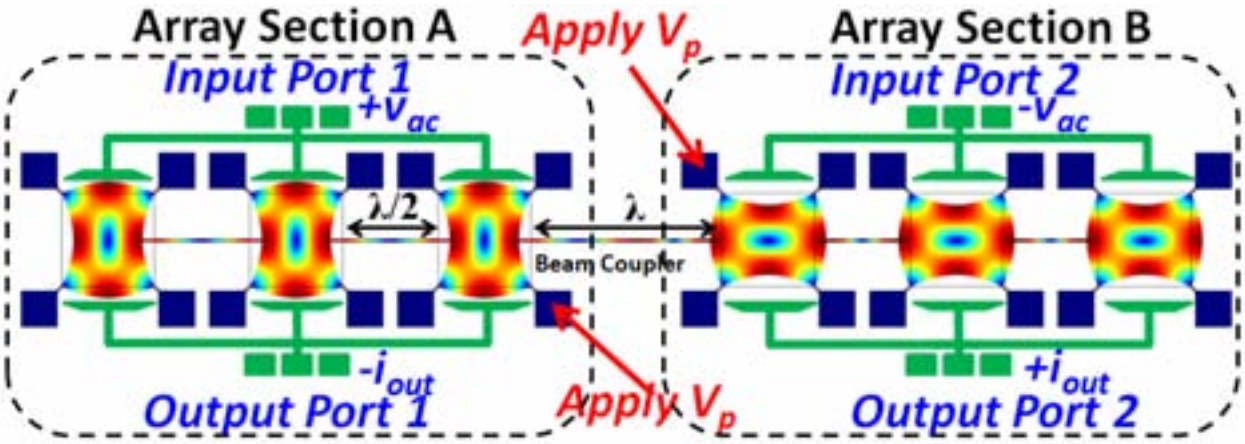

Fig. 4. An array of six resonators formed by inserting an additional resonator to each section of the 4-resonator array. Longer arrays can likewise be formed by extending the array further in the same fashion that allows the same fully-differential biasing configuration to be reused.

Based on the fully-differential mechanically coupled array configuration shown in Fig. 3 for 4 resonators, we extended the length of the array resonator up to six resonators by adding one more resonator to each section. This allows us to preserve the fully-differential biasing configuration that has the benefit of providing feedthrough cancellation. As the number count of resonators in the array increases, motional resistance should in turn decrease by the same proportion.

These devices were fabricated on a 10µm thick SOI device layer using a standard surface micromachining process, where the release of the free structure was realized by etching a trench through the substrate. The square-plate resonators had a length of 320µm, each clamped on all four corners with straight beam tethers. The above array designs were fabricated on the same die along with a single square-plate resonator for comparison (transduction gap limited to 2.5µm). Micrographs of each of these arrays are shown in Fig. 5. The electrical routing on the electrodes is marked out by the metal trace in addition to the bond pads on each anchor in order to apply a DC bias voltage.

IV. Experimental Results

The fabricated devices were electrically characterized under mTorr levels of vacuum, measuring the electrical transmission using an Agilent E5061A network analyzer. Fig. 6 shows the measured results after feedthrough has been extracted out. The resonant peaks from each measurement have been deliberately aligned for better visualization of the characteristics in relation to each other. The resonant frequency from the resonators was around 12.9MHz, with deviations in the same order that would be expected of fabrication tolerances estimated under an SEM.

The single Lamé resonator had a Q of about 1.2 million. In comparison, the resonator arrays had very similar value of Q to each other that were on average 16% lower than for the single Lamé resonator. These results show that extending the length of the array from two to six resonators reveals no conclusive trend that Q decreases as the length of the array is increased. In the results show in Fig. 6, the same source power of 10dBm was used. It can be seen that as the number of resonators in the

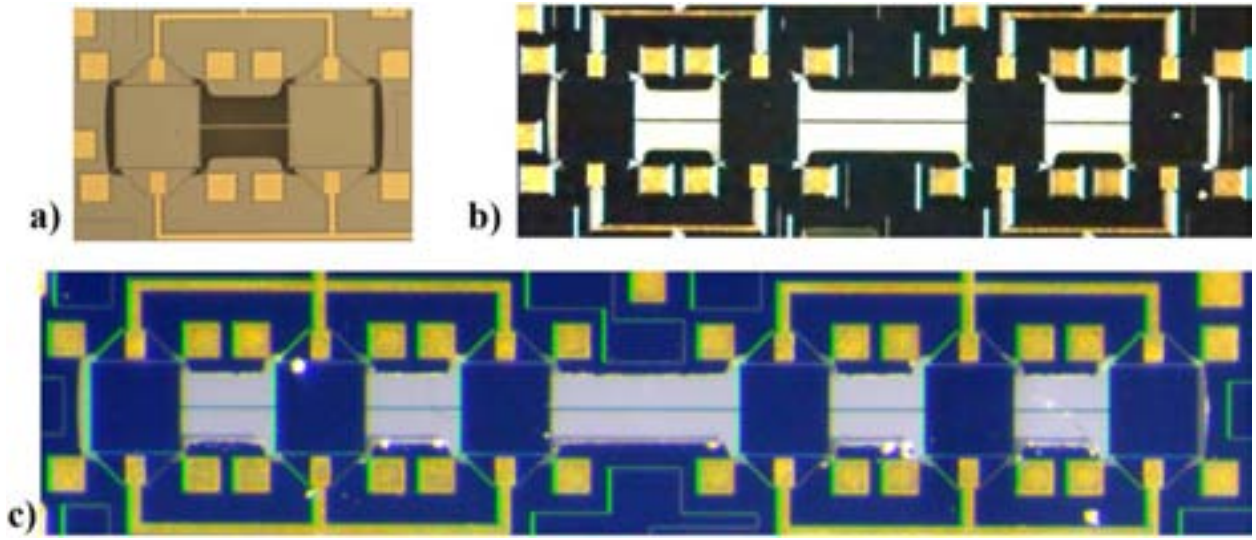

Fig. 5. Micrographs of fabricated SOI mechanically coupled resonator arrays using a standard SOI surface micromachining process comprising (a) two, (b) four, and (c) six resonators. The resonators are physically linked together by a combination of half (λ/2) and full (λ) wavelength beam couplers.

array is increased, the degree of nonlinear bifurcation (seen in the frequency shift of the peak) was reduced accordingly. This is indicative that increasing the array size could also improve the power handling capability. We have extracted the motional resistance (R_x) of each device from the measured transmission. These extracted values are summarized in Table 1 along with their respective values of Q. From Table 1, it can be seen that R_x appears to scale inversely with the number of resonators.

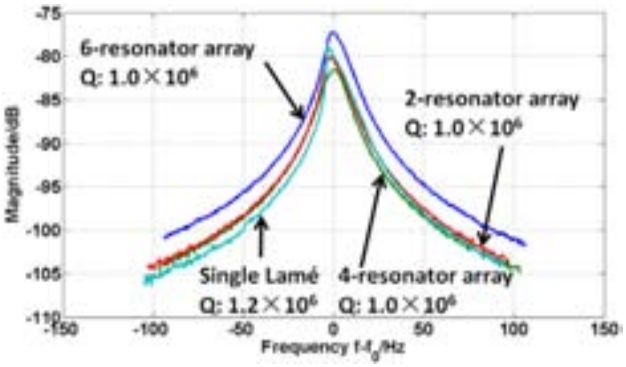

Fig. 6. Measured electrical transmission of resonator arrays as well as for a single Lamé resonator using 10dBm source power. The position of resonant peaks have been deliberately aligned for ease of comparison.

TABLE I. EXTRACTED QUALITY FACTOR AND MOTIONAL RESISTANCE OF THE ELECTRICALLY CHARACTERIZED RESONATOR ARRAYS

No. of resonators	Extracted Parameters	
	Quality factor (10^6)	*R_x (kΩ)*
2	1.03	1011
4	0.98	550
6	1.03	330

V. CONCLUSION

We have fabricated mechanical coupled arrays of low loss high Q Lamé resonators in this work to assess the attenuation in Q due to mechanical coupling. Here we have demonstrated an array of up to six resonators with a Q around a million. By a choice of the coupling beam lengths, we are able to prescribe the phase combination of the resonators in the array in order to obtain a fully-differential biasing configuration. Comparing Qs between arrays of two, four, and six resonators, no conclusive correlation between increasing the array size and degradation in Q was found. Compared to a single Lamé resonator, the Qs of the arrays were slightly lower by ~16%. It has been shown here that the motional resistance indeed scales inversely with the number of resonators in the array. This is the first time that mechanically coupled silicon resonators with Qs in the order of a million have been demonstrated. These results suggest that the approach of mechanical coupling to realize synchronized arrays could be feasible even for a low loss material like single crystal silicon and also with low damping modes like the Lamé resonant mode. Hence by coupling resonators into arrays, the motional resistance can be reduced in proportion to the length of the array. And as indicated by the results of this work, this could be achieved without significantly sacrificing the quality factor. Fabricating and characterizing even longer arrays of the Lamé mode resonators would further test the validity of this proposition.

***Abstract*—A thermally-actuated micromechanical filter with center frequency at very high frequency (VHF) range (64MHz) has been demonstrated for the first time by electrically coupling two thermal-piezoresistive (thermal actuation and piezoresistive readout) resonators. A small-signal equivalent circuit for this filter is proposed and used to analyze the measured frequency response. The filter exhibits tunability in the center frequency (72.2ppm) and relative bandwidth (0.002% to 0.004%) through the capability to tune the resonant frequency of each resonator by adjusting their bias voltages due to the Joule heating effect. Although the filter is not an optimized one, it is sufficient to achieve an out-of-band rejection of more than 10dB and ripple of less than 1dB in the pass band throughout the whole tuning range.**

Keywords- thermal actuation; micromechanical filter; parallel-resonator architecture; tunable center frequency and bandwidth

I. INTRODUCTION

In recent years, increasing efforts have been devoted to improve the performance of the micromechanical filters in order to meet the critical demand for low cost, single-chip, multi-band, multi-standard radio frequency (RF) solutions that are needed by next-generation wireless communication systems [1-6]. Compared to conventional filter implementations based on ceramic and also surface acoustic wave (SAW) technologies, micromechanical filters have significant advantages in terms of their small form factor, low cost batch-fabrication as well as compatibility with CMOS integrated circuits.

To date, two distinct transduction mechanisms technologies for micromechanical resonators have demonstrated successful realization of RF filtering function. These are based on either capacitive [1-3] or piezoelectric [4-6] transduction. Although characterized by high quality factor (Q), capacitive resonators typically suffer from high motional resistance (normally above kΩ at VHF range [1]) which leads to high insertion loss of the constructed filter referenced to 50 Ω systems. To lower the motional resistance, one common approach is to reduce the transduction gap, though this increases the complexity of the fabrication. Since the piezoelectric materials possess large electromechanical coupling coefficient, the motional resistance of piezoelectric resonators can be reduced to a few 100 Ω [5]. One of the commercially available piezoelectric filters is based on film bulk acoustic resonators (FBARs) [4]. However, the resonant frequency of FBAR is a function of film thickness, which makes multiple frequencies solution difficult to realize on a single substrate. More recently, single-chip multiple-frequency micromechanical filters based on aluminum nitride (AlN) with center frequencies in the VHF range have been successfully demonstrated. These have exhibited promising performance such as low insertion loss (4dB) and large out-of-band rejection (27dB) [6]. However, these AlN contour mode piezoelectric resonators show Qs that are typically limited to a few thousand. This is significantly lower in comparison to the level of Qs that are greater than 10,000 typical of capacitive silicon-based micromechanical resonators.

For the first time, this paper presents a thermally-actuated micromechanical filter realized by electrically coupling two identical dog-bone shaped thermal-piezoresistive resonators [7]. As a proof of concept, the filter has a modest center frequency of 64 MHz, which in principle can be scaled to yet higher frequencies. Moreover, this new class of micromechanical filters possesses a convenient tuning mechanism for its center frequency and bandwidth by adjusting the bias voltages of the constituent resonators. In addition, the fabrication process for this thermally-actuated filter is much simpler than for narrow gap capacitive devices. Compared to capacitive transduction (drive and sense), both the thermal actuation mechanism and piezoresistive readout scheme exploited here are much more efficient, allowing a significant reduction in insertion loss than if the device was activated by capacitive transduction.

II. THERMALLY-ACTUATED FILTER DESIGN

A. Structure and operation principle of the filter

Recently, thermal-piezoresistive resonators have attracted much interest by offering better frequency-scaling performance in the electromechanical transduction [7]. Fig. 1(a) depicts of the vibration mode shape of a single dog-bone resonator, which has a finite-element (FE) simulated frequency of 64.7574MHz. As the resonator vibrates, a voltage across the anchors will result in a modulated motional current due to the piezoresistive effect inherent to single crystal silicon. However, this motional current is always accompanied by a much stronger feedthrough

This work was supported by a grant under the Early Career Scheme from the Research Grants Council of Hong Kong (project no. CityU 124312), the Applied Research Grant from the City University of Hong Kong (project no. 9667062), as well as the Science, Industry, Trade and Information Technology Commission of the Shenzhen Municipality (project no. current stemming from the resistive path between input and output ports.

(a) (b)

Figure 1. (a) FE simulation of the mode shape of the dog-bone resonator using COMSOL. (b) Circuit schematic of the thermally-actuated filter realized by electrically coupling two dog-bone shaped in parallel configuration.

Fig. 1(b) provides a circuit schematic showing the thermal piezoresistive resonators configured as a parallel-class filter [1-2]. Two resonators are electro-thermally excited by the same AC drive voltage, but their output motional currents are sensed differentially. Since the resonators are designed to be identical, thus resulting in the same resistance (to the first order) in both current paths, significant resistive feedthrough cancellation can be achieved. This feedthrough cancellation idea was reported before in [8] where one of the resonators was inactive and used as dummy resonator. But distinct from [8], both resonators are active here to form a 2nd-order filter. It can also be seen from Fig. 1(b) that each resonator is biased with a DC voltage. By adjusting these bias voltages, the resonant frequencies of the resonators can be tuned independently, thus enable tuning of the center frequency and bandwidth of the filter.

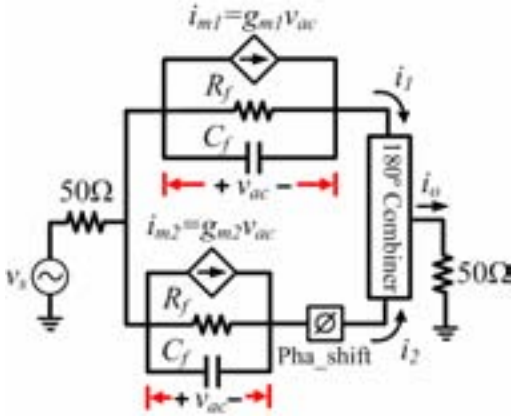

Figure 2. Small-signal equivalent circuit to capture the frequency response of the parallel-class thermally-actuated micromechanical VHF-band filter.

B. Small-signal equivalent circuit for the filter

The proposed small-signal equivalent circuit for the filter is shown in Fig. 2. The AC current in each path i_n (n = 1, 2) is a combination of the piezoresistive current $i_m = g_m(\omega)v_{ac}$, where $g_m(\omega)$ is the normalized motional conductance function and v_{ac} is the AC voltage across the resonator) and feedthrough current that is associated with a parasitic resistance R_f and capacitance C_f (Identical parasitic components are assumed for both current paths). v_s is the source voltage and i_o is output current. The motional conductance function $g_m(\omega)$ is given by [9]:

$$g_m(\omega) = \frac{\Pi}{(1-(\omega/\omega_o)^2 + j(\omega/\omega_o)/Q)} \quad (1)$$

where Π denotes a lumped parameter that describes the thermal-piezoresistive conversion in the resonator, ω_o is the angular resonant frequency and Q is the quality factor. The admittance for each path $Y_n(\omega)$ is:

$$Y_n(\omega) = \frac{i_n}{v_{ac}} = g_{mn}(\omega) + \frac{1}{R_f} + j\omega C_f \quad (2)$$

To model the phase difference between the two paths, a phase shifter is cascaded at the end of the second path. Thus, the total admittance of the two-port filter can be obtained:

$$Y(\omega) = Y_1(\omega) + Y_2(\omega)e^{jPha\_shift} \quad (3)$$

where *Pha_shift* represents the phase difference between the two paths. In the ideal case where there is no phase difference between i_1 and i_2, *Pha_shift* would simply be zero. However, a small phase difference was detected from the measurement and will be discussed in the following section.

III. MEASUREMENT AND DISCUSSION

Fig. 3 shows SEMs of a pair of 10-μm-thick dog-bone twin resonators (R1 and R2) fabricated side-by-side on the same die using a standard SOI MUMPS process. The lateral dimensions of the resonators are the same as those described in Fig. 1. The fabricated pair of devices was electrically characterized under vacuum using probe station (Janis Research ST-100) and using a network analyzer (Agilent E5061A). Short-Open-Load-Through (SOLT) calibration was performed prior to measuring the device under test. All measured results were acquired using 50Ω termination impedance.

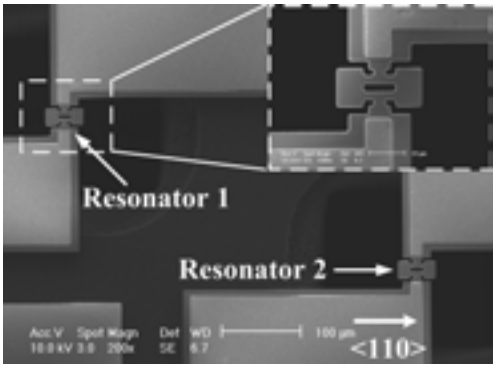

Figure 3. SEM of two 64MHz 10-μm-thick dog-bone resonators fabricated using a standard SOI MUMPS process. Both resonators are aligned along the <110> crystallographic orientation.

Fig. 4 shows the magnitude plot of the measured electrical transmission for a single resonator (R1 in this case) with bias voltage (V_{b1}) of 3.24V. The measured bias current used was 60mA. From the transmission plot we can infer that there is a high level of feedthrough that is substantial enough so as to mask the resonant peak. Fig. 5 shows the measured electrical

transmission for the parallel-class filter using the configuration shown in the circuit schematic provided in Fig. 1(b) when bias voltages V_{b1} and V_{b2} were set to be 3.24V and 0V respectively. Since no DC voltage is applied to R2 in this case, R2 serves only as a dummy in this configuration. By comparing Fig. 4 against Fig. 5, this pseudo-differential configuration provides a significant reduction in feedthrough (27.5dB), which in turn yields a larger resonant peak of 3dB. The measured resonant frequency for R1 is 64.5656MHz as shown in Fig. 5. Almost the same level of reduction in feedthrough can be found from the same pair of measurements when implemented for R2 (the magnitude plots have been omitted for brevity). However, the measured resonant frequency of R2 using the same bias voltage applied previously to R1 was found to be 64.6238MHz. This discrepancy between the resonant frequencies is less than 0.1% and is likely to stem from fabrication tolerances. The measured resonant frequencies of R1 and R2 were both lower than the value simulated by finite elements (64.7574MHz). This is expected due to the Joule heating effect involved in thermal actuation and the negative temperature dependence of Young's modulus of silicon.

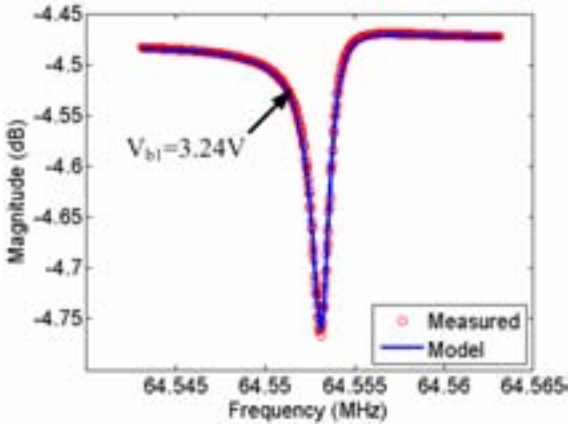

Figure 4. Measured and modeled electrical transmission (magnitude) for a single resonator (R1 in this case) with DC bias voltage V_{b1} of 3.24V, which yields a bias current of 60mA.

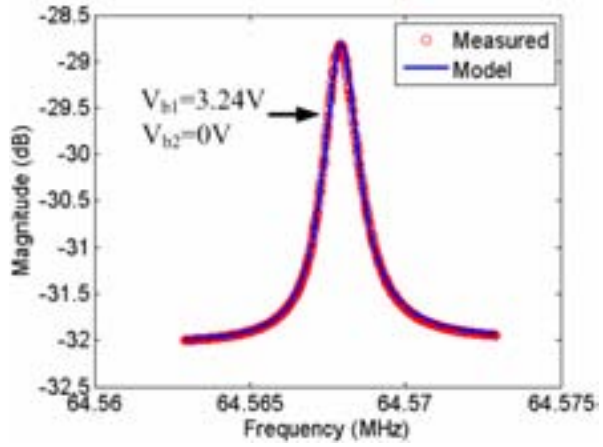

Figure 5. Measured and modeled electrical transmission (magnitude) of the filter using the configuration shown in the circuit schematic illustrated in Fig. 1(b): V_{b1} = 3.24V and V_{b2} = 0V). The measured bias current to R1 was 60mA. R2 here served as a dummy resonator.

By adjusting the bias voltages, the resonant frequencies of the two resonators can be tuned to come closer to each other to realize a bandpass filter frequency response. Fig. 6 shows one of the measured filter frequency responses (magnitude) when V_{b1} and V_{b2} were set to be 3.52V and 3.69V respectively. The corresponding measured bias currents were 60mA and 60.4mA. Compared to the previous two measurements, the bias voltage for R1 is 0.28V higher to yield same bias current (60mA). This translates to an increase in resistance by 4.7Ω. The increased resistance of R1 indicates higher ambient temperature which is caused by the additional heat generated by R2. In fact, each resonator consumes DC power of about 200mW in this case. It can also be observed that the increased ambient temperature when both resonators are actuated leads to a lower resonant frequency of R1 compared to that shown in Fig. 5.

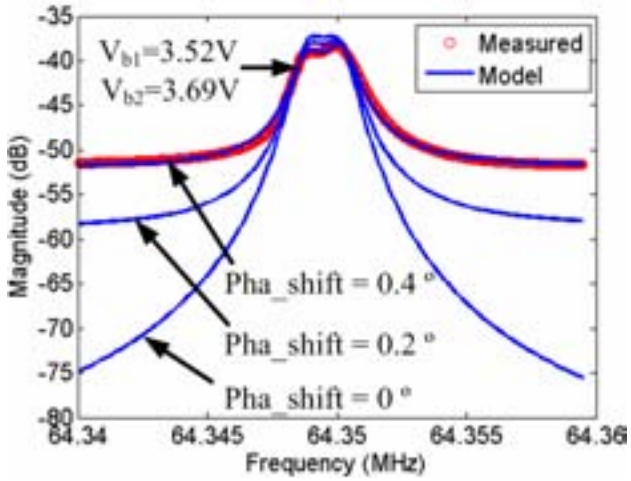

Figure 6. Measured and modeled electrical transmission (magnitude) of the filter with V_{b1} = 3.52V and V_{b2} = 3.69V. The corresponding measured bias currents were 60mA and 60.4mA for R1 and R2 respectively.

TABLE I. PARAMETERS EXTRACTED BY FITTING

Parameters extracted by fitting measured result in Fig. 5			
g_{m1}	g_{m2}	f_{o1}	Q
1.87×10^{-8}S	0S	64.5656MHz	5.16×10^{4}
Pha_shift	R_f	C_f	
-4°	64Ω	4pF	
Parameters extracted by fitting measured result in Fig. 6			
g_{m1}, g_{m2}	f_{o1}	f_{o2}	Q
1.87×10^{-8}S	64.3488MHz	64.3502MHz	5.16×10^{4}
Pha_shift	R_f	C_f	
0.4°	69Ω	6pF	

By fitting the measured result to the circuit model described in Fig. 2, the respective circuit parameters can be extracted accordingly. Table I presents the extracted circuit parameters extracted based on the measured results shown in Fig. 5 and 6. It can be seen from this table that the extracted normalized motional conductance (g_m) and Q are the same in the cases of both Fig. 5 and Fig. 6. It is also found that there always exists a phase difference between the two current paths. Interestingly,

according to the model prediction, the out-of-band rejection of the filter can be improved by a factor of more than 20dB if there is no phase difference between two paths, which is shown in Fig. 6. In addition, the extracted values of R_f successfully capture the increase in resistance observed in the measurements between actuating a single device compared to both devices at the same time.

Fig. 7 shows three measurements of electrical transmission (magnitude) of the filter when V_{b1} was kept constant at 3.52V while V_{b2} was varied. As expected, the resonant frequency of R2 is decreased with increasing V_{b2}. At the same time, it was found that the heat generated by R2 was sufficient to decrease the resonant frequency of R1 further. The downward shifts of the resonant frequencies of both devices result in a shift in the center frequency of the filter (72.2ppm). Since the variation of V_{b2} has a larger effect on the resonant frequency of R2 than on R1, the separation of the resonant frequencies and thus the bandwidth of the filter can be tuned (0.002% to 0.004%) as shown in Fig. 7. In addition, this filter exhibits out-of-band rejection of more than 10dB and little ripple in the pass band (<1dB) during the whole tuning range with the termination impedance of 50Ω.

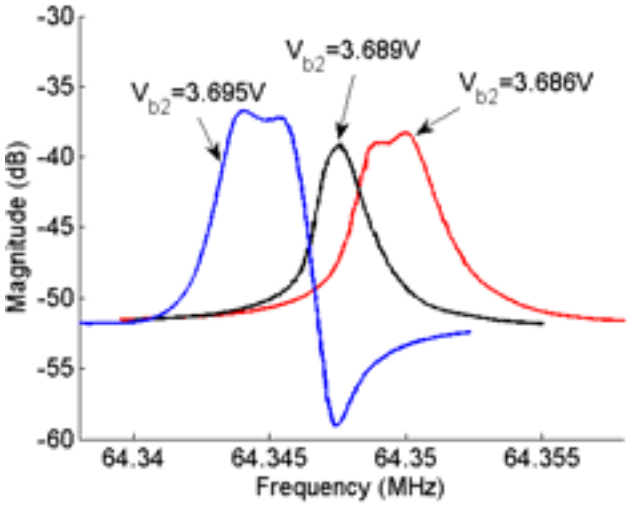

Figure 7. Measured electrical transmission (magnitude) of the filter. V_{b2} was varied to demonstrate tuning of the bandwidth while V_{b1} was kept constant at 3.52V.

Several methods to improve the performance of the filter can be explored in the future. First, two bias voltages, rather than just one bias voltage, can be adjusted at the same time to enlarge the tuning range of the center frequency and bandwidth. Second, a phase shifter could be used in either current path so as to reduce the phase difference between two paths and thus improve the out-of-band rejection of the filter. Third, the major drawback for this thermally-actuated filter is its high power consumption (about 200mW for each resonator) and the resultant heat-related issues such as the dependence of the resonant frequency on the ambient temperature. One solution for this problem is to physically scale down the resonator size towards higher operating frequencies. This will reduce the bias current required and thus DC power consumption. One actual demonstration that validates this effect of physical scaling on power reduction has been reported in [7], where submilliwatt of DC power consumption has been recorded. Hence scaling these concepts towards higher frequencies (as required of RF filtering) is also beneficial in reducing power consumption.

IV. Conclusion

A thermally-actuated micromechanical filter that employs a piezoresistive readout operating in the VHF band to lower the insertion loss is demonstrated for the first time using parallel-class configuration. A small-signal equivalent circuit of the filter is also proposed which can be used to extract the physical parameters and predict the frequency response of the filter. In addition, tunable center frequency (72.2ppm) and bandwidth (0.002% to 0.004%) are conveniently achieved by adjusting the bias voltages in this filter. With room for further optimization, this filter already exhibits an out-of-band rejection of more than 10dB and a ripple of less than 1dB in the pass band (<1dB) with 50Ω termination during the whole tuning range. Finally, several ways to improve the performance of the new filter have been briefly described.

Abstract—**In this work, we report the experimental observation of quality factor (Q) variation in piezoresistively sensed silicon micromechanical resonators vibrating in a lateral contour mode. By fine tuning the bias current, the gradual descending and ascending trend of Q is distinctively observable. It shows a drastic drop in Q by nearly one order of magnitude (from 10^5 to 10^4) at a certain bias current level. The observed Q variation is replicable even when applying a capacitive sensing configuration with bias current running through. This anomaly is consistently detected from multiple die samples including resonators aligned along both <110> and <100> crystal orientations in the (100) plane. A detailed quantitative study is currently underway.**

Keywords-micromechanical resonator; quality factor; piezoresistive sensing; single crystal silicon; microelectromechanical systems (MEMS).

I. INTRODUCTION

Silicon based micromechanical resonators are becoming an increasingly viable alternative to quartz resonators that are bulk sized and difficult to integrate with CMOS for the time and frequency control market. These devices are of great interests in the research community and have also come to the point of commercialization in recent years [1, 2]. Referred to as MEMS oscillators, some of these products that are based on capacitive transduction of the embedded resonator exhibit excellent phase noise and temperature stability performance competitive with existing temperature compensated crystal oscillators (TCXO) [3, 4]. For these capacitive MEMS oscillators, the relatively large motional impedance limits further improvements in phase noise (especially in the far from carrier portion), as a high-gain sustaining amplifier circuitry is normally required and imposes more thermal noise. Efforts have been made to shrink the transduction gap to deep submicron (~10nm) in order to obtain sufficient electromechanical coupling and lower the motional impedance [5, 6]. However, fabricating narrow gap increases the manufacturing complexity and may cause reliability issues (e.g. pull-in). Furthermore, for higher frequency applications, the reduction of lateral dimensions increases the challenge of sensing via capacitive transducers.

To overcome the weak coupling in capacitive transduction, piezoresistive sensing for silicon micromechanical resonators was introduced [7] and showed remarkable improvement in the transduction at the fundamental mode of 1.1GHz [8] by using the piezoresistance inherent in silicon. Moreover, NXP has recently demonstrated its MEMS oscillator product based on a piezoresistively-sensed dog-bone resonator recently [9]. This aside, the single-crystal-silicon (SCS) square-extensional (SE) mode resonator is of great interest due to its outstanding power handling and high Q. The first MEMS oscillator prototype that could meet the GSM specifications was based on the SE mode resonator [10]. Therefore, efforts have been made to improve transduction further via piezoresisitive sensing, and it has been reported that using piezoresistive readout can greatly boost the transduction of SE mode resonators [11, 12].

The small-signal model predicts that, for electrostatically-actuated piezoresisitively-sensed devices, the transconductance is proportional to the injected DC bias current, while assuming a constant Q [7]. Previously, some correlation between the Q and DC bias current was reported for dog-bone resonators, showing that the effective Q could be adjusted by changing the DC current; an effect attributed to the thermodynamic feedback mechanism [13]. Even self-sustained oscillation without any amplifying circuitry can be achieved with a proper design of the resonator and a certain amount of bias current due to this possibility of amplifying Q through the current [13, 14].

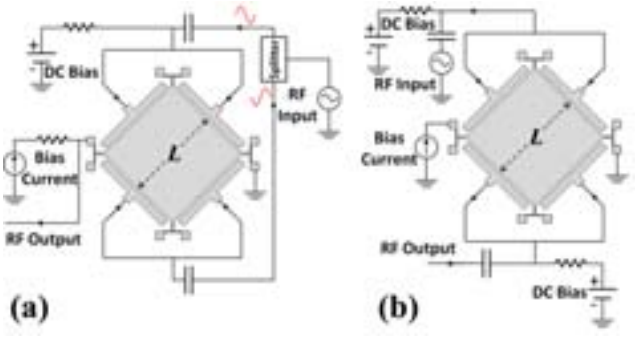

Figure 1. Schematics showing the measurement setup for SCS square-plate resonators using electrostatic actuation in combination with: (a) piezoresistive sensing; and (b) capacitive sensing.

This work was support by the strategic research grant from City University of Hong Kong (under project numbers 7002690 and 7008182) and a grant under the Early Career Scheme from the Hong Kong Research Grants Council (project number CityU 124312).

In this paper, we focus on the effect of injecting DC current on Q for SE mode resonators. The anomalous Q versus bias current profile deviates from the correlation previously found for dog-bone resonators, indicating the complex nature of the underlying thermomechanical coupling mechanisms. These results also suggest that a different mechanism is at work in the attenuation of Q in the case of the SE mode resonator.

II. Characterization Method

The square-plate resonators are surrounded by 4 electrodes with air gaps in between to perform electrostatic actuation. The T-shaped anchors function as the primary piezoresistors [11] and provides for higher Q in the SE mode of vibration. For piezoresistive sensing, the measurement setup is shown in Fig. 1a, where 2 electrodes with DC-biased AC signal are used to excite the SE-mode. The remaining 2 electrodes carry an AC signal that is out of phase in relation the other 2 electrodes to help eliminate capacitive feedthrough. Since the output current from the piezoresisitive setup involves both a capacitive and a piezoresisitive signal, to rule out a possible causal relation to piezoresistive electromechanical coupling, the devices are also characterized in a capacitive sensing setup (see Fig. 1b), but with a bias current through the device to mimic the self-heating effect in piezoresisitive sensing. From the capacitive sensing setup, the magnitude of the resonant transmission peak will also provide us with an instant indication on the change of Q as the electromechanical coupling would be independent of the bias current and the amplitude of the mechanical displacement can thus be directly associated with Q.

The square plate resonators (lateral dimension L = 800μm) were fabricated in a foundry silicon on insulator (SOI) MEMS process. Scanning electron micrographs (SEMs) of the devices are shown in the insets of Fig. 2. As the mechanical property and piezoresistive coefficients are well known to be anisotropic [15] for SCS, devices with the same dimensions but with edges aligned along different crystal orientations of interest (<110> and <100>) were fabricated alongside each other for the chief purpose of comparison. The devices were electrically probed in a cryogenic probe station and characterized via an Agilent E5061A vector network analyzer at a vacuum level ~10^{-4}mBar and room temperature.

III. Experimental Results

The resonant frequency of the SCS SE-mode resonators can be determined as follows [16],

$$f_{SE} = \frac{1}{2L}\sqrt{\frac{E_{bi}}{\rho}\left[1+\left(1-\frac{8}{\pi^2}\right)\left(\frac{\upsilon}{\upsilon-1}\right)\right]}, \qquad (1)$$

where ρ is the material density, E_{bi} is the biaxial modulus, and v is the Poisson's ratio. Due to the anisotropy of the material, the <110> and <100> resonators share the same E_{bi} (which is invariant) but have different values of v [16], given as follows:

$$E_{bi} = C_{11} + C_{12} - \frac{2C_{11}^{\ 2}}{C_{12}}$$

$$\upsilon_{<110>} = \frac{C_{11}^{\ 2} + C_{11}C_{12} - 2C_{12}^{\ 2} - 2C_{11}C_{44}}{C_{11}^{\ 2} + C_{11}C_{12} - 2C_{12}^{\ 2} + 2C_{11}C_{44}} \qquad (2)$$

$$\upsilon_{<100>} = \frac{C_{12}}{C_{11} + C_{12}}$$

where the C_{11}, C_{12} and C_{44} are elementary elastic constants of SCS. The calculated resonant frequencies are consistent with what we have measured at room temperature as well as finite element (FE) simulations, as shown in Table I. The simulated eigenmode shapes are shown in Fig. 2.

TABLE I. List of measured, calculated and simulated resonant frequency of the SE-mode resonators

Devices	Resonant Frequency [MHz]		
	Calculated	*Simulated*	*Measured*
<110> 800μm	5.470	5.447	5.453
<100> 800μm	5.299	5.310	5.310

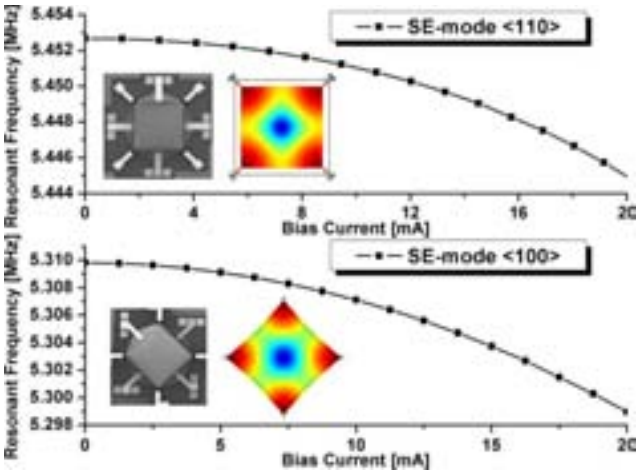

Figure 2. Measured resonant frequency vs. bias current profiles of the square-extensional (SE) mode resonators aligned along both the <110> and <100> crystal axes. Insets: SEMs of devices and FE simulated eigenmode shapes (solid lines indicate the nominal layout of the resonator; red: maximum displacement; blue: minimum displacement).

Fig. 2 shows the typical resonant frequency shift as a function of injected bias current (0 to 20mA). The measured diagonal resistance of the device is about 160Ω. The device temperature increases due to Joule heating, causing a downward parabolic drift in resonant frequency due to the negative temperature coefficient of elasticity (TCE) known for moderately n-doped SCS. As reported previously, our SE mode devices exhibit a temperature coefficient of frequency (TCf) ~-20ppm/K [16]. Associated with the TCEs of SCS, the frequency shift due to Joule heating effect is simulated via COMSOL Multiphysics. The simulated profiles of resonant

frequency versus bias current are shown in Fig. 3, indicating a downshift in frequency of ~1400ppm at 20mA for both <110> and <100> devices, which agrees well with the measurements. According to the simulations, the temperature distribution over the entire square plate is largely homogeneous (see insets in Fig. 3) with a mean temperature rise of about a 60°C for a bias current of 20mA.

Fig. 4 illustrates the variation in Q as a function of injected DC bias current for resonators with <110> crystal orientation. The measured intrinsic Qs (without bias current) are as high as 500,000 for the devices vibrating in the SE-mode. For Device 1 (D1), we first performed piezoresistive sensing with different bias currents. The measured Q is almost unaffected by varying the bias current except around 15mA bias current. As we fine tune the bias current with a step ~0.1mA, the Q (in terms of the -3dB bandwidth) as well as the maximum transmission peak height gradually decreases and then later increases, showing a severe reduction of nearly an order of magnitude at 15.2mA. The measured frequency responses with fine-tuned bias current around 15mA are shown in Fig. 5. This observation was been observed repeatedly in multiple measurements. Besides, as we switch to the capacitive sensing setup (Fig. 1b), similar trends of Q versus bias current are obtained, showing a good match with our piezoresistive sensing result. Since the coupling in capacitive transduction is not dependent on bias current, we find that the transmission level divided by Q is quite stable throughout the bias current interval. This indicates that severe dissipation is likely to be happening at a certain bias current and dampens the mechanical displacement of the resonator due to thermomechanical coupling. Multiple devices were tested and similar trends pointing to this phenomenon were found even through not exactly at the same bias current level due to fabrication variations. The profile of the measured Q against bias current of another device (D2) using capacitive sensing is also included in Fig. 4. Similar trends that include a drop in Q at around 13mA were found, illustrating that this effect can be consistently observed.

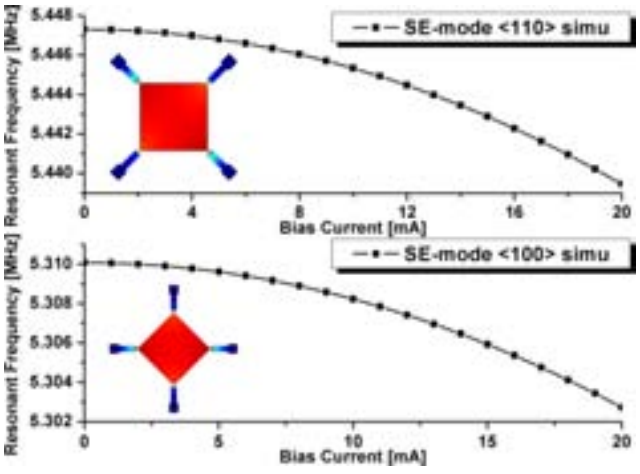

Figure 3. FE-simulated resonant frequency vs. bias current profiles of SE mode resonators aligned along both the <110> and <100> crystal axes. Insets: the simulated temperature distribution of the devices with bias current running through the structure via 2 anchors (red: highest temperature; blue: lowest temperature).

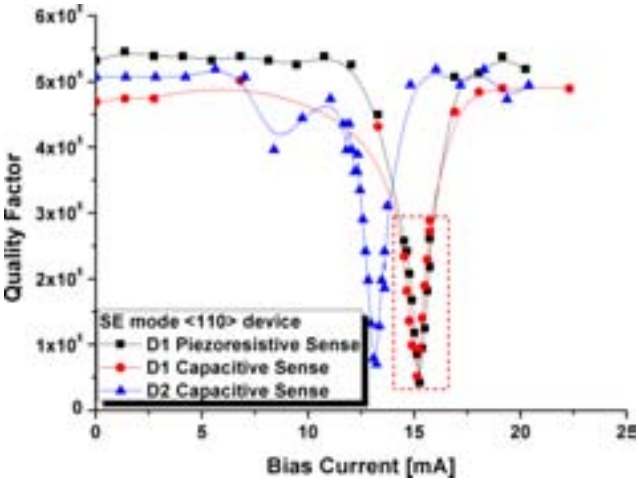

Figure 4. Q vs. bias current profile of <110> axis SE-mode resonators. Drastic Q drop at particular bias current level observed in both device D1 and D2. Similar trends of variation in Qs seen among both piezoresistive as well as capacitive sensing setup.

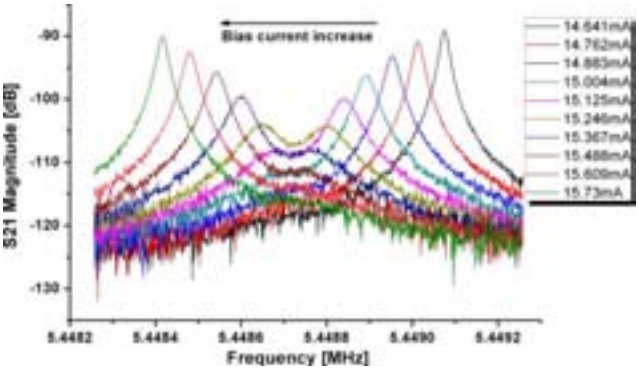

Figure 5. Measured S21 of D1 using piezoresistive sensing as bias current is fine-tuned around the Q valley. Note the significant variation in the peak magnitude of the S21.

The same measurements were carried out for the <100> devices. The measured values of Q as the bias current is swept are shown in Fig. 6. Although the resonant frequencies are different from the <110> devices due to the anisotropy of SCS, similar trends that show a drop in Q were found. Fig. 7 shows the measured frequency responses of the device as the bias current was fine-tuned at around 17mA (highlighted by the red box in Fig. 6).

The previously reported general theory of thermoelastic damping (TED) on SE mode resonator indicates that the TED limited Q is inversely proportional to the resonant frequency [17]. As such, decrease in resonant frequency due to increased joule heating should be accompanied by an inverse increase in Q that is monotonic and gradual. However, we have observed instead an abrupt change in Q, which thus cannot be accounted by the theory. This anomalous behavior, repeatedly observed in multiple experiments, may thus suggest that a more complex mechanism of thermomechanical coupling due to the injected current could be at work.

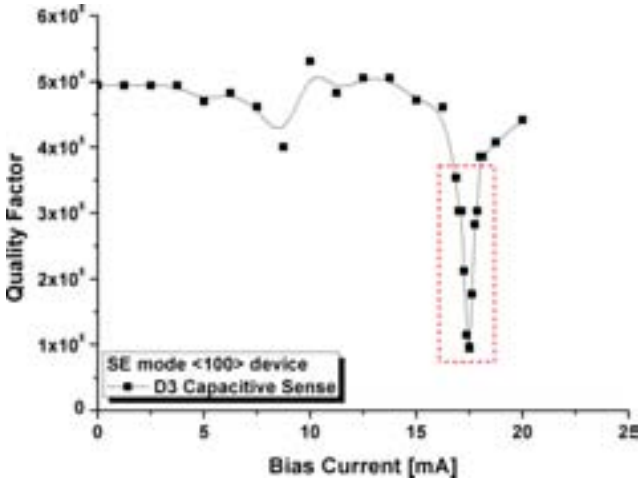

Figure 6. Q vs. bias current profile of <100> axis SE-mode resonators shown for D3 using capacitive sensing. An abrupt drop in Q is detected once again at a particular bias current level.

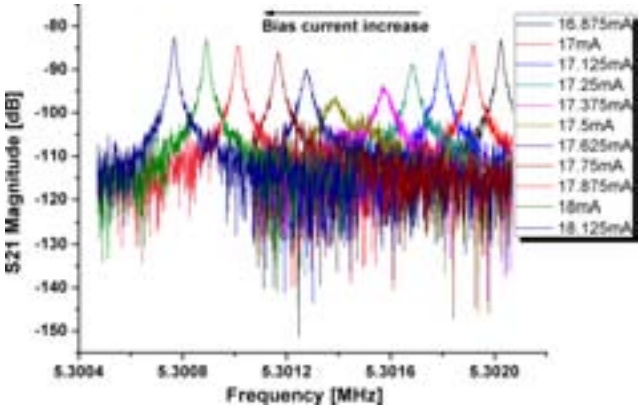

Figure 7. Measured S21 of D3 (capacitive sensing) as bias current is fine-tuned around the Q valley.

IV. Conclusion

An anomalous attenuation of Q caused by changing the DC bias current is detected and reported for the first time in SE mode microresonators. The measured Q drops by nearly an order at a certain current level. This effect is repeatedly found in multiple samples (including devices with both <110> and <100> crystal orientations) using piezoresisitive sensing, and also verified using capacitive sensing to decouple results from any causal relation with the method of piezoresistive sensing. Our study indicates a potential drawback on thermal tuning of resonant frequency since the Q can be influenced by injecting DC current as well. As demonstrated by the results reported herein, injecting a bias current can significantly reduce Q and thus hamper the transduction of the device. Understanding the underlying mechanism as such could prove to be critical for piezoresistively-transduced devices. A solid understanding of the basis of the observed anomaly would allow guidelines for designing piezoresistive resonators so as to avoid damping of Q associated with the injection of bias currents.

***Abstract*—We report on the measurements and modeling of mechanically-coupled arrays of very thin silicon carbide nanowire (SiC NW) nanomechanical resonators. The exceptional mechanical properties and attractive optical properties of SiC make it highly interesting for resonant nanoelectromechanical systems (NEMS), with resonant modes operating at high frequencies that can be exploited for resonance-based signal processing and sensing applications. In this work, we demonstrate arrays consisting of SiC NWs as narrow as 50nm, patterned by electron beam lithography and focused ion beam, on ~50–500nm SiC thin epitaxial layers and polycrystalline layers. We investigate the multimode resonances in mechanically coupled arrays. We show that by controlling the undercut ledges of suspended SiC NW arrays, we can tune the strength of mechanical coupling in such arrays and engineer their multimode resonance characteristics.**

Keywords—nanoelectromechanical systems (NEMS); silicon carbide (SiC); multimode resonance; nanowire; array; mechanical coupling; spatial mapping

I. Introduction

Resonant micro/nanoelectromechanical systems (MEMS & NEMS) have emerged as interesting candidates for components in signal processing, timing, and communication applications, because of their attractive attributes such as high quality (Q) factors, high operating frequencies, and compatibility with manufacturing of integrated circuits (ICs) [1]. Arraying and mechanical coupling in MEMS resonators have been actively pursued for attaining lower insertion losses and motional impedances in realizing devices such as filters and oscillators [2]. Recent filters demonstrated by employing mechanically coupled MEMS resonators and arrays mainly include disk arrays, beam arrays, and plate arrays, where the coupling strength between individual resonators are often determined by the dimensions and stiffness of the coupling beam [3-6].

Exploring mechanical coupling in NEMS resonators are also fundamentally and technologically important. Many cases (such as in many coupled MEMS devices) require that the mechanical coupling stiffness k_c be smaller than the device's own effective stiffness k_{eff}. This means the coupling beams or springs should be sufficiently more compliant (*i.e.*, narrower, in the case of using beams) than the individual resonators to be coupled [3]. As the device dimensions keep shrinking from MEMS to NEMS regime (*e.g.*, nanowires, nanotubes, *etc.*), however, designing and fabricating nanomechanical coupling structures with controllable coupling strength, from compliant (weak coupling) to stiff (strong coupling), become increasingly difficult, due partly to the current practical limitations in nanofabrication. Although nanowire structures have recently been used to realize novel mechanically coupled NEMS devices [7,8], these nanowire coupling structures have been enabled by advanced and expensive lithography techniques. Scaled, smaller NEMS devices may demand other techniques to enable mechanical coupling with controllable strength.

To investigate mechanical coupling in very small NEMS, here we explore the possibility of exploiting undercut ledges that are often automatically created while making suspended NEMS. We use resonant arrays of SiC NWs as the prototype systems. As shown in Fig. 1, a SiC NW array consists of a number of parallel doubly-clamped SiC NWs; the two ledges under the two clamping ports are formed by undercutting in the device release process. By engineering the width of the ledges, the coupling strength between resonators is varied.

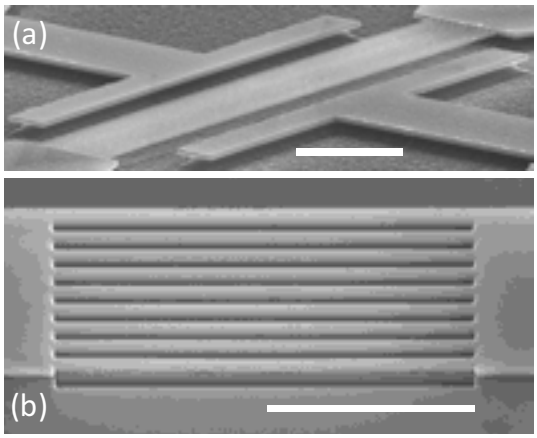

Fig. 1. SEM images of the mechanically coupled doubly-clamped SiC NW arrays fabricated by (a) EBL with metallization, and (b) FIB without metallization. *Scale bars*: (a) 2μm, (b) 10μm.

II. Device Design and Fabrication

A. Design of SiC Nanowires with Ledge Coupling

Mechanically coupled SiC NW arrays are fabricated with two different methods and studied independently. Figure 1a shows the scanning electron microscope (SEM) image of the device fabricated by using electron beam lithography (EBL),

with Al metallization on top (30–50nm thick). Each SiC NW has width of w≈50nm, length L≈10μm, and thickness t≈50nm. Figure 1b shows the SEM image of the device fabricated by focused ion beam (FIB), without metallization, and each SiC NW has w≈500nm, L≈20μm, and t≈500nm.

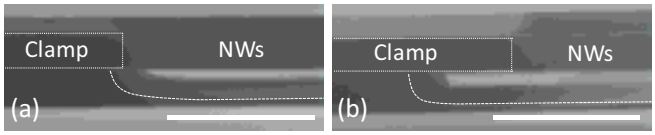

Fig. 2. SEM images of the devices with similar dimensions fabricated by FIB, with (a) narrower ledge, and (b) wider ledge, where the red dashed lines show the undercuts. *Scale bars*: 2μm.

Ledges are suspended portions of the clamping ports, thus they can provide mechanical coupling, because such suspended clamping regions are not infinitely rigid and are susceptible to motions. Figure 2 shows the SEM images of the clamping region of a FIB-enabled device with different ledge widths. The images are taken from devices with similar dimensions except the ledge width: narrower in Fig. 2a and wider in Fig. 2b. When the arrays of SiC NWs are in vibration, the ledges function as mechanical springs that couple the motions of individual NWs in the array. Intuitively, varying the width of the ledge can change the coupling strength.

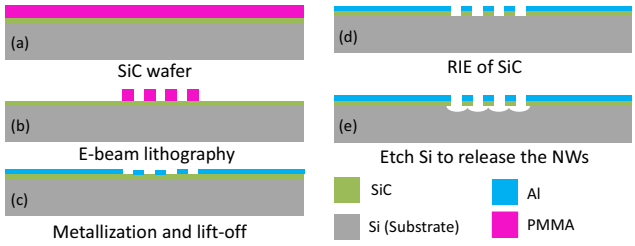

Fig. 3. Simplified fabrication process for the EBL patterned device. (a) Low pressure chemical vapor deposition (LPCVD) of SiC, and spin coating of PMMA, (b) EBL and development, (c) Al deposition and lift-off, (d) Reactive ion etching (RIE) of SiC, and (e) Isotropic etch of Si to release the SiC NWs.

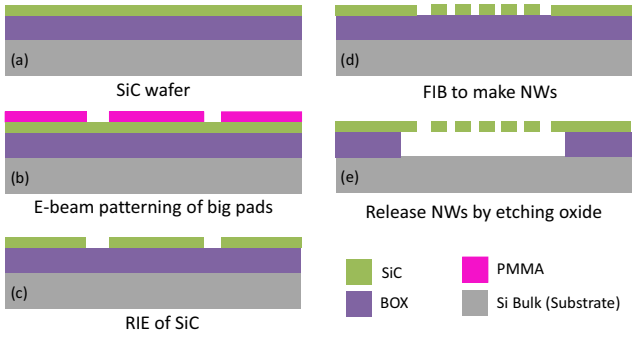

Fig. 4. Simplified fabrication process of using FIB without metallization on a novel SiC/SiO_2/Si platform. (a) LPCVD of SiC, (b) EBL for pads, (c) RIE of SiC, (d) FIB, and (e) Release the SiC NWs by etching the SiO_2 underneath.

B. *Fabrication of the Two Types of SiC Nanowires*

The fabrication of the SiC NW devices is divided into two categories: EBL and FIB. Figure 3 shows the process flow of the EBL patterned devices, while Fig. 4 shows that for the FIB defined devices. In Fig. 3, the SiC epitaxial layer is deposited directly onto Si, and is ~50nm thick. In order to facilitate out-of-plane motions, it would be better that the stiffness in the vertical direction be not higher than that in the lateral direction, thus the widths of the NWs are designed to be similar to their thicknesses. In Fig. 4, the device layer is polycrystalline 3C-SiC with a thickness t≈500nm, deposited on 500nm-thick SiO_2. So the width of the NW is designed to be w≈500nm, similar to the thickness. The width of the ledge could be simply changed by engineering the time of etching the Si (Fig. 3) or etching the SiO_2 (Fig. 4). This method provides great convenience and flexibility in tuning the strength of mechanical coupling.

III. Experimental Results

A. *Measurement System*

Detection of thermomechanical resonances of the SiC NWs is performed by using an optical interferometry with a 632.8nm He-Ne laser, as illustrated in Fig. 5. The optical signal is converted into electrical signal with a photodetector, and fed to a spectrum analyzer. Since the NWs in an array are close to each other, it is necessary to have a very small spot size to distinguish between the NWs. With the beam expander, the spot size has been reduced to ~1μm, which facilitates spatial mapping of the array of 500nm-wide NWs. The motorized X-Y stage moves the device relative to the laser spot.

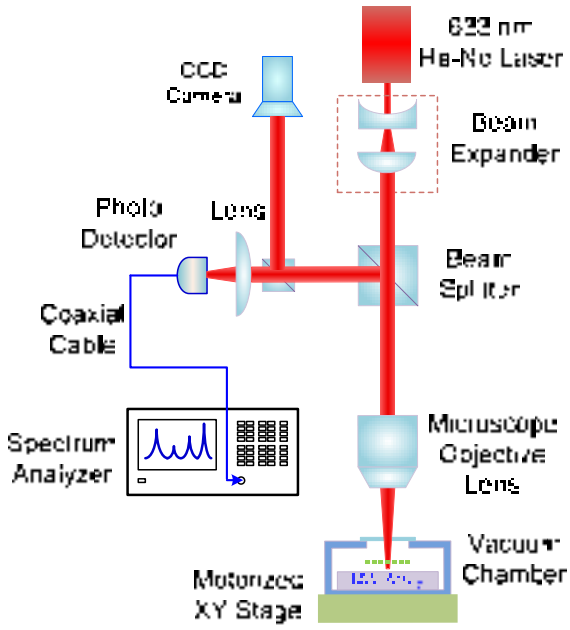

Fig. 5. Illustration of the laser interferometry system for detecting and mapping multimode resonances in the mechanically coupled arrays of SiC nanowires.

B. *Results from the EBL Device*

Figure 6 shows the measured multimode response from an array of 10 SiC NWs with individual NW dimensions L×w×t≈10μm×50nm×50nm. Sensitive detection of mechanical displacement down to the levels of Brownian motions is achieved in vacuum and room temperature. The displacement sensitivity is better than 1pm/√Hz. The resonances are shown

in Fig. 6 insets, where the fitting to the resonances shows that each mode has different *Q*. The laser spot is much bigger than the NW width (50nm) in this device. The measured resonances represent the coupled, collective motions of the arrayed NWs.

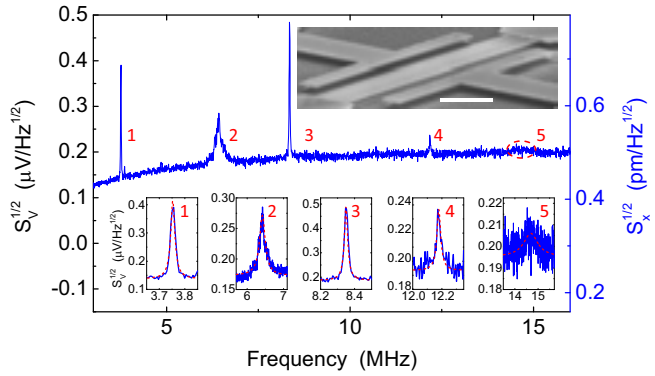

Fig. 6. Resonance spectrum measured from a SiC NW array of *N*=10. *Bottom Insets*: first 5 measured resonances (1–5) with fitting (red dashed lines). *Top Inset*: SEM image of the device fabricated by EBL. *Scale bar*: 2μm.

In order to characterize the mode shapes of the SiC NW array resonators, finite element modeling (FEM) has been performed using COMSOL. Figure 7 shows the mode shapes of the first 6 resonances with very close frequencies. The simulated device consists of 10 SiC NWs, with similar geometry to the real device, and the ledge effects are included. Mechanical coupling (via the clamping ledge) suppresses the natural modes of each individual SiC NWs, while enabling the system to exhibit new collective, coupled resonance modes.

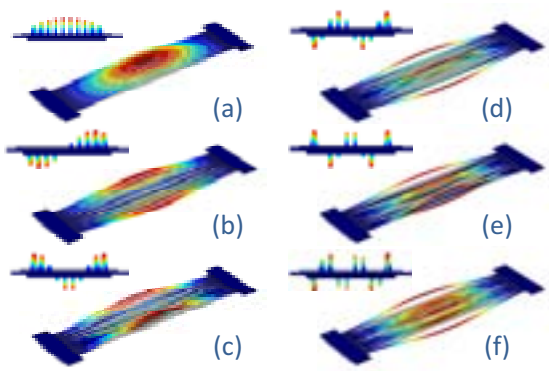

Fig. 7. (a)–(f) COMSOL simulation of the first 6 coupled modes of the array of 10 SiC NWs. *Insets*: cross-section views of the computed mode shapes.

C. *Results from the FIB Device with Narrow Coupling Ledge*

To observe the effect of the coupling ledge on the SiC NW array resonance modes, NW arrays with similar dimensions, (L×w×t≈20μm×500nm×500nm), but different ledge widths are fabricated and measured. The width of the ledge is narrow for the device measured in Fig. 8, which can be confirmed with the SEM image in the top left inset of Fig. 8a. Figure 8a shows two measured resonance spectra from two locations (indicated in the top right inset in Fig. 8a). The blue spectrum shows 3 resonances, while the red curve shows 4, and the resonance frequencies are different. The resonance amplitudes of the two resonance spectra are also different. To determine the existence of collective resonance modes, we perform mode shape mapping. This is achieved by scanning the laser spot across the NW array while recording the resonance spectrum at each position. Figure 8a bottom left inset shows the background (mapping results off any resonance), and the resulting map clearly shows the difference in the reflectivity of the surfaces, with blue area in the middle being the device area (lower reflectance). Figure 9 shows the mapping result of the four resonances, and no clear collective resonance mode is observed, presumably due to the weak coupling. Fig. 8b shows the resonance spectrum at another position, and fitting to the peaks show similar mechanical *Qs* of ~1200 and ~1250.

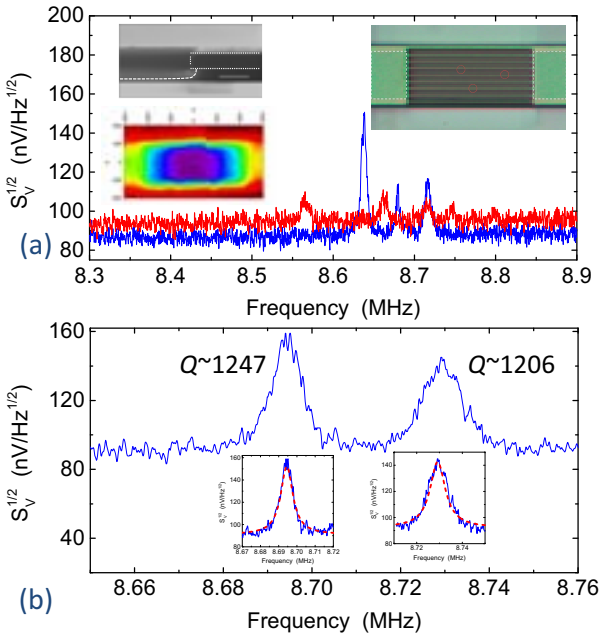

Fig. 8. Resonance spectra measured from a SiC NW array of *N*=9 patterned by FIB. (a) Data from two locations of the spots. *Top Left Inset:* SEM image of the device ledge (*Scale bar*: 1μm). *Lower Left Inset*: mapping background. *Top Right Inset*: optical image with the laser spot positions. (b) Data from the third spot location. *Insets*: fitting to the resonances.

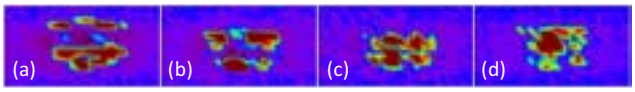

Fig. 9. (a)–(d) Spatial mapping results of the mode shapes of 4 different resonance modes shown in Fig. 8a (red curve), from low to high frequency.

D. *Results from the FIB Device with Wide Coupling Ledge*

Figure 10 shows the measured resonance spectra from another array device with similar dimensions but a wider ledge (Fig. 10a right inset). The resonance spectra show more resonance modes. We have performed spatial mapping of the mode shapes for up to 7 coupled resonance modes, as demonstrated in Fig. 11. The mapping results show that the wider ledge provides stronger coupling for this array of SiC NWs. The *Qs* of the resonances range from ~410 to ~550 (Fig. 10b), lower than the result in Fig. 8, suggesting that the wider ledge makes softer clamp, and likely have introduced more dissipation. These results clearly show that by engineering the width of the ledge, the coupling can be tuned.

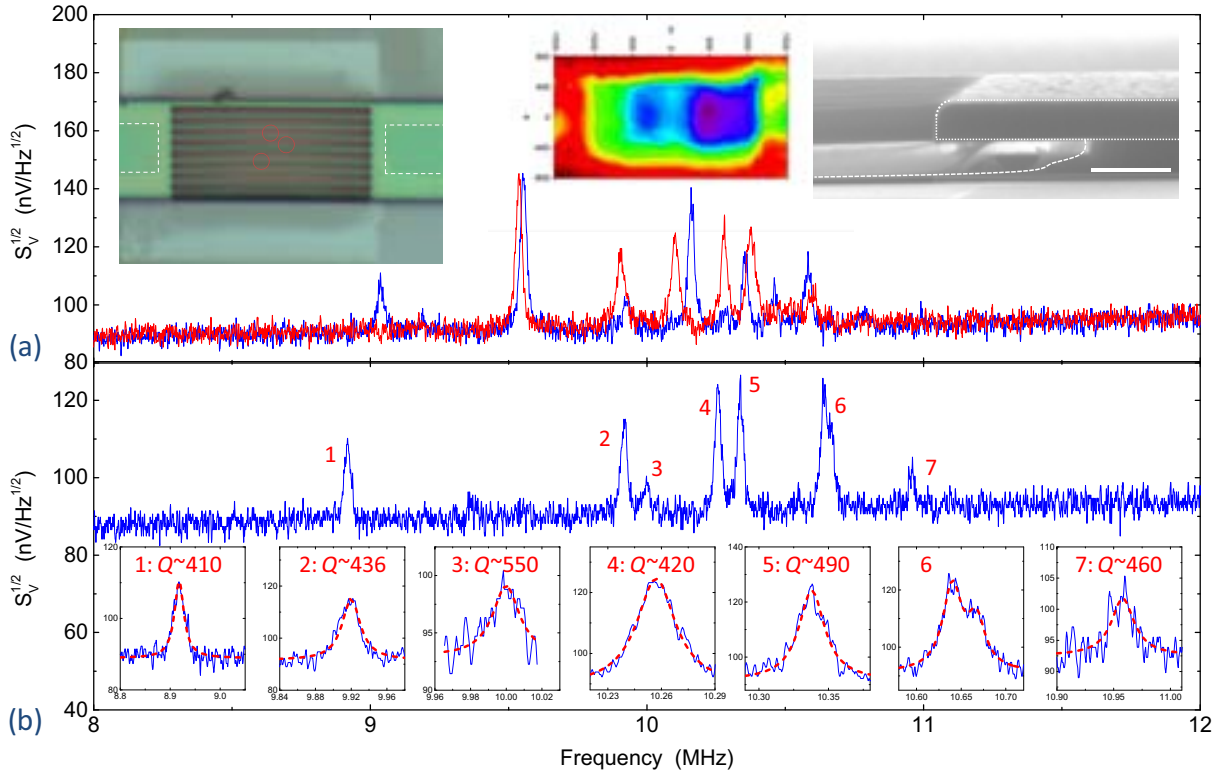

Fig. 10. Resonance spectra measured from an array device with wider ledge. (a) Data from two laser spot locations. *Left Inset*: optical image showing the laser spot positions. *Middle Inset:* mapping background. *Right Inset*: SEM image of the ledge (*Scale bar*: 1μm). (b) At another spot. *Insets*: fitting to the 7 resonances.

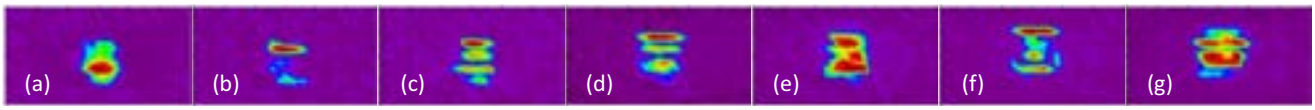

Fig. 11. (a)–(g) Optical mapping of the mode shapes for the 7 different resonance modes shown in Fig. 10b, from low to high frequency.

IV. Conclusions

Mechanical coupling among individual SiC NWs forces the arrayed system to exhibit collective resonance modes. Using laser interferometry, multimode thermomechanical resonances of high frequency resonant SiC NW arrays have been examined. Through mapping of the mode shapes of multimode resonances from devices with different ledges of different sizes, the influences of mechanical coupling in the arrays have been explored. Given the excellent mechanical, optical, chemical and thermal properties of SiC, these arrayed SiC nanodevices could be particularly interesting for sensing and signal processing applications in mesoscopic systems. The array size (N, number of NWs) can be varied to study new phenomena in large-N systems, from chaos to synchronization.

Abstract—**Voltage controlled crystal oscillators (VCXO) using CMOS varactors are investigated. The varactor is operated in the so-called inversion mode (I-Mode) with source and drain bounded together. Its capacitance is evaluated by the HSPICS-Fourier methodology. The performances of capacitance under small-signal and large-signal operations are classified. Then the frequency tuning and the related phase noise are explored. It is found that the larger the tuning coefficient has, the worse the phase noise has in I-mode varactor. The chip is fabricated by the TSMC 0.35um CMOS process. The total area including pad is 1.358 × 1.350 mm^2 and the current consumption in the core circuit is 300uA.**

Keywords- VCXO, Crystal Oscillator, Varactor, and Frequency Control, Inversion-mode

I. INTRODUCTION (HEADING 1)

Voltage controlled crystal oscillator (VCXO) is a key module in modern communication. It acts as a reference frequency in the cellular phone. [1, 2] It can also be used in the timing synchronization and clock recovery. In these applications the stringent request of phase noise is needed. CMOS process, which has the advantages of low cost and high integration, is now verified to be feasible for communication devices. The process possesses many kinds of CMOS varactor, which is used for tuning the frequency. Recently, the varactor under large-signal operation is intensively studied. [3-6] Depending on the fabrication capability, the inversion-mode (I-mode) varactor is investigated here. It has normally a steep characteristic in the C-V curve. This implies a step jump in the frequency tuning around the steep area. However, no obvious jump is observed in the measurement. It deserves us to explore intensively the basis. In this study the role of I-mode varactor through the standard process on the performance of frequency tuning and phase noise in crystal oscillators. The phase noise and tuning coefficient at different bias points are also studied. The design goal of VCXO is at 26MHz and has tuning sensitivity 25ppm/pF under loading capacitance 8pF. The parameters of the crystal are as follows: series resonant frequency fs=25.9935MHz, series capacitance Cs=4.588fF, parallel capacitance Co=1.421pF, and series resistance Rs=10Ω in 3.2×2.5mm^2 package.

The designs of varactor and VCXO are presented in section II. In section III, the performances are discussed. The experiment results are presented. Conclusions are made in section IV.

II. DESIGN OF VCXO

The schematic of the VCXO in Pierce configuration is shown in Fig. 1. [7] According to the Leeson's model, phase noise is inversely proportional to signal power. In our design, the magnitude of the signal is maximized to have rail to rail swing. The negative resistance seen into X_{in} and X_{out} by the crystal is chosen 10 times the crystal series resistance under the trade off among power, fast starting, and rail to rail swing. The aspect ratio Length/Width for each transistor is listed in the inset. m is the finger number of the gate. As the series resistance is overcome by negative resistance, the oscillation starts. According to our observation the rail to rail swing is achieved as the ratio of negative resistance to Rs is larger than seven times. The dimension of the device is listed in the table. The current consumption of the core circuit is about 300uA for low power applications. Multiple switches in capacitor bank are provided for precision control. The cascade M2 is used to reduce the effect from bias variation.

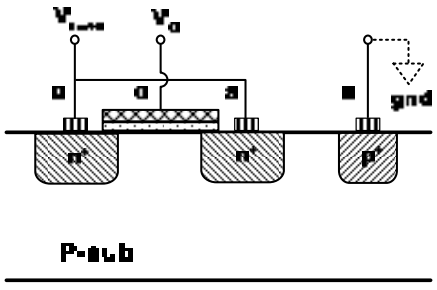
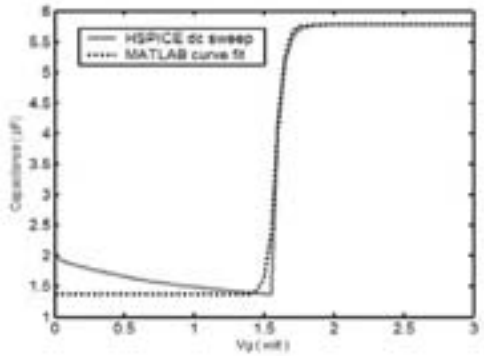
A. *I-mode nMOS Varactor*

Here two nMOS varactor M_{var1} and M_{var2} are used for positive voltage tuning. The structures are shown in Fig. 2a. For I-mode operation the drain and source are connected together and substrate is grounded. As the voltage Vgd>Vth, The channel beneath the gate is in inverted. The capacitance is equal to oxide layer capacitance Cox. As Vgd is decreased, the carrier in the channel is depleted. When Vgd=0, the carrier is fully depleted and the capacitance is reduced to Cox in series with Cj junction capacitance between depleted channel and N+ contact. Only strong inversion and depletion are functioned as Vgd is swept. The channel length is traded off between tuning ratio and quality factor. [6] It is suggested L= $L_{\min} \sim 3L\min$. Width is chosen from the magnitude of the capacitance. Multi-fingers in the gate is used to reduce the parasitic from the gate to source (drain) overlap. The dimension of width, channel length, and finger number under the goal of wide tuning and low phase noise are chosen as $W \times L \times m = 30\mu \times 1\mu \times 40$, respectively. The process is TSMC standard 0.35um mixed-mode with 2P4M and Polycide. For convenience, the variation of capacitance as a function V_g is shown in Fig. 2b at V_{tune}=0.8V. A nearly step change occurs around V_g=1.5V~1.6V. The ratio C_{max}/C_{min} of capacitance under small-signal is 5.77pF/1.38pF, which is obtained via spice model BSIM3.1.



(a)



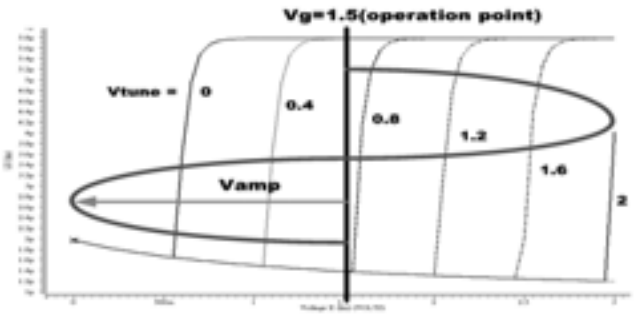
(b)

Fig. 2. NMOS varactor in (a) Inversion mode connection and (b) Variation of capacitance with V_G at V_{tune}=0.8V

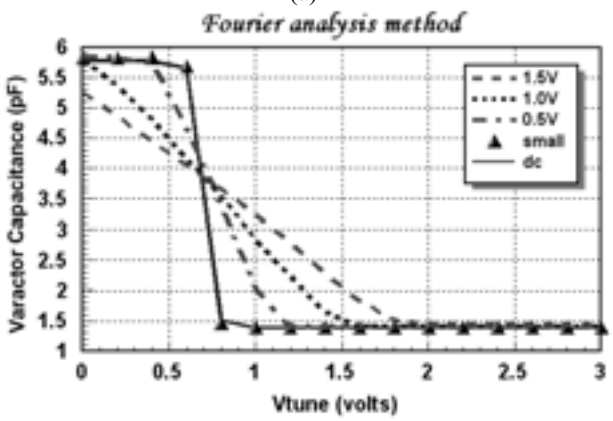
B. *Large Signal Effective Capacitance*

Actually, the gate is biased at $V_g=V_{DD}/2$=1.5V and V_{tune} is changed from zero to V_{DD} within the oscillator. For reference, the capacitance under small-signal prediction is redrawn in Fig. 3a at various V_{tune}. The ac swing at the gate node is map on the figure. After power-on, however, V_g swings between zero and 3V so that the varactor is under large-signal operation. It encounters different modes of strong inversion and depletion. The partition depends on the setting of V_{tune} voltage. At V_{tune}=0.8V, the transition is located near Vg=1.5V. It results in the equal partition in the high and low value. The average value is in the middle of two limits. When the V_{tune} is set above 2V, the swing encounters only at low limit, so that the average is fixed at low limit. On the contrary, it has high limit as V_{tune} is set to zero voltage.

The effective value of capacitance is predicted from Fourier analysis of I-V waveform. A sinusoidal swing voltage is applied to the biased varactor and the current waveform is found from SPICE. From the ratio of fundamental voltage to current waveform the effective capacitance and resistance are obtained. The effective capacitance is monotonically decreased as V_{tune} is increased. More importantly, it reveals a linear shape with less steep in slope as the ac swing is increased as illustrated in Fig. 3b. Therefore, the tuning range is increased as ac swing is increased. At V_{tune}=0.8V, the transition is located near Vg=1.5V. It results in the equal partition in the high and low value. Hence the V_{tune}=0.8V is at the center of the tuning. When the V_{tune} is set above 2V, the swing encounters only at low limit, so that the effective capacitance is fixed and frequency change is not allowed.



(a)



(b)

Fig. 3 (a) Instantaneous capacitance under large signal swing and (b) effective capacitance under various swings in I-mode varactor

III. Measurement Results

A. Frequency Prediction

The photo of the VCXO chip is shown in Fig. 4. The power supply is V_{DD}=3V. The tuning performances are shown in Fig. 5. The linear tuning range in I-mode occurs with V_{tune} from zero to 2V. Above 2V the tuning is almost fixed as predicted from the effective capacitance shown in Fig. 3b. The frequency deviation is from -30 to +21ppm. The maximal tuning coefficient occurs at V_{tune}=0.8V, which is at center of the linear tuning range, and is equal to 33ppm/V. The current consumption in core circuit is about 300uA and total current is 713uA.

B. Phase Noise calculation

Phase noises at different bias point are also examined. The measurements are performed with a Europtest PN9000 Phase Noise Test System with delay-line technique, which has the system noise floor around -152dBc. The performances are shown in Fig. 6a. In each figure two curves corresponding to the best and worst cases with noise level -100 and -90 dBc/Hz, respectively, at offset frequency 10Hz are illustrated. The worst case happens at the middle tuning V_{tune}=0.8V, which has maximal tuning sensitivity. The performance is better at both ends V_{tune}=0V or 3V. The difference is mainly from the tuning sensitivity. The reasons are, referred to Fig. 3a, the swing is almost in inversion region with V_{tune}=0V, where the capacitance appears as fixed Cox in I-mode. On the contrary, in the high end, the swing is almost in the depletion region V_{tune}=3V, where capacitance appears as fixed junction capacitance Cj.

The slope of phase noise near the carrier appears as $1/f^3$. It is evidenced by the 30dB difference at 10Hz or 100Hz offset as shown in Fig. 6b. The noise floor far away from the carrier is -150dBc/Hz. It might be limited by the system floor.

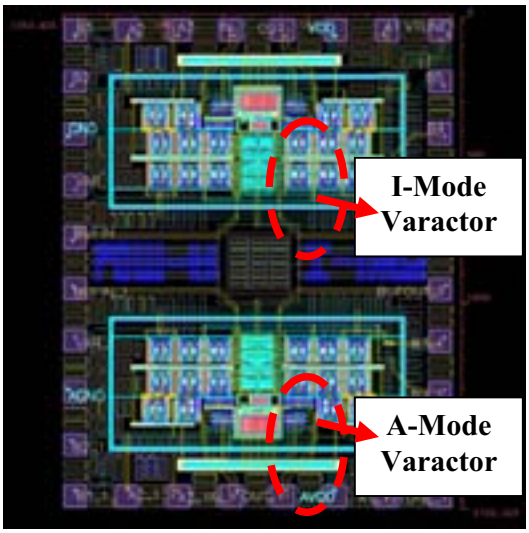


Fig. 4 Chip photograph of the VCXO

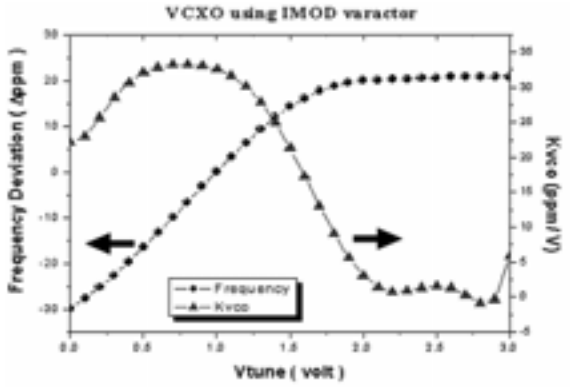

Fig. 5 Tuning capability in VCXO with I-mode varactor

As the tuning voltage is tuned at the center V_{tune}=0.8V, different regions are encountered in each swing, the noise is degraded. According to Leeson's formula, the phase noise can be described as

$$L(f_m)=10\log\left\{\left(\frac{f_o}{2Qf_m}\right)^2\left[\frac{FkT}{2P_s}\left(1+\frac{f_c}{f_m}\right)\right]+\frac{1}{2}\left(\frac{K_{vco}V_m}{2f_m}\right)^2\right\}$$

The quality factor of the tank mainly affects the $1/f_m^2$ region. So does the modulation noise voltage Vm across the varactor's terminals. It is conjectured that, for $1/f_m^3$ region, the variation of capacitance of varactor's C-V behavior plays an important role. [8] In the I-mode the lowest phase noise happens as V_{tune} is larger than 2V, in which all the swing falls in the depletion region with nearly fixed capacitance. The up-conversion effect of flicker noise is reduced. As expected, the harmonics in the I-mode is much stronger because the sharper transition from depletion to inversion region.

IV. Conclusions

In this work, two VCXOs at 26MHz are implemented by the TSMC standard 2P4M 0.35um CMOS process. The varactor is designed for I-mode operation. The effective capacitance in large-signal operation is indicated to have wider linear range. The performances of phase noise and tuning range are deeply discussed. The maximum tuning coefficient with 10dB worse in phase noise occurs at the middle tuning. The mechanism of degraded phase noise seems to be due to the channel transition between depletion and inversion.

Low Phase Noise Microwave Analog Optical Link Performance Study for High Dynamic Environment Platform

LESAGE Jean-Marc, LE PIPEC Mathieu
DGA – Information Superiority,
DGA, French MoD, Bruz,
France
jean-marc.lesage@dga.defense.gouv.fr

***Abstract*—Distribution of very low phase noise and low spurious microwave Local Oscillator (LO) is needed for most of the radar or electronic warfare applications. In this paper we study the capability to optically carry low phase noise LO, thanks to a directly-modulated optical link, while subjected to severe environmental conditions. First the optical link is compared to a coaxial cable link in terms of additive phase noise: subsequently the absolute amplitude and phase noise under random vibration are compared. It should be noticed that even in case of a wide band optical link, the phase noise floor difference between optical and coaxial cable is small even for short distance links. Secondly, the absolute amplitude and phase noise of the optical and coaxial cable link are measured with the entire optical link or only with some components of the link (10 GHz LO, optical single mode fiber (SMF), laser and photodiode) under random vibration. The phase noise degradation is almost the same when the optical or the coaxial link is under vibration and the main degradation is always due to the Local Oscillator whatever the technology is (OEO: Opto-Electronic Oscillator or traditional quartz oscillator). Some ways of improvement of optical link g-sensitivity that can be useful for OEO will be discussed. Thanks to recent experimentations done by DGA, it has been shown that very low phase noise microwave LO signals can be carried on optical link without any phase noise degradation due to the link while subjected to random vibration.**

Keywords—Opto-Electronic Oscillator; low phase noise microwave optical link ; low-g sensitivity, random vibration

I. INTRODUCTION

Nowadays, optical fibers are widely used for high speed digital link. Although optical components designed for telecommunication system are more and more efficient, they are not yet convenient for analog microwave optical link in future electronic warfare system because of the need of large bandwidth, high linearity and low noise required. Nevertheless optical links are very interesting in order to replace coaxial cable link for reasons of lower weight and cost, facility for installation, and insensitivity to electromagnetic environment.

French Mod leads a funding program in order to develop state-of-the-art microwave optical components. The links designed in this frame are very convenient because they show high-rejection of the second harmonic (H2), third harmonic (H3) and Intermodulation (IM3) over 20 GHz bandwidth.

These links can also be used for local oscillator (LO) distribution if they also show low phase noise performances. Moreover, if the link is used for airborne system, the low noise performance must not be deteriorated while subjected to high dynamic environment as for example random vibration.

In this article is firstly compared the performance of a traditional microwave cable link with a direct-modulated optical link. Secondly, these two types of links are compared under typical airborne random vibration. Finally, we extract from these experiments all the information in order to reduce the g-sensitivity of opto-electronic oscillator (OEO) because the local oscillator, whatever the technology used, remains the most sensitive component to mechanical vibration. Although opto-electronic oscillator is the most convenient technology to use in conjunction with optical microwave link, the OEO g-sensitivity must be reduced.

II. DESIGN AND PERFORMANCE OF THE STUDIED MICROWAVE OPTICAL LINK

The designed microwave direct-modulated optical link use Distributed Feed-Back (DFB) laser diode and Modified Unilateral Travelled carried (MUTC) Photodiode at 1.55 µm. The optical power of the laser is about 15 mW for a current polarization of 150 mA. The laser Relative Intensity Noise (*RIN*) floor is about - 153 dBc/Hz. The photodiode responsivity (S_{PD}) is about 0.8 A/W.

Firstly, the phase noise floor (Signal to Noise Ratio – SNR) of the otpical link is predicted thanks to a classical analytic model [1]:

$$SNR = 2\,(S_{laser} + S_{shot} + S_{th})/\,(P_m^2.S_{PD}^2.m^2) \qquad (1)$$

with P_m the fiber output optical power, m the index modulation and S_{laser} the laser amplitude noise, S_{shot} the photodiode shot noise, S_{th} the photodiode thermal noise as described as follows:

$$S_{laser} = P_m^2.S_{PD}^2.RIN \qquad (2)$$

$$S_{shot} = 2.q.S_{PD.}.\ P_m \quad (3)$$

$$S_{th} = 4.k_B.T/R \quad (4)$$

With k_B the Boltzmann's constant, q the electron charge and R the load resistance of the photodiode.

The predicted phase noise floor is about - 150 dBc/Hz when the microwave input power is at the 1 dB compression point of the link. S_{laser} mainly participate to the noise floor budget because the link is designed to be highly linear and to show large electrical dynamic range. So high power laser with low *RIN* must be used [2]. This is the most suited design for both optical RF and LO distribution.

Additive phase noise measurements are then performed in order to verify the performance of the optical link at different microwave input powers around the 1 dB compression point. The length of the optical fiber is 20 meters (with few meters more to connect the laser and photodiode) and the input microwave frequency is 10 GHz. The 10 GHz LO must be carefully chosen in order to characterize accurately the optical link added noise. A commercial synthesizer doesn't suit to added noise measurement because its amplitude and phase noise level are too high. Amplitude noise must be very low otherwise the phase quadrature doesn't show the ideal amplitude noise rejection. Phase noise must be low because of the 20 meters delay that reduces the phase noise attenuation of the source due to the quadrature. In all the experiments is used a COEO [3] which is state-of-the-art 10 GHz low phase noise oscillator. This is the reason why we show rejected relaxation peaks on the added and absolute phase noise measurements.

As shown in Fig. 1 and as expected, the optimal input power is the P1dB of the optical link and when the input power is increased or decreased, the phase noise floor is deteriorated.

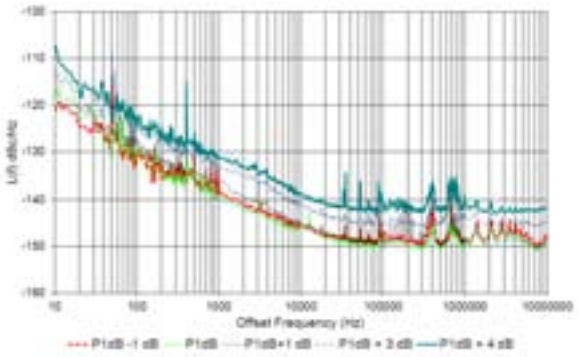

Fig. 1. Added phase noise (dBc/Hz) of the link when the input microwave power is shifted around the P1dB of the optical link

III. COMPARISON BETWEEN CABLE LINK AND OPTICAL LINK

A. Laboratory performance

Firstly are compared the two links when the input power is equal to the 1 dB compression of the optical link. The local oscillator (LO) is the same COEO used in added phase noise characterizations. The 20 meters cable losses are about 20 dB and the microwave link losses are near 30 dB because of the wide band covered by the optical link (20 GHz). So the same pre-amplifier before the links and the same amplifiers after the links are used with attenuators in order to maintain the same microwave output level in respect to Friis Formula. It is important to reach a high power output level in order to use the LO in a conversion frequency system for example. The comparison of the absolute phase noise before and after the links for input power at the P1dB is shown on Fig. 2.

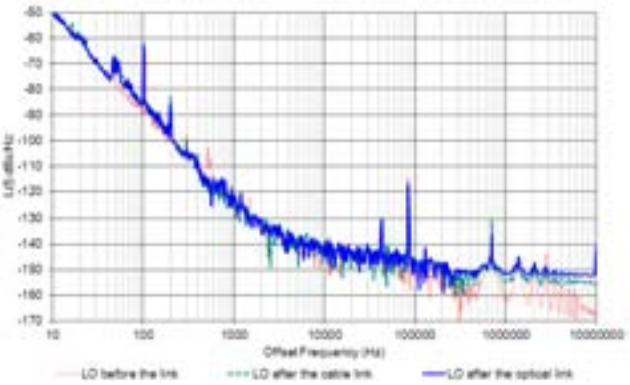

Fig. 2. Absolute phase noise of the LO only before the links, LO after the cable link and after the optical link

Concerning the phase noise floor, there is a slight difference lower than 3 dB, giving a short advantage to the coaxial cable. When no pre-amplifier is used, the input power level is decreased by 15 dB, the SNR degradation between cable and optical link increases by 5 dB. We conclude that even for low input power, the phase noise floor degradation due to the optical link is weak and acceptable for LO distribution. Of course, when the length of the link increases, the SNR of the optical link will be better than the one of the coaxial cable link.

In order to improve the noise floor, links losses have to be reduced thanks to laser and photodiode impedance matching. The bandwidth will be reduced to a few GHz which is always convenient for frequency agile LO distribution.

B. Performances under vibration

We compare the absolute phase noise of the LO at the output of the tested links when the cable or the optical fiber only or the all optical link (laser, fiber and photodiode) are under vibration. It should be noticed that no particular precautions are taken for the positioning of the classical coaxial low loss microwave cable and the classical Single Mode Fiber (SMF) in order to be representative of an airborne installation. The experiment is repeated many times as depicted in Fig.3.

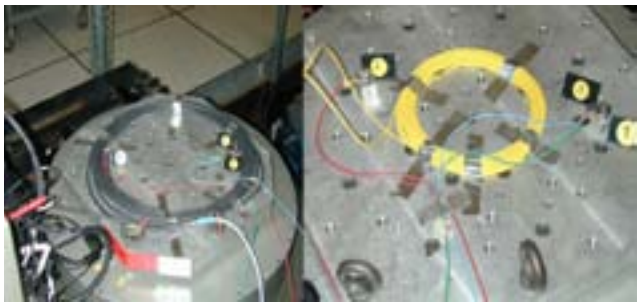

Fig. 3. Pictures of the cable and fiber vibration mounting conditions

The level of random vibration is of a few g r.m.s with typical airborne spectrum. The results are shown in Fig. 4 where the phase noise degradation is equivalent between the cable and the fiber.

The deterioration is also increased when the laser and photodiode are under vibration. But all these phase noise deteriorations are less important than the one of the LO under vibration. The COEO [3], which plays the role of LO, does not use mechanical suspension and his g-sensitivity is about few 10^{-9}/g. Whatever the used LO technology, the LO is obviously the most sensitive component of a system subjected to vibration.

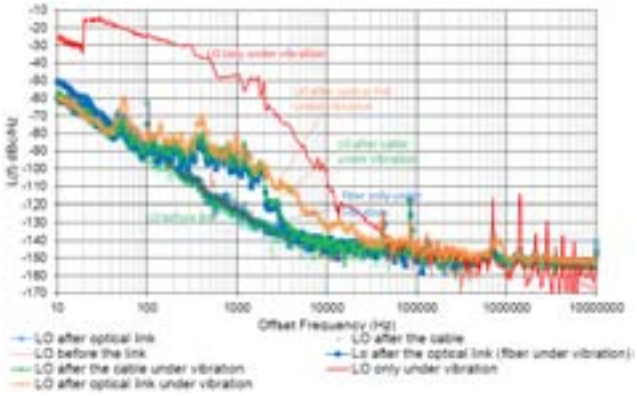

Fig. 4. Absolute phase noise (dBc.Hz) of the optical link and cable link under vibration

IV. APPLICATION TO OPTO-ELECTRONIC OSCILLATOR

As the tested optical link shows very low phase noise performance, an OEO has been built using the optical link including RF amplifier with a gain of 34 dB in order to compensate the optical link losses and narrowband filter in order to select the 10 GHz resonance frequency. The 20 meters fiber is used first and then replaced by a 1.5 kilometers one, the performances are shown in Fig. 5. The phase noise performance fits to the well-known Leeson analytical model. The 1/f added noise of the optical link with microwave amplifier is converted into $1/f^3$ absolute phase noise when the offset frequency is inferior to the Leeson frequency and the absolute noise floor is equal to the optical link SNR.

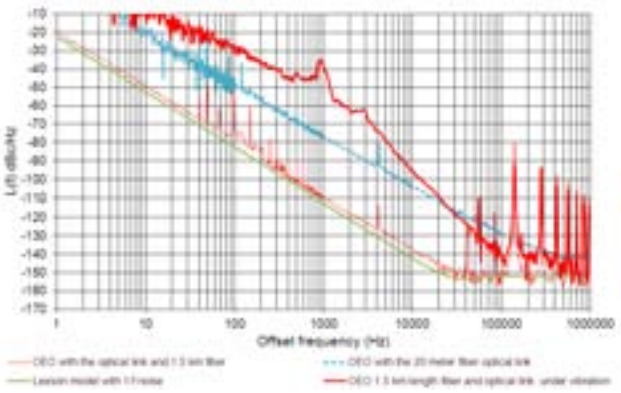

Fig. 5. Measured phase noise (dBc/Hz) of the optical electronic oscillator built with the studied optical link and 20 meters and 1.5 km fiber at 10 GHz

Although the phase noise deterioration of the optical link caused by vibration is weak (Fig4), it will become important in EOE application. Unfortunately, small phase fluctuations inside the loop directly map to larger frequency fluctuations at the output of the oscillator, thanks to Leeson model. We measure the g-sensitivity of our 1.5 km OEO at about few 10^{-9}/g. So we studied how the phase noise degradation due to the vibration can be reduced.

Firstly, we have to deal with the sensitivity of the optical fiber under vibration. Active compensation of the vibration is possible. As it is shown in [4], 1D compensation is efficient, but today, 3D compensation has not been demonstrated to our knowledge. Secondly, amplitude noise contribution may be taken into account. For an optical link with high input power (around the 1 dB compression point), the phase noise limitation is mainly due to the laser *RIN* (as predicted in the analytical model of the optical link SNR). Then optical link amplitude noise measurements under random vibration are also performed. The results are shown in Fig.6. The AM noise degradation due to the vibration must not be neglected in order to reduce the phase noise sensitivity to vibration. For instance, the photodiode must be used with an input power where the amplitude to phase noise conversion is the smallest.

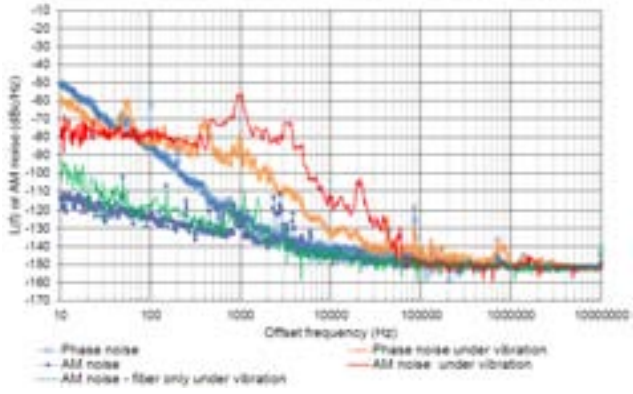

Fig. 6. Absolute phase noise and amplitude noise (dBc/Hz) of the optical link under vibration

IV. CONCLUSION AND PERSPECTIVES

Direct modulated microwave optical link designed in the frame of the DGA-funded project "ORGE" has been successfully tested in order to carry low noise LO. The noise performance is slightly degraded compared to coaxial cable link. Thanks to impedance matching of the laser and photodiode, the optical link will be appropriate to low noise microwave LO distribution.

Then, while they are subjected to random vibration, the optical link and the cable link show similar performances. Replacement of cable with optical link in airborne system can be carried out.

But when the optical link loop is closed thanks to microwave amplifier and narrowband filter in order to give a very low phase noise OEO, the phase fluctuations due to the vibration lead to larger phase noise degradation. We evaluated the g-sensitivity of state-of-the-art OEO at few $10^{-9}/g$, as much as traditional quartz oscillator without any suspension system.

In order to reduce it, on the first hand, the phase noise degradation due to the phase fluctuations of the optical fiber under vibration has to be limited or compensated thanks to 3D-accelerometer and retroaction, thanks to phase-shifter in the loop [4] for example. On the second hand, we have to keep in mind the amplitude noise degradation due to vibration.

Then, as the optical link SNR is limited by *RIN*, we may use a higher optical power laser with lower *RIN* with a photodiode at an input power where the amplitude to phase noise conversion is the smallest. The phase noise measurements of this new optical link and OEO using this link will be done under vibration soon.

ACKNOWLEDGMENT

The directly modulated optical link, designed by TSA (Thales Systemes Aéroportés) in the frame of the DGA-funded project ORGE, use semiconductor DFB laser diode and MUTC photodiode, designed by 3-5 Lab and packaged by 3S Photonics.

The authors thank also collaborators from DGA MI/MC, DGA MI/MAN/CVO and DGA IP for assistance and useful discussions.

***Abstract*—The accuracy of the Three-Cornered Hat method is discussed when not simultaneously applied to the determination of the contribution on short term frequency stability performed on ultra-stable quartz oscillators.**

Keywords—short term stability; ultra-stable Quartz; oscillator; non-simultaneity

I. INTRODUCTION

The best frequency stability ever measured on a quartz crystal oscillator was recently obtained.

This new Boitiers à Vieillissement Amélioré (BVA) oscillator has an estimated flicker frequency modulation (FFM) floor as lower as 2.5×10^{-14} at 5 MHz [1,2]. It leads to a significant step. To achieve such a low FFM floor, we assume that best resonators are fully characterized [3] and packed. It was obtained using a double rotated SC-cut quartz with low phase noise, good aging characteristics and low sensitivity to drive level dependency placed in appropriate thermostat in the first prototype of a double oven-controlled crystal oscillator (OCXO) realized in Switzerland by Oscilloquartz company.

We checked that the ultra-stable signal delivered by such a BVA oscillator can be distributed without any degradation of its short term stability [4]. It has to be underlined that precise measurements on oscillators were carefully performed at the Time and Frequency department in Prague in very favorable environmental conditions and deduced by three cornered hat analysis [5,6,7,8] on a dedicated system [9]. Our process for short term is analogous to what occurs for long term frequency stability characterization, but could provide questionably a precise determination of FFM floor.

The analysis proceeds by matching the theoretical and the best experimental curves not exactly simultaneously. In this paper we discuss the accuracy of our method.

II. EXPERIMENTAL RESULTS

A. State-of-the-art oscillator design

The best resonator was manufactured by Oscilloquartz Company in 2010. It was placed in appropriate thermostat [10] in the first prototype of an Oven-controlled crystal oscillator (OCXO) called 8607-C. It consists in a new BVA type oscillator where electrodes are deposited not on the resonator itself but on inner sides of two condenser discs made of adjacent slices of the quartz from the same bar, forming a three-layer sandwich with no stress between the electrodes and the vibrating element. Turnover temperature of the resonator is 88.6°C. Unloaded Q factor is 2.6×10^6. Regarding experimental phase noise measurements, QL can be given by the 1.6 Hz intercept point between 1/f slope (phase flicker noise) and $1/f^3$ slope (frequency flicker noise). $QL = 1.6 \times 10^6$.

Thermostats are especially developed by Oscilloquartz with double oven for this new model, with drastic optimization. Electronics circuits are entirely renewed to reduce contribution of the 1/f noise of the amplification elements [11], considering the goal is to decrease the 1/to curve in the time domain, where to is the integration time.

B. Frequency stability measurements

Determination of the short term frequency stability of the new oscillator is performed thanks to a Dual Mixer Time Difference Multiplication (DMTDM) [9] based 'IPE3' system developed at the Institute of Photonics and Electronics (IPE) in Prague, with a beat frequency of 5 Hz, where each measure gives 5,000 samples separated by a basic 200 ms integration time [2]. Frequency stability limit of the IPE3 bench is determined by rejecting one BVA Oscillator. Then it is possible to deduce a flicker phase of respectively 8×10^{-15} and 1.1×10^{-15} at 1 s and 13 s. Contribution of the instrumentation can be negligible between 0.2 s and 100 s where the FFM floor is expected. To determine the frequency stability of the 8607-C prototype, it is measured with two other ultra stable BVA oscillators, respectively serial number 543 and 567. The

frequency stability curves are obtained for each pair of oscillators. The contribution of each oscillator is deduced for every measure performed on each pair by the 3 cornered hat analysis [6]. One can note that, even if the two oscillators referenced 543 and 567 are much stable in terms of aging, the new one has the best FFM floor. Principle is schematically represented on figure 1.

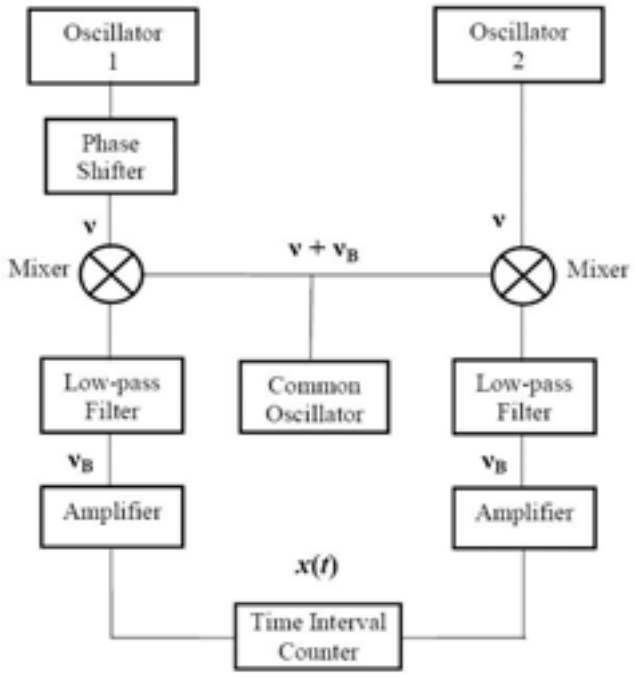

Fig. 1. Principle of DMTDM frequency stability measurement.

The experimental results are given in reference [1]: it shows that the frequency stability of the 8607-C prototype is less than 4.5×10^{-14} for integration times between 1 s and 50 s. The best obtained FFM floor is 2.5×10^{-14} for an integration time in the range 10 to 12 s.

This new prototype of 5 MHz 8607-C BVA oscillator with highly optimized double oven and low noise electronics, present the best FFM floor ever measured on a BVA quartz oscillator, at 2.5×10^{-14}, as shown on figure 2.

III. Discussion about the accuracy of the method

Estimated uncertainty for the frequency stability at 12 s is equal to $\pm$ 3×10^{-15} [12]. As we started to discuss in the introduction, we can underline that our process for short term is to be considered as analogous to what occurs for long term frequency stability characterization. But actually it could provide questionably a precise determination of FFM floor. We can have a doubt or interrogation as the analysis proceeds by matching the theoretical and the best experimental curves not exactly simultaneously. Shall we take into account the fact that we make only a single measure for one couple of oscillators, but we don't characterized the frequency simultaneously for the different couples of the 3 oscillators to be measured?

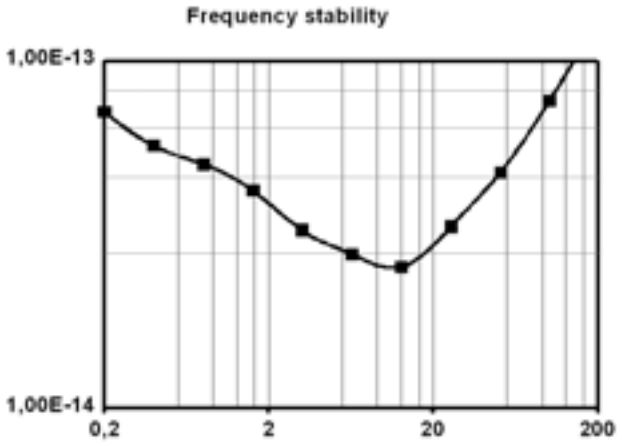

Fig. 2. Best frequency stability deduced for a 5 MHz quartz oscillator [1]. The overlapping Allan variance is given versus integration time (in s).

The Three-Cornered Hat is a well known style of hat that was popular during the late 17th century and 18th century. But in our case, it is the method used to determine the contribution to the phase noise or frequency instability by analyzing the contribution of three different pairs of oscillators. The three-cornered hat allows the extraction of stabilities for three clocks when the only available information is the time or frequency differences between the clocks [12]. Normally this method should proceed simultaneously by sampling each 200 ms integration time [2] in parallel in order the deduced contribution of each oscillator to be valid.

- To understand how the measure is performed, one should keep in mind that we work in the short term domain where the contribution of the instrumentation can be negligible between 0.2 s and 100 s, where the FFM floor is expected.
- An other important fact is the large number of samples during the acquisition. It can be considered that 5,000 samples is enough to avoid artifacts.
- We also proceed by comparing the data performed on the same pair of oscillators, but at a different time or day. Then we keep only the best reproducible measures containing successively those 5,000 samples by considering that the worse data are consequently due to external contribution. For instance the low variation of the room temperature can affect the noise.
- But we also reject the very best data to ensure the repeatability to be enough reproducible.

.With all these conditions, we simply try to get rid of the condition of simultaneity formally necessary to in the Three-Cornered Hat method. Finally we proceed as following. Three pairs of oscillators are fully characterized successively, but by performing several time, and at different moment the data acquisition. Compiling a large quantity of data, we are ready to extract from the whole dataset what is supposed to be the real contribution of each pair, when external contribution to the

noise are minimized. We assume the non-simultaneity of the measurements do not affect the right to deduce the contribution of each oscillator to the frequency instabilities.

To illustrate our method, we can see as it is analogous to how the barycenter "O", which is the point between two objects "A" and "B", respectively with a mass "M1" and "M2", where they balance each other, is determined in a triangle. In a pair the contribution of each signal generated by each oscillator to the noise is similar to a balance with different mass.

When the two mass are at equilibrium, the following condition (1) is respected:

$$(M1)x|0A| = (M2)x|OB| \quad (1)$$

In our case we consider vectorial and scalar Leibniz functions related to barycenter.

IV. Conclusion

Despite that it was not formally possible to proceed at the same time to measure the different pairs of oscillators, we assume that precise measurements on oscillators carefully performed at the Time and Frequency department in Prague in very favorable environmental conditions and deduced by the main guidelines of the three cornered hat analysis allow the validation of the best performances deduced on a 5 MHz BVA Quartz oscillator.

Very Low Power Consumption, Ultra Low Phase Noise, Miniature Conventional OCXO

Roman Boroditsky, Jorge Gomez
NEL Frequency Controls
Burlington, WI USA
romanb@nelfc.com gomezj@nelfc.com

Abstract **- Battery powered equipment, whether instrumentation, underwater exploration, or military require high performance frequency sources with very low power consumption for obvious reason. Current state of the art in the area of very low power consumption OCXO [1]., [2]. employs evacuation of the entire (or almost entire) electronic circuit with crystal resonator in metal enclosure and internally heating the content. Although achieving the goal of significant reduction in power consumption (60 – 80 %), this approach has some serious drawbacks. The phase noise performance of one of the implementations is average at best, of another - is outright poor. Evacuation of the entire OCXO requires very complex and tedious processes, since any minute contamination can destroy deep vacuum, needed for device to operate. The availability of die semiconductor components, a necessity for inside the vacuum, is very limited. The devices are susceptible to exposure of elevated temperatures, which might induce internal outgassing and deterioration of vacuum level. The goal of this work was to create a device, which would eliminate above mentioned drawbacks i.e. employ conventional heating technique, use off-the shelf widely available components, have comparable to evacuated devices power consumption and size, and exhibit superior phase noise performance. The goal was achieved by implementing special thermal insulation technique, and NELs ULPN technology in 20x20x10 mm package. While the steady state power consumption at room temperature is less than 250 mW, the phase noise at 10 Hz offset at <-145 dBc/Hz is better by 20 to 45 dBc than published specifications, and at -174 dBc/Hz, by 10 to 30 dBc on the floor.**

I. Introduction

The goal of this work was to design and develop a small form factor OCXO, which would have very low power consumption, suitable for operation in battery powered equipment, while possessing ultra low phase noise performance. Currently very low power consumption OCXOs described in papers and offered on the market are based on evacuation (to the deep level) of the (almost) entire OCXO circuitry with open blank crystal resonator in metal enclosure. The temperature of the entire assembly is controlled by the internal oven. This approach (to different extent) allows for significant reduction in power consumption and warm-up time of the OCXO, however it has some inherent drawbacks. Evacuation of the entire OCXO requires very complex and tedious processes, since any minute contamination can destroy deep vacuum, needed for device to operate properly. The more components and materials are involved (including inevitable organics) the more the probability of vacuum deterioration. The availability of die semiconductor components, a necessity for inside the vacuum, is very limited. The devices are susceptible to exposure of elevated temperatures above specified operating limits, which might induce internal outgassing and deterioration of vacuum level. One of the requirements for presented effort was to simplify the processes and construction and use only conventional oven design with just a crystal resonator evacuated (which are available from several vendors on the market). The phase noise performance of the above-mentioned evacuated OCXO is average in one case and outright poor for the other according to published data sheets. Substantial improvement in this department was another major purpose of presented development.

II. Design

Basic design concept is shown on Fig.1. The enclosure of the OCXO is standard in the industry miniature 20x20x10 mm^3 5-pin metal case. Internally design is based on low profile TO8 3rd overtone SC-cut crystal resonator with conventional oscillator and oven circuitry assembled on the PCB. The whole assembly is then thermally insulated from the base and the cover by NEL proprietary insulation materials. Electrical connections are made with thin wires for the same purpose of thermal insulation. The circuit design is similar to the NEL ultra low phase noise circuits, employed in larger OCXO with some minor shortcuts due to real-estate limitations. In order to maintain very low power consumption with normal operating temperature range OCXO is designed to operate at lower supply voltages either 3.3 V or 5 V DC. The experimental results shown below are for devices operating at 5 V DC power supply.

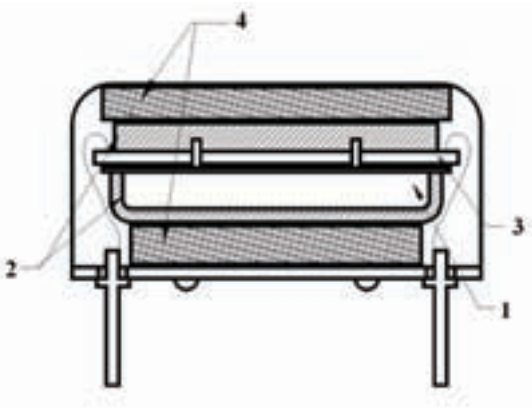

Fig. 1. Basic OCXO construction. 1 – crystal resonator; 2 – oven; 3 – PCB with circuitry; 4 – thermal insulation.

III Test results

A. Phase noise

6 units at 10.000 MHz were built and tested on 2 different instruments: DCNTS from Noise XT and 5120A-01 from Symmetricom. The plots are shown on Fig. 2. through Fig. 7.

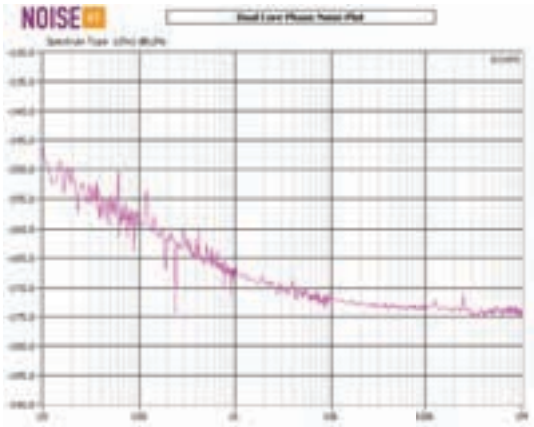

Fig. 2. Phase noise, unit #1

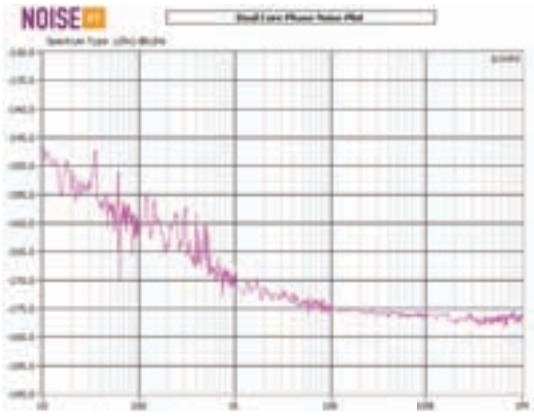

Fig. 3. Phase noise, unit #2

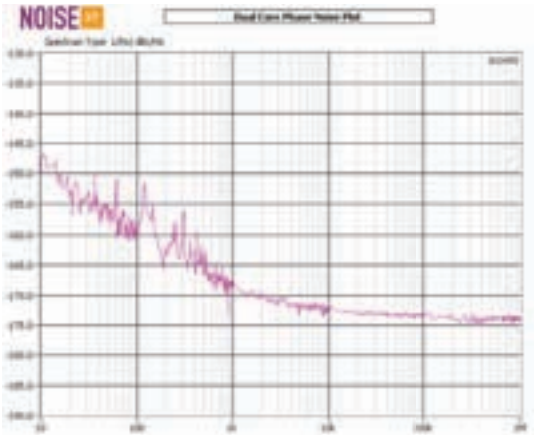

Fig.4. Phase noise, unit #3

On units #1 through unit #3 the measurements were made on DCNTS from Noise XT, on Units #4 through #6 they were made on 5120A-01 from Symmetricom. The latter has limitation on the noise floor at larger offsets (-170 dBc/Hz, guaranteed).

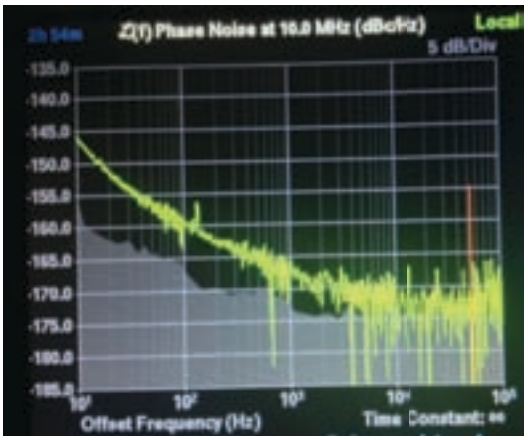

Fig. 5. Phase Noise, Unit #4

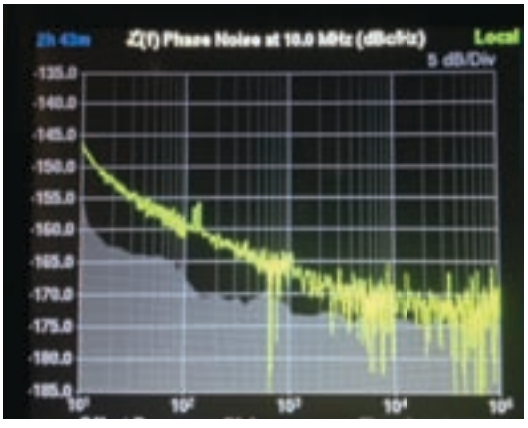

Fig. 6. Phase noise, unit #5

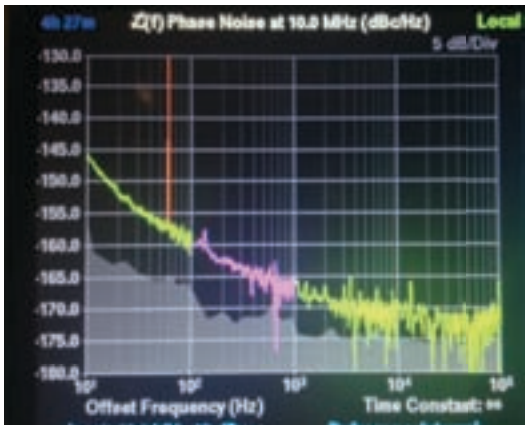

Fig.7. Phase Noise, unit #6

As one can see the phase noise of all the units is outstanding and consistent from unit to unit. It's better than -145 dBc/Hz at 10 Hz offset, close to -160 dBc/Hz at 100 Hz offset, and less than -173 dBc/Hz on the noise floor.

B. Power consumption

The data is presented in Table I.

TABLE I

POWER CONSUMPTION

Unit #	Oven Set Temperature°C	Icc at 25°C, mA	Power Consumption, mW
#1	82	52	260
#2	84	55	275
#3	80	50	250
#4	85	56	280
#5	78	49	245
#6	82	52	260

There's apparent correlation between power consumption and oven set temperature, as expected. Typical figure is about one quarter of a watt with maximum value not exceeding 300 mW at room temperature.

C. Warm-up

The warm-up data is presented in Table II.

TABLE II

Unit #	Start current, mA	Start-up power, W	Warm-up time to 0.1 ppm, s
#1	420	2.1	51
#2	400	2.0	52
#3	410	2.05	52
#4	410	2.05	53
#5	400	2.0	53
#6	420	2.1	51

While the power at start-up is rather moderate, just about 2 W, the warm-up time to the accuracy of ± 0.1 ppm (from the frequency after 1 hour) is less than 1 minute for all of the tested units.

D. Frequency Stability Over Temperature

Frequency stability curves over temperature are shown on Fig. 8. Since one of the purposes of the development was to create a building block for double oven, the oven set point was selected to attain maximum flatness in the 70°C area. Nevertheless, the overall stability in the 0°C to 75°C range did not exceed ±5 ppb.

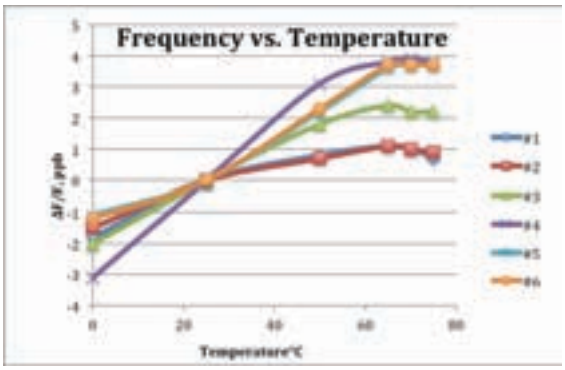

Fig. 8. Frequency Stability vs. Temperature.

E. Storage Temperature exposure

One of the important motivations for the project was to eliminate the probability of deep vacuum deterioration, and hence significant performance deterioration, after exposure to elevated temperatures. In some applications the maximum storage temperature is specified at 125°C, which may create outgassing problems in evacuated devices, where most (all) of the circuitry and structures are evacuated. All 6 units were exposed (non-operationally) to the temperature of 125°C for a total of 48 hours with data on current consumption taken after 1, 2, 4, 8, 24 hours and at the end of the experiment. The units were allowed to stabilize for about 1 hour before the measurements were taken. The frequency drift, though not documented on all units did not exceed typical for 3rd overtone SC-cut resonators retrace value after the end of the test. The current consumption data is shown on Fig. 9. Some minor fluctuations of the values can be explained by ambient temperature fluctuations in a not tightly controlled environment.

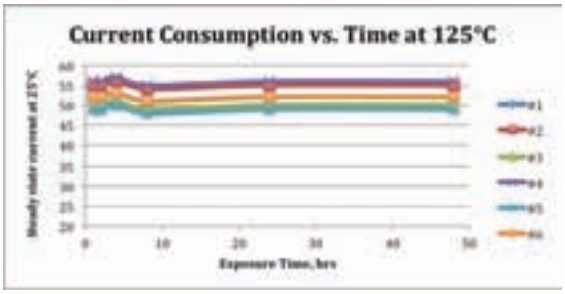

Fig. 9. Current consumption vs. time exposed to elevated temperature.

IV. Conclusions

The developed ULPN very low power consumption miniature OCXO performance met the set design goals. It exhibited outstanding phase noise, excellent stability, and very fast warm-up time, while consuming close to one quarter of a Watt power at room temperature. All is achieved with conventional technology, where only crystal resonator being sealed in vacuum, using readily available off-the shelf components. Comparison to two existing on the market evacuated OCXO (per published data sheets) is shown in Table III.

Phase Group Characteristic Based Frequency Measurement Method with Wide Band and Fast Response

Shaofeng Dong, Wei Zhou, Jinsong Zhan, Wei Hu
Department of Measurement and Instrument
Xidian University
Xi'an, China

Abstract—**As the rapid development of frequency standard, the need arises to measure frequency fast in a wide band with a high resolution. The frequency measurement instrument in commerce nowadays cannot meet the demand. And the generally existing ± 1 counting error limits the improvement of measuring precision. By analyzing the phase variation rule between every two periodic signals with different frequency, the phase group characteristics, such as phase group synchronization, are revealed in the paper. Based on the phase group characteristics and phase coincidence detection, a wide band frequency measurement method is proposed in this paper. Two adjacent phase coincidence points of the reference frequency and the measured frequency are used to generate the measurement gate, and ± 1 counting error can be eliminated effectively. Fine phase shift is used in some special situation on the reference frequency to shorten the measurement time. Experiment results show that this method achieves a precision higher than 1×10^{-13}/s in frequency standard comparison, and the typical precision of signal from 30 kHz to 100MHz achieve $6\sim8 \times 10^{-12}$/s.**

Keywords-frequency measurement; wide band; fast response; phase group characteristic

I. INTRODUCTION

With the technology progress of communication, measurement, aerospace, navigation and positioning, higher measuring precision of frequency standards is required [1], and the need arises to measure frequency fast in a wide band with a high resolution. Time-interval counting [2][3] is a basic technique of time and frequency measurement. However, ± 1 counting error generally exists in most time-frequency measuring instrument, which limits the improvement of measuring precision. Kinds of techniques designed to improve the measuring precision, such as analog interpolation, vernier, time-digital conversion [4], cannot effectively eliminate the influence of counting error. Also, the traditional frequency measurement instruments require complex frequency conversion circuits to accomplish high resolution frequency measurement in a wide band.

On the basis of analyzing the phase variation rule between every two periodic signals with different frequency, phase group characteristic and phase coincidence detection can be used to generate the measurement gate. In his paper, a wide band and high resolution frequency measurement method is proposed. And fine phase shift is used in some special situation on the reference frequency to shorten the measurement time. This method eliminates ± 1 counting error effectively, measures any frequency with high resolution and fast response in a wide range.

II. PHASE GROUP CHARACTERISTIC AND WIDE-BAND FREQUENCY MEASUREMENT METHODE

Phase processing is commonly used in high-precision and high-resolution time and frequency measurement, but the traditional phase processing is limited to the frequency comparison at the same nominal value [5][6]. For the frequency comparison between two different frequencies, frequency conversion is required, which increased the circuit complexity and cost, introduces extra noise.

Besides the periodic changes of two frequency signals, the study found, it is the regular changes of phase differences that have a significant impact on measurement, comparison and control. We characterize the regular changes of phase differences and the frequency relations of signals in terms of the greatest common factor frequency [7], the least common multiple period, equivalent phase comparison frequency [8] and so on. The phase difference variation rule between two different frequency signals is shown as Fig. 1.

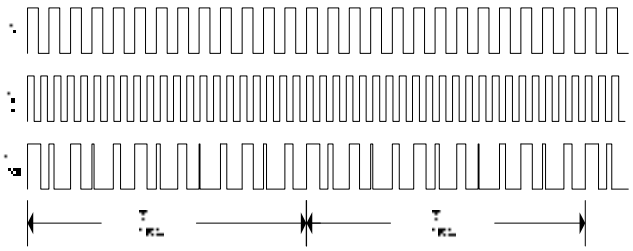

Figure 1. The phase difference variation rule between two different frequency signals.

In Fig. 1, f_{out} represents the output of phase comparison between f_1 and f_2, with f_1 used as the reference signal. It is known that the phase processing is always carried out by

Supported by the Fundamental Research Funds for the Central Universities No. K5051204003 and No. K5051304018 , the National Natural Science Foundation of China under Grant No. 10978017.

period. Because f_1 and f_2 have different frequency, it is impossible to perform phase processing continuously like the traditional way that compares phase in successive periods., the phase relationship between every two frequency signals is very complex. However, it can be seen that the same phase difference distribution appears repeatedly in each $T_{\min c}$. If all phase differences in one $T_{\min c}$ are considered as a group, the phase processing between different frequency signals can be realized in multiple periods such as the least common multiple period $T_{\min c}$. It also can be seen from Fig. 1, the phase difference between two different frequency signals reflects the periodic change characteristic with the least common multiple period $T_{\min c\,c}$ as the period. We define the phase difference in one $T_{\min c}$ as phase group, and characterize the above phenomenon as phase group synchronization. Phase group synchronization refers to the strict repeatability of the phase differences between two different frequency signals with the least common multiple period as the period. We note that, every phase group always starts at the phase coincidence point between two different frequency signals, stops at the next phase coincidence point. The start and stop points of phase group are strictly synchronous with the two different frequency signals, which means the numbers of the two compared frequency signals in one whole phase group are two integers.

Based on the phase group characteristic, a wide-band frequency measurement method is proposed in this paper. In this method, two adjacent phase coincidence points of the reference frequency f_0 and the measured frequency f_x are used to generate the measurement gate. Because f_0 and f_x are synchronized strictly with the start and stop signals of the gate, ± 1 counting error can be eliminated. In gate time, the counting numbers of f_x and f_0 are N_x and N_0, respectively, thus the measured frequency is expressed as:

$$f_x = f_0 \times \frac{N_x}{N_0}. \tag{1}$$

In this method, we can complete a wide band frequency with one high stable reference frequency signal, such as 10MHz.

III. Fine Phase Shift to Complete Fast Frequency Measurement in a Wide Band

The above wide-band frequency measurement method is based on the rapid and accurate detection of the phase coincidence between any two frequency signals. However, the frequency relation of the two compared signals has a big influence on measurement precision and response time.

For example, if the generation of phase coincidence only relies on the least common multiple period between two frequency signals, the phase coincidence point may not be able to form in the condition of complex frequency relationship between two compared signal or two signals comparing at the same frequency with a small initial phase difference, which will affect the measuring response time and accuracy of measurement.

Therefore, fine phase shift is used in this paper on one compared frequency signal, such as the reference frequency signal, to actively create phase coincidence points between the reference and measured frequency signals.

The fine phase shift on reference frequency signal is realized by a combination of wide range phase shift on chip and high resolution phase shift off chip.

A. *Wide Range Phase Shift on Chip*

Wide range phase shift on chip is realized by a high frequency clock driving a shift register. The signal to be delayed is input into the shift register, the number of shift register level is determined by the required time delay. For example, a 2.5 ns accurate phase shift can be obtained by 400 MHZ clock driving shift register.

B. *High Resolution Phase Shift off Chip*

In order to further improve the accuracy of phase shift, phase shift off chip is used. Phase shift off chip is realized by RC phase shift circuit, by adjusting the resistance R to realize the precise phase shift value control of each level.

IV. Experiment and Analysis

According to above analysis, the wide-band and fast response frequency measurement module is realized by FPGA chips combined with RC phase shift circuit. The resolution of phase shift on chip is 2.5 ns, the number of shift register is 50. The resolution of phase shift off chip is 60ps, using 42 levels RC phase shift circuits.

Based on the above phase shift resolution settings, 10 MHZ continuous frequency measurements results are shown as Fig. 2, in the condition of a high stability of 10 MHZ signal used as reference signal, measurement gate is 0.01 s.

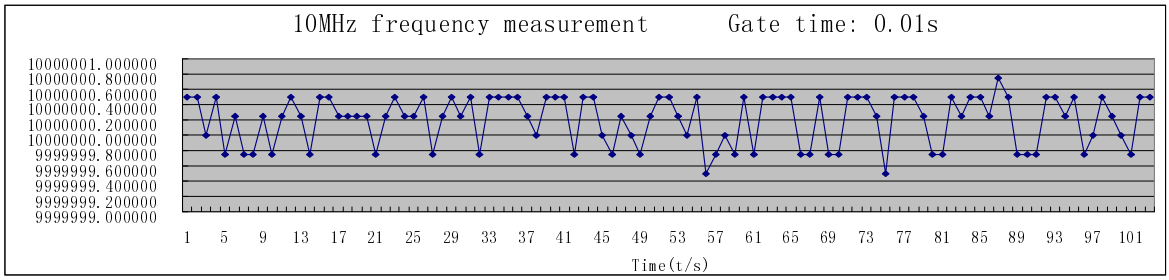

Figure 2: 10 MHZ frequency measurements results

V. CONCLUSION

Based on the phase group characteristic, this paper introduced a wide-band frequency measurement method. This method can eliminate the influence of counting error in theory and improve the measuring precision greatly. And fine phase shift on reference is used to shorten the measurement response time. Experiment results show, the method achieves a precision higher than 1×10^{-13}/s in frequency comparison, the typical precision of signal from 30 kHz to100MHz achieve $6\sim8\times10^{-12}$/s. With the improvement of phase coincidence detection resolution, phase shift precision and component response speed, the precision of this method can be further improved.

***Abstract*—We are reporting on the latest experimental results achieved with an event timing device using a surface acoustic wave filter as a time interpolator. During the tests of the first version of the device, the noise of the filter excitation was identified as the dominant source of the measurement error. Therefore a new concept of the excitation with very low level of the noise energy was designed. This new solution led to considerable improvement of the device performance. It results from the experimental measurements that the single shot precision is repeatedly lower than 500 fs RMS when time marks generated synchronously with the time base are measured. When asynchronous time marks are split into two event timers and the resulting time difference is measured, the single shot precision is below 700 fs RMS per channel. In this case the measurement is affected not only by random errors, but also by non-linearity of the time interpolation. The temperature dependence is below 0.1 ps/K. Operating the device in a common laboratory environment without temperature stabilization, the stability TDEV better than 3 fs has been routinely achieved for range of averaging intervals from 10 s to several hours.**

Keywords—event timing; time interval measurement; time interpolation; surface acoustic wave filter

I. INTRODUCTION

All highly precise time interval and event time measurement devices are based on time interpolation between ticks of a reference time scale. An overview of traditional approaches to the time interpolation problem can be found in papers [1]-[2]. A new time interval measurement method based on a transversal SAW (Surface Acoustic Wave) filter as a time interpolator was introduced in [3]-[4]. This filter after a short excitation generates a time finite signal with highly suppressed spectra outside a narrow frequency band. It results from the sampling theorem that such a signal can be very precisely reconstructed from a finite number of its samples. This property makes the transversal SAW filter an ideal mean for the time interpolation.

The time interval measurement device using a SAW filter for time interpolation can take various forms. The simplest one is shown in Fig. 1. It measures time interval between two pulses at the single input. Each of the pulses excites a SAW bandpass filter whose output is sampled at clock ticks. The samples are then converted by an ADC (Analog to Digital Converter) and buffered. After both responses have died out, they are reconstructed from the samples and compared by means of the cross correlation to eventually estimate the time interval between the two input pulses. All the processing steps can be integrated into a simple algorithm based on fast Fourier transform. To ensure the correct operation of the interpolator, the sampled responses must not be aliased. Therefore the filter parameters must be properly chosen.

Fig. 1: Block scheme of the time measurement device using a SAW filter for time interpolation. The input pulses excite a transversal SAW band-pass filter, its output is sampled at clock ticks, the samples converted by an analog-to-digital converter and buffered. After both responses have died out, they are reconstructed from the samples and compared by means of the cross correlation to eventually estimate the time interval between the two input pulses.

An analysis of the deterministic measurement error, i.e. time interpolation nonlinearity, of this method has been given in [3]. It results from the analysis that the source of this error is an imperfect suppression of the spectra of the response outside the required band. Therefore the quality of the time interpolation depends on the stop-band attenuation of the SAW filter. It was shown that when common SAW filter parameters are considered, the resulting time interpolation error relative to clock period is very small and an accurate measurement can be achieved even with relatively low clock frequency.

A detailed analysis of random measurement errors caused by noise of excitation, noise of amplifier, quantization noise and the sampling and reference clock jitter is a subject of the paper [6]. It implies from this analysis that the noise influence is partially suppressed thanks to averaging effect because the interpolation process is not based on the only one observation but many samples taken at different times. In general, the random errors can be minimized choosing a sufficiently high center frequency of the filter and a sufficiently high clock frequency. On the other side, the filter bandwidth should be kept as small as possible. The bandwidth reduction, however, is

limited due to the increasing probability of false ambiguity solution.

Another effect which can degrade the spectral purity and the interpolation nonlinearity is the harmonic distortion of the filter response in the amplifier and the ADC. This effect was analyzed in paper [7] with a conclusion that the resulting interpolation nonlinearity has a form of a sine wave oscillating very quickly in comparison to the reference clock which was in agreement with experimental observations.

Based on the theoretical background above, a prototype of a two-channel event timing device was designed and constructed. Each channel of the device measures time of events represented by pulses at its input with respect to a common reference time scale. The architecture of one channel is in accordance with Fig. 1. An extremely good stability and reproducibility of the event timing is achieved thanks to shot-by-shot self calibration. Once the response to an input pulse has been processed, an internally generated time mark is applied to the input. This internal time mark is generated synchronously with the time base reference thus the device measures the interval between the external pulse and a selected reference clock tick and the influence of internal delays is eliminated. For the time interpolation a SAW filter with the central frequency of 525 MHz and bandwidth of 18 MHz has been used. The internal time base is based on the 100 MHz clock which serves also as the sampling signal. To make the device more flexible in usage there is an in build frequency divider and hence the input frequency 100 MHz or 200 MHz can be used. We have also succeed in implementing the computation algorithm in to the FPGA. It results in faster operation of the device, which can time-tag input pulses with repetition rate more than 10 kHz.

The experimental results achieved with this prototype were presented in [5], [7] and [8]. The resulting single shot precision was typically 900 fs RMS and the timing stability TDEV of 4 fs was achieved for averaging intervals in the range from 300 s to 2 h with the measurement repetition frequency of ~800 Hz. After adjusting the filter excitation level to the optimum, the interpolation nonlinearity was below 200 fs RMS.

II. New concept of filter excitation

During tests of the first prototype, the noise of the filter excitation was identified as the dominant source of the measurement error. The influence of this noise was estimated to be around 75 % of the overall error budget. Therefore we focused on the research of the filter excitation with the goal to design an optimal excitation concept for the new generation of the timing device.

The new exciter is a nonlinear pulse circuit activated just for a very short period. For the rest of the time its noise is effectively suppressed. The length of the excitation pulse is optimized to achieve the maximum energy spectral density of the excitation at the filter centre frequency and keeping the energy of the noise as low as possible. This solution led to considerable improvement of the device performance. The error budget estimation based on measured noise levels and the theoretical analysis [6] is summarized in Tab. 1. The error budget includes only random errors caused by noise. The influence of the dominant source of the measurement error is now negligible.

TABLE I. Error Budget

Source of error	RMS error contribution	
Noise of excitation	negligible	0 %
Noise of amplifier	235 fs	37 %
Quantization	70 fs	3 %
Clock and sampling jitter	300 fs	60 %
Overall error	390 fs	100 %

III. Experimental Results

With the aim to verify the precision and stability of the improved event timer, we have completed several experiments using test pulses generated synchronously to the local time base. First, the precision of the ToA (Time of Arrival) measurement was tested. The reference clock as well as the test pulses were generated from the MTI 260 10 MHz OCXO with a low-noise frequency multiplier [10]. The measured ToAs of 20 000 test pulses are summarized in the centered histogram in Fig. 2. The error distribution is close to Gaussian with standard deviation of 490 fs RMS. It is worth mentioning that this value does not result only from the timing precision of the tested device, but also from the jitter of the test pulses itself. Therefore this value should be understood as an upper estimation of the ToA measurement precision.

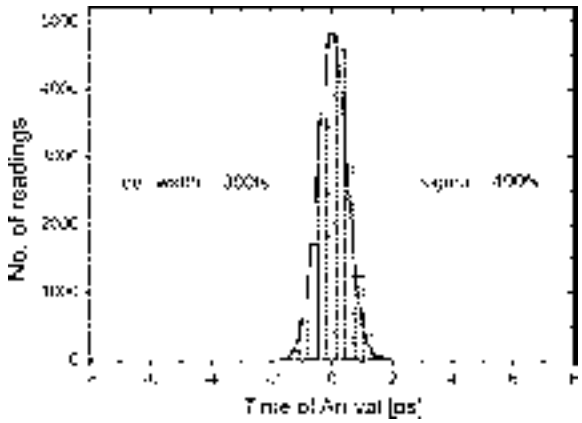

Fig. 2: Centered histogram of measured ToAs of 20 000 test pulses generated synchronously with the time base. The resulting standard deviation 490 fs includes also the time jitter of the test pulses (~300 fs RMS).

The other experiment was focused on the long-term stability of the measured ToAs and their temperature dependence. The measurement started approximately 1 hour after the device was powered on. The averages of recorded ToAs are plotted in Fig. 3. Every black point represents an average from 1000 successive measurements, i.e. all measurements from a 100 ms interval, and the white line is a 100 s moving average. Together with the ToA measurements also the surrounding temperature was recorded thus we could estimate the temperature dependence. The results are plotted in

Fig. 4. During the measurement the temperature decreased approximately by 1 K. Within the temperature range close to the common operation temperature the dependence is linear with a temperature coefficient of −169 fs/K. This value includes also a temperature dependence of interconnecting coaxial cables Huber+Suhner, SUCOFLEX 301. After this influence is corrected, the temperature dependence of the event timer itself is -70 fs/K.

The timing stability TDEV has been computed from measurements with the test pulse repetition frequency of 10 kHz. The timing stability depends not only on the event timer itself, but also on the quality of the reference clock. Therefore it was evaluated from three measurements with different clock reference sources: MTI 260 10 MHz OCXO with a low-noise frequency multiplier, Wenzel 100 MHz Ultra Low Noise OCXO, and Wenzel 100 MHz Sprinter OCXO. The length of each measurement was at least 2 hours. The resulting TDEV plots are in Fig. 5. In all three cases the TDEV dependence falls with $\tau^{-1/2}$ up to $\tau = \sim 10$ s, implying that errors of measurements acquired within an interval shorter than 10 s can be considered uncorrelated. In this region, the best results provides the clock reference generated from the MTI 260 1 OCXO with the frequency multiplier which has the lowest jitter. For averaging intervals $\tau > 10$ s the TDEV fall stops on the flicker floor which also depends on the quality of the reference clock. The best stability in this region has been achieved using the Wenzel100 MHz Ultra Low Noise OCXO. In all three cases the flicker floor was TDEV < 3 fs.

For the rest of the experiments we used 10 kHz test pulses generated from an asynchronous pulse generator. The output of the pulse generator was split to inputs of both event timers and the time difference between measured TOAs was evaluated. In this case the measurement is affected not only by random errors, but also by non-linearity of the time interpolation. The results based on 20 000 measurements are summarized in the histogram in Fig. 6. The error distribution is again very close to Gaussian. The resulting standard deviation of the time difference was 984 fs which corresponds with a ToA single shot precision of 695 fs in each channel.

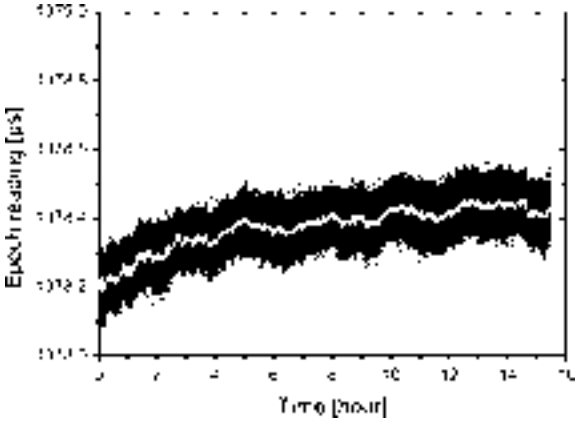

Fig. 3: The averages of recorded ToAs for 10 kHz repetition frequency of test pulses. Every black point represents an average of measurements on an interval of 100 ms, the white line is a 100 s moving average. During the measurement the temperature decreased approximately by 1 K.

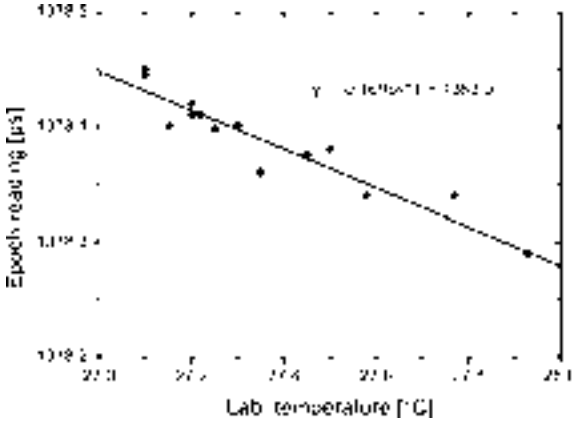

Fig. 4: Temperature dependence of the measured ToAs is −169 fs/K. After the influence of temperature dependence of interconnecting cables is corrected, the temperature coefficient of the event timer itself is -70 fs/K.

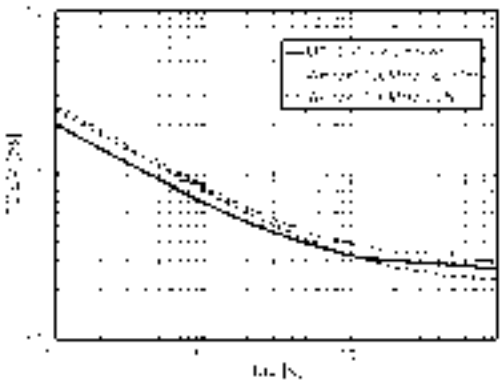

Fig. 5: Timing stability TDEV measured with three different sources of the reference clock, test pulse repetition frequency of 10 kHz, the resulting flicker floor TDEV < 3 fs in all three cases.

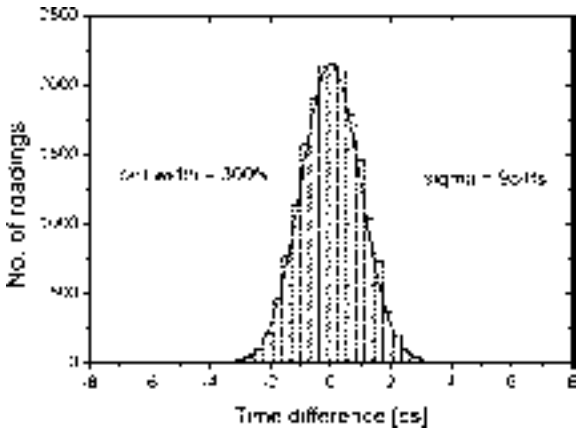

Fig. 6: Centered histogram of 20 000 time differences between ToAs measured by two event timers with the same asynchronous test pulses at the inputs. The resulting standard deviation of the time difference was 984 fs which corresponds to a single shot ToA precision of 695 fs in each event timer. In this case the measurement is affected not only by random errors, but also by non-linearity of the time interpolation.

IV. Conclusion

A new concept of the low-noise filter excitation has been designed for the event timing device using a transversal SAW filter for the time interpolation. This new solution led to considerable improvement of the device performance. It results from the experimental measurements that the single shot precision is now repeatedly lower than 500 fs RMS when time marks generated synchronously with the time base are measured. The behavior of the observed fluctuations can be well described as white noise with Gaussian distribution. When asynchronous time marks are split into two event timers and the resulting time difference is measured, the single shot precision is below 700 fs RMS per channel. In this case the measurement is affected not only by random errors, but also by non-linearity of the time interpolation. The temperature dependence of the measurements is below 0.1 ps/K. Operating the device in a common laboratory environment without temperature stabilization, the stability TDEV better than 3 fs has been routinely achieved for range of averaging intervals from 10 s to several hours.

The event timer is capable of a stand-alone operation or several event timers can create a net of timing units distributed in an area where unified time is kept using optional Two-Way Time Transfer modules [9]. A pair of event timers with a common time base can be used as a classical time interval counter.

***Abstract*— We present a fourth- design generation Free Running Oscillator and Voltage Controlled Oscillator using integrated bipolar circuitry in the lid wafer with a temperature-compensated FBAR resonator in the base wafer. The goal is to produce a high frequency, low-noise oscillator. Because there are ~15,000 oscillators per wafer, we can develop very sensitive testing procedures to study the oscillator behavior. For example, we have determined our frequency measurement accuracy and precision to be ~ 0.2 parts-per-million (1 σ), and our phase sensitivity floor to be less than -180 dBc/Hz. Measurements on package hermeticity, suggest that the oscillators behave with the same level of integrity as our standard FBAR filters.**

I. INTRODUCTION

Today, millions of FBAR Filters and Duplexers are sold into cell phones every year. The all-silicon package used to package these filters (providing both package integrity and hermeticity) has been utilized for the past 10 years and, to our knowledge, no part has been returned for compromised integrity or hermeticity failures. The lid wafer in the all-silicon package has, until recently, only been used to provide through-Si vias from the FBAR filter to the outside pads. The addition of circuitry to the lid enables a host of new applications. Examples include the integration of SiGe LNAs with filters to provide extremely compact filter/amplifier functionality, circuitry with integrated sensors. We call this platform; FMOS (for FBAR, Metal, Oxide and Semiconductor). Our first application is the integration of oscillator circuitry with a temperature-compensated FBAR resonator. The resulting chip-scale oscillator produces a single, well-defined frequency, and is highly sensitive (on the parts-per-million level) to package hermeticity. This allows for the design and optimization of a robust package for yield and performance, and for the testing of new markets not dominated by filtering.

The goal of this program is to demonstrate a robust, repeatable, chip-scale oscillator with superior performance.

II. DISCUSSION

FBAR resonators using traditional electrode and AlN piezo materials have a linear temperature coefficient on the order of about -27 ppm/ ^{o}C [1]. An oxide layer with a positive temperature coefficient is placed inside the bottom electrode and as part of the acoustic stack, counter balances the negative coefficient of temperature given from the AlN and metal electrodes[2,3]. These temperature compensated resonators have a zero drift linear component of frequency shift relative to temperature. We call these devices Zero Drift Resonators or ZDR.

It should be noted that although the linear component of frequency shift with respect to temperature is zero, there is both a quadratic and tertiary component. A typical quadratic term, β, as measured in the resonator ranges from -20 to -25 ppb/ ^{o}C ^{2}. In FMOS oscillators, we have obtained a better effective β with a mean of -15 to -18 ppb/ ^{o}C ^{2}, via careful tuning of the oscillator. It is critical that the Turn over Temperature (TOT) lie somewhere near the center of the commercial or industrial range (0 to 70 ^{o}C for commercial and -35 to 85 ^{o}C for industrial). Assuming TOT is in the center, the total frequency excursion for a +/- 60^{o}C swing (assuming -15 ppb/ ^{o}C ^{2}) is +/- 27 ppm. However, if the TOT is off by 40 ^{o}C (as an example), then the total frequency excursion is +/- 75 ppm (60 ^{o}C + 40 ^{o}C = 100 ^{o}C → (-15 ppb/ ^{o}C ^{2} * 10,000 ^{o}C ^{2})/2 = 75 ppm).

The third order term appears to create a ~ 10ppm perturbation on the quadratic effect on temperature and hence is ignored – for now.

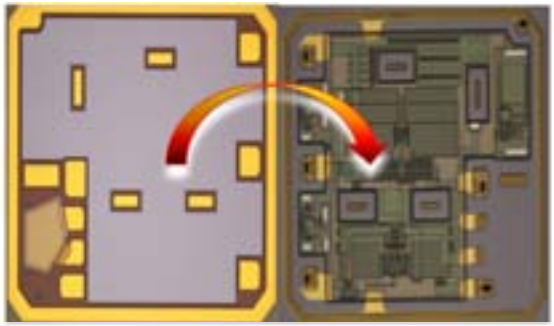

Fig.1; Optical micrograph of the base wafer containing the high Q zero drift resonator and the lid wafer containing the circuitry. The two wafers (lid and base) are bonded together and further processing forms the through vias and pads. Afterwards, the on-wafer oscillators are tested and then singulated into individual die.

Figure 1 shows an optical micrograph of a die from the base wafer (containing the ZDR) and a die from the lid wafer (containing the oscillator circuit). The two wafers are bonded together and then singulated to form the FMOS device.

III. RESULTS

There are several advantages to integrating the oscillator circuit with the resonator. One is the relative insensitivity to acceleration of a discrete oscillator using a ZDR compare to an FMOS oscillator. FMOS oscillators have about 1 ppb/g as compare to a range of 1 to 100 ppb/g for a discrete oscillator. The fact that the oscillating circuit and the resonator are 'locked' relative to each other (integrated) gives a far superior performance relative to a discrete oscillator.

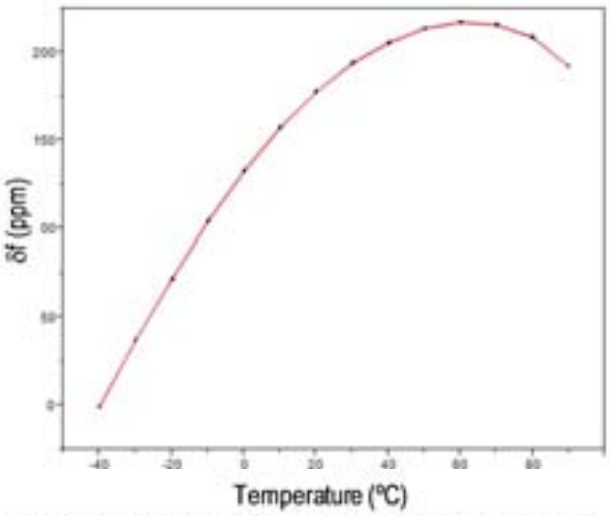

Fig.2; Change in frequency (ppm) vs Temperature. The temperature was swept between -40°C and 90°C six times. The 6 sets of data are overlaid. For this device, the TOT was60°C and the measured β was ~ -20 ppb/°C². No hysteresis is observed.

Next, having an integrated oscillator, we see repeatable δf vs temperature sweeps. Figure 2 shows δf vs. temperature for 6 temperature sweeps from -40 to 90C. Another advantage is the impedance of the circuit – as seen by the resonator – is well determined. This gives a much tighter spread in phase noise and power output power. This becomes more relevant at higher frequencies (above ~ 1 GHz). In general, variation in SMT components, pcb changes and wire bond and over mold can impact frequency repeatability, stability and apparent aging (i.e. changed in frequency over time).

Finally, we have over 15,000 oscillators on a wafer. Using a frequency counter on an ElectroGlas Probe station, one can test three Oscillators/s or 100% probe in little over 1 ½ hours per wafer. Using N-parallel probes, this number can be reduced accordingly by N (N = 1, 2, 3…). Even if only a small percent of the working oscillators are tested, one can begin to create large data bases to observe and measure trends and subtle interactions. The first test is to measure a large sample of oscillators across a wafer and, without moving the wafer, re-test. One can then plot the change in frequency of each measured resonator and plot this as a distribution. One can also un-load and re-load a wafer and measure the same oscillators again and get a sense of the measurement precision due to loading and un-loading. Figure 3 show the change in frequency for a control wafer measured six times (unloading and re-loading) spaced over 7 weeks. For a stationary wafer, the repeatability is about 200 ppb, 1σ. This precision degrades to about 1 to 2 ppm, 1σ, for load and un-load. In Fig. 3, the blue line is the first time measurement, T1, minus itself (hence 0 change). It is tempting to believe from this figure that had we used the second measurement taken at T2 (data taken a week later, red line) then the data taken at T3-T2, T4-T2, T5-T2 and T6-T2 would have been nominally a set of vertical lines. This is not the case, as each oscillator shift is random from one measurement to the next. In other words, had we used T2 or T3 etc…, as the reference frequency; this figure would still look the same! Note: we have also looked at 6 wafers measured in the same fashion and the plotted date looks similar to Fig.3. The mean is zero ppm in all these cases.

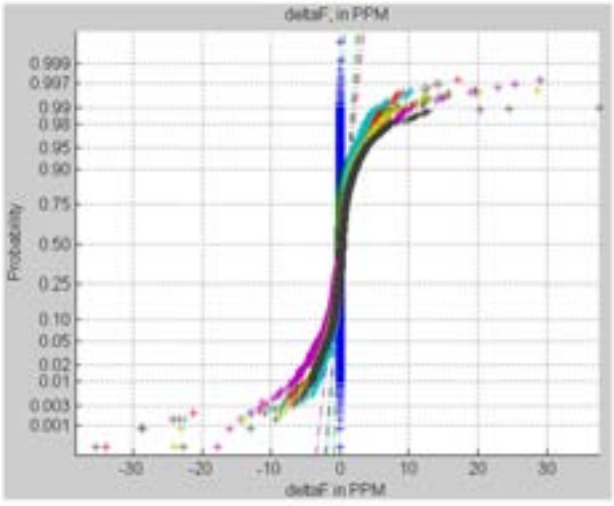

Fig. 3; Probability plots of the change in frequency for ~3000 oscillators as measured across a control wafer. The first measurement (blue) taken at time T1 is subtracted against itself (hence 0 shift). The next measurement (red) was taken at T2 (about 1 week later) and plots the change in frequency relative to the same oscillator at T1 (i.e. f2-f1). Each color represents a delta frequency measurement at T2-T1, T3-T1, T5-T1, T6-T1.

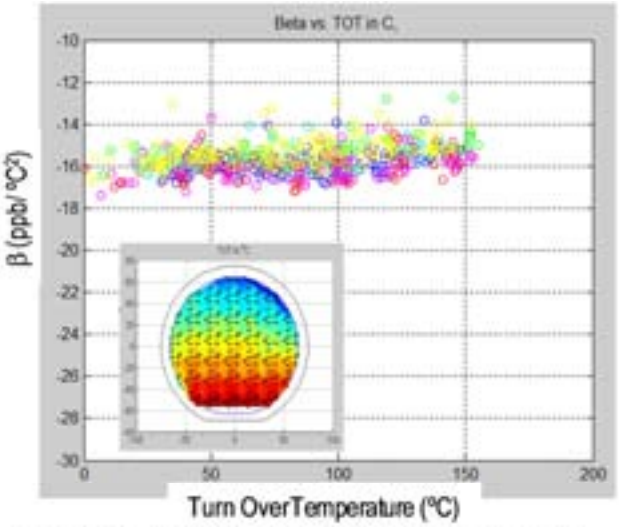

Fig.4; Parametric Plot of Turn over Temperature, TOT, (x-axes) and β (y-axes). Inset shows the TOT variation across a wafer. Here, a 'wedge' was ion milled into one of the layers to create a spread in TOT. The bottom of the wafer is ~150 °C and the top is 0 °C

We can use the ability to collect large amounts of data to study the effect of 'design' on the physical parameters of the oscillator. One key parameter of a ZDR is the quadratic coefficient of temperature, β, of our device. This property is extracted from thousands of measured oscillator frequencies over a range of temperature (from -40C to 120C). Figure 4 shows a plot of the Turn over Temperature (TOT) and β as measured over hundreds of oscillators across the wafer. It should be noted that we ion milled a 'wedge' in the thickness of the oxide, hence the TOT has a range of values across the wafer. However, it can be seen that β is steady at about -15 to -17 ppb/^{o}C ^{2} over a range of thicknesses. The data shown also includes a variety of circuit oscillator topologies. As can be seen circuit topology does not play a role in β.

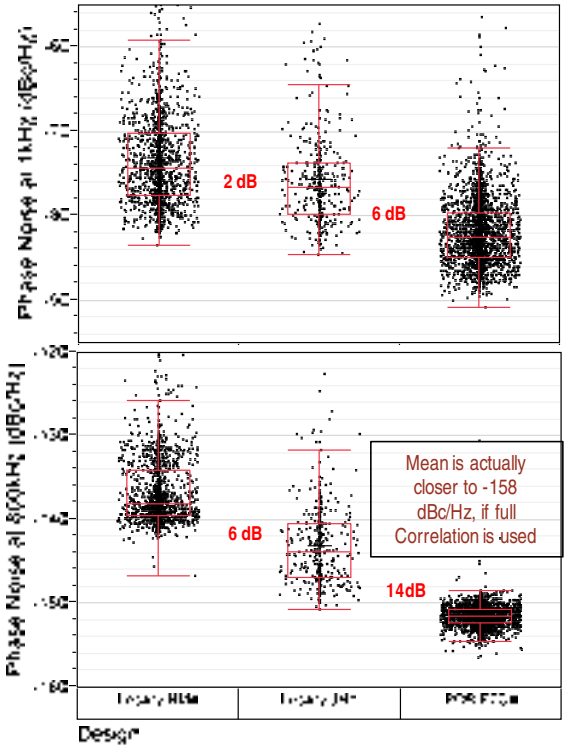

Fig.5; Phase noise measurements on ~3000 oscillators at 1 KHz offset (5a) and 800 KHz offset (5b). Plotted are the spreads in phase noise for a legacy device, the same circuit adopted to our new layout and a the final circuit topology. The delta are given in red (not shown is the improvement using correlation).

Figure 5 shows the relative improvements in phase noise (close-in at 1 KHz offset and far-from-carrier at 800 KHz) for the first design (a legacy design), a 2nd design where we optimized the layout of this legacy design and a 3rd design (labeled F7CX) using a different circuit topology. In Fig. 5, it should be noted that we originally did little or no correlation with the Agilent Signal Source Analyzer 5052B. For the newest designs, we realized that the measured phase noise floor (-156 dBc/Hz) was, in fact, the floor of the 5052B. When we turned on correlation and did long correlation times, the mean went from -153 dBc/Hz to -158 dBc/Hz, an improvement of 5 dB. The mean integrated jitter of the PORF7C devices (as measured on thousands of oscillators) is 7.5 fs (measured with correlation). The integration range for this number is 12 KHz to 20MHz. This new mean jitter performance is a factor of 4X better than published previously[4].

Figure 6 shows the phase noise plots for a device measured at -40 ^{o}C, 30 ^{o}C and 105 ^{o}C. As can be seen the phase noise is nearly constant over a wide range in temperature. We have also studied the effect of Q on the phase noise on phase noise plots. One first needs to reference Leeson's model given in (1)[5]. The model can be 'fleshed' out by observing that the onset of 'flicker noise', f_c, from the oscillating circuit is between 10 and 20 KHz, the far-from-carrier noise floor is -160 dBc/Hz.

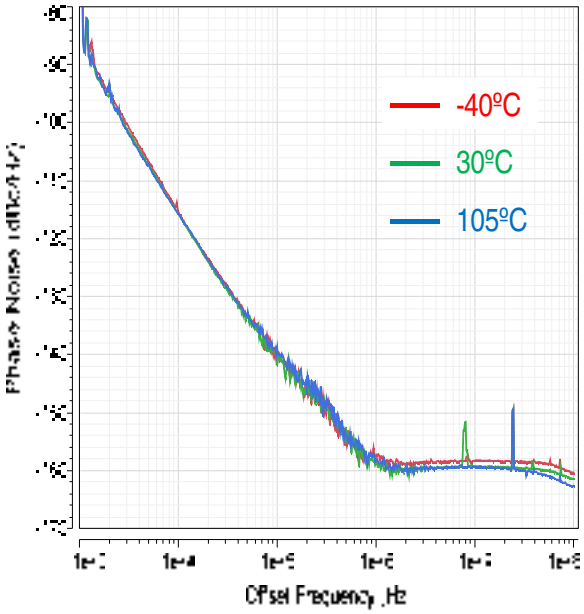

Fig.6; Phase noise of a Free Running Oscillator (F7CX) measured at 3 different temperatures. The output frequency is 2608.0 MHz and the Vcc = 3.3 V and Icc = 18 mA.

From Leeson's equation, we see that if we double the Q, we can reduce the close-in phase noise by 6 dB. In fact, a small adjustment was made in our design to optimize Q by 15%. This resulted in the measured mean of Q at 1 KHz offset improving by 1.2 dB.

$$L(f_m) = 10Log[((\frac{f_o}{2Q * f_m})^2 + 1) * (\frac{f_c}{f_m} + 1) * (\frac{2FkT}{P})] \quad (1)$$

More interesting is the effect of power injected into the resonator. In a separate set of experiments, a discrete oscillator was built using a stand-alone resonator, we were able to reduce the far from carrier average noise to -170 dBc or better. This was done by injecting more current into the resonator (~2X) and better 'tweaking' of the circuit topology. Figure 7 is the phase noise of this device. The fact that these small resonators can handle power is a testament to AlN piezoelectric resonators!

Although the phase noise at 1 KHz offset is better in the device shown in Fig 7 (vs Fig. 6), as we continue to optimize

the Q we do see that our median phase noise at 1 KHz offset on more recent runs is also about -90 dB.

A key factor to any new technology is its ability to handle extreme environmental changes. Companies have incorporated a variety of stress tests to any product to ensure that it is reliable and will work under all conditions over several years. For microcap products [6,7], our concern is that the die will lose hermeticity over time. Compromised integrity in the lid will cause failures. Running 15,000 oscillators through a variety of environmental chambers, ESD testers and thermal shock testers gives good indications (i.e. significant data) of how well the bond is and what impact a design in process, circuit or package has on the final robustness. Based on our strife data, we believe that we can deliver fully qualified parts to our customers.

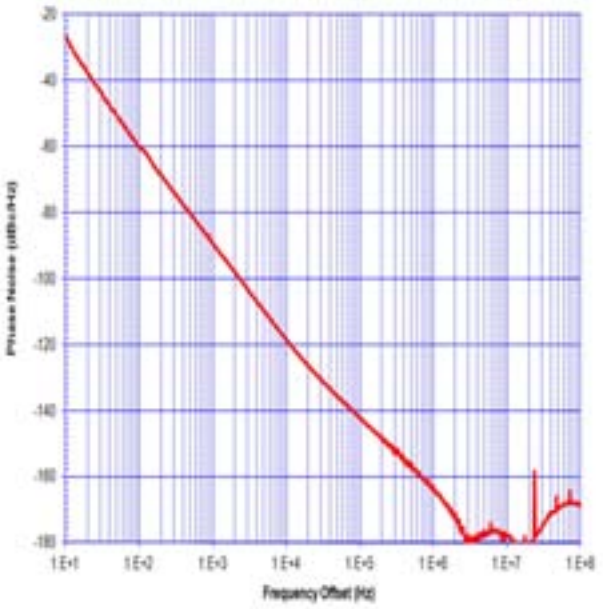

Fig.7: Phase noise of a VCO using a ZDR resonator and discrete components to make up a oscillator. The output frequency is 2500 MHz and the Vcc is 5V and Icc is ~20 mA. The Q's of the resonator in this device is comparable to the Q of the resonator shown in Fig. 6. The 5 dB difference between the two phase noise measurements at 1 KHz offset shows that other factors beside Q play a role in the close in phase noise.

IV. Conclusion

We have measured tens of thousands of oscillators and observe a mean jitter performance between 12kHz and 20MHz of 7.5 femto seconds. Output power is 2.4 dBm and the output drives 100 Ω differential. The mean phase noise of the 2608 MHz oscillator at 800 kHz offset is -158 dBc/Hz and the mean at 10 kHz offset is -118 dBc/Hz. The device draws 18.8 mA at 3.3V, and the phase noise at all frequency offsets stays within 1 dB over the temperature range from -40 to 120°C. We see a 1 to 1 correlation between resonator Q improvement and close-in phase noise: a 15% improvement in Q between two wafer lots improves close-in phase noise by 1.2 dB. Far from carrier noise is set by the power delivered to the resonator. Due to the ability of the resonator to remain linear at high powers, we have seen far-from-carrier phase noise as low as -180 dBc/Hz. The sensitivity to acceleration of these oscillators is on the order of 1 ppB/g and the start up time is measured to be less than 10 μsec.

It should be noted that the title of the paper includes VCOs as well as free running oscillators. For these devices, the only difference between the two is that for the former, we connect one pin to an external varactor and matching circuit. We have measured a tuning range of ~1400 ppm with ~2.5V tune voltage. The jitter degrades to about 20 → 25 fs (over temperature and Vtune). However, we believe we can recover the sub 10 fs jitter performance with modest redesign of the circuit. Process variation, temperature variation and Vcc pulling (and load pulling) takes up about 1000 to 1200 ppm of the tuning range, leaving enough tuning range to give the customer a guaranteed +/- 50 ppm.

Acknowledgment

The Authors would like to thank Prof. Otis for his insights and enthusiasm. We would also thank our managers and the folks in the Fort Collins IC fab for their support. And, we would like to thank the discrete oscillator team for Fig. 7

***Abstract*—Transient stability measurement of frequency source plays an important part in the real-time short-term stability and the characterization of distal phase noise, so its accurate measurement is of great significance. Measurement of transient noise and short-term stability of signals with the conventional digital counting methods is very difficult and the measurement accuracy is low. So we introduce a unique phase coincidence detection technology which is an important detection method and our group has worked on it for decade to measure the frequency source transient stability. When the phase difference of two signals is less than a certain value, phase coincidence detection circuit will output a narrow pulse which represents the phase coincidence, we call it the phase coincidence detection resolution threshold. When the phase difference of two signals is adjusted to the verge of coincidence detection resolution, we can judge the transient frequency stability of signals accurately from the continuity and discontinuity of the coincidence information. According to the results of multiple phase coincidence detection circuits which combine as a coincidence detection array, the phase variation in detail can be obtained. The measurement resolution depends on the stability of the coincidence detection circuit. This paper describes the principle, the experiment process and the results of transient stability measurement methods.**

Keywords—stability; Threshold; Phase coincidence detection

I. Introduction

Frequency stability measurement refers to the measurement of random fluctuation characteristics of output frequency from frequency source. The characterization of frequency stability in the time domain and frequency domain can be converted from each other. [1][2][3] The conventional time domain frequency stability measurements use the conventional counting measurement method, which the measure gate usually ranges from 1ms to 10s. [4]Measurement resolution is significantly lower in shorter gate, for example, only 10 numbers can be counted in measuring the 10 MHz frequency in the 1 μ s gate time, high precision is hard to achieve. However, the possibly short measurement gate is important to reflect the distal phase noise condition of frequency source using time domain method intuitively. So this paper proposes a new method for transient stability measurement of frequency source through the phase coincidence detection technology which has been proved as a high resolution periodic signal measurement technology[4][5][6].

II. The measurement of frequency source transient stability

A. The measurement method

With common digital method of counting measurements in measuring the signal transient noise and short-term stability, it is difficult to produce very short gate and achieve high measurement accuracy. Phase coincidence detection technology is the frequency and phase difference measurement technology that we have been developing over the years[5][6], and plays a key role in the high-resolution frequency measurement. It can detect the same information about their phases between two detected signals with identical or different nominal frequencies, such as two signals at the instant of the zero phase give particular phase coincidence information at the same time[7].It is always difficult to reach "absolute" coincidence in the implementation of phase coincidence. Thus we introduce the threshold of phase coincidence detection sensitivity, which is the value such that we recognize phase coincidence when the signal phase difference is less than it.

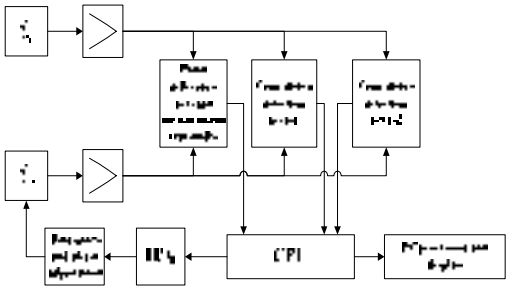

Fig. 1. Transient stability measurement block diagram.

Fig. 1 is a schematic diagram of transient stability measurement between the same nominal frequency sources, which is to regulate the phase difference between the two signals on the coincidence detection resolution threshold, to calculate the transient stability as well as time and frequency domain phase noise index from the discontinuity of the

coincidence information. The two signal frequency values can be equal or multiple. Then one can accurately measure many frequencies with a nominal value frequency.

B. Phase difference adjustment

Specific transient stability measurement block diagram shown in Fig. 1. At first, we should measure the phase difference between reference signal and measured signal. Then adjust the reference signal so that the phase difference between the reference signal and measured signal will be adjusted to the edge value of coincidence detection resolution.

In the measurement process, we can also adjust phase difference between signals to a value greater than the phase coincidence detection circuit threshold, in order to detect the degree of phase fluctuation caused by noise.

C. Coincidence detection circuit

About coincidence detection circuit, we adopt the method of D flip-flop. When the reference signal and the measured signal has a certain frequency difference and no noise influence, assume that $f_x > f_0$,($f_x < f_0$ follows the same result), we get the phase coincidence detection circuit as shown in Fig. 2.

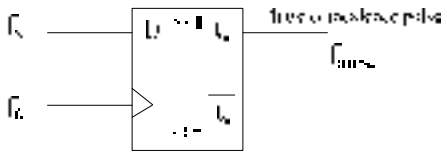

Fig. 2. .Phase coincidence detection circuit diagram.

Use the rising edge of f_0 as the clock signal, collect the f_x state as the output signal, then we get the phase coincidence detection waveform diagram as shown in Fig. 3.

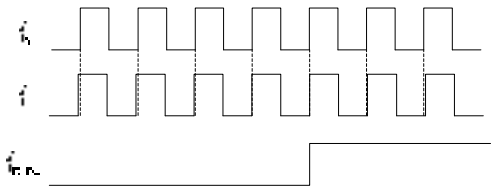

Fig. 3. Waveform diagram of phase coincidence detection.

When the nominal frequency of f_x and f_0 is the same, adjust the phase difference between the two signals to the edge of the coincidence detection sensitivity. If there is no influence of noise, it will maintain a continuous output level. But if there is noise, the phase variation will be between the inside and outside of the verge, thus the level of phase coincidence will alternate between high level and low level. The detection signal waveform diagram of one coincidence detection circuit as shown in Fig. 4, when f_x has noise.

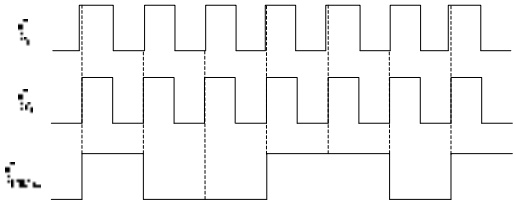

Fig. 4. Coincidence detection of "1", "0" of the signals with fixed phase difference (threshold).

In order to get more detailed quantified information, we can adopt detection circuits working in parallel with different phase coincidence detection resolution stability.

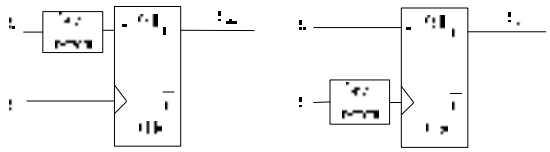

Fig. 5. Phase coincidence detection circuit of one input plus delay.

In order to quantify the change of the phase difference of the acquired signal and avoid the difficulty of getting detection circuits of different stability levels, we adopt a large number of identical phase coincidence detection devices. That is to say, 2 coincidence detection symbols in Fig. 1 represent 2 phase coincidence detection arrays. Each phase coincidence detection circuit in the array has the same degree of coincidence detection resolution stability, such as close to 1ps; but different thresholds, which means to add phase delay to one of the input signals, as shown in Fig. 5, so that each phase coincidence detector's partial coincidence information deviates from "strict phase coincidence" position, and appears a step-by-step pattern. The coincidence detection array outputs "1" and "0" selectively based on the amplitude of the noise of measured signals. It is worthwhile to mention that "1" and "0" has different quantity for the different detection circuits. So we can detect the amplitude of the noise which is closer to the actual situations as shown in Fig. 5.

Due to the use of the phase coincidence detection arrays, what we need to do is to overlap areas of noise performance from arrays. Therefore, the previous requirement of phase measurement and adjustment is greatly reduced.

D. Calculation of frequency source transient stability

Shown in Fig. 5 is the restored phase difference change curve over a short period of time. We can get the corresponding change of phase difference by using the selected sampling interval τ to intercept the curve. The average frequency value of the time τ can be obtained, the corresponding frequency stability indicators can be acquired. We generally adopt the square root of the Allan variance as a

unified representation of the time domain frequency stability. The common formula of Allen variance [9]is

$$\sigma_y(\tau) = \frac{1}{f_0}\sqrt{\sum_{i=1}^{m}\frac{(\Delta f_{i+1} - \Delta f_i)^2}{2m}} \quad (1)$$

Considering the frequency and phase relationship: $\frac{\Delta f}{f_0} = \frac{\Delta T}{\tau}$.

Formula (2) can be deduced from Formula (1).

$$\sigma_y(\tau) = \frac{1}{\tau}\sqrt{\sum_{i=1}^{m}\frac{(\Delta T_{i+1} - \Delta T_i)^2}{2m}} \quad (2)$$

Where ΔT represents the phase difference, and τ represents the duration of the corresponding period time. This formula was originally calculated for the same nominal frequency signal stability by the measurement results of phase comparison method. The deduction and change provide important foundation for the frequency stability which processed from the coincidence detection information. If we consider the response time corresponding to the period of the lower frequency signal, the coincidence detection cycle is precisely the period τ of the lower frequency signal. The change of ΔT obtained through the continuous detection of coincidence state. The ΔT_i inside is the phase difference change between the signal before and after τ.

III. Experiment and results

The schematic diagram of phase difference adjusts to the phase coincidence detection threshold is shown in Fig. 6.

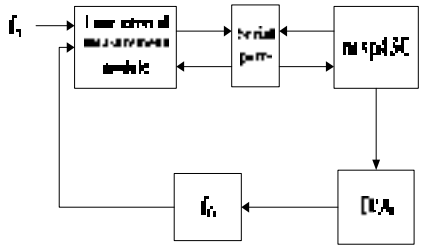

Fig. 6. Block diagram of phase difference adjustment.

Experiment process is as follows. Use time interval measurement module to measure the phase difference between standard signal and the measured signal, then msp430 microcontroller read the value of the measured phase difference through the serial port. After that, calculate the voltage value of voltage controlled oscillator, then get the analog voltage value through the D/A conversion and adjust standard oscillator phase. After taking repeated measurements and adjustments, the phase difference between the standard signal and the measured signal will be adjusted to be close to the phase coincidence detection circuit threshold.

For phase coincidence detection circuit, using a D flip-flop array plus delay to detect the phase coincidence.

When the reference signal and the measured signal have a certain frequency difference, a single coincidence detection circuit can get the phase coincidence detection signal similar to that shown in Fig. 7 Here we use a coincidence detection circuit with better performance.

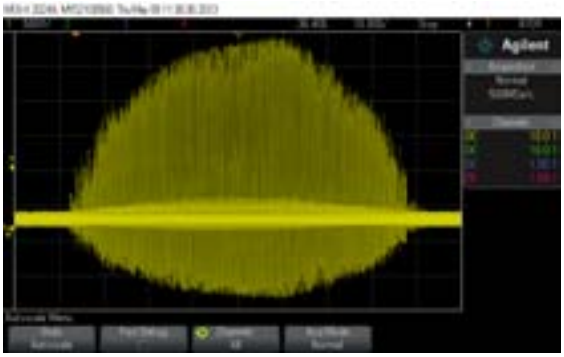

Fig. 7. Phase coincidence detection waveform of two signals with a certain frequency difference.

Experiment 1: Transient stability measurement between two 10 MHz high stability crystal oscillators. 7 sets of data are measured separately, the calculated results of the frequency stability of 100ns Allan variance are: 5.35×10^{-5}、5.45×10^{-5}、5.31×10^{-5}、5.14×10^{-5}、5.10×10^{-5}、5.11×10^{-5}、5.15×10^{-5}. Fig. 8 is the phase noise measurement result between two identical signals.

Experiment 3: Transient stability measurement between two 18.6 MHz phase-locked crystal oscillators. 7 sets of data are measured, the calculated results of the frequency stability of 53.8ns Allan variance are: 7.95×10^{-4}、7.83×10^{-4}、8.03×10^{-4}、8.29×10^{-4}、8.79×10^{-4}、8.95×10^{-4}、1.83×10^{-3}. Fig. 10 is the phase noise measurement result between two signals.

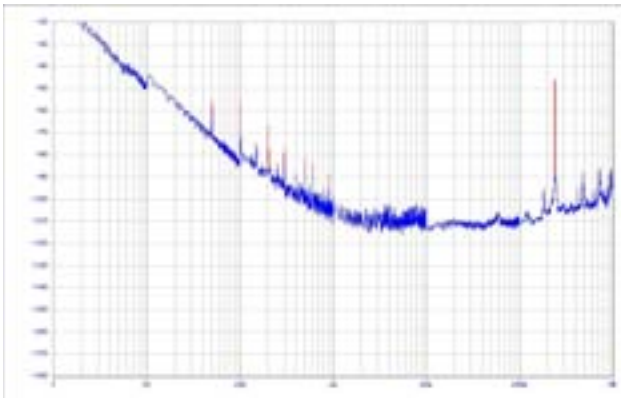

Fig. 10. The phase noise between two 18.6 MHz phase-locked crystal oscillators.

IV. CONCLUSION

Phase coincidence measurement is used mainly for high resolution frequency or phase difference measurement between signals in the past[10]. It is mainly used to capture strict phase coincidence information between the signals, we can achieve high resolution measurement between the signals under the condition that the measurement gate and signals are strict synchronous. When the signals are in the specific and stable state, the transient stability can be measured through the phase coincidence detection that reflects noise. This method makes use of periodicity of signal itself to make repeated coincidence detections, and makes use of the coincidence detection array to quantify the ups and downs of measured signal phase noise, therefore we can obtain fast response time and high resolution.

***Abstract*— Gallium nitride (GaN) is of interest with respect to electronics as it features both semiconducting and piezoelectric properties. We explore the possibilities for employing a GaN-based surface acoustic wave oscillator as a sensor of ultraviolet radiation, consider its thermal properties and phase noise.**

I. Introduction

Gallium nitride (GaN) as well as related semiconducting substances are of interest for application to devices which employ both semiconducting and piezoelectric properties of the structure. One of them is a surface acoustic wave (SAW) oscillator. Usually, such oscillators use a SAW delay line as a feedback circuit. In this case, the oscillation frequency is determined by the geometry of the structure and the velocity of SAW propagation. The velocity, on the other hand, is generally dependent on factors such as temperature and illumination, which offers a possibility for designing appropriate sensors.

Frequency response of a GaN-based SAW delay-line oscillator to ultraviolet (UV) illumination has been demonstrated [1, 2]. The effect has been found to be selective with respect to the wavelength of the incident light – it nearly vanishes when the wavelength exceeds 400 nm [2].

However, very important features of such oscillators – the phase noise and thermal effects – have not yet been investigated. We describe the dependences of oscillation frequency on intensity of UV illumination and ambient temperature and discuss the phase noise for a GaN-based SAW delay-line oscillator.

II. Experimental

The experimental setup of the oscillator is shown in Fig. 1. We use a layer of GaN grown by low-pressure metalorganic chemical vapor deposition on a (0001) sapphire substrate with a pair of aluminum interdigital transducers deposited on the surface of the GaN layer. Each transducer consists of 100 pairs of electrodes fabricated with the period Λ=24 μm and thus is 2.4 mm long. The distance between the central points of the transducers is 11.1 mm. Thickness of the GaN layer is 2.5 μm. The resonant frequency of the structure is 212.34 MHz. The aperture is 1.38 mm.

The two-port SAW delay line is connected to a feedback loop of a wide-band amplifier. We feed the output signal of the SAW oscillator to a SR 620 frequency counter disciplined to the 10 MHz signal of the Lithuanian national time and frequency standard HP5071A. The readings of the counter are saved every second. For UV illumination, we use a TH36 type LED (SEOUL OPTODEVICE) and a 15 W lamp of the BLB type with the radiation intensity maximum at about 365 nm.

We use a MMT-1 type thermometer resistor (with 2,2 kΩ nominal resistance) calibrated to the Lithuanian national temperature standard for measurements of temperature and a commercially available low-capacity cooler to cool the structure down and to achieve operation in a wider temperature range than naturally occurring variations of the room temperature.

III. Results

Fig. 2 shows the variation of temperature and frequency with time without cooling. As indicated on the picture, the experiment begins with UV illumination present. After some time, it is switched off. Fig. 3 shows the same magnitudes with and without cooling. The experiment begins with cooling on, in darkness (without UV radiation). Then, UV radiation is switched on. Finally, cooling stops, while UV illumination continues. The coefficients of linear dependence of oscillation frequency on temperature are the following:

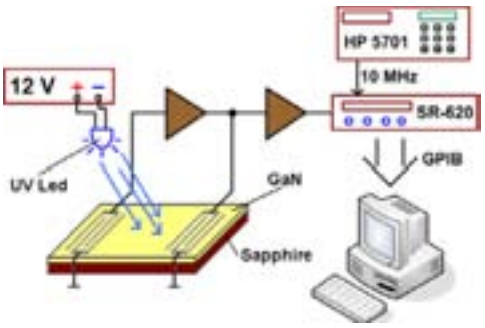

Fig.1. Experimental setup

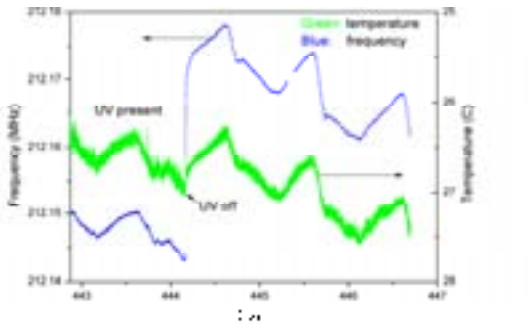

Fig. 2. Variation of temperature and frequency with time without cooling

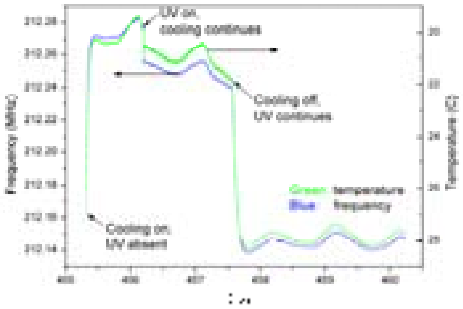

Fig. 3. Variation of temperature and frequency with time with cooling on and off

From the results of Fig. 2:

a) in the darkness: $f = 212.554$ MHz – (14271 t) Hz

b) with UV: $f = 212.475$ MHz – (12291 t) Hz

From the results of Fig. 3:

a) in the darkness: $f = 212.554$ MHz – (14031 t) Hz

b) with UV: $f = 212.585$ MHz – (15914 t) Hz,

where t is the temperature in degrees of Celsius. We can see that the coefficients of the "dark" operation are very similar in both experiments, while the coefficients under illumination differ significantly; the data are insufficient to prove that thermal sensitivity of the frequency depends on UV illumination.

Fig. 4 shows the dependence of the frequency shift on the intensity of UV illumination. It is seen that it is nonlinear, and the frequency shift at the maximum illumination intensity corresponds to that due to the change in temperature of $\sim 2\ ^{o}$C.

The spectral densities of fractional frequency fluctuations, $S_y(f)$, observed at different conditions of oscillator operation, are presented in Fig. 5 – 7. Spectral densities $S_y(f)$ were calculated using "Stable 32" software. It should be expected that different mechanisms of the phase noise can occur in such an

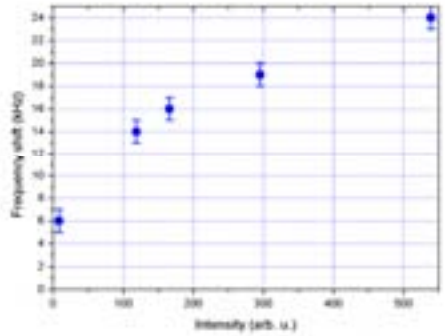

Fig.4. Frequency shift versus intensity of UV illumination

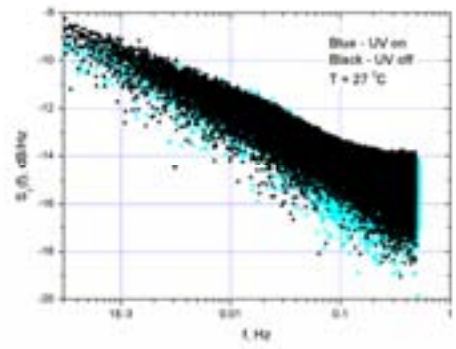

Fig. 5. Spectral densities of fractional frequency fluctuations $S_y(f)$ with the LED UV illumination on and off. Oscillator was kept at the temperature of 27 ^{0}C

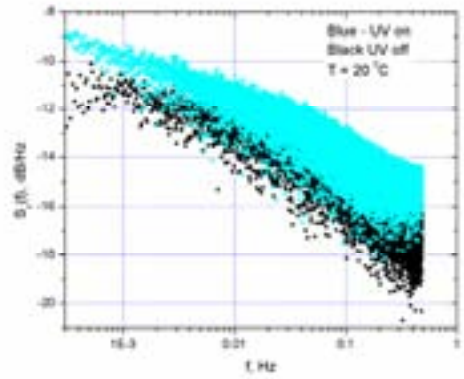

Fig. 6 Spectral densities of fractional frequency fluctuations $S_y(f)$ with the LED UV illumination on and off. Oscillator was kept at the temperature of 20 ^{0}C

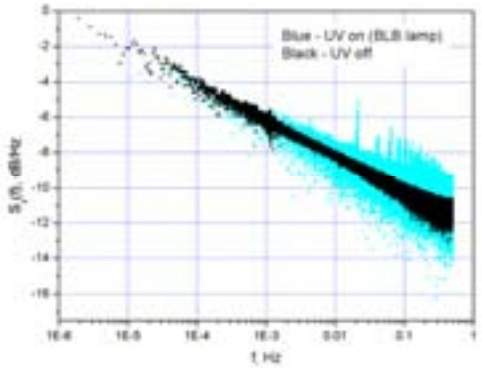

Fig. 7. Spectral densities of fractional frequency fluctuations $S_y(f)$ with the BLB lamp UV illumination on and off. Oscillator was kept at the temperature of 23 ^{0}C

experiment. However, deeper insight into this issue is necessary.

IV. Conclusion

We have demonstrated the effect that UV illumination and temperature have on oscillation frequency of GaN-based SAW delay-line oscillator. The findings imply that the frequency shift varies linearly with temperature. Therefore, using such a system as a sensor for UV illumination requires taking into account the value of temperature.

Abstract—**The balanced SAW oscillator in the modified Colpitts configuration is studied. To enhance the start up a cross-coupled pair is embedded. Owing to the insulating feature of SAW resonator, the problem of latch may happen. With a careful design in the aspect ratio of CMOS transistors between main amplifier and cross coupled pair, this problem is solved. By the aid of inherent opposite polarity of cross-coupled pair appeared on the terminals of SAW resonator, the star up grows much fast as compared to the well known Colpitts oscillator. The transition period is significantly shrunk. For completeness three kinds of oscillator with single ended, balanced Colpitts, and cross coupled one are compared in terms of figure of merit (FOM) under the same magnitude across the resonator. The power consumption and phase noise are also indicated.**

Keywords- SAW, Balanced Oscillator, Cross Couple, CMOS.

I. INTRODUCTION

Clock oscillators often utilize the high quality factor and high frequency surface acoustic wave resonators (SAW) to obtain the stable frequency. As the author's knowledge, the configuration of the oscillators normally adopt the Pierce or Colpitts oscillators with single ended output. [1] The output needs an extra step to be converted to a differential pair before connected to next stages, such as mixer in receiver, divider in PLL, or phase detector in CDR as shown in Fig. 1. The differential topologies can take advantages of reduced noise, good power supply rejection ratio, and direct matching to the inputs of preceded stages. Recently two types of balanced SAW oscillators with either two parallel Colpitts or cross-coupled pair have been presented. [2-5] As compared, the former has better phase noise but suffers from the long transition due to the lack of phase inversion in initial growing. On the contrary, the latter has the inherent phase inversion, which results in fast transition. In this study a modified Colpitts architecture with embedded cross-coupled pair is presented to take the advantages of quick transition and good phase noise. The phase noise and transition time are especially investigated. In the meantime, a comparison in performances with other balanced type of Colpitts is presented.

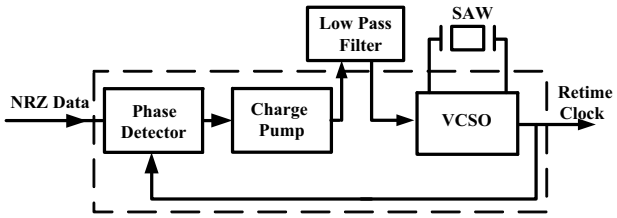

Fig. 1 Application of VCSO in giga-bit CDR

II. OSCILLATOR WITH DIFFERENTIAL OUTPUTS

The schematic of VCSO is briefly shown in Fig. 2. Two stacks in CMOS process are used for low voltage operation. M5 and M6 in combination with capacitance C1-C4 form two parallel Colpitts oscillators, which are coupled through a one-port SAW resonator. The SAW resonator exhibits a series LC resonance Ls, Cs, and Rs in parallel with a capacitance Co regarding to motional vibration and parasitic of interdigital electrodes, respectively, as shown in Fig. 3a. The parameters of equivalent circuit are listed in Table I. Under fully differential situation, the SAW resonator now is able to be re-modeled as two series resonators with center point virtually grounded as shown in Fig. 3b.

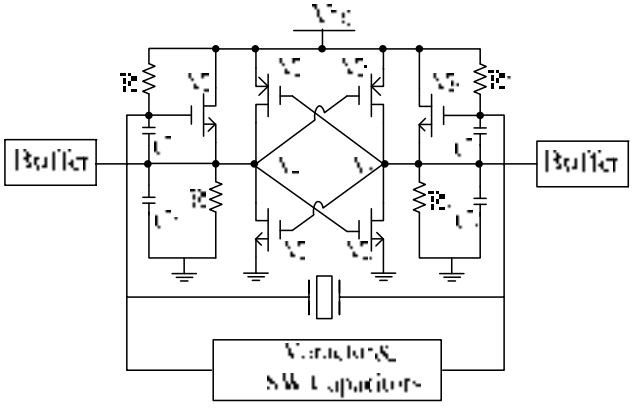

Fig. 2 Schematic of the balanced Colpitts oscillator with embedded cross-coupled CMOS pair.

(b)

Fig. 3(a) SAW Model and (b) remodel in differential case

Table I Parameters of 425MHz SAW Resonator

Co	Rs	Ls	Cs
3.8pF	**10.53Ω**	**46.3uH**	**3.03fF**

For clearance, the capability of the balanced Colpitts oscillator is initially described. It is basically consisted of two single-ended Colpitts oscillator sharing the common SAW resonator. M5 and M6 are the main amplifiers, which combine C1/C2 and C3/C4, respectively, to form the negative resistance seen into the gate terminals. As applied to oscillator, the resonator has two operating modes. One is the series mode and the other is the parallel mode. The former has the resonator acted in series short circuit, while the latter acts as parallel circuit. Here, the latter is utilized. The SAW resonator in parallel mode provides the effective inductances to form the differential Colpitts oscillators. The frequency tuning is accomplished by the extra parallel switched capacitors and varactors. Unfortunately, the effective parasitic from the metal electrodes as illustrated in Fig. 3b now becomes 2Co, which will degrade the negative resistance as compared to that in single ended case. It causes more current consumption. The rf output power is also degraded, so as the phase noise.

It is noted that the tuning varactor is also in parallel with the SAW resonator. In some sense the larger the varactor has, the larger the tuning range has. However, this fact also degrades the negative resistance from active devices and causes low output power. Hence, a trade off exists between phase noise and tuning range. The figure of merit given by

$$FOM(dB) = 10\log\left[\left(\frac{\omega_o}{\Delta\omega}\right)^2 \frac{1}{L(\Delta\omega)\times P}\right]$$

is used to evaluate the performance, where P is the power consumption of the core circuit, $\Delta\omega$ is the offset angular frequency from the carrier, ω_o is the center frequency, and L(Δω) is the phase noise. The figures of merit (FOM) in single and balanced cases are typically around 207 and 201, respectively. The balanced one has worse phase noise.

It has been indicated that the turn-on transitions about 150us in oscillators with cross-coupled pair is faster than the previous one. [4] This is due to the nature of the phase inversion in cross coupled pair. The function of phase inversion needed by the parallel Colpitts can be easily accomplished by embedding the cross-coupled pair M1-M4 as shown in Fig. 2. M1–M4 are the cross coupled pair to enhance the negative resistance of Colpitts pair. With the pair embedded, the ac signal is amplified so that its transition is speeded. It is worth noting that, the cross-coupled pair also acts as latching in digital circuit. Therefore, the aspect ratio of the pair CMOS must be carefully traded off between latching and output power level. It is expected that the current consumption is raised, however, the output power is increased significantly. The composite configuration indeed behaves better performance in terms of FOM.

III. Performances

The layout is illustrated in Fig. 4 with die area about 0.545×0.510mm^2. The chip is fabricated by TSMC 0.18um CMOS process. V_A is the analog tuning voltage for varactor and V_B and V_C are the digital control voltage for switch bank. Due to the manufacture variation and temperature, Tuning capability is needed to overcome the frequency offset. Here, two switched capacitances are inserted to fulfill the requirement. The calculated phase noises are illustrated in Fig. 5a. For comparison the result from only cross coupled pair is included in Fig. 5b. It reveals the composite one has phase noise better than 8.9dB. The penalty in current consumption is about 1.6dB. The FOM achieves 211. It is concluded that the composite has better performance in terms of FOM. The details are listed in Table II.

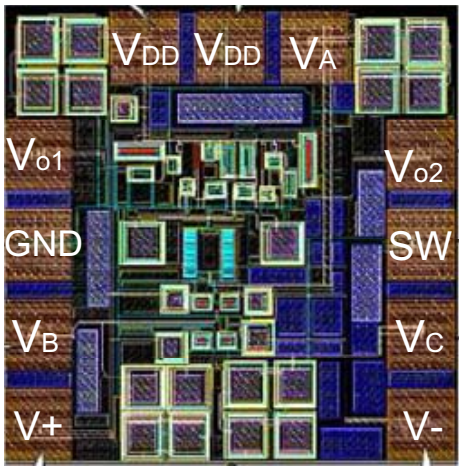

Fig. 4 Layout of the cross coupled SAW oscillator

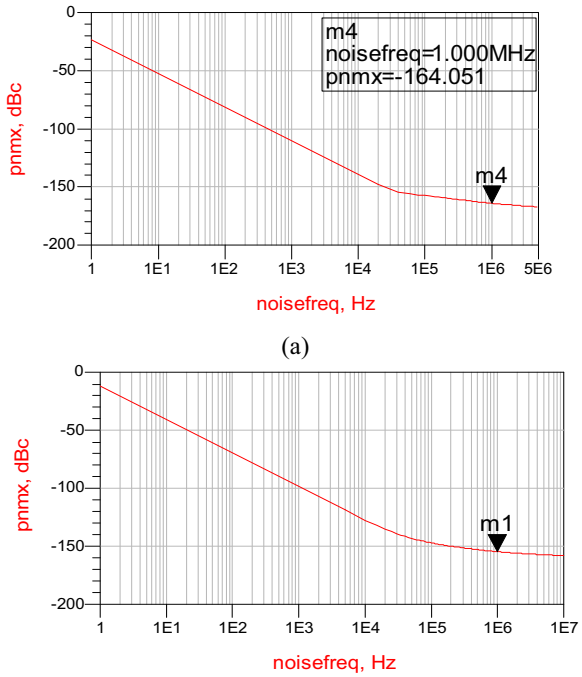

(a)

(b)

Table II Performances List of Two Oscillators

$FOM = 10\log\left[\left(\frac{\omega}{\Delta\omega}\right)^2 \times \frac{1}{L(\Delta\omega)\cdot P}\right]$		

IV. Conclusion

In this study a balanced VCSO using the composite configuration of Colpitts and cross coupled pair is presented. First, the comparison in single and differential Colpitts is made to indicate the effect of parasitic capacitance doubling, which causes the more current consumption. Next, the property of inverse polarity between two outputs is easily achieved by embedding the cross coupled pair. This function drives quickly the oscillator into steady state as compared to the balanced Colpitts one. The latched problem is solved by trimming the MOS size. The design is traded off between latch and phase noise. It is demonstrated that the composite configuration has better performance in terms of FOM. Our results can be extended to other high frequency and high Q resonators such as MEMS and FBAR.

***Abstract*—This paper is based on background research [1] in which a manufacturability analysis was carried out for of an oscillator made for 5 GHz satellite and radar bands. The electronic circuit uses two cascaded bipolar microwave transistors in an emitter feedback amplifier configuration which is combined with a cylindrical dielectric resonator. Three miniature coupling loops are included in it, one for amplifier input, one for amplifier output via a Wilkinson power divider and another for the optional tuning varactor diode. We have formulated two research questions: Firstly, how much is it possible to increase the Q-value of the resonator by improving the manufacturing quality of its milled geometries? Secondly, is it possible to describe the required manufacturing accuracy with the Q-value added to the Product Data Management (PDM) data set? This paper focuses on the multidisciplinary aspects of the integrated performance and production oriented design of satellite oscillators. For the first time, the quality characteristic (Q-value) could be utilized directly in the mechanical PDM data of an oscillator to guide production.**

Keywords: oscillators, Q-value, PDM data

I. INTRODUCTION

In this research, three separate resonators were constructed and measured with different coupling loops. One of the resonators, shown in Fig. 1a, has a quartz plunger for the height adjustment of the dielectric disc, as indicated in Fig. 1b. The silver-coated resonator cavity itself is shown in Fig. 1c. An HP scalar network analyzer system was utilized and the resonator center frequency, insertion loss, and quality factor were measured with different vertical and horizontal disc positions.

Figure 1. a) Test resonator. b) Resonator cover showing the ceramic disc and its quartz plunger. c) Cavity interior.

II. RESEARCH METHODS APPLIED

Laboratory tests were conducted to measure the achievable surface quality and dimensional and geometric tolerances of the milled resonator cavities. To find answers to the research questions, three different research methods have been applied. Firstly, computer aided EdgeCAM simulations were used to evaluate the efficiency of the machining phases of the oscillator body and to establish the relative machining times for each machining phase. These EdgeCAM simulations were also used to evaluate the required PDM data for guiding the milling tools. Secondly, laboratory tests were conducted to measure the achievable surface quality of the resonator cavity. Thirdly, dimensional and geometric tolerances of the milled resonator cavity were measured. In this paper, the main focus is on the results dealing with the experimental evaluations of the effects of dimensional uncertainties analyzed by constructing three resonators with different coupling loops.

III. RESULTS

A. Performance aspects

In our tests, the direction convention was chosen from Fig. 1a so as to have positive x-values to the right, positive y values away from the viewer and positive z values up from the desk surface. A typical wide-band view is shown in Fig. 2 and a 3 dB width measurement example in Fig. 3. Results obtained are collected into Table 1.

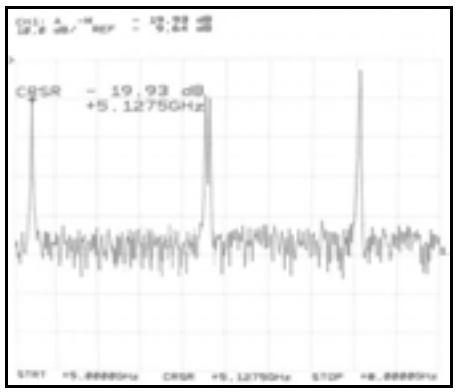

Figure 2. Wide-band spectral response of resonator I.

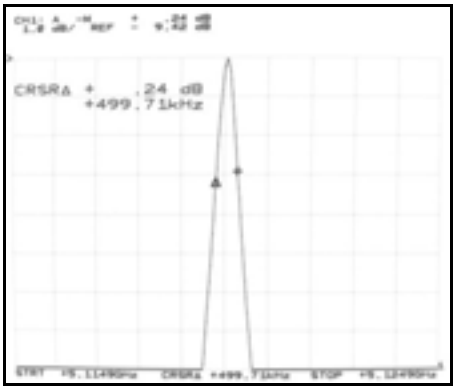

Figure 3. A close-up of the resonance characteristics revealing the 3 dB bandwidth.

TABLE I. ELECTRICAL PERFORMANCE FACTORS FOR DIFFERENT MISALIGNMENTS

Δx (mm)	Δy (mm)	Δz (mm)	f_c (GHz)	IL (dB)	Q
0	0	0	5.1196	9.52	10246
+0.5	0	0	5.1196	9.57	10225
+1.0	0	0	5.1196	9.57	10225
+1.5	0	0	5.1199	9.52	9752
+2.0	0	0	5.1201	9.65	9309
-0.5	0	0	5.1197	9.49	9770
-1.0	0	0	5.1198	9.69	10225
-1.5	0	0	5.1200	9.72	10225
-2.0	0	0	5.1204	9.98	9309
0	+0.5	0	5.1197	9.34	10246
0	+1.0	0	5.1198	9.11	9746
0	+1.5	0	5.1199	8.96	9746
0	+2.0	0	5.1204	8.70	9312
+0.5	+0.5	0	5.1199	9.12	9310
0	0	+0.5	5.1197	9.60	10246
0	0	-0.5	5.1199	9.63	10776

In order to study the effects of a non-circular cavity cross section, we added a sheet of 0.1 mm aluminum foil to cover 90 degrees of the circumference in the middle of the two active coupling probes and carefully pressed it to meet the cavity wall curvature. Other dimensional variables were kept at zero. This caused the center frequency to rise to 5.1206 GHz, the insertion loss was 10.60 dB and the Q-value dropped to 8533. If the foil was larger and covered almost 270 degrees (from probe to probe), the quality factor would be below 5000. The measured data of the two remaining test resonators is displayed in Table 2.

TABLE II. TEST RESULTS OF TWO ADDITIONAL RESONATORS.

Resonator	Notes	f_c (GHz)	IL (dB)	Q	Loop type
II	min. f	5.0468	7.66	9388	wire
II	max. f	5.0473	8.86	9858	wire
III	no cover	5.0471	4.27	6208	wire

Based on these experiments, it seems apparent that the ceramic resonator disc alignment or its position in the cavity as such are not critical compared to the circular symmetry requirement of the cavity itself. Even a very coarse mounting error of the order of 1-2 mm will only cause some de-tuning, but the quality factor will stay sufficiently high to keep the oscillator phase noise level within acceptable limits.

No measurable difference was noticed when the 0.1 mm sheet was placed inside the real active oscillator cavity, as is evident from Fig. 4 and Fig. 5. The sheet covered again one quarter of the cavity circumference. The result is partly obvious because the test system noise floor was limited by the available 100 Hz resolution bandwidth, and even with the sheet, the quality factor is above 8000. However, as was observed already with the plain resonator (see Table 1), the oscillator center frequency was changed, but surprisingly, it declined even though the resonator was tuned up. Also, the magnitude of the shift was lower, approximately 700 kHz. Nevertheless, because the entire tuning range of the oscillator (screw plus possible varactor) is only 2 MHz, it appears that the shape deformation of the cavity is also in this sense quite critical.

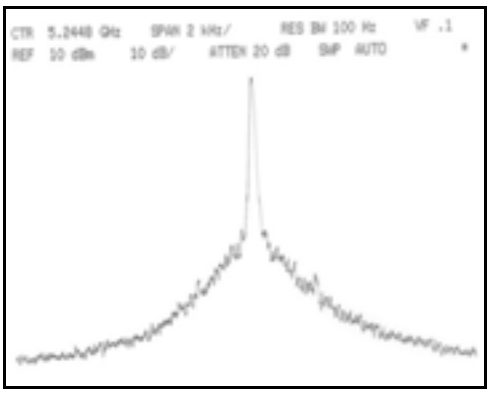

Figure 4. Oscillator spectrum without artificial shape deformation sheet.

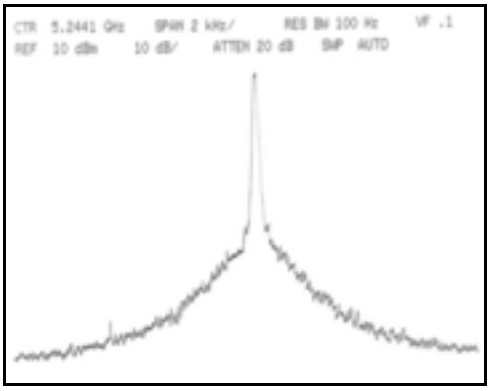

Figure 5. Oscillator spectrum with artificial 0.1 mm sheet in the cavity.

B. Production aspects

The first key observation is that both the resulting surface roughness and the geometric accuracy of the cavity seem to exceed the theoretical minimum requirements given in scientific literature. The required values for similar applications in this frequency range would be IT10 and Ra=12.8 μm [3].

However, we know that some unwanted, excessive structural inaccuracy of the construction could be caused by 1) the gluing process of the resonator buck and the quartz tube, 2) the machining challenges of these ceramic components, 3) the difficult positioning control of the power feeding loops and the resonator puck and 4) some errors of the gold coating process of the cavity (e.g. pinholes, nicks or unwanted roughness [4]). Therefore, it would be valuable to be able to produce a "buffer" against these inaccuracies by optimal handling of the machining phases of the cavity geometry. Detailed tests and analysis of the test results dealing with mechanical engineering are documented in [1] and [2]. One example of the EdgeCAM model is presented in Fig. 6.

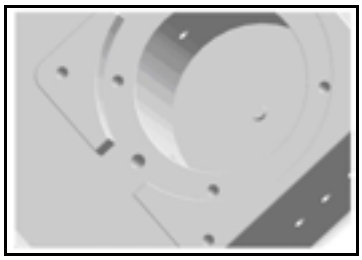

Figure 6. Example of the EdgeCAM model.

An interesting detail of the production analysis was the finding that only 20% of the machining time is spent on milling the cavity itself. Approximately 60% of the time is used for drilling and threading the small assembly holes [2].

The oscillator types which were analyzed in this paper were silver coated, but typically also gold-coated versions are used. One option for gold coating is to use a standard plating of 5ou" electrolytic gold according to MIL-G-45204 over 5ou" electrolytic nickel according to QQ-N-290. Thin layers of silicon dioxide deposited on the surfaces can also protect metals in the space environment. In addition, titanium-aluminum-nitride coatings have been tested for satellite temperature control applications [5]. Geometrical inaccuracy seems to be independent of the material selection of the coating layer. It depends rather on the selected coating process.

IV. CONCLUSIONS

A scalar network analyzer system was utilized and the resonator center frequency, insertion loss, and quality factor were measured with different vertical and horizontal disc positions. The wide-band spectral response of each resonator was established. Based on the results, the ceramic resonator disc alignment or its position in the cavity was not critical compared to the circular symmetry requirement of the cavity.

When analyzing the effects of the non-circular cavity cross section, it was noticed that e.g. 0.1 mm deflection, which covers 90 degrees of the circumference of the cavity, causes the center frequency to rise to 5.1206 GHz. Meanwhile, the insertion loss was 10.60 dB and the Q-value dropped to 8533. These tests were repeated to collect and construct the corresponding PDM data set, which illustrates the relationships between the values of the circularity and dimensional inaccuracy of the cavities and the corresponding changes of the Q-values and the center frequencies.

The findings presented in this paper are in line with the viewpoints presented by Wall and Sinnadurai [6], who identified the trends of the component industry, examined the methods of achieving "space quality", discussed the challenges of the space industry, and finally, considered the performance specifications. Our results are also supported in [7] and [8] by Lohtander, who discusses the design and manufacturing aspects of modern microwave components.

***Abstract*—This paper describes a redundant frequency source system with seamless switchover that produces a stable and continuous output frequency signal. This system has primary and backup frequency produce links to generate the reference frequency. It has the ability to monitor the integrity of the frequency produce links and switchover seamlessly between the primary and the backup links. By use intermediate oscillator of the measurement system as a third party criterion, the autonomous monitor integrity of frequency produce links was achieved without external reference signal. The excellent short-term stability characteristics of intermediate oscillator improves the accuracy and real-time for the monitoring of sudden failure and the degradation of performance. Seamless switchover was defined as the maintenance of both output phase and frequency continuity while and after the switcher from the primary to the backup links. It was initiated when system detects a degradation of the integrity of primary links. The experiment result has been presented showing that there were no detectable change in phase and frequency after the switchover, and the jump of frequency was less than 2e-13, the change of phase less than 100ps.**

Keywords-redundant frequency standard; autonomous integrity monitoring

I. INTRODUCTION

This paper describes a redundant frequency source system to provide the reference frequency signal as the reference of high resolution electronics. In order to guarantee the reliability and stability of the frequency source of the electronic system, it usually adopts the method of redundant to deploy the frequency source, which uses multiple frequency source for the system. To ensure the reliability and continuity of the produced reference frequency signal, the system can quickly switch to other frequency sources when a certain frequency source is the degradation of performance or failure.

The research based on the research of the current redundant frequency source designs a redundant frequency source, which can achieve Seamless Switchover and is according to more than one single frequency source as reference, including the two frequency produce links of the primary and the backup. Through the high precision measurement phase difference of the output frequency signal of the primary and backup links, it designs the real-time autonomous monitoring algorithm for the integrity based on Kalman filter's model for the primary and backup links, so it can achieve independent monitoring for system integrity. And it uses the method of the phase-locked for the link output signal after the switching, to ensure that the output signal frequency of the system and the phase of the primary and backup links maintain continuously before and after switching, thereby the seamless switching of the primary and backup links for the output frequency signal is achieved.

II. SYSTEM COMPONENTS

This system is composed of the redundant frequency source, the phase measurement, the control and integrity monitoring, the generating signal of the primary and backup links, the phase-locked of the output, the system structure is shown in Figure 1.

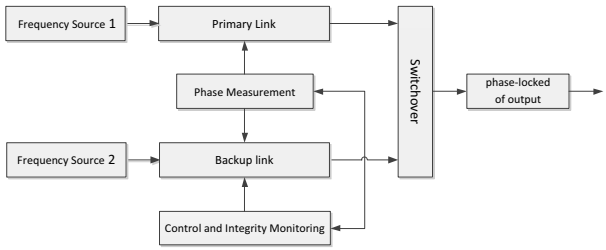

Figure 1. Schematic Diagram of Systems

The redundant frequency source includes the two atomic frequency standards, namely providing the independent frequency signal for the primary link and the backup link. The output signal of atomic frequency standard of the primary and backup links as a reference signal generate the signal of the primary and the backup, and through the switching selecting the primary signal outputs to the phase-locked loop (PLL). The primary signal final outputs after locked. The frequency signal of primary and backup links can be adjusted to achieve the seamless switching for the different frequency signal.

The phase difference measurement section real-timely measures the phase difference of output signal between the primary and backup links. And the mathematical model is done through integrity monitoring and the control part. The signal adjustment amount of the backup link is calculated, to control the output signal of the primary and backup links to maintain consistently. While the integrity of the primary link is monitored to control the seamless switching for the primary and backup links based on the monitoring results.

Supported by National Natural Science Foundation of China, No.61001076

III. THEORY OF OPERATION

A. *Signal phase mathematical model of primary and backup links*

In order to get an accurate sample of the sampled result, phase measurement method is designed based on low sampling rate. The method introduces the public oscillator as a reference source to improve the phase measurement accuracy, and through the double-balanced design structure eliminates the phase noise introduced by the common oscillator, in the case of the lower sampling rate to achieve the 0.1 nanosecond of phase measurement accuracy.

The accurate mathematical model of phase difference data is built based on obtaining accurate phase difference measurement. There are many ways of modeling, commonly used quadratic polynomial model, gray model and Kalman filter model. The Kalman filter model considers the phase bias of the system clock and the random errors. It can better describe the change of phase difference. The Kalman filter model also has the characteristics of the real-time, and it is conducive to achieve the real-timely monitoring of the phase difference.

B. *Real-time autonomous integrity monitoring algorithm of primary and backup links*

- Observations Selecting

In order to use existing equipment, the relative frequency difference of the primary link and the backup link, the relative frequency difference of the primary link and the intermediate oscillator and the relative frequency difference of the backup link and the intermediate oscillator as observations are selected. It achieves the integrity of autonomous monitoring without additional hardware.

The observations with above-mentioned are generated through the deviation measurement equipment of the primary and backup links in multi- Redundant frequency source. The observations can directly get involved in computing, and then be modeled using the Kalman filter. Then the associated detection algorithm is running to detect integrity exception and determines the abnormal attribution.

- Detection of Signal Leap

The tends of phase and frequency difference between the primary-backup links and the intermediate oscillator is real recursive fitting approximation and prediction, which uses the recent M measurement results and based on the Kalman filter model. Then the signal leap and mutation of the primary and backup links are decided according to the size of the measured frequency difference and the predicted frequency difference. The specific works is shown in Figure 2.

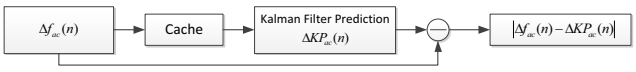

Figure 2. Detection Principle of Kalman Filter Prediction for Signal Leap

The detection threshold selection is very important in real-time autonomous integrity monitoring algorithm, it will directly affect the algorithm to detect the ability of abnormal situations. Detection threshold has relations with the abnormal state of the primary and backup links, and the tracking accuracy of Kalman filter model for the phase difference. The characteristic of the primary and backup links anomalies needs to be considered when choosing threshold, it also takes into account the impact of the Kalman filter for tracking error. By selecting the appropriate data buffer and anomaly detection threshold at a lower false alarm rate can be the case, the frequency hopping of the output signal of the primary and backup links can achieve the detection rate of 99.99% or better.

- Monitoring of Signal Degradation

Monitoring the signal degradation is achieved through using the assessment method of the signal frequency stability in design. The frequency stability of σ_{ab}^2, σ_{ac}^2 and σ_{bc}^2 of the deviation between the primary link, backup link, and the intermediate oscillator can be calculated according to the recent measurement results and the relative frequency difference, which contains the relative frequency difference of $\Delta f_{ac}(n)$ between the primary link and the intermediate oscillator, the difference of $\Delta f_{bc}(n)$ between the backup link and the intermediate oscillator and the difference of $\Delta f_{ab}(n)$ between the primary and backup links.

$$\begin{cases} \sigma_a^2 = \frac{1}{2}(\sigma_{ab}^2 + \sigma_{ac}^2 - \sigma_{bc}^2) \\ \sigma_b^2 = \frac{1}{2}(\sigma_{ab}^2 + \sigma_{bc}^2 - \sigma_{ac}^2) \\ \sigma_c^2 = \frac{1}{2}(\sigma_{ac}^2 + \sigma_{bc}^2 - \sigma_{ab}^2) \end{cases} \quad (1)$$

The obtained frequency stability needs to be processed by using tricorn, the specific algorithm is shown in Equation 1. Through the further processing, the relatively independent stability of σ_a^2, σ_b^2 and σ_c^2 of output signal between the primary and backup links and intermediate oscillator can be calculated. Through real-timely analysis and evaluation them σ_a^2, σ_b^2 and σ_c^2, the frequency stability of the primary and backup links can be derived. Thus the monitor of performance of the primary and backup links output signal can be achieved.

- Detection of Signal Loss

In the primary and backup links under normal operating conditions, the frequency difference and phase difference measuring device will output the correct measurement results. When the primary link or backup link signal is missing, the device will not output the measurement, the integrity monitoring will not be able to obtain the correct observables. Through continuously observing the phase and frequency difference measurement and selecting the appropriate threshold, at the same time using the single-step predicted values of the Kalman filter model, so the anomalies of signal missing whether the primary and backup links occurring can be determined.

C. The Precision Control Method of Primary and Backup Links Output Signal

The output signals of the primary and backup links are independent, which has a certain phase deviation and frequency deviation, and this deviation will gradually drift over time. In order to make primary and backup links maintain the consistent output signal, the primary and backup links needs to be real-timely controlled.

Before switching on the primary and backup links, the backup link has no output signal. The output signal of the backup link is directly controlled based on the phase difference measurements of the primary and backup links and remove outliers, to match the primary link consistently.

After the primary and backup links switchover, the output signal of the backup link is the system reference frequency signal. Based on the mathematical model of the phase difference established before switching, the primary link is real-timely controlled after the switch, its characteristics is consistent with the primary link before switching. Selecting the exact amount of the control in the control process, the control does not affect the stability and accuracy of the signal itself before and after.

Control in this manner, the adjustment of each control is controlled in an appropriate range. This can ensure the continuity of the signal in the control process, and guarantee the change of the signal frequency and phase within the allowable range.

D. Seamless Switchover of Primary and Backup Links

In order that the system output frequency signal is not interrupted in the primary and backup links before and after the switch, the method of output phase-locked is used to switch seamlessly in primary and backup links, so as to maintain the continuity of the system output signal. The PLL circuit is added after the primary and backup links. The output signal of switch is the reference frequency of the PLL. The signal of PLL is the final frequency signal of the system.

While the output signal of the primary link occurring phase anomalies or failures, etc is monitored, the switch will select the backup link as the output signal. The signal through precise control before switching in the primary and backup links is basically the same. And the signal switching time is very short. The PLL output signal can be remained to be not interrupted in the operating time of the switch, which uses the holding function of the PLL itself. The seamless switching for the primary and backup links can be achieved.

Using the method of the output phase lock, the system output frequency signal can be maintained continuously and without interruption. But the moment of the switch operation, the reference signal of the phase locked loop will appear transient disappearance and there may be a PLL loses lock. This leads the output signal to occur leap. The phase-locked loop enters the locked state again until the reference signal occurs, then the output signal will regain stability.

To solve the output frequency signal in the primary and backup links with switching process may cause the problem of output PLL loses lock, a PLL circuit having a holding function of the output signal of the phase-lock after switching is designed, which is shown figure 3.

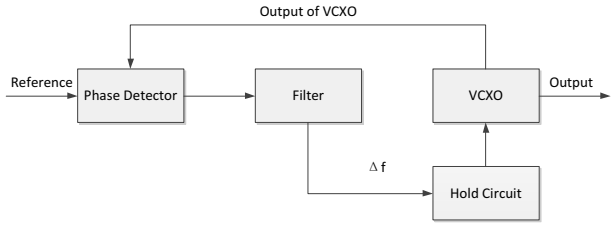

Figure 3. PLL circuit with a holding Circuit

Compared with the ordinary phase-locked loop, the PLL with the role of the holding has increased the maintaining circuit. The error controlling voltage of the loop of the loop filter output is not directly input to the voltage controlled crystal oscillator (VCXO), but by the holding circuit and then output to the VCXO, so as to control the output frequency of the VCXO.

Under the normal operating condition, the phase detector generates the adjusting voltage according to the phase difference between the reference signal and the output signal of the VCXO. The adjusting voltage processed by the loop filter generates the loop error voltage, which outputs to the VCXO through the holding circuit. When the reference signal is lost or occurs unusual, the loop will enter the state of the losing lock. In this case, the output voltage signal of the phase detector will be a large variation, this results that the output error voltage signal of the loop filter also occurs a big change. At this time the holding circuit determines the abnormality loop error voltage signal and continues to output the loop error voltage stored in history to the VCXO. The obvious changes of the output frequency signal will not occur until the reference signal is restored to the normal, the PLL enters the locked state again.

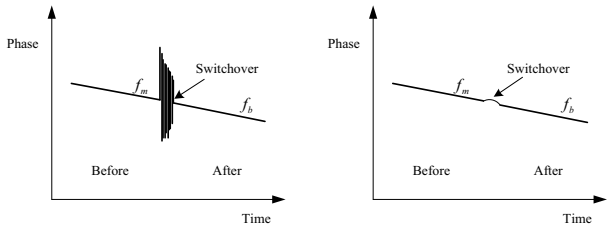

Figure 4. Output of Switchover with Different PLL

Using the function of the holding PLL to lock the output signal after switching and adopting the common PLL to lock, the switching process of the primary and backup for the output signal of the primary and backup links is shown in Figure 4. From the picture, when using the function of the holding PLL lock to output, the output signal of the system before and after switching is consistent. The large frequency and phase fluctuations do not occur. The signal of seamless switching can be achieved.

IV. THE FIRST MEASUREMENT

To measure the output signal frequency and the specific jump variables of the phase in the primary and backup links before and after switching. The master clock signal of the NTSC is a reference signal, and it is through the high-precision frequency source to generate a reference signal. Then the output signal as a test signal inputs the multi-channel phase testing instrument. Last the instrument measures the phase change volume between the test signal and the reference signal, and the time of switchover is recorded.

When the output of the system is switched from the primary link to the backup link, the moment of switching in the primary and backup links is recorded. The phase change of the test signal is calculated in the final measurement results. And the average frequency change of the signal is calculated after continually running for a period of time.

A. Result

The measurement results are shown in figure 5 and figure 6.

In Figure 5, the abscissa is the measured time in seconds; the vertical axis is the phase change value of the output signal, in units of seconds. The system carried out the four switching in the measurement process, the phase change of the switching time is indicated in the figure by a red circle. From the figure it shows that the phase change of the system before and after switching in the primary and backup links is about 0.1ns.

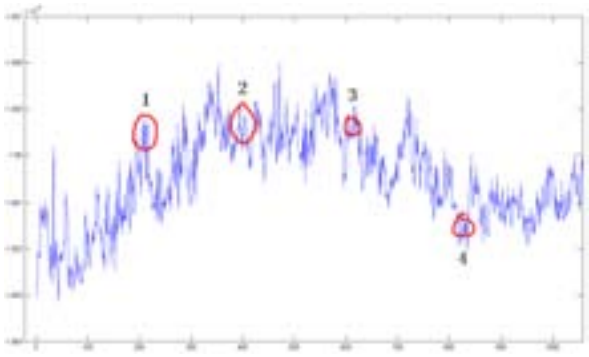

Figure 5. Phase Changes of output with Switchover

In Figure 6, the horizontal axis is the measurement time, in seconds, the figure shows that the result is the phase change from the 3800 to 14000 seconds; vertical axis is the phase change value of the output signal, in seconds, the switching time of the primary and backup links occurs in the first 4085 seconds. Seen from the figure, the initial phase value of the output signal is -7.0952μs at the switching time, after switching the phase accumulation is to -7.0937μs in 2 hours. Which is known :

$$\Delta f = \frac{-7.0937-(-7.0952)}{2\times 3600} = \frac{1.5ns}{7200s} = 2\times 10^{-13} \qquad (2)$$

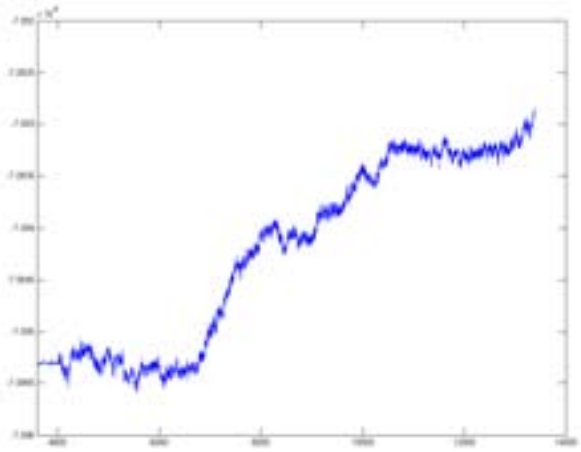

Figure 6. Signal Phase Changes with Switchover after 2 hours

It is concluded that the average frequency jump of the output signal of the system is 2×10^{-13} when the primary and backup links switchover after two hours.

V. CONCLUSIONS

The redundant frequency sources is designed in this paper, it is included the two frequency generation links with the primary and backup links. The redundant frequency sources combines with integrity monitoring method for the primary and backup links, link control strategies and the seamless switching method. It effectively simplifies the structure of the redundant frequency source, and improves its continuity and reliability of the output signal. It can generate a continuous long-term stability of high precision time and frequency signal. The redundant frequency sources meet the high reliability requirements of the current frequency source for the electronic information system.

***Abstract*— Design of a programmable delay controller (PDC) within an aerospace-compatible field-programmable gate array (FPGA) fabric is presented. Although PDC is a common digital block nowadays, the possibility to use it for low-jitter arbitrary frequency generation constrained only by minimum edge-to-edge time still seems to be uncovered. The novel idea of the developed PDC is seamless line delay switching at sampling frequencies corresponding to the generated output frequency, unleashing a possibility of arbitrary binary waveform (frequency) generation. The maximum frequency is constrained only by the FPGA fabric performance, and by idle delay of available multiplexers. Glitch-free operation with no unintentional edges is employed for proper PDC control signal switching. The overall output signal jitter is composed solely of the jitter of input signal and propagation jitter of the delay elements ($\sigma_{max} = 4.1\,\mathrm{ps\,RMS}$). Measured resolution of the PDC is $\pm\Delta\tau_{max}/2 = \pm 7.5\,\mathrm{ps}$. Measured temperature drift of the PDC is $\sim 30\,\mathrm{ps\,K^{-1}}$. An ability of PDC to generate fractional frequency from the input has been demonstrated on a simplified, low-resolution variant, delivering $33.\bar{3}\,\mathrm{MHz}$ out of $50\,\mathrm{MHz}$ input.**

I. Introduction

Design of a programmable delay controller (PDC) within an aerospace-compatible, FLASH-based field-programmable gate array (FPGA) fabric will be presented. Although PDC is a common digital block nowadays, the possibility to use it for low-jitter arbitrary frequency generation still seems to be uncovered. The objective is to provide a versatile PDC block capable of generating arbitrary binary waveform constrained only by minimum achievable edge-to-edge switching time. The discussed PDC may be able to replace current building blocks such as direct digital synthesizer (DDS), phase-locked loop (PLL), micro phase stepper, or various modulators; all within purely digital circuit (FPGA, custom CMOS).

Let us call the time interval between control signal changes (updates) the sampling period T_s, and let the time interval between the consecutive edges of output signal be called the output interval T_o. Current PDC designs [1], [2], [3], [4], [5], [6], [8] operate at $T_s \gg T_o$, Fig. 1a. The key idea of our proposal is seamless PDC operation at $T_s \to T_o$, Fig. 1b. Such a development unleashes following advantages:

- generation of arbitrary binary waveform constrained only by $T_o \geq T_s$,
- generation of arbitrary frequency, constrained by $f \leq \frac{1}{2 \cdot T_s}$,
- under proper treatment, no edge will be created by the switching elements themselves; therefore, the overall jitter will be composed solely of the jitter of input signal and propagation jitter of the delay elements.

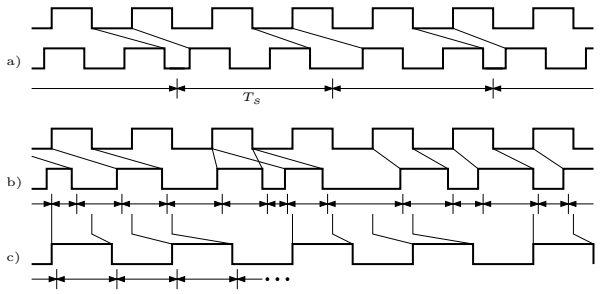

Fig. 1. Input and output waveforms for (a) ordinary PDC, (b, c) PDC allowing rapid switching

Design and implementation details of the PDC circuit are described. Performance figures, such as pass-through random jitter, achieved delay granularity, and temperature drift follow.

II. Circuit design

A. Delay line design

This section describes design of the essential PDC component: a delay line. Typical PDC based on a digital circuitry consists of fixed-length delay elements (transmission lines, gates) composed into signal path by electronic switches (multiplexers). An input signal passes through the delay elements and multiplexers to the output. The multiplexers are switched by means of another digital control signal.

The most common approach is to form the delay line as a cascade of binary elements, Fig. 2a. A favorable property of this design is that n elements may cover 2^n equidistant delay steps, provided element delays follow $K2^{-k}$ distribution, i. e. $d_{k+1} = d_k/2$. Such a delay line acts similarly to a Digital-to-Analog Converter (DAC), but working in time domain. Moreover, the conversion is monotonic by design. Since there is a lack of short delay elements within FPGA fabric, a differential

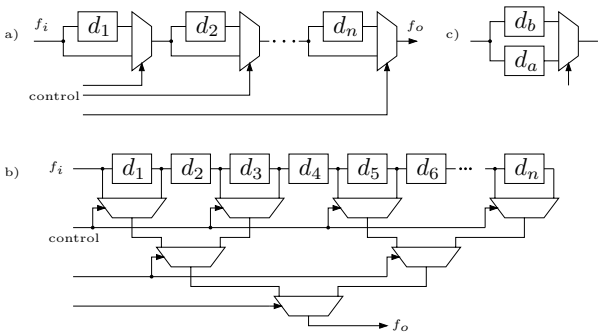

Fig. 2. PDC delay line structure: (a) cascaded design (b) tree-like design (c) fine differential delay

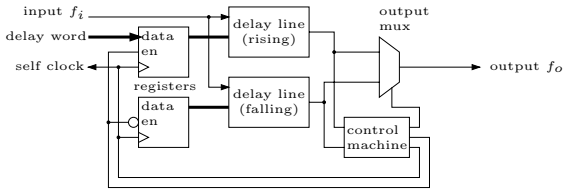

Fig. 3. Complete PDC with dual delay lines and control logic

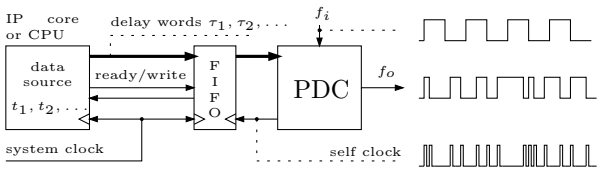

Fig. 4. Self-clocked PDC data-flow

approach to achieve very fine resolution is employed, Fig. 2c. Only $d_b - d_a$ effectively applies, allowing to push resolution down to $\sim 10^{-12}$ s level.

Another approach to delay line uses continuous, tapped line and a binary tree of multiplexers, Fig. 2b. Despite its large area consumption ($\sim 2^{b+1}$ cells for b bits), there is an advantage of uninterrupted delay line, always filled with valid, running signal. See more about its impact in Sec. II-B.

B. Control logic design

In order to achieve versatile signal generation as outlined in Sec. I., we have concluded that the multiplexer control signals should be switched at instants derived from output signal edges (of both polarity) thus operating PDC in a self-clocked manner. It is the most straightforward way to assure proper switching instants. Together with standard asynchronous FIFO, the PDC forms a circuit converting integer numeric data-stream consisting of desired output edge instants $t_1, t_2, \ldots$ into actual binary waveform, Fig. 4.

Block diagram of the PDC circuit is shown in Fig. 3. There are two identical delay lines, in order to mitigate glitches which may occur at the output of the delay line during control input reconfiguration. Just after a rising edge passes through the upper delay line, output multiplexer is switched down to the other delay line. Until next (falling) edge passes, the upper delay line may be safely reconfigured. After passage of the falling edge, the multiplexer is switched back to the upper line, and the lower delay line may be rearranged. Then, the process repeats. Both delay lines are controlled by binary delay words, one for the rising edges, other for the falling edges. The words are stored in respective registers. Loading of the registers and switching of the output multiplexer is controlled by the key part of the design, asynchronous state machine. Most importantly, it generates a non-uniform clock signal derived from the delayed edges. This clock also governs readout of the delay words from data source, i.e. a sequencer (in case of fixed sequence) or FIFO (if delays come from a complex computing system).

The most severe difficulty of the design lies in an unwanted (idle) delay between delay line reconfiguration instant and settling of output signal. In case of cascaded structure (Fig. 2a), only d_1 has always up-to-date signal at its input and inside. But $d_2 \ldots d_n$ have to absorb new input condition upon re-configuration, what may take up to $\sum_{k=2}^{n} d_k$ amount of time. Pass-through delay of all multiplexers adds up. The tree-like structure (Fig. 2b) does not suffer from such transient problem, so its settling delay belongs solely to the multiplexers.

Suppose a PDC with resolution h and maximum delay T is requested. The cascaded structure would settle in $\sim T/2$ plus delays of multiplexers. Where differential elements (Fig. 2c) are used (FPGA fine part), the common mode delay adds up. The tree-like structure exhibits unwanted delay $\log_2 T/h$ times a multiplexer delay; unfortunately, it requires $\mathcal{O}(T/h)$ macros. We see that the proposed kind of rapidly switching PDC is hard to fit into ordinary FPGA fabric.

III. Implementation

A. Delay line implementation

The delay line was implemented inside Actel/Microsemi ProASIC3E FPGA. The line is composed of two distinct parts: coarse, and fine. Two versions of delay lines, with 5 and 13 control inputs (bits), were implemented. The coarse line (5 bits) is made up of $1, 2, 4, \ldots$ combinatorial macro cells ("gates") of the same type in chain. The fine line follows differential structure, with two specially selected macros, one per a branch.

In order to obtain reasonable resolution, all the cells should be well selected as to provide fine granularity over all 2^n bit words. To our knowledge, delay models of FPGA macros are not available in open format. Therefore, we have ran place-and-route tool chain in cycle, iterating over whole macro library, and extracted delay values from SDF back-annotated files [7]. Figures were far from accurate, and lacked an important kind of information: in multiple-input cells, the delay from one input to output may depend on a state of other inputs – this has not been reflected in SDF files (although it is possible by specification [7]). Nevertheless, the obtained timing data served us well as an initial guess. In following automated analysis, every possible cell pair was coupled

with appropriately (non-)inverting multiplexer (yielding non-inverting line element). All these combinations were examined for differential delay, sorted, and shortest candidates for given differential delay were selected. Interval from zero to $\sim 0.5\,\mathrm{ns}$ has been continuously populated with $1\,\mathrm{ps}$ step. From this, candidates were picked up by hand, and subcircuit netlist has been generated. Candidate delay line, implemented into FPGA, has been measured (Sec. IV-A), and unsatisfactory cells were reassigned by hand in next iteration. This process was repeated three times.

First experimental delay line, used for performance analysis, was of 13 bit cascaded structure, 45 cells in total including multiplexers. For a frequency synthesis scenario (Sec. IV-B), 5 bit tree-like structure has been used in order to mitigate idle delay; also, elements counts were doubled to cover $50\,\mathrm{MHz}$ period.

B. Control logic implementation

PDC core controller has been designed by hand as an asynchronous state machine. An intuitive match of the machine to a set of 3-LUT macros of the ProASIC3E FPGA architecture was checked for equivalence in state encoding and transition maps to eliminate hazards. For demonstration purposes, only a fixed delay word sequence has been wired into shift-register based sequencer: approximations of $(0, T/4, T/2, 3T/4)$ for nominal input signal frequency $f_i = 50\,\mathrm{MHz}$ (Fig. 1c). The aim was to demonstrate generation of $f_o = (2/3)f_i$ frequency by the PDC.

IV. Results

A. Delay line characteristics measurements

There have been performed two fundamental experiments testing the performance of the delay line. The block diagram of measurement setup in which the PDC line resolution and linearity were measured using time interval counter (SR620 [10]) is shown in Fig. 5. The SR620 synchronous reference signal (1kpps) was connected into the FPGA fabric. Inside the FPGA, the signal is split into the PDC input and directly to the output of the FPGA chip and consequently into the A channel of the SR620. The output of the PDC was fetched into the B channel of the SR620. The time difference between the channel A and B was measured for all PDC delay line settings.

Measurement took 54 hours, pseudo-random delay words were intermixed with zero delay settings. Individual element delays have been computed from the overdetermined set of bit word to delay correspondences by least mean square fit, results are plotted in Fig. 6. Total operational line delay is $T = 8.72\,\mathrm{ns}$. Maximum step size (resolution) between adjacent delay words is $\Delta\tau_{max} = 14.9\,ps$.

Temperature in a vicinity of the FPGA chip has been measured as well. Fig. 7 shows temperature variation during experiment together with offset and PDC scale variations. In linear approximation, the offset drift is $23\,\mathrm{ps\,K^{-1}}$, the scale drift is $8.4 \times 10^{-4}\,\mathrm{K^{-1}}$, yielding $30\,\mathrm{ps\,K^{-1}}$ in the worst case.

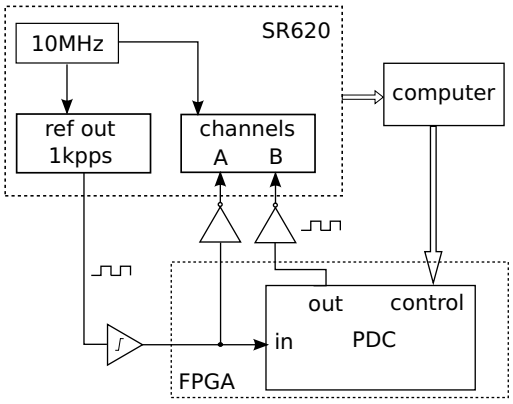

Fig. 5. PDC line resolution and linearity measurement setup

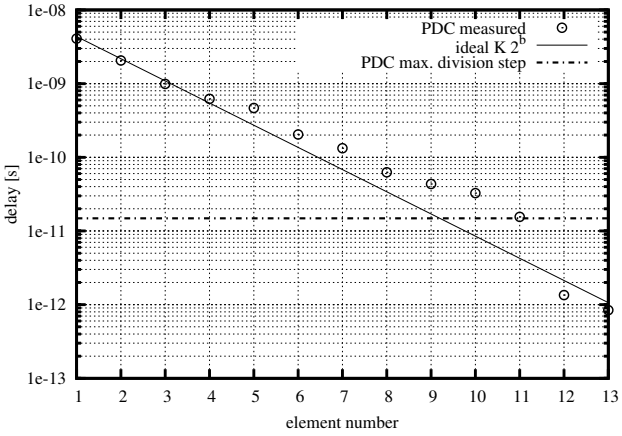

Fig. 6. PDC line resolution and linearity

The propagation jitter of the PDC was determined with the measurement setup depicted in Fig. 8. For precise jitter measurements, NPET device is employed having single shot precision of $\sigma_{NPET} = 1.0\,\mathrm{ps\,RMS}$ [9]. The NPET generates 100pps reference signal ($\sigma_{ref} = 1.2\,\mathrm{ps\,RMS}$) being synchronous with its internal clock; the reference is fed into the PDC input. The NPET measures the jitter of the reference signal propagated through the PDC for different delay settings; each single delay element is enabled at a time.

Propagation jitter of the delay line ranged from $3.9\,\mathrm{ps\,RMS}$ to $5.0\,\mathrm{ps\,RMS}$ (all delays on) for different line configurations. A jitter of signal mirrored at the output of the FPGA, but not passing through PDC, was measured $2.9\,\mathrm{ps\,RMS}$. Under assumption of independent, normal noises, jitter $\sigma_{max} = 4.1\,\mathrm{ps\,RMS}$ may be attributed to delay line in its longest configuration.

B. Frequency synthesis

Generation of $f_o = (2/3)f_i$ frequency has been performed in order to prove the concept of control logic. Input and output waveforms acquired are shown in oscilloscope screen shot Fig. 9. Waveform distortion is caused by coarse line length

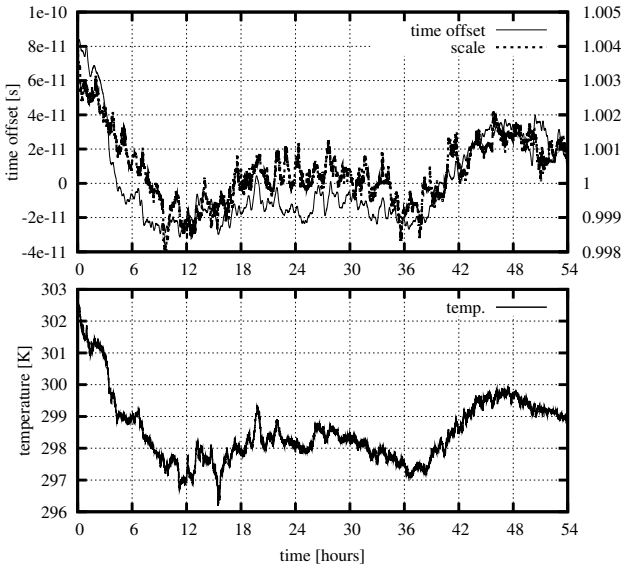

Fig. 7. Temperature and drift of PDC offset and scale

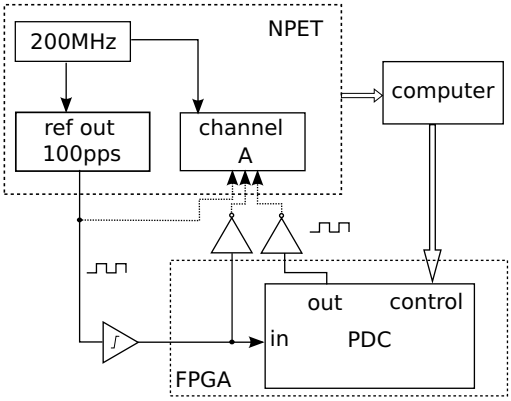

Fig. 8. PDC delay line elements jitter measurement setup

(5 bits) and unoptimized delay words.

V. Conclusion

A presumably novel type of PDC has been presented. The delay line cascaded of 13 elements exhibits a deterministic resolution $\pm\Delta\tau_{max}/2 = \pm 7.5\,\mathrm{ps}$, random jitter $\sigma_{max} = 4.1\,\mathrm{ps\,RMS}$, temperature drift $8.4 \times 10^{-4}\,\mathrm{K}^{-1}$, drift including offset up to $30\,\mathrm{ps\,K}^{-1}$. The performance is comparable to recent works [2], as well as to dedicated ECL circuits [5]. Further improvement of resolution is possible by adding more delay elements. Temperature compensation seems plausible by a measurement of reference delay line element, e. g. using ring oscillator, or Time-to-Digital Converter [11].

An ability to generate waveform differing in frequency and phase from the input signal has been demonstrated as a proof-of-concept. The effect of idle delay is severely limiting factor here, especially in an FPGA. We would like to examine pos-

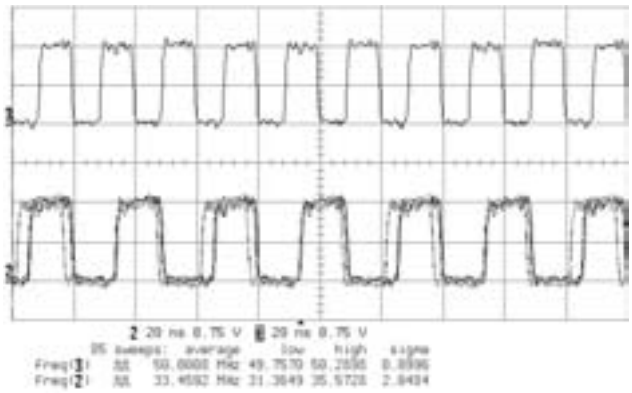

Fig. 9. Frequency synthesis by rapidly switching PDC

sible improvement by combining tree-like structure for coarse line with cascaded structure for the fine part. An implementation into ASIC shall yield significantly better performance, due to much lower multiplexer delays and unnecessity of differential delay elements.

An Efficient Room Temperature Only (RTO) Trimming Solution for an Accurate Self-Compensated Oscillator (SCO)

A. Elkholy, A. Ahmed, M. Shadoufa, M. Sakr, A. El-Sayed, M. Yousef, A. Helmy, M. Essam, N. Sinoussi

***Abstract*—CMOS process variations create a major trimming challenge for a cost effective, accurate and fully-integrated CMOS LC-based reference clock generator. This work presents a new room temperature only (RTO) trimming solution for an all CMOS self-compensated oscillator (SCO) that is highly stable across temperature. Self compensation across temperature is achieved by adjusting the phase of the LC-tank at a specific temperature null (TNULL) phase where the frequency deviation across temperature is minimized. The proposed RTO trimming solution utilizes integrated heaters to thermally modulate the oscillator then uses smart algorithms to select the optimum phase setting that minimizes the frequency variation of the SCO. The integrated RTO intelligence allows trimming SCO parts in parallel with minimum testing overhead. Utilizing the RTO, the SCO achieves ±50ppm of frequency stability across temperature from -20°C to 70°C with less than one second of trimming time consumed per part.**

***Index Terms*—Single point trimming, oscillator trimming, XO replacement, self-compensated oscillator, LC oscillator, temperature null.**

I. Introduction

A reference clock generator is the heart of any electronic system. Owing to their superior frequency stability, and excellent phase noise, quartz crystal oscillators (XOs) have rightfully earned their position as the industry $de\,facto$ frequency reference since their introduction in 1919 [1]. However, XOs impose a lot of limitations on electronic systems regarding integrability and lead time which are eventually translated to increasing the overall cost of the system [2]. Driven by the continuous need for integration and cost reduction, research is eager to find a truly CMOS compatible replacement for quartz crystal oscillators [2], [3], [4], [5].

Cost is the main edge offered by the CMOS LC solution. Compared to the equivalent XOs, the cost of the CMOS LC solution is superior from two main perspectives. First of all, XOs require the presence of an extra component which is the quartz crystal (XTAL) itself. Furthermore, XOs require special, relatively expensive, packaging solutions to protect the XTAL from aging [6]. On the contrary, CMOS oscillators tolerates cheap plastic packages [4]. However, the overall cost structure of any timing solution is influenced by another important factor which is the trimming and calibration. XOs enjoy the extremely mature XTAL fabrication technology where the accurate mechanical control over the XTAL physical dimensions and cutting angle guarantees both the XOs initial accuracy and temperature dependence to an appreciable extent. For example, the AT-Cut XTAL intrinsically achieves ±50ppm across temperature from -40°C to 85°C without any compensation or trimming [7]. On the other hand, CMOS LC oscillators suffer from process variations which change the target frequency and temperature dependence. Thus, trimming is required to compensate for these variations. In order to conserve the excellent cost structure of the CMOS LC solution, trimming has to be efficient and cost effective. Hence, trimming forms one of the major challenges in having a highly accurate and fully-integrated CMOS LC based reference clock generator.

In a previous work [2], a self compensated CMOS LC oscillator (SCO) based on LC tank temperature null (TNULL) phenomenon was introduced. The design area has been reduced in [5]. However, trimming is required to achieve the target SCO performance.

This work presents a new on-chip room temperature only (RTO) trimming solution for a highly accurate SCO with minimum testing overhead. Section II highlights the basic concepts of the LC-based Self-Compensated Oscillator (SCO). Section III illustrates the main challenges of a cost effective trimming solution for the SCO, and the proposed RTO trimming solution is demonstrated. Section IV summarizes the measurements results and the overall oscillator performance. Finally, section V concludes the main points of this work.

II. LC-Based Self-Compensated Oscillators

Conventional LC oscillators exhibit thousands of PPMs of frequency deviation across temperature from 0°C to 70°C [2], [5]. The poor temperature stability of LC oscillators is justified by examining the phase versus frequency characteristic of the tank impedance across temperature which is shown in Fig. 1. LC oscillators operate with zero phase shift across the LC tank impedance leading to the frequency deviation Δf_1 annotated on Fig. 1.

However, a more desirable phase operating point (φ_{NULL}) is annotated on Fig. 1 at which the LC tank impedance exhibits minimal variation across temperature. The resulting frequency deviation (Δf_{NULL}) at φ_{NULL} is in the order of tens of PPMs which is an improvement over the conventional LC oscillator by a factor of 100 [2], [5]. Fig. 2 illustrates a hypothetical oscillator that can force the tank to operate at this non-zero phase. The phase shifter "$e^{j\varphi}$" is programmed to satisfy the condition: $\varphi = -\varphi_{NULL}$.

The reduced LC tank temperature sensitivity at the specific phase φ_{NULL} is denoted as the temperature null (TNULL)

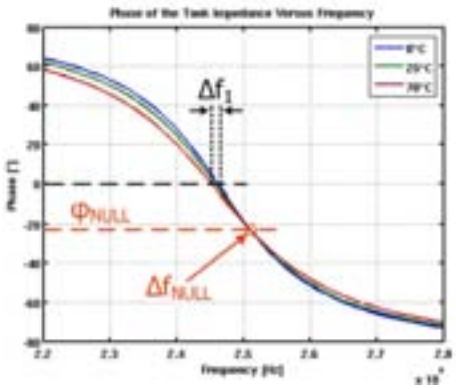

Figure 1. Phase versus frequency characteristic of the LC tank impedance at different temperatures [5].

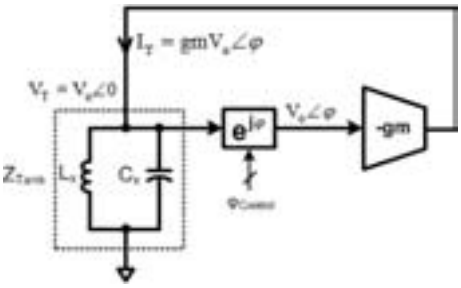

Figure 2. Block diagram of Self-Compensated LC Oscillator (SCO) [5].

phenomenon [2]. Furthermore, the oscillator that can utilize the TNULL phenomenon to achieve a stable output frequency is said to be a self-compensated oscillator (SCO) [2].

III. Room Temperature Only Trimming

A. SCO Trimming Challenges

The high sensitivity of the LC tank impedance versus temperature (Fig. 1) implies that the tank TNULL phase φ_{NULL} must be obtained with a high level of accuracy. Otherwise, the frequency stability across temperature is appreciably degraded. In order to achieve an adequate performance, measurements show that φ_{NULL} should be obtained with a maximum error of $\pm 0.1^{\circ}$. However, the exact value of φ_{NULL} varies with process, oscillation frequency and the required operating temperature range. Moreover, the absolute frequency of the oscillator varies with process and has to be adjusted to the required output frequency. Trimming is required to compensate for these variations and to set the oscillator phase to φ_{NULL} while adjusting the oscillator frequency to the required output frequency. Trimming has to be accurate, robust and cost effective.

The main challenge is that there is no direct method to measure the tank phase across temperature to determine directly the value of φ_{NULL}. The brute force trimming solution to find φ_{NULL} is to sweep the phase setting (PS) at the two extreme temperature points while measuring the frequency. The PS that minimizes the frequency difference between the two extreme temperature points is considered the optimum phase

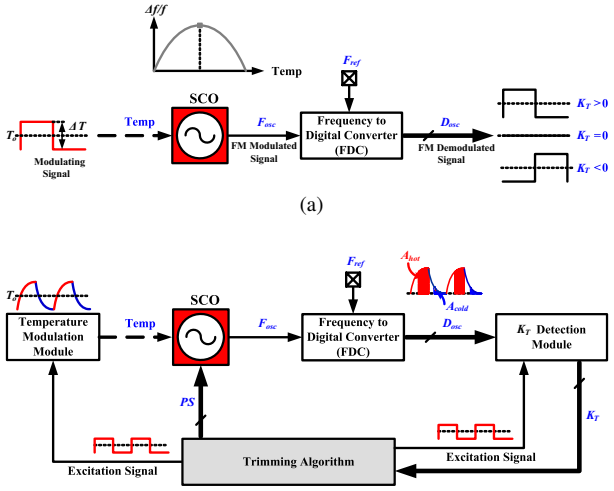

Figure 3. (a) Conceptual illustration of measuring the temperature sensitivity of the SCO by applying a thermal modulating signal, (b) Block diagram of the trimming infrastructure utilized to measure K_T of an SCO.

setting PS_{opt} or φ_{NULL} . However, this two temperature points trimming solution is very expensive due to the high cost of the two required temperature insertions, especially the cold insertion. Furthermore, a very long testing time is usually required for this large number of accurate frequency measurements. This work, proposes a single point trimming (SPT) algorithm at room temperature that enables achieving a highly accurate and cost effective SCO oscillator.

B. Single Point Trimming Basic Concepts

The main idea of the proposed SPT solution is based on estimating the oscillator temperature dependence by modulating its temperature using on-chip heaters. By applying a square wave temperature modulating signal at a temperature (T_o) as shown in Fig. 3(a), the oscillator output becomes a frequency modulated (FM) signal that depends on the frequency temperature sensitivity or slope (K_T) at this temperature. A frequency-to-digital converter (FDC) uses an accurate external reference clock to do FM demodulation to the oscillator output, where the oscillator frequency (F_{osc}) is converted into a digital word (D_{osc}) . The difference between $D_{osc}(T_o + \Delta T/2)$ and $D_{osc}(T_o - \Delta T/2)$ is utilized to estimate the value of K_T at T_o , where ΔT represents a variation in temperature around T_o. The difference between these two digital words gives an accurate digital representation of K_T that is utilized in the proposed SPT trimming algorithm.

C. Single Point Trimming Implementation

There are several non-idealities that can affect the accuracy and cost of the proposed room temperature only trimming. Practically, the thermal modulation frequency is limited by the thermal time constant of the packaged part under test. Thus, the thermal modulating square wave is low pass filtered as illustrated in Fig. 3(b). The thermal time constant is a

strong function of the die size and the package size. As the thermal modulation frequency decreases, the trimming routine becomes slower. Thus, testing cost increases impacting the overall cost of the SCO. Consequently, it becomes very important to reach PS_{opt} in a minimum number of thermal modulation cycles. This can be achieved using smart trimming algorithms.

Oscillator thermal and flicker phase noise are considered another source of non-idealities that affect the accuracy of the SPT algorithm especially when K_T approaches zero as the magnitude of the demodulated signal becomes very close to zero. Since detecting K_T depends on the difference between two frequencies, the impact of phase noise at very low frequency offsets on K_T is negligible . On the other hand, phase noise at high frequency offsets can be suppressed by incorporating an integrate and dump filter. Only parts of the heating and cooling periods are utilized by the integrate and dump filter due to the low pass filter effect induced by the slow thermal time constant of the package under test. A part of the heating period is integrated into A_{hot} and similarly another part of the cooling period is integrated into A_{cold} as shown in Fig. 3(b). The difference between A_{hot} and A_{cold} is a digital word that represents K_T more accurately in the presence of the oscillator phase noise and the large thermal time constant. Overall, trimming is only affected by phase noise at frequency offsets close to the thermal modulation frequency, thus trimming can be highly accurate.

The objective of the phase trimming algorithm is to search for PS_{opt} that adjusts the SCO K_T to a target slope control word (KCW). The selection of KCW depends on many parameters such as: operating temperature T_o, the predetermined temperature range and the desired SCO temperature dependence curve. For RTO trimming ($T_o = 25°$C), usually a value of KCW that is approximately zero is used to optimize the SCO temperature dependence for the different temperature ranges. The proposed SPT employs integrated on-chip heaters for thermal modulation to detect K_T as highlighted previously. Moreover, it utilizes smart search algorithms rather than extensive sweeps to set PS_{opt}.

A digital frequency locked loop (DFLL) is used to adjust the oscillator frequency by changing the oscillator frequency setting (FS) based on a target frequency control word (FCW). The FDC output (D_{osc}) is subtracted from FCW to give a digital word that represents the frequency error (f_e) between F_{osc} and the target frequency. f_e is then accumulated to control FS. The accumulator is loaded by an initial frequency setting (FS_{init}) to speed-up the frequency settling. The loop settles when the oscillator frequency is equal to the required frequency ($F_{osc} = FCW \times F_{ref}$) at steady-state. At the end of the trimming routine, the oscillator trimmed parameters PS and FS are programmed in a one-time programmable (OTP) read only memory (ROM) module. The OTP ROM holds the trimmed parameters in normal-operation after trimming is complete and is automatically loaded at power up.

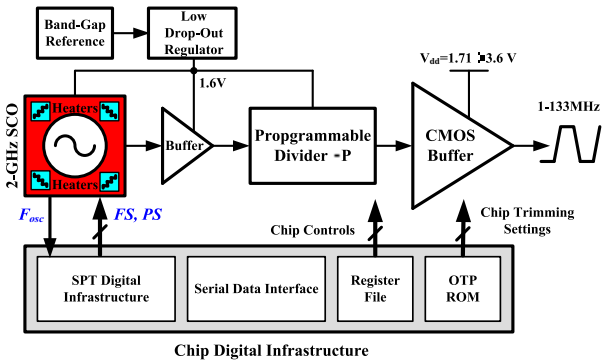

Figure 4. Chip architecture of the implemented SCO with a 1 – 133MHz CMOS output clock.

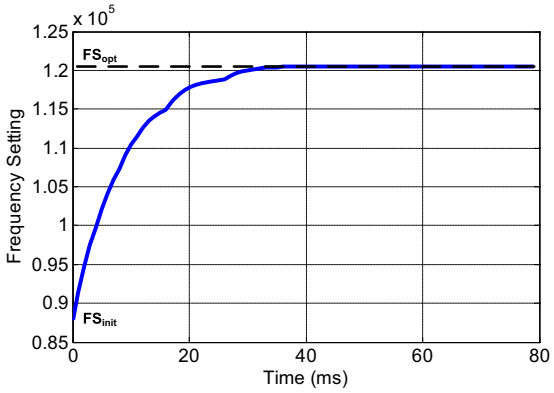

Figure 5. Measured results of FS settling from FS_{init} to FS_{opt} using DFLL.

IV. Measurement Results

The proposed RTO trimming solution was integrated with the SCO in a 0.18μm CMOS process with a single poly and 6 aluminum metal layers. The chip architecture is illustrated in Fig. 4, as in [2], where the SCO operates at 2GHz and a number of integrated heaters thermally modulate the SCO frequency during SPT. FS controls a bank of capacitors to adjust the SCO absolute frequency with an accuracy of ±2.5ppm. The SCO is followed by a programmable divider so that the output frequency ranges from 1MHz to 133MHz. The chip has a CMOS single-ended output buffer that can drive a 15pF load. The chip works with any supply voltage from 1.71V to 3.6V since an internal band-gap referenced low drop-out (LDO) regulator produces a 1.6V supply to all blocks. A serial data interface is used to communicate with the chip during testing. The die (1.55mm×1.05mm) was packaged in a 4-pin 5.0×3.2mm ceramic package and a custom DFN 5.0×3.2×0.8mm plastic package.

The proposed SPT algorithm was used at room temperature to trim 50 ceramic and 50 plastic packaged parts at the TNULL to produce 25MHz. The integrated on-chip heaters were used to modulate the SCO temperature while searching for the optimum settings of the oscillator PS_{opt} and FS_{opt} to achieve the target output frequency and temperature stability across the

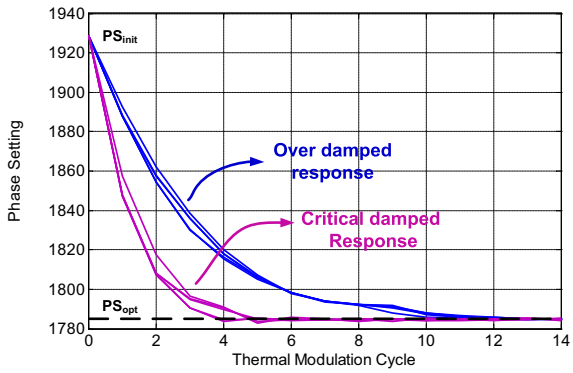

Figure 6. Measured results of trimming algorithm starting from PS_{init} to PS_{opt} using two different loop parameters, each for five iterations.

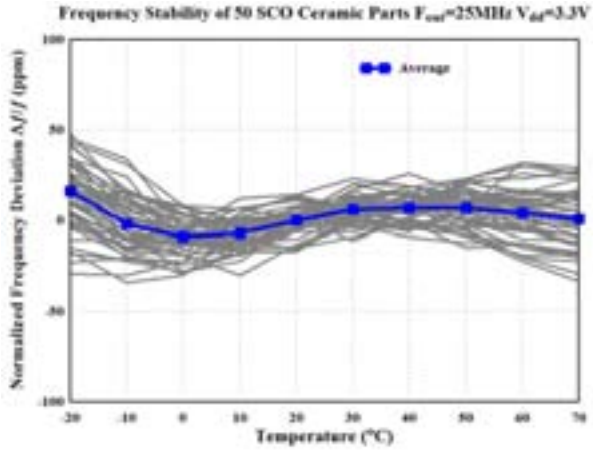
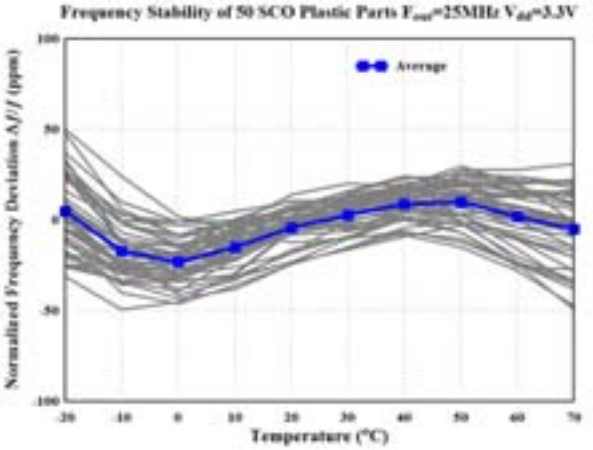
target temperature range. An accurate 1kHz reference clock was used during trimming as the reference to the FDC, thus minimal external equipment is required. Fig. 5 demonstrates measured settling behavior of FS using DFLL to reach FS_{opt}. Fig. 6 illustrates the measured settling behavior of PS to reach PS_{opt} using the proposed RTO trimming for two different loop settings, each for five iterations. By proper adjustment of trimming loop parameters, critical damped response can be achieved which minimizes the number of thermal modulation cycles used in trimming, consequently reducing the testing time and cost. The parts are trimmed in parallel such that the average trimming time consumed per part is less than 1s. The frequency stability performance was measured across temperature from -20°C to 70°C with a 10°C step. The results of the 50 parts in a non-hermetic ceramic package and the 50 plastic packaged parts are illustrated in Fig. 7 (a) and (b) respectively. All 100 parts are showing excellent frequency stability performance within ±50ppm across a (-20 – 70)°C temperature range.



(a)



(b)

Figure 7. Normalized frequency stability across temperature of parts trimmed to 25MHz (a) 50 ceramic packaged parts and (b) 50 plastic packaged parts.

V. Conclusions

A new low cost RTO complete trimming solution for highly accurate SCO is proposed. It utilizes integrated heaters to thermally modulate the oscillator to detect the oscillator temperature dependence using on-chip FDC. Moreover, it incorporates smart search algorithms to select the optimum phase setting that minimizes the frequency variation of the SCO. The integrated intelligence offers the merit of trimming large numbers of SCOs in parallel with minimum testing overhead. Without the need for temperature insertions, the RTO solution trims the SCO to achieve $\pm 50\text{ppm}$ of frequency stability across temperature from -20°C to 70°C with less than one second of trimming time consumed per part.

***Abstract*—The Gravity Recovery and Interior Laboratory (GRAIL) mission successfully ended in December, 2012 after an extended science phase of over 280 days mapping the gravitation field gradient of the Moon with a precision of better than 50 E-6 g's over the entire lunar surface. The mission was performed by two tandem flying spacecraft, both of which carried a Microwave Dual One-way Ranging (DOWR) instrument that together formed a highly precise relative measure of the distance between the two spacecraft as they orbited the Moon.**

The precision of the radio link maintained by the DOWR instruments was derived from the frequency stability of the ultra-stable oscillators (USOs) on-board each spacecraft. The opportunity to observe the USOs frequency throughout the GRAIL mission provides a record of not only the intrinsic performance of the oscillators, but their behavior during exposure to space conditions. We describe the effect to the frequency of each GRAIL USO, A and B, resulting from the March 7th, 2012 X5.4 level solar flare, just several days into GRAIL's science collection phase. We discuss the impact of this radiation exposure, and the asymmetric behavior of two USOs coincidentally perturbed by the same space-weather event.

Keywords—GRAIL, oscillator, space-weather, irradiation

I. INTRODUCTION

The Johns Hopkins University Applied Physics Laboratory (JHU/APL) delivered four ultra-stable oscillators (USOs) in 2010 to the Jet Propulsion Laboratory of the California Institute of Technology (JPL) for integration into the Lunar Gravity Ranging System (LGRS) of the NASA Gravity Recovery and Interior Laboratory (GRAIL) twin spacecraft. The twin GRAIL A and B spacecraft (later named Ebb and Flow) were placed into a tandem flying orbital formation over the Moon to form a single-axis gradiometer, accomplishing the primary science mission of mapping the Moon's gravitational field with sufficient accuracy to work out many long-standing questions about the Moon's cratering process, internal structure, and thermal evolution [1].

As reference sources for the LGRS, the USOs frequency stability and phase noise were one of several principal contributors to the precision and resolution of GRAIL's gravity measurements. By the mission's end in Dec. 2012, the quality of the in-flight LGRS science return allowed the resolution of lunar highland crust and maria, addressing impact, magmatic, tectonic and volatile processes shaping the Moon's near surface. This required ranging precision nearly ten times better than the base mission requirements within spatial resolution of lunar features as fine as 30 km. In terms of frequency stability, the JHU/APL USOs were found to provide Allan deviation (Adev) performance of better than 1 E-13 over 1 to 100 s time intervals, temperature coefficients of < 5 E-13 per C, and aging rates below 1 E-11 per day.

Because of the unique design of GRAIL's radio science beacon links to NASA's Deep Space Network (DSN) ground, and spacecraft inter-ranging using JPL's dual one-way ranging (DOWR) method, the in-flight frequency behavior of each USO A and B was highly resolved. This allowed incidental environment or anomalous perturbations of < 1E-12 to be attributed and characterized. The capability to resolve the in-flight oscillator frequency behavior to this degree of precision is a rare feature in deep space operations. Our paper describes the incidence of a solar flare on the GRAIL A and B spacecraft while in lunar orbit on March 7th 2012, and characterizes the coincident frequency perturbations observed on the respective USOs A and B. The observed frequency perturbations are attributed to the sensitivity of quartz resonators to irradiation by protons in the 10 to 100 MeV range.

A. *GRAIL Science Objectives and Mission*

Understanding the structure and thermal evolution of a large rocky body such as the Moon is achieved through determining its density profile from its crust to interior, and assessing surface mass concentrations (mascons) associated with early magmatism and asteroid impacts. As discussed in [1], GRAIL was focused on resolving six primary mission lunar science objectives:

1. Map the structure of the lunar crust and lithosphere.

2. Understand the Moon's asymmetric thermal evolution.

3. Determine the subsurface structure of impact basins and the origin of mascons.

4. Ascertain the temporal evolution of crustal brecciation and magmatism.

5. Constrain the deep interior structure from tides.

6. Place limits on the size of the possible inner core.

Measurements of gravity variation on planetary-scale bodies traditionally use perturbations in the orbital dynamics of satellites assessed through radiometric Doppler-based range-rate methods. The principle behind this Doppler-based method is to coordinate the frequency change observed in the radio telemetry downlink against the ground system clock to planetary surface features in a line-of-sight manner with the Earth, after the navigation solution for orbital determination is applied to remove all expected Doppler frequency shifts.

The Moon, of course, offers a complication to the single satellite Doppler-based gravity method since its synchronous orbit with the Earth prevents the far-side from observation. The GRAIL mission was designed to remove this constraint through the use of a tandem flying two satellite approach, where the change in the relative distance between the spacecraft allows the measurement of gravity by directly observing the phase between two counter-opposed one-way radio links. Fig. 1 from [2] depicts the signaling scheme used in the GRAIL mission for navigation and communication. Two Ka band (32 GHz) carrier phase tracking loop assemblies, one in each spacecraft at slightly frequency offsets, perform the inter-satellite ranging determination (KBR). Coordinately, each spacecraft sends an X-band radio science beacon (RSB) to the NASA DSN to obtain the Doppler based range rate. Since the KBRs and RSBs of each spacecraft are coherent with their respective on-board USOs, the method of DOWR was used to extract lunar gravity variation from these two radiometric observables.

GRAIL's mission design is an analogue of the proceeding Gravity Recovery and Climate Experiment (GRACE), launched in 2002, which continues to measure the gravity field of the Earth. In GRACE, the DOWR method is applied and, as GRACE flies in LEO at about 500 km in altitude, takes advantage of GPS for absolute positioning and timing synchronization. Timing synchronization error between spacecraft in the DOWR method is a key driver in the precision of extracting gravity from the radiometric observables.

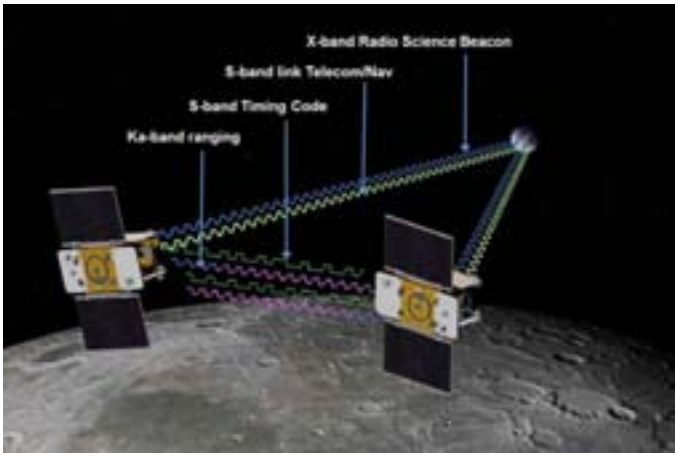

Fig. 1. Image above depicts the signaling scheme used in the GRAIL mission for navigation and communication. Two Ka band (32 GHz) carrier phase tracking loops, one in each spacecraft at slightly offset frequencies, are used for inter-satellite distance determination.

Clearly, the GRAIL LGRS could not use GPS for this purpose, and to maintain the required synchronization to better than 632 ps/Hz½ (corresponding to an error in inter-satellite distance precision of approximately 4 μm/Hz½), the LGRS design implemented an S-band inter-satellite time transfer system (TTS). [3] The performance of the TTS allowed inter-satellite synchronization to be maintained for up to 16 hours without ground link calibration. The TTS also permitted the demonstration of the first mission critical formation-flying satellite autonomous navigation around a planetary body beyond the Earth.

The primary mission of GRAIL was designed to execute three 27.3 day lunar mapping cycles over an 84 day Science Phase. The timing of the Science Phase was chosen to preserve a better than 40o sun-aspect to the spacecraft's fixed body solar panels, maintaining the highest possible power support for the LGRS. The GRAIL mission timeline from [1] is presented in Fig. 2 in a heliocentric viewpoint. GRAIL A and B launched on Sep. 10th 2011, after which they transferred to the Moon over a 107 day cruise, using the EL-1 Lagrange point. Lunar orbit insertion (LOI) occurred on Dec. 31st 2011 and Jan 1st 2012 for GRAIL A and B, respectively. Once the orbits and positions of GRAIL A and B were achieved, the Science Phase began on March 1st, 2012. The success of the initial mapping promoted an Extended Mission where the spacecraft were placed in a nearly circular orbit, 23 km in altitude. This vantage, along with the extremely-well performing instruments, allowed the measurement of lunar highland crust and maria structure, assessing the effect of dynamic processes which shaped the Moon's near surface. GRAIL A and B finished science collection on Dec. 14th at an altitude of 11 km.

B. LGRS Instrument Overview

As partially described above, the LGRS of GRAIL consists of a payload of radiometric instruments and data processing assemblies. As shown in Fig. 3, from [3] each GRAIL spacecraft USO provides a coherent frequency reference for the X-band RSB used for Doppler ranging and USO calibration, Microwave Assembly (MWA) which transmits and receives the KBR signal, and Gravity Processor Assembly (GPA) that processes phase changes to a precision of better than 10-4 cycles/Hz½ of the 32 GHz KBR signal (~1 μm/Hz½ of relative distance between the spacecraft). The GPA also maintains the timekeeping of the S-Band TTS. The LGRS operates in a continuous manner with the capability to process KBR downconverted signals into correlated baseband measurements (through synchronization provided by the TTS) at a running rate of 10 samples/s. The GPA is necessary since GRAIL must map on the far-side of the Moon with no ability to transfer or receive signals to Earth.

USOs A and B are offset in frequency by about 20.5 ppm to create a 670 kHz non-zero baseband IF signal in the MWA. The use of the non-zero baseband IF signal is identical to GRACE, and was chosen to mitigate cross interference within the MWA transmit and receive channels, while balancing the USO noise residual present in the non-zero mixing products. Direct down conversion of the KBR signals is accomplished by the comparison of the received signal to the transmitted signal,

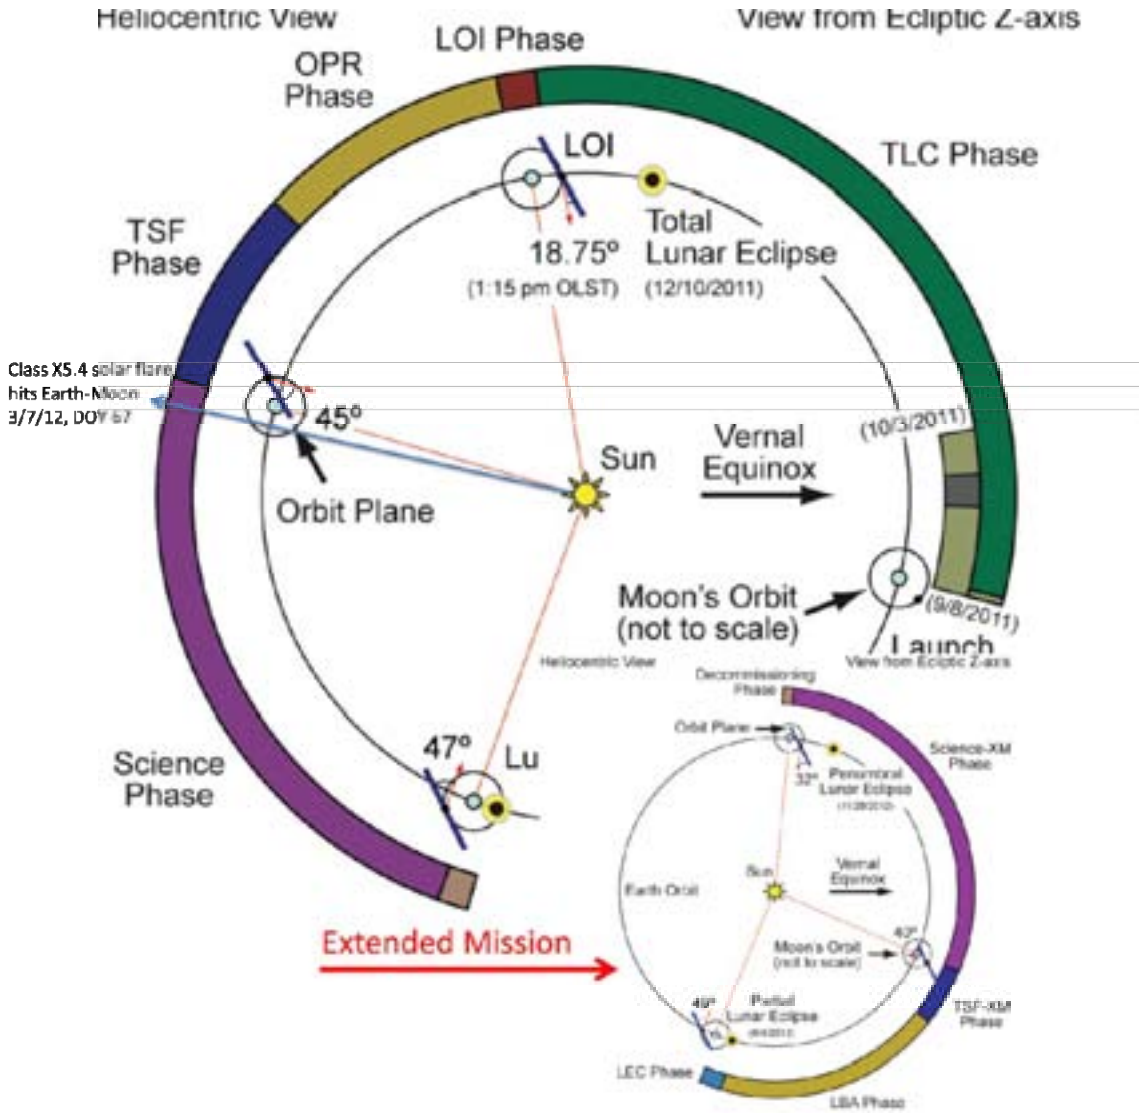

Fig. 2. The GRAIL mission timeline is presented above in a heliocentric viewpoint. GRAIL A and B launched on Sep. 10th 2011, after which they transferred to the Moon over a 107 day cruise, using the EL-1 Lagrange point. Lunar orbit insertion (LOI) occurred on Dec. 31st 2011 and Jan 1st 2012 for GRAIL A and B, respectively.

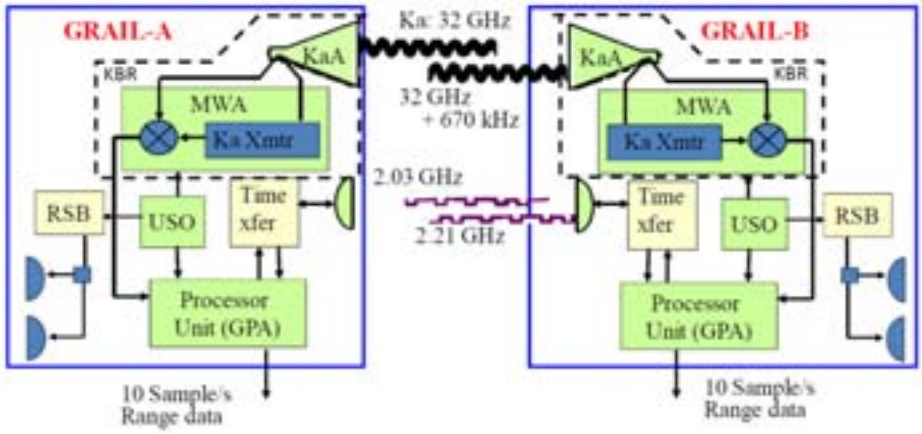

Fig. 3. Block diagram of LGRS, each GRAIL spacecraft USO provides the frequency reference for the Radio Science Beacon (RSB) used for Doppler tracking and USO calibration, Microwave Assembly (MWA) which creates and processes the ranging signal, and Gravity Processor Assembly (GPA) detects phase changes of 10-4 cycles (~1 μm of relative movement) and updates the S-Band Time Transfer System.

alternating the LO arrangement in each spacecraft's MWA. In this way, the low Fourier offset USO phase noise is cancelled in a high-pass manner, proportional to the one-way light time required to travel between the spacecraft. The change in distance or KBR phase between the two spacecraft is correlated so that the resulting IF phase information when summed in post-processing represents twice the actual distance change, which imparts one sense of the use of "dual" in the DOWR method. The doubled residual from the summed phase (two-clock) comparison is halved in post-processing when recovering acceleration.

To allow the summing of the correlated change of distance, the residual phase data associated with the clock comparison pairs, A to B and B to A, must be time coordinated. The TTS transmits a pseudorandom noise modulated signal across the link for timing information in the form of a pseudo-range measurement, equivalent to the one-way light time between the two spacecraft plus the time offset between clocks A and B. At each satellite, the received TTS signal is processed using GPS C/A code receivers inherited from GRACE. Frequency Division Multiple Access is implemented to avoid self-jamming. The two TTS transmit frequencies (2.032 GHz for spacecraft A and 2.207 GHz for spacecraft B) also avoid interference with the S-band spacecraft telecommunications and navigation downlink signals which transmit at approximately 2.280 GHz. TTS timing data is transmitted from the spacecraft as part of the instrument science data.

C. In-flight Instrument Performance and USO Verification

The 107 day cruise period of the mission design allowed for a highly desired stabilization period for the USOs, which were powered on shortly after launch, and remained powered throughout both the primary and extended mission. The long cruise using EL1 also allowed key performance evaluations of the LGRS prior to its arrival at the Moon, essentially using a gravitational quiet zone where gravity field perturbations are expected to be small. In [3], a post-launch check out on Sept. 22nd, 2011 validated the required sensitivity of the LGRS while also measuring a small relative acceleration between the spacecraft, accurately following the gravitational gradient expected from the Earth at 1 E+6 km. At the post-launch check-out, the Adev comparing the mutual stability of USOs A and B was also directly recovered by using the LGRS phase data in a novel way.

In [4], D. G. Enzer, et. al. describe the rare ability to extract the frequency stability of the paired in-flight GRAIL USOs without the need for compensation from X-band atmospheric propagation or the direct use of the DSN ground-clock for comparison. As described above, the DOWR method uses the sum of the correlated baseband phase data from spacecraft (A to B and B to A) to resolve twice the change of distance between the spacecraft.

Most conveniently, [4] derives an equation showing that, by differencing the two phase observables, successive phase differences in the two clock offsets, will form as,

$$\varphi_A^B(t) \text{ and } \varphi_B^A(t) \tag{1}$$

$$\frac{\varphi_A^B(t) - \varphi_B^A(t)}{2f_{avg}} + \frac{\Delta f}{f_{avg}} * t \tag{2}$$

where Δf is the 670 kHz KBR frequency offset, and f_{avg} is the average of the two KBR frequencies. The results calculated from (2) can be used to create the time series data necessary to directly estimate the Adev of USO A against USO B. Fig 4. from [4] plots the Adev of the relative phase offsets between USOs A and B under three conditions. The first was pre-launch prior to the integration of the science payload onto the spacecraft, where RF cabling was used to emulate a free-space link. The second was performed at the Sept. 22nd, 2011 post launch check-out described above. The third and final direct Adev measurement was made in lunar orbit just after the start of the Science Phase.

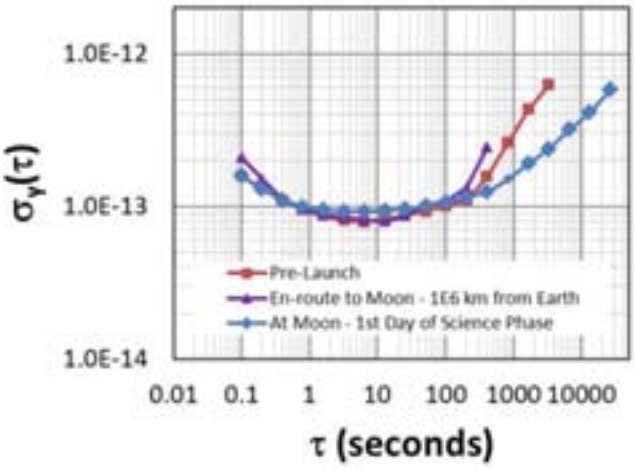

Fig. 4. The stability plotted above is the measurement of USO A against USO B at ground, and two mission conditions (en-route and on-orbit)

The USO performance shown by the three in-flight measurements is highly similar in the 1 to 100 s region, and this performance agrees well with both JHU/APL pre-ship measurements and JPL verification. The difference among the apparent drift beyond 100 s for the en-route and at-moon measurements is consistent with a maturing long-term trend as the USOs become adjusted to space conditions, revealing an apparent aging drift between the units of 2.4 E-12 per day at the start of the Science Phase. As fate would issue, this well-earned USO stabilization was to be upset 6 days later when an X5.4 level solar flare exploded from the Sun of March 7th, 2012.

II. GRAIL USO Frequency Change Observed Coincident with Solar Flare

Hereon, we describe the effect on the frequency to each GRAIL USO A and B resulting from the March 7th, 2012 X5.4 level solar flare, just several days into the Science Phase. We discuss the impact of this radiation exposure, and the asymmetric behavior of two space-oscillators coincidentally perturbed by the same space-weather event. One interesting aspect of the solar flare event was that the Moon was in a full

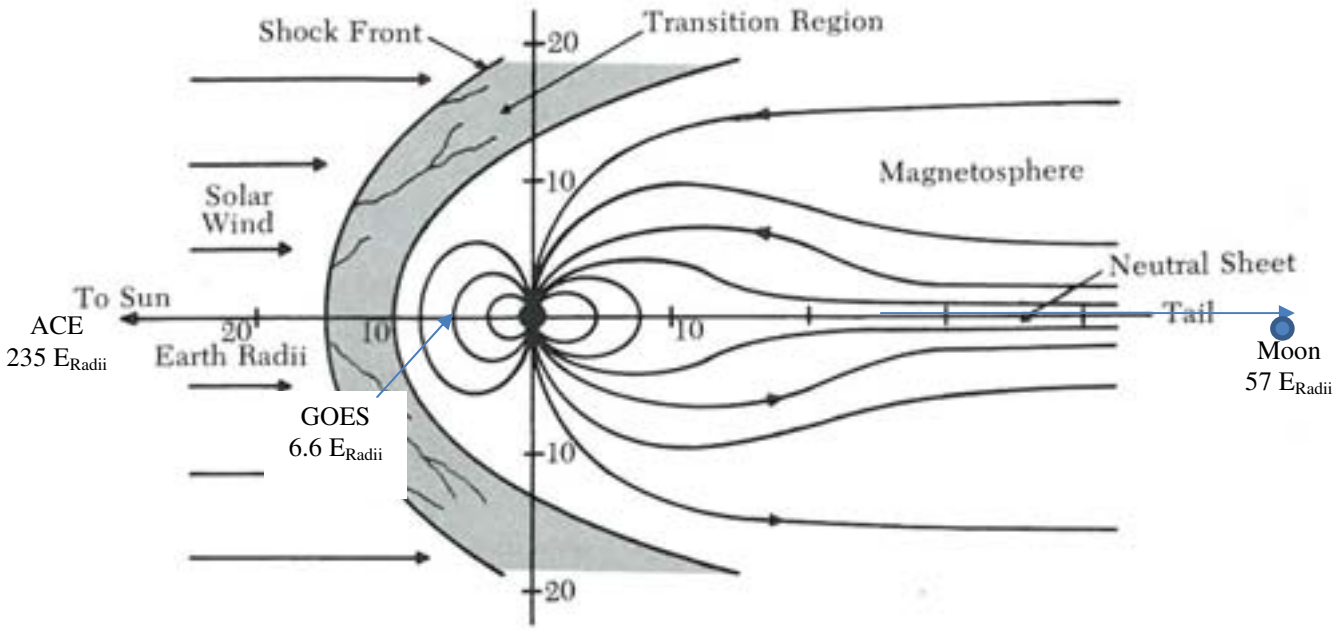

Fig. 5a. Earth magnetosphere scale cartoon showing Moon (and GRAIL spacecraft) in the magnetotail; full-moon of March 8th 2012.

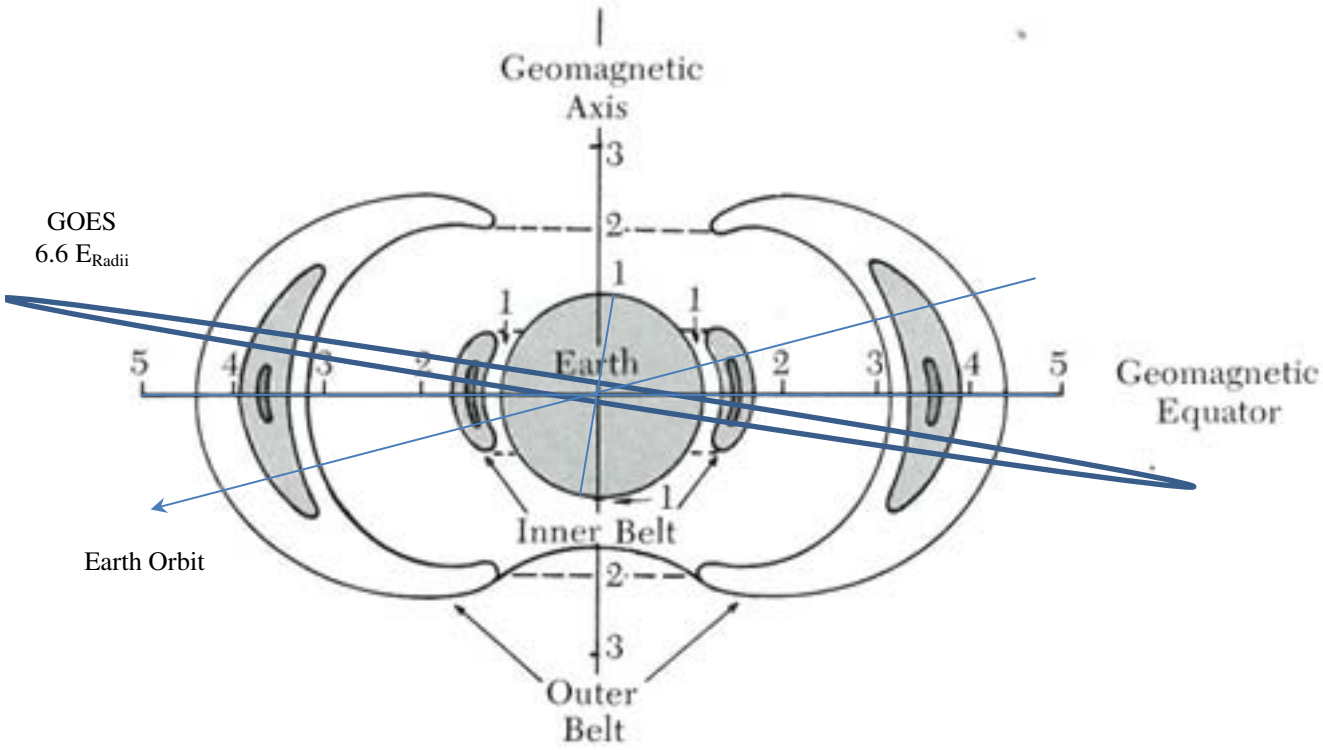

Fig. 5b. Earth Van Allen belt scale showing GOES spacecraft orbit; GOES 13 and 15 would be coming forward toward this daytime spring approximation, into the flux of the March 7th flare.

phase when the proton flux from the solar flare became incident on the Earth-Moon system, with the Moon well positioned in the Earth's magnetotail. This direct Sun-Earth-Moon alignment supports the use of Earth orbiting satellite data, collected during and after the flare for estimating particle flux, spectral energy distribution, time of flight and possibly dosimetry to GRAIL A and B.

A. *Characterization of Near-term Space weather after March 7th, 2012*

Figs. 5a and 5b show the position of the Moon (and GRAIL spacecraft), the Advanced Composition Explorer (ACE) spacecraft and the Geostationary Operational Environmental Satellite (GOES) geostationary orbit with respect to the Earth's

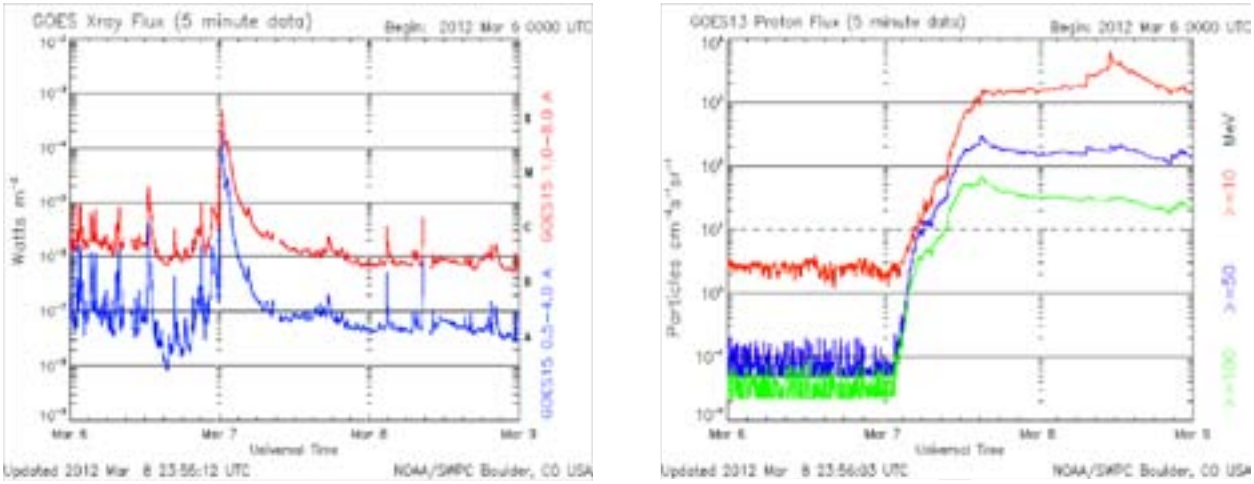

Fig. 6. GOES 15 data for X-ray flux(on-left) and GOES 13 for proton flux (on-right).

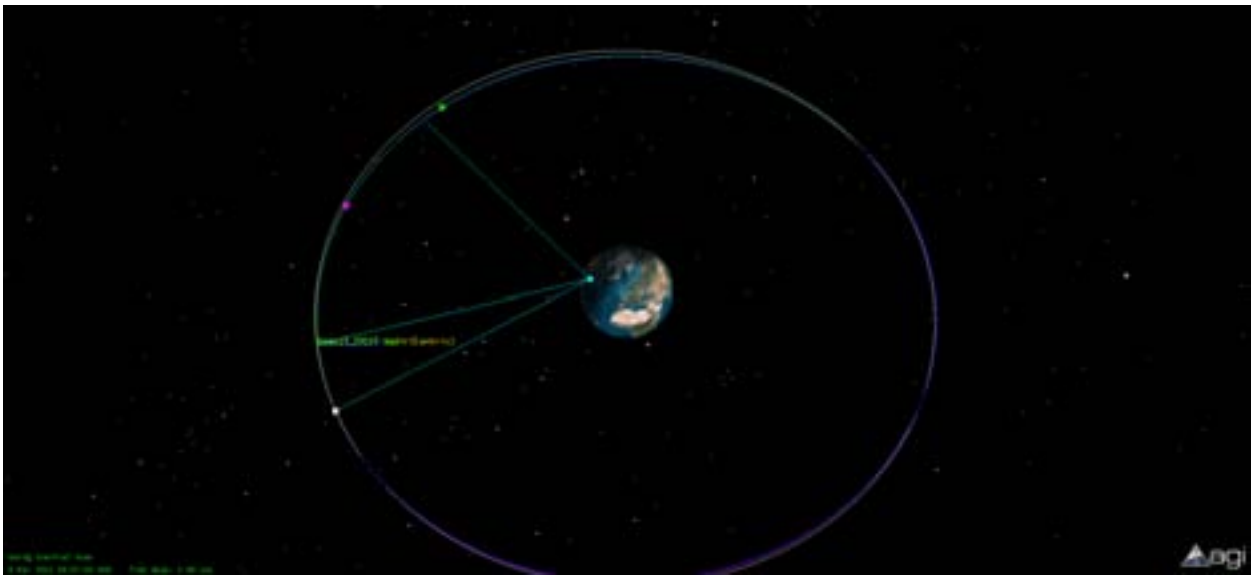

Fig. 7. Image shows position of GOES 13 on Mar 8th, 9:07 UT, sweeping into the incoming plasma front.

magnetosphere and Van Allen radiation belts. Fig. 5a is at the magnetosphere scale (measure in tens of Earth radii), while Fig. 5b is on the Van Allen belt scale (measure in Earth radii). The positions of these spacecraft are important to our observations, as we discuss the GRAIL USO frequency perturbations of Mar. 7th. ACE indicated the leading plasma edge on Mar. 7th 10:42 UT. ACE orbits the Sun-Earth L1 point approx. 1.5 million km toward the Sun from the Earth, slightly in advance of the Earth's magnetopause. GOES 15 data for X-ray flux and GOES 13 for proton flux is shown in Fig. 6. Fig. 7 shows the position of GOES 13 and 15 on Mar 8th, 9:07 UT, sweeping into the incoming plasma front.

B. USO Frequency Behavior at the Moon after Solar Flare

Fig. 8 shows short-term frequency behavior of GRAIL USOs A and B twelve hours before the solar flare, marked at almost exactly midnight of Mar. 7th (DOY 067 at 00:00 UT) and several days after the event . Inset of the chart shows the orbital position of GRAIL A and B as viewed from the Sun over the Science Phase of Mar. 4th to May 31st. The inset shows GRAIL B leading by 60 km in the early part of March. The start of the maximum rate of frequency change appears contemporaneous with the ramping proton flux detected by GOES 13. Fig. 9 shows the frequency history of the GRAIL A and B USOs about one week before the Mar. 7th flare (DOY 67) and for 30 days afterwards. The magnitude in observed frequency change in Hz at the NASA Deep Space Network (DSN) X-band downlink frequency (~8400 MHz) equates to parts in 1 E10, consistent with ionizing radiation exposure of in-flight USOs.

C. Comparison to Previous In-flight USO Exposure and Ground Irradiation Experiments

Reaction of quartz resonators (such as used in the GRAIL USOs) to ionizing radiation is well known. In 2003, an analysis of the Milstar FLT-1 on-board oscillator's frequency behavior during exposure to solar flares, described as a space experiment, was performed using space-weather data

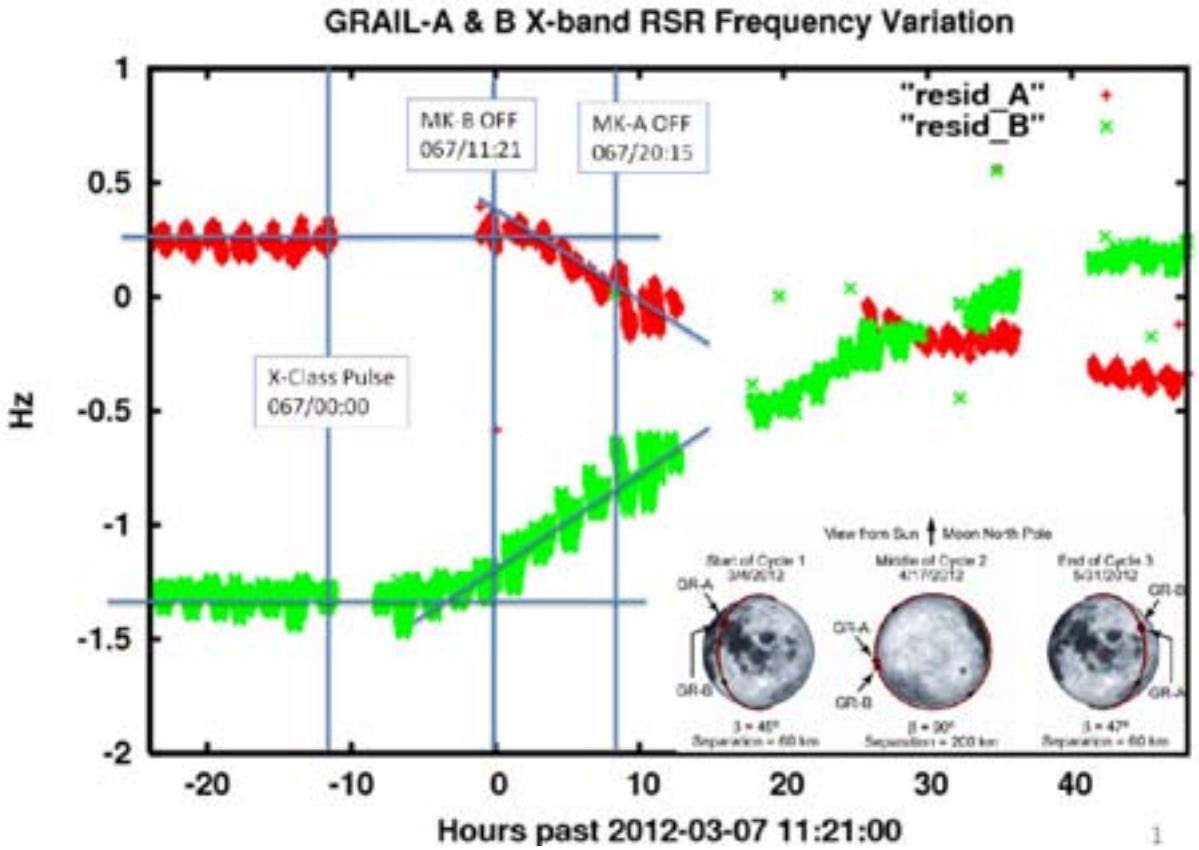

Fig. 8. Chart above shows short-term frequency behavior of GRAIL USOs A and B twelve hours before the solar flare, marked at almost exactly midnight of Mar. 7th (DOY 067 at 00:00 UT) and several days after the event . Inset of the chart shows the orbital position of GRAIL A and B as viewed from the Sun over the Science Phase of Mar. 4th to May 31st. The inset shows GRAIL B leading by 60 km in the early part of March. The start of the maximum rate of frequency change appears contemporaneous with the ramping proton flux detected by GOES 13.

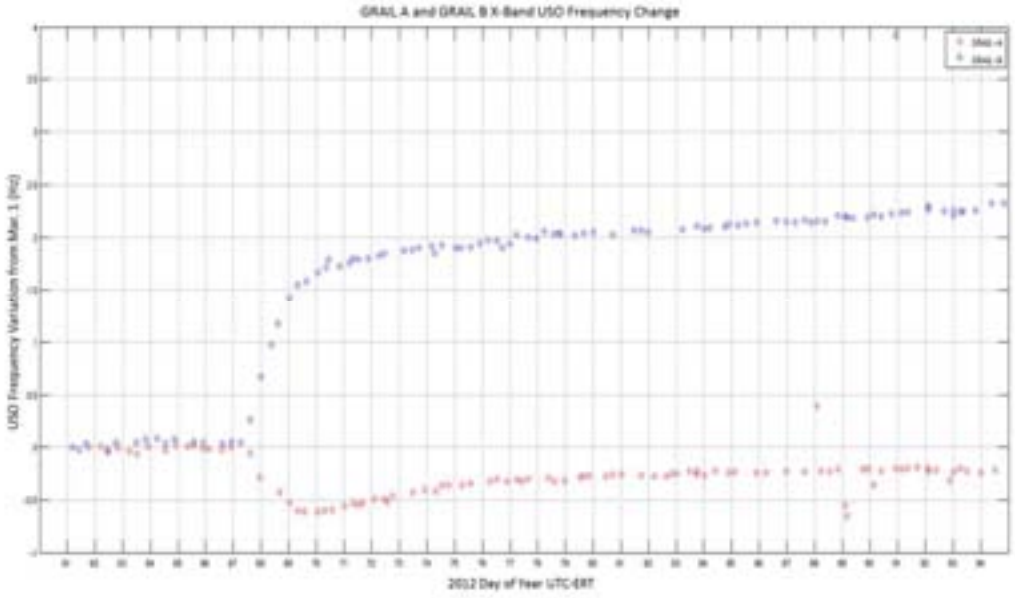

Fig. 9. Chart shows the frequency history of the GRAIL A and B USOs about one week before the Mar. 7th flare (DOY 67) and for 30 days afterwards. The magnitude in observed frequency change in Hz at the NASA Deep Space Network (DSN) X-band downlink frequency (~8400 MHz) equates to parts in 1 E10, consistent with ionizing radiation exposure of in-flight USOs.

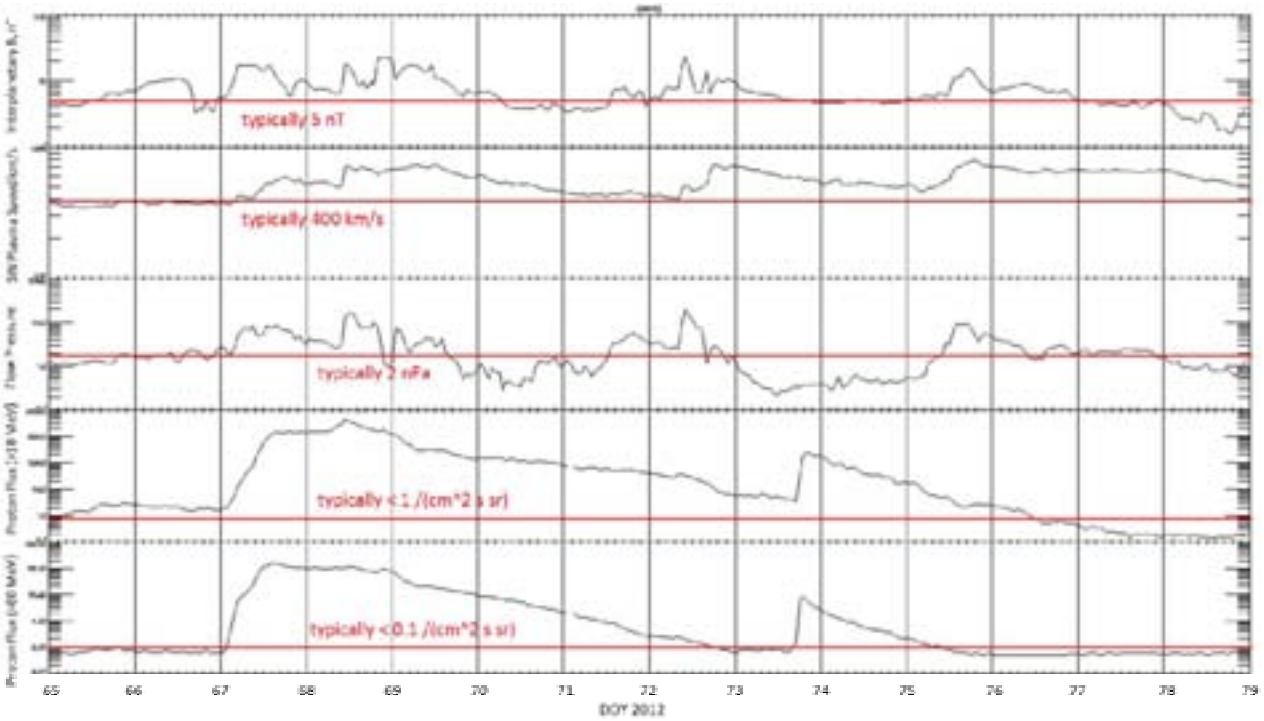

Fig. 10. chart gives a variety of solar wind parameters from NASA's OMNIWeb for the interval from Mar. 5-18, showing disturbed solar wind conditions and enhanced magnetosphere activity for much of this interval. The red overlays gives typical levels.

accumulated by the GOES [5]. Entirely similar, our observation of the GRAIL USO A and B behaviors after the Mar. 7th flare is an additional in-flight experiment with the added feature of two USOs being exposed at the same time within the same environment. Moreover, the unique frequency recovery enabled by the NASA JPL DOWR instrument removes concern that the frequency change observed at X-band by the DSN could be influenced by ionospheric perturbation due to the flare event.

Fig. 10 gives a variety of solar wind parameters from NASA's OMNIWeb for the interval from Mar. 5-18, showing disturbed solar wind conditions and enhanced magnetosphere activity for much of this interval. The red overlays gives typical levels. The correlation of the GRAIL USO A frequency change magnitude to the 10 and 80 MeV proton flux (last two plots of Fig.10) over the two weeks following the flare can be clearly distinguished, and such coordinate behavior is expected with quartz radiation sensitivity. The frequency behavior of GRAIL USO B, being opposite in sign, and not diminishing with decreasing proton flux is not inconsistent with cyclotron quartz resonator screening data.

Table 1 below shows the summary of seven quartz resonator radiation sensitivity experiments using 60 MeV proton irradiation. The proton flux ranges and frequency changes from the screening data are similar in magnitude with the solar wind data and GRAIL USO behavior described above. Also found in the screening results were varying polarities of frequency change, annealing character and irregular (non-linear) reactions [6].

TABLE I. PROTON IRRADIATION RESULTS OF QUARTZ RESONATORS FROM [6]

Exp #	Test Bed	Start Date, Time	Flux range [p/cm^2/sec]	Adjusted mean df/f per rad(Si)	Polarity	Annealing	Character
1	SC10	10/22, 9:55	2774 - 13126	-5.875E-11	-	YES	irregular: b, m
2	SC9	10/22, 14:19	3006 - 10584	5.529E-11	+	?	irregular: b, s
3	HQ23	10/22, 21:16	3007 - 9869	5.512E-11	+	NO	linear: slight b
4	P2	10/23, 7:20	3140 - 10694	1.720E-11	+	?	irregular: b, m , i
5	HQ24	10/23, 12:30	2639 - 10821	-1.906E-10	-	NO	linear: b
6	P1	10/24, 8:44	1016 - 6325	1.869E-10	+	NO	linear
7	PB	10/24, 11:18	3399 - 10197	4.541E-11	+	?	irregular: i

III. CONCLUSION

The interaction of the GRAIL USOs with the Mar 7th solar flare suggests science value in the characterization of USO radiation sensitivity prior to launch. These results continue to reveal that USO's, with properly calibrated sensitivities, can be an important adjunct to mission science collection as sensors for experiments in the deep space environment

ACKNOWLEDGMENT

We thank Dr. Timothy J. Stubbs of NASA Goddard Space Flight Center for consulting about behavior of solar wind particles at the Moon while in Earth's magnetosphere and the data of Fig. 10.

***Abstract*—A low phase noise oscillator referenced to a wine-glass disk MEMS resonator, hermetically vacuum packaged in a purpose-built packaging system, and measured in a double-oven, has provided a first long-term measurement of a MEMS disk oscillator over 10 months. After an initial burn-in period, the frequency can be seen to stabilize to within the short-term measurement variation of 300 ppb over a period of months, a significant improvement from previous studies on other MEMS resonator types, where frequency fluctuations were between 3.1 ppm and 1.2 ppm over similar time scales. Including burn-in, the total observed aging of 10 ppm is now on par with many consumer-grade quartz oscillators designed for timing applications and sufficient for target wireless sensor network applications.**

Keywords—MEMS oscillator, aging, long-term stability, hermetic packaging.

I. Introduction

MEMS-based resonators have emerged in recent years as low cost, on-chip alternatives to traditional quartz frequency references for use in timing applications [1]. Such devices offer not only valuable space savings in ever-shrinking consumer devices, such as cellular handsets, but also offer paths towards meeting the ultra-low-power requirements demanded by future wireless sensor networks [2]. While short-term stability of MEMS-based oscillators has proven to be quite good, where even the challenging GSM phase noise specifications were met some time ago [3], the long-term reliability and stability of such resonators has been largely unstudied.

Long-term frequency stability of reference oscillators is essential to maintain reliable radio communication without signals drifting into nearby bands. Typical frequency stability requirements are application-dependent and can range from tens of ppm per year to less than one ppm [4]. Cell phone requirements, for instance, remain one of the most challenging, with GSM requiring ±0.1 ppm reference oscillator stability [5]. Requirements for local-area wireless standards are much more lenient, however, with typical stability requirements of ±40 ppm [6]. Although the small size of MEMS resonators make them an exciting alternative to traditional quartz, they at the same time raise concerns of increased aging effects due to mass loading, package leaks, or stress fatiguing [7].

Some of the first published investigations on wafer-scale encapsulated resonators [8] indicated good stability, but measurements were of resonators only, not full oscillators, and were limited by experimental setup fluctuations to an accuracy of only ±3.1 ppm. Some more recent efforts have shown limited stability data of oscillators. One study [9] used an Aluminum-Nitride bulk acoustic wave resonator reference over 50 days of measurement. Here too, measurement setup fluctuations and lack of vacuum packaging, a necessary component for achieving the high Q of MEMS resonators, limited measurements to shorter time-scales and frequency fluctuations of ±1.2 ppm. Another study on a commercial device fabricated by SiTime [10] demonstrated exceptional short-term frequency stability of ±3 ppb, but only made measurements over periods of up to 15 minutes. Yet another study [11] demonstrated very close differential frequency tracking of two resonators over periods up to 30 days, but again intrinsic frequency stability was limited by measurement setup fluctuations.

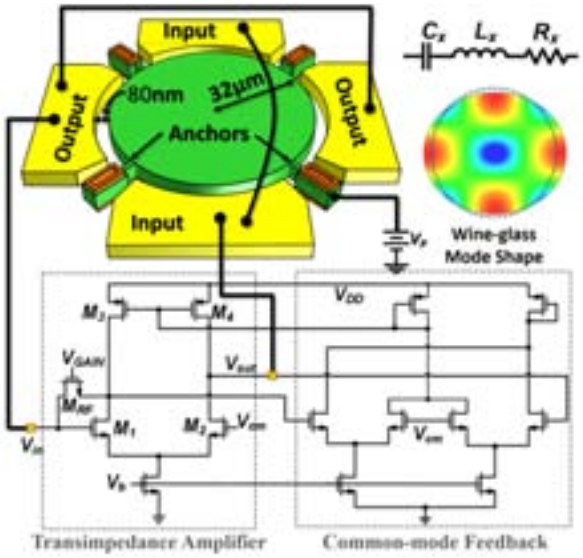

Fig. 1: Circuit schematic of the tested transimpedance amplifier-based micromechanical wine-glass disk oscillator, with the simplified equivalent circuit and mode shape for the MEMS resonator.

Meanwhile, wine-glass disk oscillators are known to exhibit exceptional short-term stability, with demonstrated phase noise below the GSM spec. [3] and superior insensitivity to vibration versus typical quartz counterparts [12]. But studies of long-term stability have until now been unpublished. To remedy this, this paper presents a first measurement of the MEMS oscillator of Fig. 1, comprised of a wine-glass disk resonator bond-wired to

This work was supported in large part by the DARPA N/MEMS S&T program.

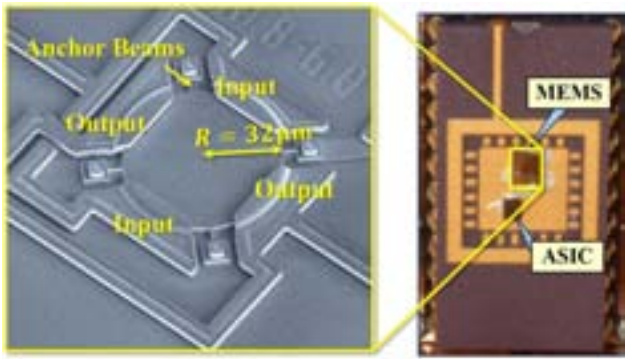

Fig. 2: SEM of the wine-glass disk resonator, left, bondwired into a DIP package with the ASIC amplifier, right.

an ASIC transimpedance amplifier and hermetically packaged in a custom-built vacuum-packaging system capable of maintaining μtorr pressures. A double-oven system maintains a constant oscillator temperature at 34°C with less than 0.001°C deviation, a key improvement over previous studies.

The long-term frequency drift of this MEMS oscillator is measured over 10 months and found to stabilize to within the short-term measurement variation of ±300 ppb over a period of months after an initial burn-in period. This marks a significant improvement from previous studies on other MEMS resonator types, where frequency fluctuations were ±3.1 ppm [8] and ±1.2 ppm [9] over similar time scales. Including burn-in, the total observed aging of 10 ppm over 10 months is now on par with many consumer quartz oscillators designed for timing applications [4] and marks performance sufficient for use in short-range wirelesss sensor networks.

II. The MEMS Oscillator

The wine-glass disk resonator used in this work, cf. Fig. 2, was fabricated using the same process as [13] and consists of a 3μm-thick, polysilicon disk with 32μm-radius supported by four beams and surrounded by electrodes separated by a tiny 80 nm capacitive gap. The resonator motion is coupled to the electrical input and output via a bias voltage V_P applied to the disk. An ac drive voltage applied to the input electrode combines with V_P to produce a force across the input electrode-to-resonator gap that drives the resonator into the compound (2, 1) mode shape, shown in Fig. 1, which comprises expansion and contraction of the disk along orthogonal axes with nodal points located at support beam attachment locations. The relationship between the drive voltage and ensuing current generated by dc-biased mechanical modulation of the electrode-to-resonator gaps at each port is aptly modeled by the equivalent *LCR* circuit shown in Fig. 1. This mode's resonance frequency is given by:

$$f_{nom} = \frac{K}{R}\sqrt{\frac{E}{\rho(2+2\sigma)}} \qquad (1)$$

where R is the disk radius, $K = 0.373$ for polysilicon structural material, and E, σ, and ρ are Young's modulus, Poisson ratio, and density of the structural material, respectively.

To form an oscillator, the resonator is placed in the feedback path of a transimpedance amplifier similar to that of [12] and consisting of a fully differential CMOS amplifier connected in shunt-shunt feedback on one arm, with output taken from the other to realize a 0° phase shift from input to output. Transistors, M_1-M_4, comprise the basic differential pair biased by a common-mode feedback circuit that preserves low output resistance and cancels out common-mode noise. The MOS transistor M_{RF} is biased in the triode region to serve as a voltage controllable shunt-shunt feedback resistor that allows convenient adjustment of the TIA gain via its gate voltage, V_{GAIN}. When gain of the TIA is greater than the motional resistance of the resonator, R_x, the positive loop gain amplifies the (initially Brownian) motion until nonlinearity in either the amplifier or resonator (or both) limits the oscillation amplitude.

The amplifier IC was fabricated in a 0.35μm CMOS technology. Although the entire die occupies an area of 900μm×500μm, the actual sustaining amplifier only consumes about 100μm×100μm. The rest of the area is consumed by an on-chip buffer used to drive 50 Ω measurement systems and by-pass capacitors for noise reduction.

III. Stable Measurement Environment

A. Packaging

Of central import in MEMS oscillator stability is packaging. For example, exposure to air is known to produce frequency shifts due to oxidation or moisture absorption even in quartz oscillators [4]. The tiny size of MEMS resonators makes environmental control even more important. For the typical resonator used here, even a single additional monolayer of atoms, from sources such as contamination or package leakage, would correspond to a frequency change of over 30 ppm.

Beyond material aging concerns, a good vacuum environment is also needed to reduce air damping and enhance resonator Q. Fig. 3 gauges the degree to which air damping affects a typical wine-glass disk resonator used in this study with a measured plot of Q versus pressure that indicates a required operating pressure of below 1mtorr to remove air damping as a relevant loss mechanism. Achieving reliable hermetic packaging at such pressures is a challenge in a laboratory environment, and a chief obstacle in past long-term studies.

Pursuant to this goal, the vacuum packaging system of Fig. 4 was constructed to facilitate hermetic sealing using AuSn solder seals with a variety of conventional ceramic packages in a vacuum environment. In this system, a heated chuck holds the ceramic package containing the bond-wired MEMS resonator and ASIC while the package lid and magnetically attach to a linear motional feedthrough.

To package an oscillator, the ASIC and MEMS die, along

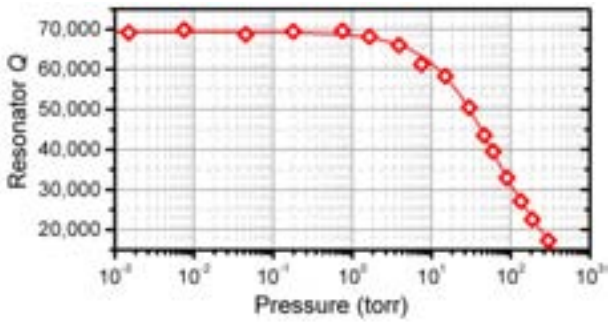

Fig. 3: Measured wine-glass disk MEMS resonator Q as a function of ambient air pressure.

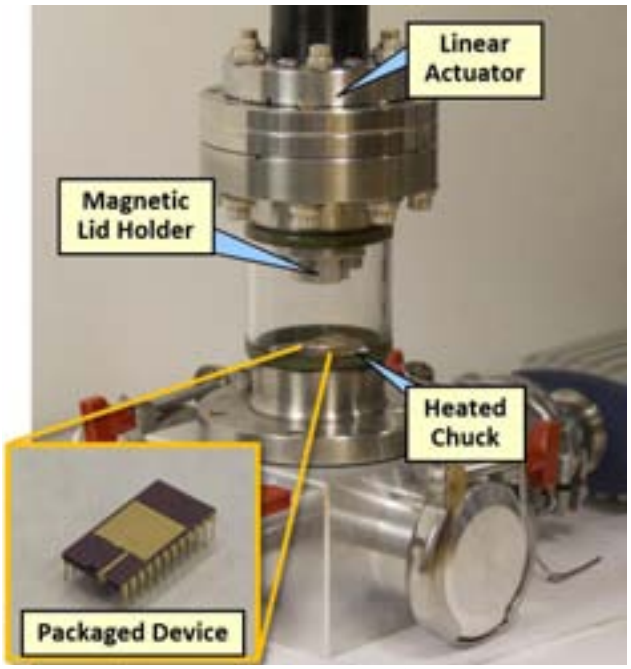

Fig. 4: Hemermetic vacuum packaging tool with zoom-in (inset) on a DIP package sealed via the tool.

with Ti metal shavings used as a getter, are first glued within the package using Ceramabond 552 high-vacuum ceramic adhesive. The package is mounted in the packaging chamber and pumped to µtorr vacuum. Following a 2 hour bakeout at 220ºC, the package lid with AuSn preform is pressed with ~10 lbs. of force against the package and heated to 350ºC for 1 minute. The package and chuck are allowed to cool to room temperature before venting and unloading. For the oscillators in this study, Kyocera KD-78382-01 24-pin dual in-line packages (DIP) and HRC-2578 lids were used.

B. Temperature Control

In order to accurately measure true aging-induced frequency drifts, the oscillator temperature environment must be very tightly controlled or compensated. For the polysilicon devices used here, the measured temperature coefficient of frequency is on the order of $T_{CF} = 21$ ppm/°C, which allows excessive frequency shifts when ambient temperature fluctuations are not compensated. In the past, two methods of temperature compensation have been applied to MEMS oscillators. Passive compensation seems to be limited to ±40 ppm total frequency shift over commercial temperature ranges [9]. On the other hand, active temperature compensation is widely used in production MEMS oscillators to provide full temperature range stability to better than ± 10 ppm [14]. But to accurately observe true frequency drift in the absence of thermal variations, an even more stable temperature environment is needed.

To this end, the work presented here employs the double-oven setup of Fig. 5 to house the measured oscillators. The outer oven consists of a Cincinnati Sub-Zero MCB-1.2 chamber which keeps the internal temperature within ± 0.1C. To further stabilize temperature, a second internal oven combines a computer controlled heating element and temperature sensor incorporated into the box used to mount the oscillator. An ultra-stable Measurement-Specialties 46007 glass-encapsulated thermistor serves as the temperature monitor and control, measured using an Agilent 34420A micro-ohm meter. This double oven was observed to hold temperature to within ~200 µK in the face of typical daily external temperature fluctuations.

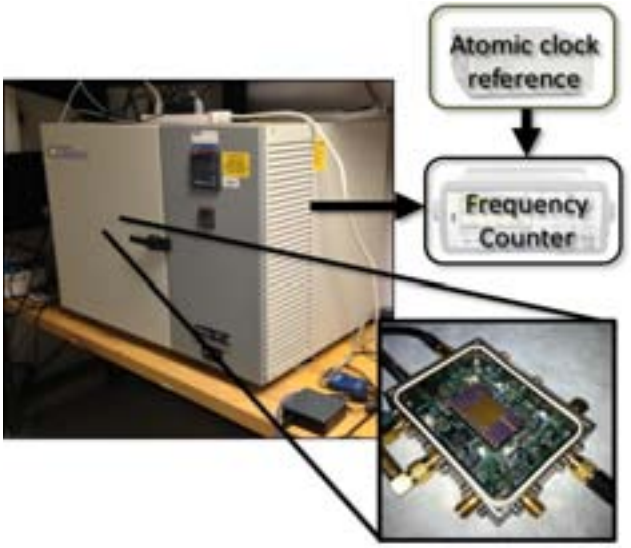

Fig. 5: Experimental measurement setup showing the oscillator mounted in the first temperature controlled oven (inset) and placed in a second environmental chamber oven for further temperature stability. The oscillator frequency is measured via a zero dead-time counter referenced to an atomic clock.

C. Frequency Measurement

When emplaced in the temperature-stable double-oven system, the oscillator output is measured using an Agilent 53230A frequency counter which allows high-resolution measurement with no dead time, i.e., no gap between measurements. For highly-stable measurements over long periods, a Stanford Research Systems FS725 atomic clock provides a frequency reference specified with ±5 ppb aging over a 20 year lifespan.

IV. Measurement Results

Fig. 6 presents typical 1 day data for the oscillator mounted in the double-oven stabilization system and demonstrates remarkable frequency stability down to ±150 ppb. Fig. 7 presents measured oscillator frequency versus time data over a 10 month aging period, exhibiting the same logarithmic decay behavior typical of quartz oscillators [4]. The increasing frequency suggests possible stress relaxation or changes to the resonator material properties over mass loading or package leaks

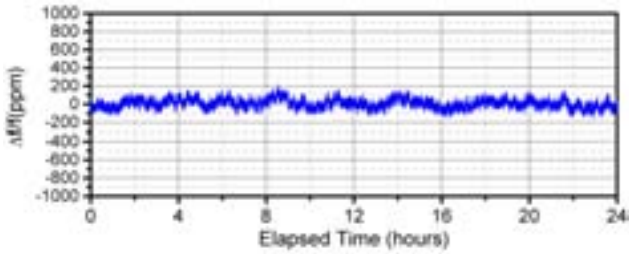

Fig. 6: Typical oscillator stability over 24 hours with a 1s averaging time.

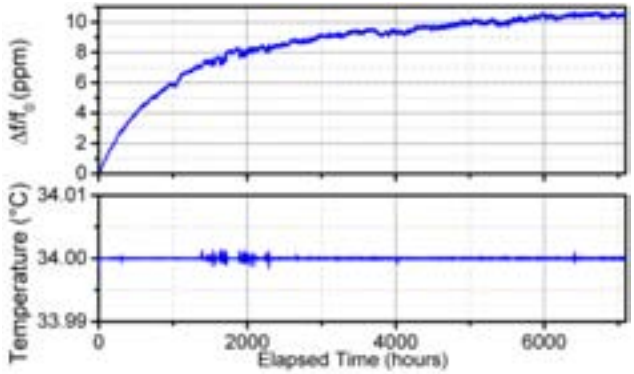

Fig. 7: Measured frequency drift and temperature stability of the MEMS oscillator. Frequency measurements were made using an Agilent 53230A frequency counter and shown here with a 100s measurement time.

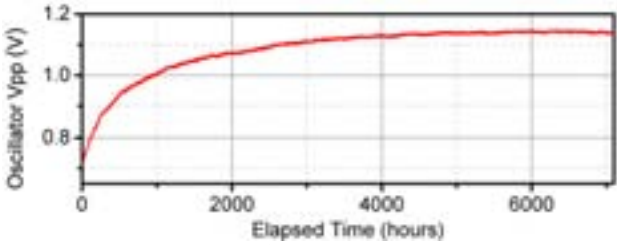

Fig. 8: Amplitude of oscillation during a long-term measurement.

as the aging mechanism. Stress relaxation in particular would be expected to contribute as both bond-wires and high-temp glue adhering the die to package would be expected to produce strain and have been observed to produce over 100 ppm/week drift in flexural mode devices [15]. Despite this, performance is good, on par even with low-cost quartz oscillators. This is not unexpected for such wine-glass devices, for which supports attached to quasi-nodal points on the resonant disk structure greatly isolate the disk from the substrate and its associated stress changes.

Interestingly, Fig. 8 presents oscillation amplitude data taken from this same time range, and shows an unexpected increase closely following the frequency drift seen. As the amplifier gain is kept fixed, this points to a surprising decrease in the R_x of the resonator over time. This again suggests that increased mass loading or air damping is not a factor here and further confirms a reliable package over the measured time span.

To better gauge the performance of this oscillator, Allan Deviation, σ_y, can be calculated from the fractional frequency shift $y_n = \Delta f / f_0$ using

$$\sigma_y^2(\tau) = \frac{1}{2}\langle(\bar{y}_{n+1} + \bar{y}_n)^2\rangle \qquad (2)$$

Fig. 9 presents Allan deviation vs. averaging time for the oscillator here. This plot closely follows typical performance of crystal oscillators [4], with decreasing Allan deviation for increasing measurement times up to approximately 1s as white phase and frequency noise are averaged out. Above 1s averaging time, the Allan deviations achieves a floor of $\sigma_y = 1.5\ x\ 10^{-8}$, competitive with typical quartz timing oscillators. As averaging time is increased, Allan Deviation remains constant till it begins to increase due to longer-term random walk noise, ultimately becoming dominated by long-term frequency drift effects.

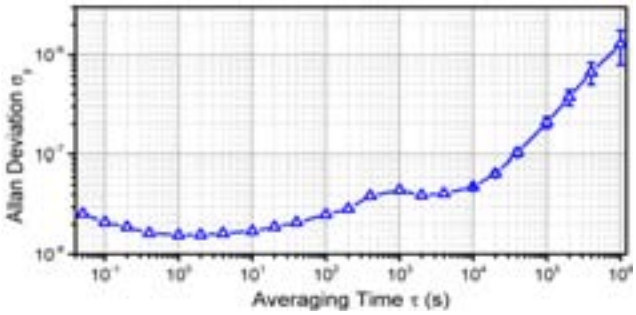

Fig. 9: Allan deviation as calculated from stability data with differing averaging times. Data with averaging time below 400s was calculated from shorter data sets taken at 0.01s sample time, while longer averaging time data was calculated from the full long-term stability data.

V. Conclusions

In this first study of long-term frequency drift in micromechanical wine-glass disk oscillators, performance is seen to be quite good, achieving stability within ± 300 ppb over a month after a burn-in period. With burn-in, the total drift is only 10 ppm over 10 months, well within required limits for many short-distance wireless communication specifications despite concerns that the small size of such MEMS resonators would lead to drift and reliability issues. Moreover, the increasing amplitude of oscillation over time suggests actual improvement in resonator quality factor and demonstrates that even simple in-house vacuum packaging is sufficient to achieve reliable operation of these MEMS devices. Whether or not Q's truly increase with time, the long-term stability measured here, together with the GSM-compliant phase noise already demonstrated in parallel work [3], elevates micromechanical wine-glass disk oscillators as some of the best MEMS has to offer, and encourages their use in small form factor, low power applications, such as the autonomous wireless sensor market, expected to grow exponentially in the coming years. More challenging cell phone reference oscillator requirements remain a target for future improvement.

***Abstract*—All-digital frequency synthesis based on single-bit, Nyquist-rate, quantization of sinewave with independent and identically distributed random amplitude dithering is proposed. The output spectrum of the quantizer is derived in closed form and is related to the distribution of the random dither. Conditions for spurs-free output are derived, and the output dynamic range is defined. MATLAB simulation examples illustrate the results of the proposed approach.**

Keywords—Digital-to-frequency converter, direct digital synthesis, frequency spurs, quantization

I. INTRODUCTION

The interest in all-digital frequency synthesis (FS) has been intensified in the R.F.I.C. industry over the past few years due to the increasing challenge in the design and the extra cost of fabrication of R.F. analog and mixed-signal I.C. versus standard digital ones in modern nano-scale I.C. technologies, e.g. [1]-[3]. Efforts towards all-digital FS can be traced at least thirty years back [4][6].

Replacing a complex analog or mixed-signal frequency synthesizer with a fully digital one can result in faster concept to market cycle, lower design effort and cost and the advantage of using digital design and verification tools.

Moreover, synchronous single-bit digital outputs of all-digital synthesizers, having sinewave-like spectrum can be used as local-oscillator signals in RF chains and, they can be amplified for transmission or internal use without distortion and with very high efficiency using a switching amplifier. Also one can incorporate digital or analog phase, frequency and amplitude modulation directly in an all-digital synthesizer [7].

The proposed single-bit-output Nyquist-rate sinewave quantization scheme is practically realized by a Direct Digital Synthesizer (DDS) with a 1-Bit output Nyquist-rate Digital to Analog Converter (DAC). Dither is added to the output of the Look-Up-Table (LUT) before the hard quantization to alleviate the nonlinearity and suppress the output spurs by breaking the periodicity of the truncation error.

Note that the DAC is only virtually there representing the act of signum function, or similarly that of an MSB extractor, applied to the sum of the LUT's output with the dither.

In the above setup, single-bit quantization alone, i.e. without dithering, typically results in dense and high-power frequency spurs making the output single-bit digital signal unusable for analog and R.F. applications (although it can by used for clocking digital circuitry).

The paper derives analytically the spectrum of the single-bit dithered quantizer as a function of the dither's Cumulative Distribution Function (CDF) when the dithering sequence is formed of Independent and Identically Distributed (IID) random variables. Moreover, the noise floor power due to random dithering is derived analytically and the output dynamic range is defined and calculated explicitly.

II. DEFINITIONS AND ASSUMPTIONS

Random dithering is commonly used to suppress the spurs and shape the noise of quantization in DDS [8] and data converters [9] and to eliminate periodic patterns in fractional-N frequency dividers [10].

Here we consider the extreme case of amplitude dithered DDS with single-bit output quantization (DAC) without oversampling [9] shown in Figure 1. The cosine can be generated using a phase accumulator and a LUT, and the Zero Order Hold (ZOH) outputs a continuous-time single-bit digital waveform. All blocks are clocked by a clock reference of frequency $f_S = 1/T_S$.

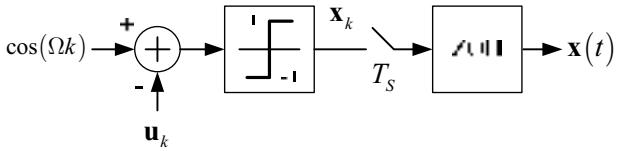

Figure 1: Dithered single-bit quantization of a sinewave

The dithering random sequence $\{\mathbf{u}_k\}$ is subtracted from the sinewave resulting in the discrete-time single-bit (± 1) signal $\mathbf{x}_k = \mathrm{sgn}\left(\cos(\Omega k) - \mathbf{u}_k\right)$ where "sgn" is the signum function.

Throughout the paper we assume that the random sequence $\{\mathbf{u}_k\}$ is formed of IID random variables having CDF $G:[-1,1]\to[0,1]$ which is continuous and has continuous second derivative in $[-1,1]$. Therefore, for every $k\in\mathbb{Z}$ and $u\in[-1,1]$ it is $\Pr(\mathbf{u}_k\le u)=G(u)$, so implicitly we assume that essentially $\mathbf{u}_k$ takes values only within $[-1,1]$. This is plausible because $\cos(\Omega k)$ does the same and hence any larger value range of the dither would be unnecessary.

It also makes sense from an application perspective to assume that $\Omega/(2\pi)$ is rational, i.e. $\Omega=2\pi w/q$ for some integer w such that $0<w<q/2$. In this case

$$\mathbf{x}_k=\operatorname{sgn}\left(\cos(2\pi wk/q)-\mathbf{u}_k\right) \tag{1}$$

and since $\{\mathbf{u}_k\}$ is an IID random sequence and $\cos(2\pi wk/q)$ has period $q/\gcd(q,w)$, the random sequence $\{\mathbf{x}_k\}$ is cyclostationary of the same period. Since q is a multiple of $q/\gcd(q,w)$, $\{\mathbf{x}_k\}$ is also cyclostationary of period q and we consider it as such in the rest of the paper to simplify notation.

A. The Period-Average Autocorrelation of $\{\mathbf{x}_k\}$

The Power Spectral Density (PSD) of a discrete-time wide-sense stationary (WSS) process is the Discrete-Time Fourier Transform (DTFT) of its autocorrelation function [11]

$$r_x(n,m)=E\{\mathbf{x}_n\mathbf{x}_m\}. \tag{2}$$

Since $\{\mathbf{x}_k\}$ is not WSS but cyclostationary of period q its PSD, $s_x(\omega)$, is commonly defined as the DTFT of its period-average autocorrelation [11]-[12], i.e., of

$$\bar{r}_x(k)=\frac{1}{q}\sum_{m=0}^{q-1}r_x(k+m,m) \tag{3}$$

and

$$s_x(\omega)=\sum_{k=-\infty}^{\infty}\bar{r}_x(k)e^{-ik\omega}. \tag{4}$$

To calculate $\bar{r}_X(k)$ we express the CDF $G:[-1,1]\to[0,1]$ as a series of Chebyshev polynomials of the first kind, i.e.,

$$G(u)=\frac{1}{2}+\frac{1}{2}\sum_{j=0}^{\infty}a_jT_j(u). \tag{5}$$

The summand and multiplying factor $1/2$ is used to simplify the algebra. Coefficients a_j are derived according to [13]

$$a_0=\frac{2}{\pi}\int_{-1}^{1}\frac{G(u)}{\sqrt{1-u^2}}du-1,\quad a_{j>0}=\frac{4}{\pi}\int_{-1}^{1}\frac{G(u)T_j(u)}{\sqrt{1-u^2}}du. \tag{6}$$

Since G was assumed continuous, its series expansion (5) converges to G everywhere in $[-1,1]$. Inversely, G can be defined using coefficients a_j as long as series (5) converges to a continuous function and G is indeed a CDF. Assuming further that series (5) is term-by-term differentiable, a necessary and sufficient set of conditions for G to be a CDF is

$$G(-1)=0,\quad G(1)=1\quad\&\quad G'(u)\ge 0\quad\forall u\in[-1,1] \tag{7}$$

Since $T_j(\pm1)=(\pm1)^j$, $j=0,1,2,\ldots$, and $T_j'(u)=j\cdot U_{j-1}(u)$, for $j=1,2,3,\ldots$, where U_j is the j-th Chebyshev polynomial of the 2nd kind [13], Eqs. (7) can be written as

$$\begin{aligned}&\sum_{j=0}^{\infty}(-1)^j a_j=-1,\quad \sum_{j=0}^{\infty}a_j=1\\ &\sum_{j=1}^{\infty}ja_jU_{j-1}(u)\ge 0\quad\forall u\in[-1,1]\end{aligned}. \tag{8}$$

Section IV illustrates how coefficients a_j are calculated for two cases of CDF G and used to derive the PSD.

III. Power Spectral Density and Dynamic Range

Using the above definitions we can express $\bar{r}_X(k)$ as a function of the coefficients a_j, $j=0,1,2,\ldots$. Specifically, we have that [14] the period-average autocorrelation $\bar{r}_X(k)$ of $\{\mathbf{x}_k\}$ is given by (9) where $\delta_0=1$ and $\delta_{k\ne0}=0$.

$$\bar{r}_x(k)=a_0^2+\sum_{j=1}^{\infty}\frac{a_j^2}{2}\cos\left(\frac{2\pi kjw}{q}\right)+\left(1-a_0^2-\sum_{j=1}^{\infty}\frac{a_j^2}{2}\right)\delta_k \tag{9}$$

Note that $\bar{r}_x$ comprises of DC term a_0^2, harmonics of $\cos(2\pi kw/q)$ and an impulse term at $k=0$. Moreover, the amplitude of the j^{th} harmonic, i.e., $a_j^2/2$, is half the square of the projection of CDF G to the j^{th} Chebyshev polynomial according to Eqs. (6). This implies that by selecting CDF G we can "shape" the period-average autocorrelation function and so the PSD of $\{\mathbf{x}_k\}$. Note however that time is discrete and the harmonics of $\cos(2\pi kw/q)$ in Eq. (9) are subject to aliasing and folding into the frequency domain $\omega\in[0,2\pi)$ simply because $\cos(2\pi kjw/q)=\cos\left(2\pi k\left((jw)\bmod q\right)/q\right)$.

A. Power Spectral Density of the Output Signal $\mathbf{x}(t)$

The output $\mathbf{x}(t)$ of the ZOH in Figure 1 is a continuous-time signal which can be written in the form

$$\mathbf{x}(t)=\sum_{k=-\infty}^{\infty}\mathbf{x}_k p\left(\frac{t}{T_S}-k\right) \tag{10}$$

where $T_S=1/f_S$ is the sampling period and pulse $p(t)$ is 1 for $t\in[0,1)$ and zero otherwise corresponding to ZOH's operation. It can be shown [14] that the PSD of $\mathbf{x}(t)$ is

$$S_x(f)=T_S\cdot\operatorname{sinc}^2(f\cdot T_S)\cdot s_x(2\pi fT_S) \tag{11}$$

where $s_x(\omega)$ is the DTFT in Eq. (4) of the period-average autocorrelation $\overline{r_x}$ and $T_S \cdot \mathrm{sinc}^2(f \cdot T_S)$ is due to the shape of the pulse $p(t)$. Combining Eqs. (4), (9) and (11), and after a lengthy algebraic manipulation we can derive the following Theorem whose proof can be found in [14].

Theorem: Following the above definitions and assumptions and further assuming that $\gcd(w,q)=1$ the PSD of $\mathbf{x}(t)$ is

$$S_x(f) = \mathrm{sinc}^2\left(\frac{f}{f_S}\right) \cdot \left(S_{HA}(f) + S_N(f) + S_{DC}(f) \right) \quad (12)$$

where HArmonics, Noise and DC components are given by

$$S_{HA}(f) = \frac{1}{4}\sum_{h=1}^{\infty} b_h \left(\delta\left(f - \frac{h}{q} f_S\right) + \delta\left(f + \frac{h}{q} f_S\right) \right), \quad (13)$$

$$S_N(f) = \frac{1}{f_S} \cdot \left(1 - a_0^2 - \frac{1}{2}\sum_{j=1}^{\infty} a_j^2 \right), \quad (14)$$

and

$$S_{DC}(f) = \frac{b_0 + 3a_0^2}{4}\delta(f) \quad (15)$$

respectively. For $h = 0,1,2,\ldots$ the power of the frequency components at $\pm(h/q) f_S$ in Eq. (13) is $b_h/4$ and

$$b_h \triangleq \sum_{r=-\infty}^{\infty} a_{I(h,r)}^2 \quad (16)$$

where $I(h,r) = |j_1 h + qr|$; constant j_1 (and k_1 which is not involved in the expression) is derived solving the Diophantine equation $wj_1 + qk_1 = 1$. Specifically coefficient b_w of the frequency components at $\pm(w/q) f_S$ is $b_w = \sum_{r=-\infty}^{\infty} a_{|1+qr|}^2$. □

Observing Eq. (16) we note that the contributions of coefficients a_j to the total power of frequency component at $\pm(h/q) f_S$ are cumulative since $a_{I(h,r)}^2 \geq 0$. Therefore, to minimize the spurs in the output we should zero as many of the coefficients a_j as possible because the smaller the set of nonzero coefficients a_j is, the smaller the set of frequency components present in $S_{HA}(f)$ will be.

Note that in order to derive coefficient b_h we first find a solution (j_1, k_1) of the Diophantine equation $wj_1 + qk_1 = 1$ using the Euclidean algorithm ("gcd" function in MATLAB). This is always possible due to our assumption that $\gcd(w,q)=1$. Any (j_1, k_1) of the infinitely many solutions is acceptable but one with absolutely small j_1, k_1 is convenient. Then we apply Eq. (16) where only j_1 is used in $|j_1 h + qr|$. The procedure is illustrated in the examples of Section IV.

B. *Noise Floor and Dynamic Range*

Typically, the desirable frequency component at the output is at frequency $(w/q) f_S$ with amplitude $\mathrm{sinc}^2(f/f_S) \cdot b_w/4$, captured by $S_{HA}(f)$ in Eq. (13). Also, the output noise (which is the only component of continuous spectrum) has PSD $\mathrm{sinc}^2(f/f_S) \cdot S_N(f)$. We define the Dynamic Range (DR) of the output as the ratio of the signal power to noise's PSD

$$DR = 10\log_{10}\left(\frac{\mathrm{sinc}^2(f/f_S) \cdot b_w/4}{\mathrm{sinc}^2(f/f_S) \cdot S_N(f)} \right) \quad \text{(dB)}$$

and after replacing the values of b_w and $S_N(f)$ we get

$$DR = 10\log_{10}\left(\frac{\sum_{r=-\infty}^{\infty} a_{|1+qr|}^2}{1 - a_0^2 - \sum_{j=1}^{\infty} \frac{a_j^2}{2}} \right) + 10\log_{10}(f_S) - 6.02 \quad \text{(dB)} \quad (17)$$

The definition of the DR can be used for other frequency components of interest as well. Also, note that the summand $10\log_{10}(f_S)$ in Eq. (17) is expected since the power of the sinewave's quantization error is spread over frequency bandwidth proportional to the sampling frequency. The use of Eq. (17) is illustrated in the examples of Section IV.

IV. Examples and Simulations

First we emphasize the importance of dithering in spurs suppression in the case of single-bit quantization by considering the case of $w = 25$ and $q = 64$ without dither. This is the limiting case of the above setup when CDF $G(u)$ is zero for $u \in [-1, 0)$ and one for $u \in (0, 1]$, i.e. $\mathbf{u}_k = 0$ with probability one. Figure 2 shows the output spectrum ignoring the weighting factor $\mathrm{sinc}^2(f/f_S)$. The spectrum is the result of MATLAB simulation and coincides completely with the theory, Eq. (12). Note that although G is discontinuous at $u = 0$ its series expansion, Eq. (5), is valid for $u \neq 0$ implying $a_{2k} = 0$ and $a_{2k+1} = 4(-1)^k / ((2k+1)\pi)$ for $k = 0,1,2,\ldots$.

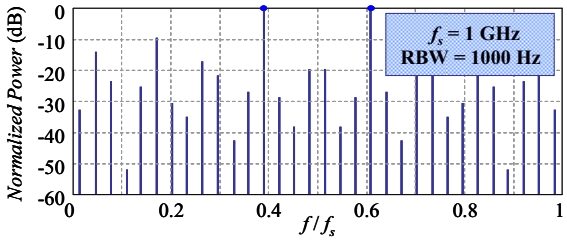

Figure 2: Spectrum of single-bit quantized sinewave without dithering when $w = 25$ and $q = 64$; ignoring the weighting factor $\mathrm{sinc}^2(f/f_S)$.

Now we consider the same case of $w = 25$ and $q = 64$ when the dithering sequence $\{\mathbf{u}_k\}$ is formed of *uniformly*

distributed IID random variables, i.e. the probability density function is constant, $G'(u)=1/2$ in $[-1,1]$ and so the CDF is $G(u)=(u+1)/2$. Since $T_1(u)=u$ we derive by inspection that $a_0=0$, $a_1=1$ and $a_k=0$ for $k=2,3,4,\ldots$.

To derive the coefficients b_h in the Theorem we find a solution of the Diophantine equation $25j_1+64k_1=1$, e.g. $(j_1,k_1)=(-23,9)$. For b_h, $h=0,1,2,\ldots$ to be nonzero, there must exist some $r\in\mathbb{Z}$ for which

$$I(h,r)=\left|j_1h+64r\right|=1 \tag{18}$$

This is because $a_1=1$ and $a_0=0$, $a_k=0$ for all $k=2,3,4,\ldots$, therefore only a_1 can contribute to b_h. Since $25j_1+64k_1=1$, a particular solution of $j_1h+64r=1$ is $(h,r)=(25,k_1)$ and so the general solution of Eq. (18) is

$$(h,r)=\pm(25,9)+\rho(64,23),\ \rho\in\mathbb{Z} \tag{19}$$

Since it is $h\geq 0$ we conclude that the (only) non zero coefficients b_h, $h=0,1,2,\ldots$ are b_{25} and $b_{\eta\cdot 64\pm 25}$, $\eta=1,2,3,\ldots$ From Eq. (16) we also get that $b_{25}=b_{\eta\cdot 64\pm 25}=1$, $\eta=1,2,3,\ldots$. So we derive that

$$S_{HA}(f)=\frac{1}{4}\sum_{\substack{h=25,\ \eta\cdot 64\pm 25\\ \eta=1,2,3,\ldots}}\left(\delta\left(f-\frac{h}{q}f_S\right)+\delta\left(f+\frac{h}{q}f_S\right)\right),$$

$S_N(f)=1/(2f_S)$ and $S_{DC}(f)=0$. The result coincides completely with the PSD derived using simulation, shown in Figure 3 where the weighted factor $\mathrm{sinc}^2(fT_S)$ is ignored.

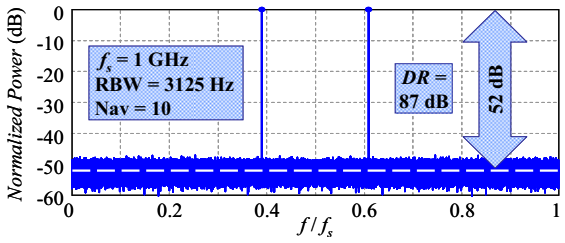

Figure 3: Spectrum of single-bit quantized sinewave with uniformly distributed dither when $w=25$ and $q=64$; the weighting factor $\mathrm{sinc}^2(f/f_S)$ is ignored. $f_S=1\,GHz$, Resolution BW = 3125 Hz and waveform averaging Nav=10 runs.

We note that there are only two frequency components in the frequency range $[0,f_S]$, the desirable one at $(25/64)f_S$ and the image of it at $((64-25)/64)f_S$ due to the discrete time nature of $\{\mathbf{x}_k\}$. The second one cannot be eliminated unless a continuous-time filter is used. Since no spurs are present we conclude that the uniform CDF results in spurs-free output. This is true in general for every integers w and q satisfying our assumptions.

Since $a_0=0$, $a_1=1$ and $a_k=0$ for $k=2,3,4,\ldots$, the dynamic range derived from Eq. (17) is expressed as

$$DR=10\log_{10}(f_S)-\ 3.01\ \text{dB} \tag{20}$$

In the PSD graph of the case $w=25$ and $q=64$ shown in Figure 3 the dashed white line indicates the averaged noise floor power. For $f_S=1\,GHz$ we get $DR\cong 87$ dB. Subtracting $10\log_{10}(RBW)$ dB, where $RBW=3125\,Hz$, to account for the resolution BW used for the simulation we get a very good match to the simulated 52 dB (Figure 3).

V. Conclusions

All-digital frequency synthesis using single-bit, Nyquist-rate quantization of sinewave and random dithering formed of independent and identically distributed random variables has been studied mathematically. The output spectrum has been calculated analytically as a function of the dither's Cumulative Distribution Function. It has been shown that uniformly distributed dither with range equal to that of the sinewave results in spurious-free output spectrum. The noise floor level due to dithering has been calculated analytically and the output dynamic range has been defined and calculated explicitly for the case of uniformly distributed dither. Examples based on MATLAB have been presented to illustrate the theory. The simulation results are in complete agreement with the theory.

***Abstract*—Numerical modeling of different compact slowing schemes designed for a satellite slow-beam microwave atomic clock is presented.**

I. INTRODUCTION

Space-based frequency standards are probably the most important parts of any global navigation system. Due to their specifics, these devices must meet a number of demands, which usually are: the daily stability of 10^{-15}, volume on the order of 0.01 m^3, weight less than 10 kg, power consumption less than 100 W, and continuous operation for at least 5 years. Optical frequency standards demonstrating the unique stability of $10^{-16} \div 10^{-18}$ are extremely promising for space applications. Nevertheless, at the moment the stringent requirements listed above force us to look for simpler technical solutions, which, in particular, would not require a transfer of the stabilized frequency from the optical range. Among these, the radiofrequency standards using cold atom beams seem to have the greatest potential.

Consequently, the compaction and the energy consumption reduction of such standards together with improvement of their stability become the research priority, and one of the solutions involves the use of CPT-Ramzey resonance optical detection.

II. STATEMENT OF THE PROBLEM

Since the sensitivity of any scheme of registration of radio-optical resonance in an atomic beam is limited by the longitudinal velocity of the atoms, the longitudinal velocity of the order of 1 m/s and registration area length of at least 0.5 m are required for obtaining stability of 10^{-15}. The combination of these requirements, in turn, limits the allowable transverse velocity of the atoms in the beam.

Note that the optical preparation of the atomic beam characterized by the longitudinal velocity of 1 m/s and a divergence of 0.05 rad is a difficult task due to the limitations of the existing slowing schemes. There are two types of these schemes – one using time-dependent frequency tuning of optical radiation (so-called «laser chirping»), and other using spatially inhomogeneous magnetic field to change the frequency of the atom in order to adjust the frequency of the transition (Zeeman slowing); the latter allows a continuous beam of cold atoms to be obtained, which is considered an advantage. In practice, however, none of these schemes in their classic versions provide a longitudinal deceleration of atoms below $10 \div 20$ m/s; this limitation arises because significant time is needed for slowing the atoms from the whole initial thermal distribution to a narrow velocity peak. During a long (several ms) interaction time the atomic beam starts blurring in the transverse direction, essentially losing intensity. Since the time of longitudinal slowing of the atomic beam linearly decreases with the initial velocity of the atoms, it has been proposed to significantly reduce the upper limit v_0 of the initial velocities of the atoms that interact with the laser radiation [1].

In this case, the time of longitudinal deceleration, as well as the transverse dimension of the atomic beam, dramatically decreases, which gives hope for obtaining the number of atoms with velocities ≤ 1 m/s sufficient for registration. Of course, some loss of intensity of the atomic beam occurs in this scenario, since only the slowest part of the thermal beam interacts with the cooling light. Thus, at a speed v_0 corresponding to one-half of the average thermal velocity, about 2% of a thermal beam is effectively used; this is compensated by shorter time (and hence the shorter slowdown length and less required power), and smaller transverse dimensions of the beam of atoms in the registration area.

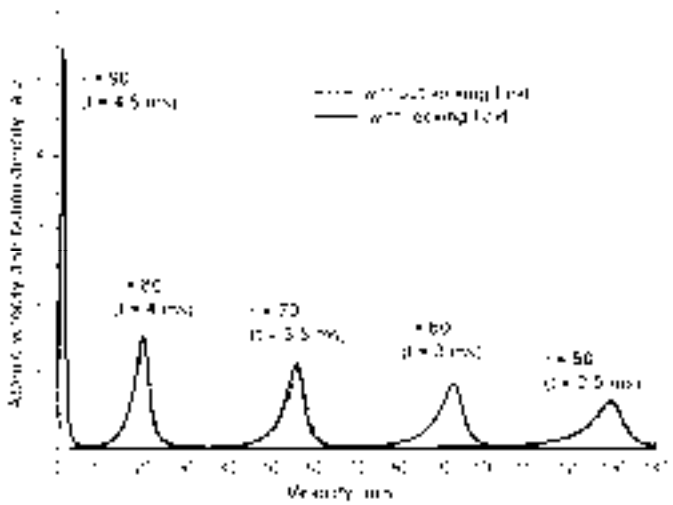

Fig. 1. Linear frequency sweeping

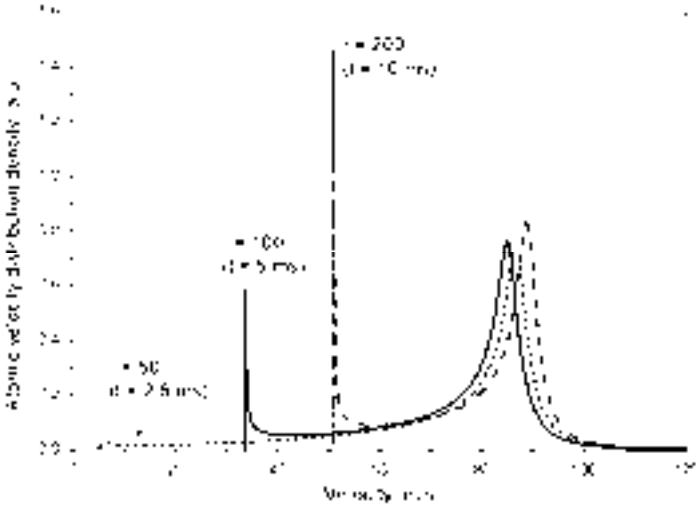

Fig. 2. Nonlinear frequency sweeping

The operating mode of such a slower will always be pulsed regardless of the method of the Doppler shift compensation, because it is necessary to let the fast atoms with $v > v_0$ leave the interaction area before the final stage of the cooling starts. Therefore Zeeman slowing method loses its main advantage – the continuity of the cooling process. On the other hand, advantages of the laser chirping methods include low energy consumption (since no strong magnetic field is needed), as well as low requirements for magnetic shielding around the registration area. In this report different versions of this method are investigated and compared.

III. The Proposed Solution

The base for modeling of longitudinal cooling process is the Fokker–Planck equation

$$\left(\frac{\partial}{\partial t}+v_z\frac{\partial}{\partial z}\right)w=-\frac{\partial}{\partial p_z}\left(F_z w\right)+\frac{\partial^2}{\partial p_z^{\,2}}\left(D_{zz}w\right), \qquad (1)$$

where $w\equiv w(v_z,t)$ is one-dimensional distribution function; $F_z=-\hbar k\gamma\dfrac{G}{1+G+(\delta+kv_z)^2/\gamma^2}$ is the light pressure force along z axis; $D_{zz}=\hbar^2k^2\gamma\dfrac{G}{1+G+(\delta+kv_z)^2/\gamma^2}$ is the pulsed diffusion coefficient; $G=2\Omega^2/\gamma^2$ is the saturation parameter; Ω is Rabi frequency; $\delta=\omega-\omega_0$ is the laser frequency $\omega=kc$ detuning from atomic transition frequency ω_0; 2γ is radiation width (FWHM) of the transition.

It is known [1], that the pulse diffusion at typical slowing times (tens ms) practically does not affect the width of the final atomic velocity distribution. Therefore we used the spatially homogeneous Liouville equation:

$$\frac{\partial}{\partial\tau}w=\frac{\partial}{\partial\tilde{v}_z}\left(f_z w\right), \qquad (2)$$

containing dimensionless variables $\tau=(\hbar k^2/m_{Rb})t=\omega_R t$, $\tilde{v}_z=(kv_z)/\gamma$, $f_z=F_z/\hbar k\gamma$.

We use the following procedure to calcule the final velocity distribution: during the first step ($\tau=0$) the initial distribution

$$w(\tilde{v}_z,\tau=0)=(\tilde{v}_z{}^3/<\tilde{v}_z>^4)e^{-\left(\frac{\tilde{v}_z}{<\tilde{v}_z>}\right)^2}, \qquad (3)$$

where $<\tilde{v}_z>$ is the most probable speed, is split to some number of small intervals $(\Delta\tilde{v}_z(t=0))_i$, and the partial number of atoms $S_i(t=0)$ is calculated for each interval. During the next step, the kinetic equations describing the action of the force f_z are solved for each interval, resulting in a new set of velocities $(\Delta\tilde{v}_z(t))_i$ corresponding to the time t. Since the total number of the atoms in each interval stays constant, the new value of atomic density $S_i(t)$ can be obtained from the old one:

$$S_i(t)=S_i(t=0)\frac{(\Delta\tilde{v}_z(t=0))_i}{(\Delta\tilde{v}_z(t))_i}. \qquad (4)$$

We started numerical simulation of longitudinal laser cooling of Rb thermal beam ($<\tilde{v}_z>=400$ m/s) on D_1 line, using one laser field with fixed detuning $\delta+k<v_z>=\dfrac{\delta}{\gamma}+\dfrac{k}{\gamma}<v_z>=\Delta+<\tilde{v}_z>=0$. In this case the model predicts a fast forming of a narrow peak in atomic distribution, and slow (tenths of second) shifting of this peak to the zero velocities. In order to increase the cooling efficiency,

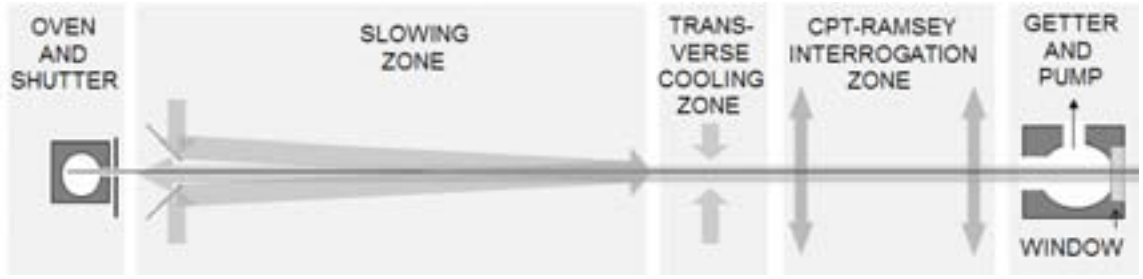

Fig. 3. Basic sheme of the atomic beam preparation/registration unit

which in our case is determined by the speed of shifting the peak to the zero velocity zone, we also modeled laser cooling with variable detuning ("chirping"): $\omega = \omega(0) + y(t)$, and, correspondingly, the light slowing force

$$F_z = -\hbar k \gamma \frac{G}{1 + G + (\delta + k v_z + y(t))^2 / \gamma^2}. \qquad (5)$$

The upper limit v_0 of the initial velocities of the atoms that interact with the laser radiation is determined by the initial detuning. For our simulation we have chosen an intermediate v_0 value: $v_0 = < \tilde{v}_z >$.

Indicated by solid lines on Fig. 1 is the evolution of the longitudinal velocity distribution of the atoms in the beam in case of the linear sweeping of the slowing light frequency $y(t) = a \cdot t$ in presence of the "locking" field, i.e. laser light propagating along the atomic beam, as was proposed in [3]. The parameters of the model were: the speed of slowing light frequency sweep $a = 3.2 \cdot 10^{12}\ c^{-1/2}$, the slowing light saturation parameter $G = 100$, the locking light saturation parameter $G_L = 3$, the locking light detuning $\delta_L = 0$.

As demonstrated in Fig. 1, it takes less than 4.5 ms to shift the atomic distribution peak to the velocity 7 m/c, and therefore the length of the slowing zone can be reduced to ~16 cm. One can chose the final speed of the beam by varying δ_L. The efficiency of the slowing process decreases drastically without the locking light, mainly because the atoms are "blown" back to the atomic source.

Indicated by dot-dashed lines on Fig. 1 is the evolution of the same distribution in the case of two counter-propagating beams symmetrically detuned from $< \tilde{v}_z >$; both frequencies are being swept linearly, as in the previous case. There is no stationary locking field in this case: the detunings of both the slowing and the locking fields are being simultaneously shifted to the zero velocities. The detunings satisfy the condition $\delta_1 + \delta_2 = 2k < v_z >$: $\delta_1 / \gamma = -260$, $\delta_2 / \gamma = -540$. It is still possible to shift the peak of the atomic distribution to the zero speed area in this configuration, but (unlike in the previous case) most atoms acquire negative v_z projection before reaching the interrogation zone.

We have also investigated variations of the methods described above, in different combinations. Fig. 2 shows the evolution of the longitudinal velocity distribution in the case of the nonlinear sweeping of the slowing light frequency: $y(t) = a t^2, a = 3.2 \cdot 10^9\ c^{-2}, \delta_L = 0$. As illustrated on Fig. 2, one (at $t < 2.5$ ms) or two (at $t > 2.5$ ms) peaks can be formed, corresponding to the roots of quadratic polynomial in the denominator of the expression describing the light pressure force; the slowing efficiency is low compared to the previous versions.

IV. Conclusion

According to the results described above, it is advisable to use linear sweeping for fast and effective cooling; presence of "locking" light beam, propagated along the atomic beam, is critical. It is possible to obtain sufficient number of atoms using slowing methods described above; short cooling time allows a rather compact beam (1.6 cm at $t = 4$ ms and initial divergence 0.02 rad) to be obtained on the interrogation zone input.

The basic scheme of the atomic beam preparation/ registration unit is shown in Fig. 3. Its drawbacks are obvious, and include: the need for an atomic beam shutter; the difficulty of forming a co-propagating "locking" beam; and the danger of covering the window (situated in the pump unit) by hot atoms. At present we are developing a modification of this construction, which promises to be free of these flaws; this modification implies placing the oven output at some angle to the unit axis, followed by selective declination of the atoms with $v < v_0$ to the unit axes. These atoms will then form an additional weak atomic beam, which will be slowed as described above.

***Abstract*—We present the short-term noise budget and metrological studies on the medium- to long-term stability of our Rb standard. Our clock exhibits a short-term stability of $\sim 1.4\times10^{-13}\ \tau^{-1/2}$. The dependance of microwave power shift on light intensity, and the possibility to nullify the microwave power shift is demonstrated. The perturbing *vapor cell geometric effect* on medium- to long-term time scales, limiting the stability around 6×10^{-14} level is identified. Further required improvements are discussed.**

I. Introduction

Compact rubidium (Rb) frequency standards form the back bone of today's satellite navigation systems [1]. Recently developed laser-pumped Rb cell standards exhibit short-term frequency stabilities by at least one order magnitude better than the conventional lamp-pumped standards [2], [3].

We are developing a compact laser-pumped high-performance Rb cell standard exhibiting the performances of a passive H-maser [4], but with a reduced volume (< a factor of 10), mass (< a factor of 5) and power consumption (< a factor of 4). Our Rb cell standard is based on the Continuous-Wave (CW) Double-Resonance (DR) principle [6]. The improvement in the short-term stability of our clock has already been demonstrated [2], [5], [6], with the recent performance being a short-term stability of $\sim 1.4\times10^{-13}\ \tau^{-1/2}$ [6].

In this proceeding, we present the noise budget of the short-term clock stability. We also present a systematic metrological characterization of perturbing physical effects influencing the medium- to long-term clock frequency instability, such as the 2^{nd}-order Zeeman shift, light-shifts, microwave power shift, cavity pulling, spin-exchange shift, and the temperature coefficient shifts.

II. Experimental setup

The details of our experimental clock setup were already presented in [5]. The setup consists of three main components, (i) the frequency stabilized compact Laser Head (LH) with an overall volume and mass of < 0.9 dm^3 and < 0.6 kg, respectively, (ii) the Physics Package (PP) with an overall volume and mass of < 0.8 dm^3 and < 1.4 kg, respectively, and (iii) the low noise microwave synthesizer (Local Oscillator, LO), which is presently a rack-mount device. The laser is a DFB diode emitting at 780 nm (Rb D2 transition). The laser is frequency stabilized using an evacuated Rb reference cell that is integrated in the LH assembly. Further details on the laser head were reported in [7]. The details on the PP were reported in [5][6]. The core of this PP consists of a glass cell of 25 mm diameter that has Rb vapor and a mixture of buffer gases. Our Rb cell has two distinct parts; *cell volume*, where the ^{87}Rb vapor is interrogated with laser and microwave to obtain the DR signal, and *cell stem* that acts as reservoir for metallic Rb. This cell is situated inside a newly developed compact magnetron-type microwave resonator (V < 45 cm^3), and the details of which can be found in [8]. The details on microwave source (the LO) including the digital lock-in and clock loop electronics were presented in [3]. The phase noise of the LO was measured by cross-correlation method. At a carrier frequency of 6.8 GHz it has a noise level at -70 dBrad^2/Hz at 1 Hz Fourier frequency and noise floor at -111 dBrad^2/Hz from 10^3 Hz to 2×10^4 Hz.

III. DR signals and short-term stability noise budget

We measured a narrow DR signal linewidth of 334 Hz (FWHM) and a signal contrast of 26%. The shift in the centre frequency (from the unperturbed ^{87}Rb ground-state clock transition) mainly due to the buffer gas collisions was measured to be 3390 Hz, giving the centre frequency value of 6.834686 GHz. The error signal generated by frequency modulating the microwave frequency in the closed-clock-loop configuration gave a discriminator slope of D = 1.52 nA/Hz. The photocurrent of 1.6 μA at FWHM corresponds to an estimated shot-noise limited frequency stability of $4.9\times10^{-14}\ \tau^{-1/2}$. However, the short-term stability of our clock presently has a signal-to-noise (S/N) limit of $\sim 1.2\times10^{-13}$, mainly due to FM-to-AM conversion of laser FM noise in the atomic vapor [9]. Measurements on the noise budget limiting the short-term stability of our clock is presented in Table I.

The limit on short-term stability also includes the influences due to the intermodulation effects on the phase noise of the LO and the laser intensity and frequency fluctuations. The overall short-term clock stability can be estimated from

TABLE I. SHORT TERM NOISE BUDGET OF THE 25 MM CELL CLOCK.

Source	Instability, σ_{inst}(y) $\tau^{-1/2}$
Detector dark noise	2.5×10^{-14}
Shot-noise limit (from DR signal)	4.9×10^{-14}
Microwave noise	5.1×10^{-14}
Laser noise (microwave off)	1×10^{-13}
Total noise	1.15×10^{-13}
S/N measured (clock loop noise)	1.17×10^{-13}

the sum of the squares of the individual limits of S/N, the LO phase noise and the laser frequency and intensity fluctuations as $\sim 1.4\times10^{-13}\ \tau^{-1/2}$. This short-term stability was measured and reported in [6].

IV. MEDIUM- TO LONG-TERM STUDIES

Various physical perturbations affecting the medium- to long-term clock stability were measured and evaluated and are presented in this section.

A. 2^{nd}-order Zeeman shift on clock transition

Though the clock transition: $5\ ^2S_{1/2}|F_g = 1, m_F = 0\rangle \longleftrightarrow |F_g = 2, m_F = 0\rangle$ (in the case of ^{87}Rb) is unaffected by the magnetic field in first-order, the second-order perturbations due to magnetic field variations give rise to the 2^{nd}-order Zeeman shift [10], given as [11],

$$\Delta\nu_Z = A_0|\mathbf{B}\cdot\hat{z}|^2, \qquad \text{with } A_0 = 575.14\ \ \mathrm{Hz/G^2}, \quad (1)$$

where, $\hat{z}$ is the quantization axis direction and $\mathbf{B}$ is the resultant total magnetic field that has a contribution due to the applied quantization magnetic field $\mathbf{B_0}$, the residual field $\mathbf{B_r}$ and the field related to the noise of the magnetic shields $\mathbf{B_s}$. By considering all the above noise contributions, we estimate the influence of the 2^{nd}-order Zeeman shift on the clock frequency stability to be $\sigma_y(\tau) \approx 2.7\times10^{-15}$ up to 10^5 s integration times, however this value could degrade to the level of 10^{-14} in highly perturbed magnetic conditions.

B. Intensity & Frequency Light-Shifts (LS)

Theoretical description of the light-shift (AC Stark shift) can be found in [12], [13]. At a fixed laser frequency (i.e. when we stabilise our laser to a particular sub-Doppler transition), the clock frequency shift was measured as a function of the input laser intensity to get the intensity LS coefficient, α [13]. For the transition $|F_g = 2\rangle \rightarrow |F_e = 01\mathrm{Cross-Over}\rangle$, we measured the lowest intensity light-shift coefficient, $|\alpha|$ = 1.46 Hz·mm^2/μW.

Furthermore, when the laser intensity was kept constant, the clock frequency shift was measured as a function of laser frequency that gives the frequency LS coefficient, β [13]. At our input laser intensity I_L = 0.46 μW/mm^2, we get a frequency LS coefficient value of 82 mHz/MHz. The frequeny LS coefficient can be suppressed in the pulsed-mode. In the CW operation, it is not possible to completely suppress β, but the influence could be reduced by reducing the input laser intensity. Our measurements showed that the dependance of β on laser input intensity has a slope of 184 mHz/MHz·mm^2/μW.

C. Microwave Power Shift & dependance on light-intensity

The microwave power shift in buffer gas cell is an unavoidable phenomenon, because the atoms are relatively motionless during the microwave interaction, thereby causing the detected overall signal to be an inhomogeneous integration over the occuring spatial gradients [10][14][15]. It can be attributed to the field distribution (mode) inside the cavity. The observed shift is a weighted average of the ensemble of atoms that is dependent on each atom's position inside the cell. Therefore, the light-shift varies continuously along the path of the light beam in a buffer gas cell thereby causing inhomogeneous broadening of the resonance signal [10][16]. Hence, in a DR signal, we can say that the measured resonance frequency is a function of the applied microwave (RF) power. This inhomogeneity causes the shift on the clock hyperfine frequency and is termed as power shift, $|\mu_{PS}|$. The observed shift is dependent on light intensity and mimics the light-shift behavior, known as pseudo-light-shift effect [17].

The μ_{PS} was measured in the following method. At each fixed microwave power input, the clock frequency shift was measured as a function of laser intensity. Then, the light-shift free, meaning the pure microwave power shift value, was extracted by extrapolating to zero laser intensity, I_L. These extracted shift values at each microwave input power are plotted in Fig. 1, the slope ($\approx 4\times10^{-13}$/dBm) gives the pure microwave power shift on the clock frequency. Its effect on medium to long-term clock frequency is evaluated in Table II.

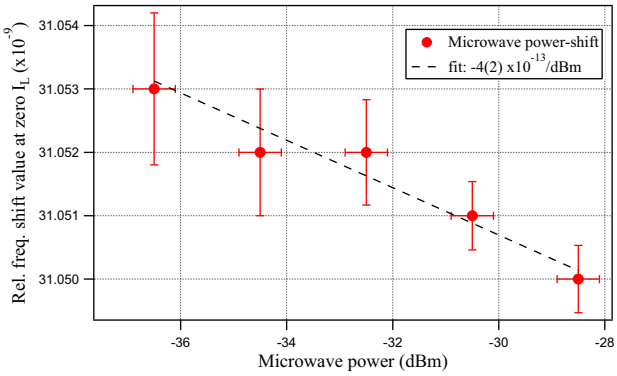

Fig. 1. Microwave power shift. The y-scaling shows relative frequency shift as the clock is referred to active H-maser.

In addition, we evaluate the dependancy of $|\mu_{PS}|$ on the input light intensity. At a smaller intensity LS coefficient of 19.5 mHz·mm^2/μW, the dependancy of input light-intensity effect on the microwave PS is well pronounced. Fig. 2 shows the microwave PS coefficient (in Hz/dBm) dependancy on the interrogating laser light intensity I_L. For instance, at an input laser intensity of $\approx$ 0.1 μW/mm^2, one can suppress the effect of microwave power shift in CW operation.

D. Temperature Coefficients

The shift due to the ^{87}Rb-buffer gas collisions is dependent on the temperature of operation of the clock [10]. A mixture of buffer gases can be used to reduce the temperature coefficient. We use a mixture of argon and nitrogen as buffer gases. Argon

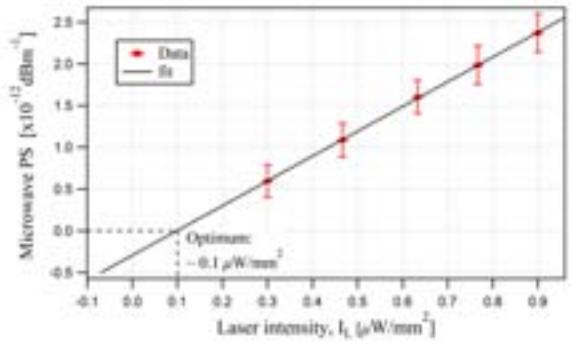

Fig. 2. Microwave power shift dependance on the input laser intensity.

has a negative linear temperature coefficient, whereas nitrogen has a positive linear temperature coefficient and due to their (much smaller) quadratic temperature coefficients, the mixture of these two at a certain temperature can give, in principle a "zero" (or inversion point) temperature coefficient [10], [18]. When the stem temperature was fixed (T_s = 321 K), a temperature coefficient value of TC_v = -1(1)$\times10^{-12}$/K has been achieved at the inversion temperature point (336 K) by a linear-fit , and the quadratic TC gives a value of -4.34$\times10^{-12}$/K^2.

The temperature coefficient was also measured as a function of the stem temperature changes, at a fixed T_v of 336 K, we get a slope of +1.22$\times10^{-11}$/K. The limits on the clock stability due to these temperature coefficients are evaluated and presented in Table II. The stem TC effect is a factor of ten higher than the cell volume TC effect. The use of BG mixtures help only to reduce the TC in the cell volume but not for the stem TC. Further studies were done to vindicate the effect due to stem TC (see Section IV-G).

E. Other perturbations

The clock frequency shift due to Rb-Rb spin-exchange collisions in the range of our operating temperatures (between 333 K to 343 K) is estimated to be ΔT_{SE} = 5$\times10^{-12}$/K. For this estimation we followed the method explained in [19].

The cavity pulling effect arises due to the feedback of the cavity on the atoms confined inside the vapor cell, because of the cavity detuning from the DR centre frequency [10]. For our magnetron-type cavity, with a measured Q-factor of ~80, the temperature dependent cavity pulling shift was estimated to be 2.9$\times10^{-14}$/K.

F. Medium- to long-term perturbations summary and contribution on clock instability

In Table II, all the above detailed perturbations are summarised along with their contributions on the clock's medium-to long-term instability at 10^4 s.

From Table II, it is clear that presently the limiting perturbations in reaching the level of 1$\times10^{-14}$ (equivalent to reach the time accuracy $<$ 1 ns/day) are the frequency LS effect $|\beta|$ and the stem TC $|TC_s|$. However, it is possible to reduce the effect of $|\beta|$ on clock frequency instability by operating our clock at lower input light intensities as explained in Section IV-B. But, we found that the stem TC arises due to our vapor cell geometric effect, as explained in the below section IV-G.

TABLE II. SUMMARY OF INSTABILITY CONTRIBUTIONS OF PHYSICAL PERTURBATIONS ON THE CLOCK TRANSITION IN MEDIUM TO LONG-TERM TIME SCALES. THE ESTIMATION IS DONE AT 10^4 S INTEGRATION TIME.

Physical effect	**Instability at 10^4 s**
Intensity LS effect, $\|\alpha\|$	9.9$\times10^{-15}$
Frequency LS effect, $\|\beta\|$	3.7$\times10^{-14}$
Microwave PS, $\|\mu_{PS}\|$	8.9$\times10^{-16}$
Cell volume TC $\|TC_v\|$ *(linear fit)*	3.5$\times10^{-15}$
Cell volume TC $\|TC_v\|$ *(quadratic fit)*	5.3$\times10^{-17}$
Stem TC $\|TC_s\|$	5.52$\times10^{-14}$
Spin ex. shift $\|\Delta T_{SE}\|$	$<$2.3$\times10^{-14}$
Cavity pulling $\|\Delta\nu_{CP}\|$	$<$ 1.5$\times10^{-16}$

G. Vapor cell geometric effect

As mentioned before, our Rb cell has two distinct parts; *cell volume*, where the ^{87}Rb vapor is interrogated with laser and microwave to get the DR signal, and *cell stem* that acts as reservoir for metallic Rb. The stem is also useful to better control the vapor pressure of the Rb inside the cell volume, and helps to increase the operation life-time of the clock.

As pointed out recently by Calosso et al., [20] a simple model of ideal gas law suggests that the temperature fluctuation in the stem results in redistribution of buffer gas particles in the entire cell; they call this effect Enhanced Temperature Sensitivity (ETS). This effect is not due to changes of interaction between Rb and buffer gas atoms, rather due to the buffer gas density variations between the cell body and the stem volumes, which is purely a geometrical effect (the stem part stays outside the microwave cavity and hence does not contribute in the microwave interrogation). In other words, one can say that the temperature gradient between the cell volume and the stem is responsible for this geometric effect. We calculated this geometric effect in our vapor cell and obtained the value 1$\times10^{-11}$/K. This calculated value matches well with the measured result of stem temperature coefficent (see Section IV-D).

V. MEASURED CLOCK STABILITY

Our clock was operated in typical ambient laboratory conditions, in air and not under vacuum. The clock's frequency stability was measured over a period of 9 days and its Allan deviation is shown in Fig. 3. The limit at 10^4 s of $\approx 6\times10^{-14}$ is in excellent agreement with the limit due to the stem temp. Coefficient, $|TC_s|$, which is attributed to the cell's geometric effect.

VI. CONCLUSIONS

DR Spectroscopic and metrological studies affecting the clock's medium- to long-term frequency stability were presented. The combined volume of our LH and PP is $<$ 1.7 dm^3, with a total mass of $<$ 2 kg. Our clock exhibits the S/N limited short-term stability of $<$ 1.4$\times10^{-13}$ $\tau^{-1/2}$. The short-term noise budget was presented showing the S/N limit. The

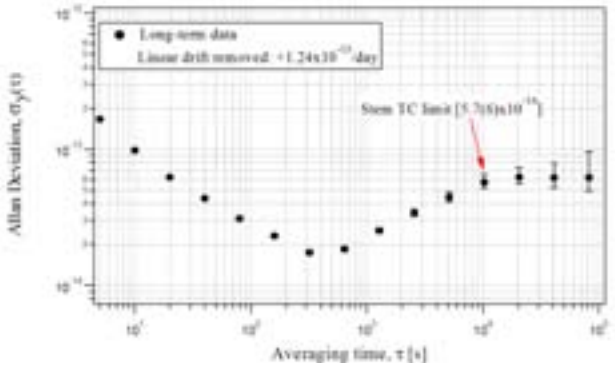

Fig. 3. Clock stability showing the limit due to stem TC at medium- to long-term time scales. This clock stability was not measured in the optimised conditions for the short-term.

Microwave power shift and its dependance on laser intensity, especially at reduced LS coefficient condition, was demonstrated. We have shown that the frequency LS coefficient (β) could be reduced by operating at lower laser input intensities. The clock's stability at 10^4 integration time is presently limited at $\sim 6\times10^{-14}$ due to the stem TC, that is characterized as the vapor cell geometric effect. By reducing the volume of the stem, we forsee to minimise the geometric effect and futhermore by operating our clock under vacuum we could reach stability levels below 1×10^{-14}.

The 2nd Harmonic Signal in Vapor-Cell Clocks & Error-Signal Quality: Does S_2 imply $dS_1/d\Delta$?

***Abstract*— How does one directly assess the quality of a Rb atomic clock signal remotely and in real time? Typically, one monitors the clock's 2nd harmonic signal, S_2, which in the quasi-static approximation is a measure of the correction signal's slope, $dS_1/d\Delta$. Unfortunately, in real vapor-cell clocks the quasi-static approximation is not valid, and the physics relating S_2 to $dS_1/d\Delta$ is complicated and not well understood. We have begun a series of studies aimed at elucidating the relationship between S_2 and $dS_1/d\Delta$, and here we present our preliminary results.**

Keywords—atomic clocks, Rabi resonance, frequency modulation, second harmonic, Rb atomic clock, vapor-cell clock

I. Introduction

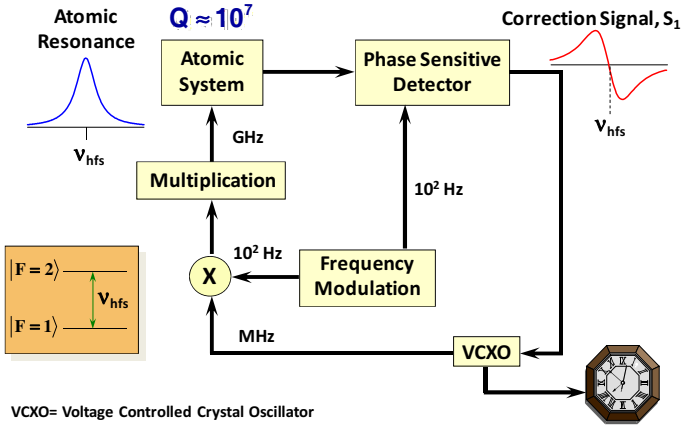

Fig. 1. The basic frequency feedback loop of a Rb atomic clock. The output frequency of a VCXO undergoes frequency modulation at some relatively low Fourier frequency (e.g., 10^2 Hz), and is then multiplied up to the microwave regime where it interacts with an ^{87}Rb vapor, causing the atomic system to undergo a state change, $|F=1\rangle \leftrightarrow |F=2\rangle$. The atoms' response to the microwave signal is monitored using phase sensitive detection (i.e., the atoms' response is demodulated at f_m), which produces a correction (or error) signal that keeps the VCXO locked to the atoms' state-transition frequency, ν_{hfs}.

In the Rb atomic clock, as illustrated in Fig. 1, the output frequency of a VCXO is multiplied up to the microwave regime, and this microwave field's frequency is modulated at f_m. Using phase sensitive detection, the atoms' response to the field is demodulated at f_m producing a 1st harmonic signal, S_1, which has a "derivative-type" shape as a function of microwave frequency. The 1st harmonic correction (or error) signal is then fed back to the VCXO, effectively locking its output frequency to the Rb atom's ground-state hyperfine transition frequency, ν_{hfs}. Specifically, defining M as the frequency multiplication factor and with $\Delta \equiv M\nu_{VCXO} - \nu_{hfs}$, the feedback loop continuously adjusts the VCXO's output frequency so that $\Delta = 0$. Clearly, the quality of the VCXO stabilization process depends on the correction signal's slope near $\Delta = 0$: $dS_1/d\Delta$, and any means of measuring $dS_1/d\Delta$ therefore provides an immediate status-of-health indicator for the clock's operation.

From an engineering perspective, the atomic dynamics that occur in an atomic clock are often conceptualized in terms of the quasi-static approximation, QSA [1]. Briefly, one assumes that the modulation period, $1/f_m$, is long compared to the time scale of atomic processes, so that the atoms effectively reach a steady state at each instantaneous frequency of the modulated microwave field. Consequently, writing $\Delta(t)$ as $\Delta_o + \delta_m g(t)$, where δ_m is the frequency modulation amplitude, Δ_o is the average microwave detuning, and g(t) is some modulation waveform (e.g., $g(t) = \sin(2\pi f_m t)$); the atoms' response to the modulated field, s(t), can be expanded in a Taylor series about Δ_o [2], yielding

$$s(t) = s(\Delta_o) + \delta_m g(t)\left.\frac{ds}{d\Delta}\right|_{\Delta_o} + \tfrac{1}{2}(\delta_m g(t))^2 \left.\frac{d^2 s}{d\Delta^2}\right|_{\Delta_o} + \ldots \quad (1)$$

For sine wave modulation, it is straightforward to show that

$$s(t) = S_o + S_1 \sin(2\pi f_m t) + S_2 \cos(4\pi f_m t) + \ldots \quad (2)$$

where

$$S_o \cong s(\Delta_o) + \left.\frac{\delta_m^2}{4}\frac{d^2 s}{d\Delta^2}\right|_{\Delta_o} \quad (3a)$$

$$S_1 \cong \delta_m \left.\frac{ds}{d\Delta}\right|_{\Delta_o} \quad (3b)$$

$$S_2 \cong -\left.\frac{\delta_m^2}{4}\frac{d^2 s}{d\Delta^2}\right|_{\Delta_o} \cong -\left.\frac{\delta_m}{4}\frac{dS_1}{d\Delta}\right|_{\Delta_o}. \quad (3c)$$

Thus, in the QSA we interpret the amplitude of the 2nd harmonic signal as a measure of the clock's correction signal slope, and therefore a measure of clock-signal quality.

However, in order to obtain large signal-to-noise ratios and narrow atomic linewidths, it is typical to operate atomic clocks under conditions such that $f_m \sim \Omega \sim \gamma$, where Ω and γ are the

This work was funded by the U.S. Air Force Space and Missile Systems Center under Contract No. FA8802-09-C-0001.

Rabi frequency and dephasing rate, respectively. Unfortunately, this regime of operation is neither quasi-static (large γ), adiabatic (large Ω), nor sudden (large f_m). Consequently, none of the standard approximations of atomic dynamics legitimately apply, notably the QSA. Therefore, while Eq. (3c) certainly provides qualitative engineering guidance, we must question its *quantitative* utility. For example, how should we interpret a sudden 10% change of S_2 in terms of $dS_1/d\Delta$? Does it imply a 10% change in $dS_1/d\Delta$, something significantly larger, something significantly smaller? In what follows, we describe our first experimental results exploring the relationship between S_2 and $dS_1/d\Delta$.

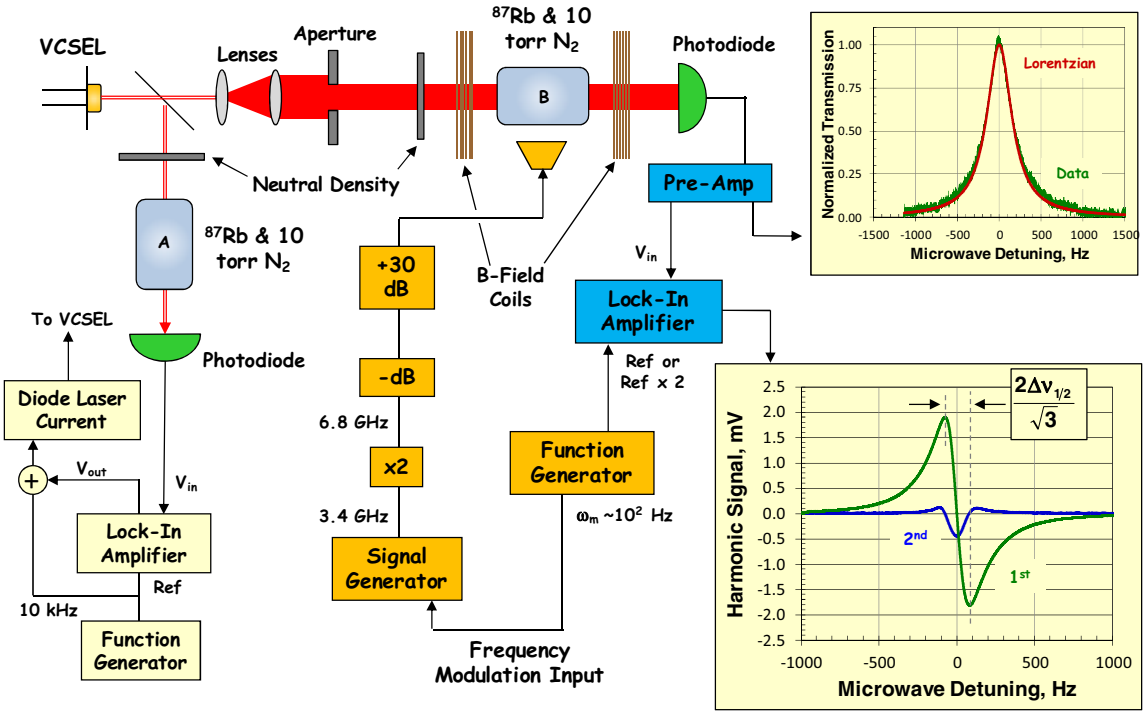

Fig. 2. Block diagram of the experimental arrangment. The block labeled "–dB" is an attenuator, and the box labeled "+30 dB" is a fixed gain amplifier. The microwaves are emitted by a 15 dB microwave horn located about 15 cm above cell B.

II. The Experiment

Figure 2 shows a block diagram of our experimental arrangement. We stabilize our VCSEL diode laser wavelength using the ^{87}Rb resonance cell on the left of the figure (cell A); this cell contains 10 torr of N_2 as a buffer gas, and is maintained at a temperature of ~37 ^{o}C. Though the Rb atomic clocks employed in GNSS and satellite communication systems use an rf-discharge lamp rather than a diode laser as their light source, we use a laser to give us better control of the light field. With the laser, we not only have the ability to vary the intensity of the light and see its effect on the 2nd harmonic signal, we can also easily vary the laser frequency. Varying the laser center frequency gives us an opportunity to mimic spectral shifts in an rf-discharge lamp's output [3], and to study the effect of such variations on the 2nd harmonic signal, which might arise as a consequence of the light shift [4].

The light intensity passing through cell A is kept very low, so that optical pumping does not occur. The laser light also passes through a second ^{87}Rb resonance cell (cell B), which again contains 10 torr of N_2 as a buffer gas. The laser light optically pumps the rubidium atoms in cell B, which is our atomic-clock signal cell, and creates a population imbalance between the atom's ground state hyperfine levels. Since the optical pumping process essentially removes atoms from the optically-absorbing hyperfine level, the laser light passing through this second cell is relatively high when the optical pumping process completes. (The optical pumping process is relatively fast, taking roughly a millisecond to complete.) If microwaves of the appropriate frequency impinge on the vapor, however, atoms are forced to return to the optically absorbing hyperfine level with a concomitant decrease in the transmitted light intensity. Consequently, as illustrated in the top graph on the right, plotting the vapor's absorption as a function of microwave frequency yields a Lorentzian absorption profile. In addition, we modulate the frequency of the microwaves in our experiment at f_m = 47.3 Hz. We can then monitor the atoms' first harmonic response to the microwaves or the atoms' second harmonic response to the microwaves using a lock-in amplifier and the appropriate reference frequency. Examples of our S_1 and S_2 data are shown in the lower graph on the right in Fig. 2. In this work, we are primarily concerned with the amplitude of the 2nd harmonic signal when the microwaves are on resonance, corresponding to locked vapor-cell clock conditions. Table I provides our experimental parameters.

For our measurement procedure, we record the in-phase and quadrature voltage components (V_I and V_Q, respectively)

of the 1st and 2nd harmonic signals, and we use these to define the harmonic signal's amplitude, A_n, and phase, θ_n (n = 1 or 2):

$$A_n = \sqrt{V_I^2 + V_Q^2} \tag{4a}$$

$$\theta_n = \tan^{-1}\left[\frac{V_Q}{V_I}\right]. \tag{4b}$$

From these data, we compute S_1 and S_2 as

$$S_1 = A_1 \cos(\theta_1 - \psi_1) \quad \text{and} \quad S_2 = A_2 \cos(\theta_2 - \psi_2), \tag{5}$$

where ψ_1 is chosen to maximize $|dS_1/d\Delta|$ on resonance and ψ_2 is chosen to maximize $|S_2|$ on resonance. The reason for including ψ_1 and ψ_2 in the computations of S_1 and S_2 is that with phase sensitive detection one routinely adjusts the reference signal's phase to maximize the in-phase component of the detector's output. Finally, we calibrate the attenuator setting to Rabi frequency using $\Delta\nu_{1/2}$ as indicated in the lower right inset of Fig. 2. Figure 3 shows $\Delta\nu_{1/2}$ plotted as a function of the relative microwave field strength, though we actually calibrate $\Delta\nu_{1/2}$ to Rabi frequency assuming linearity between the linewidth *squared* and the microwave *power* [5].

TABLE I. EXPERIMENTAL PARAMETERS

Parameter	Value
Optical Depth, NσL	1
Photon Absorption Rate, R_{ph}	25 Hz
Residual Dephasing Rate,[a] γ	46 Hz
Resonance Cell Temperature	34 °C
Laser Beam Diameter at Cell Entrance	0.4 cm
Modulation Frequency, f_m	47.3 Hz
Modulation Amplitude, δ_m	30 Hz
Axial Magnetic Field, B_z	260 mG

[a] The total dephasing rate is given by $R_{ph}/2 + \gamma$

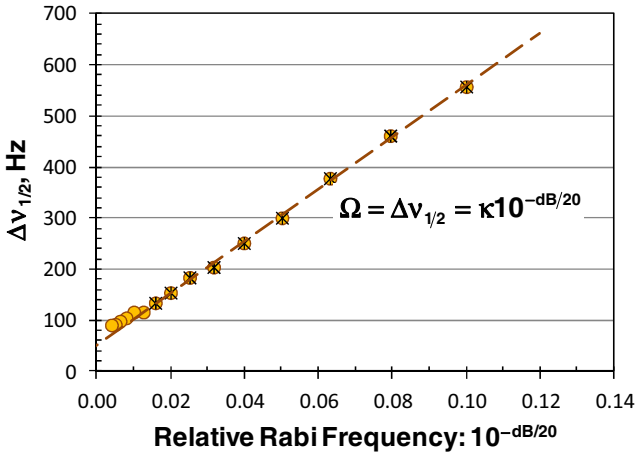

Fig. 3. This figure shows the linewidth, $\Delta\nu_{1/2}$, determined from S_1 (as illustrated in Fig. 2) plotted as a function of the relative Rabi frequency, which is determined by our attenuator setting. Since the linewidth *squared* scales with the microwave *power*, and is directly related to the Rabi frequency, we use this data to determine κ.

III. RESULTS

Our principal results are collected in Figs. 4. In Fig. 4a, we show $dS_1/d\Delta$ and $4S_2/\delta_m$ plotted as functions of the Rabi frequency; the solid lines are Gaussian fits to the data. Figure 4b shows our experimental values of $4S_2/\delta_m$ along with a full density matrix calculation of $dS_1/d\Delta$ and $4S_2/\delta_m$ [5]; there are no free parameters in the density matrix computations.

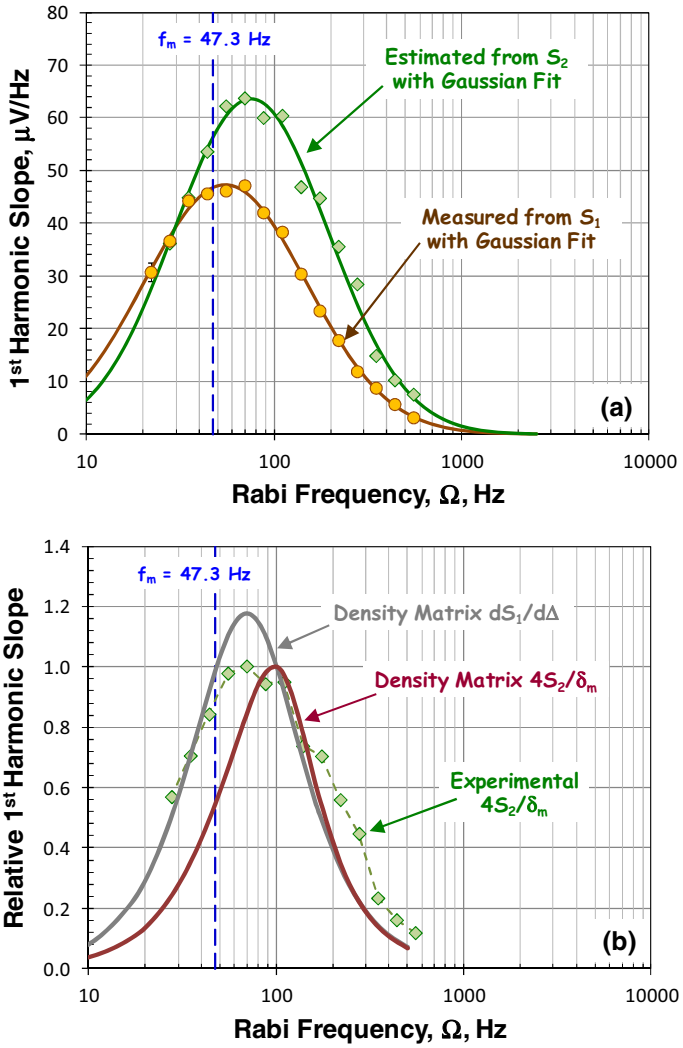

Fig. 4. (a) Experimental results of $dS_1/d\Delta$ and $4S_2/\delta_m$ as a function of Rabi frequency. The solid lines are Gaussian fits to the data. (b) A comparison of full density matrix theory with experiment. Note that the full density matrix theory is based on the Generalized Vanier Theory of the 0-0 transition lineshape as discussed in Ref. 5; there are no free parameters in the density matrix computations.

There are two things worth noting regarding the results displayed in Figs. 4a and 4b:

1. Relative to the experimental values, the theoretical values of $dS_1/d\Delta$ are too large. Additionally, relative to the experimental values, the theoretical values of $4S_2/\delta_m$ have too narrow a distribution. These observations cannot be explained by inhomogeneous broadening of the hyperfine transition. As a test, we included ~ 40 Hz of inhomogeneous broadening in the

density matrix computations with little effect on the results. At the present time, we believe the discrepancy between theory and experiment is due to spatial inhomogeneity of the Rabi frequency. Spatial variation of the Rabi frequency could arise, since the Rabi frequency is defined by a scalar product between the microwave magnetic-field vector and the static axial magnetic field, B_z. Depending on the coil geometry and the Earth's magnetic field, B_z could vary spatially.

2. Given that the peaks of $dS_1/d\Delta$ and S_2 are displaced from one another experimentally and theoretically, the $dS_1/d\Delta$ vs. S_2 relationship will only be "quasi-linear." This is illustrated more clearly in Fig. 5. Though the theoretical and experimental curves are on opposite sides of the QSA ideal result (i.e., $dS_1/d\Delta = 4S_2/\delta_m$ shown as the dashed line), they both nonetheless show that $dS_1/d\Delta$ is non-monotonic in S_2.

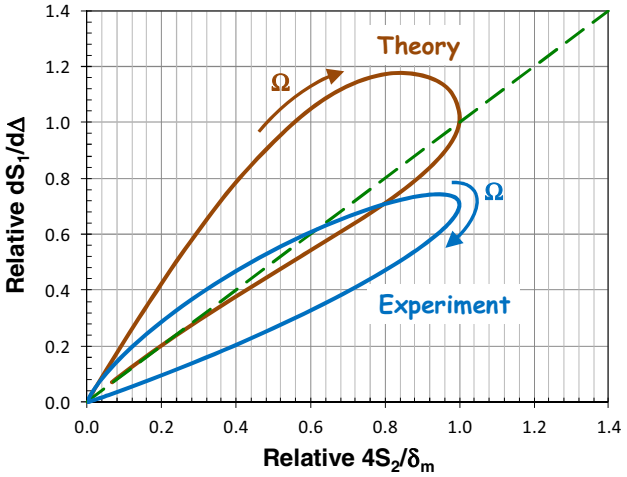

Fig. 5. The $dS_1/d\Delta$ vs $4S_2/\delta_m$ relationship. The experimental curve comes from the Gaussian fits to the data. The dashed line represents the QSA ideal: $dS_1/d\Delta = 4S_2/\delta_m$.

IV. Summary

In this paper, we have outlined our progress studying the relationship between the slope of a Rb clock's correction-signal, $dS_1/d\Delta$, and the clock's 2nd harmonic signal, S_2. Though S_2 has a "quasi-linear" relationship with $dS_1/d\Delta$, it is unfortunately non-monotonic. Moreover, the *quantitative* relationship between S_2 and $dS_1/d\Delta$ likely depends on spatial variations in the dynamics over the clock-signal's volume, arising from spatial variations in the Rabi frequency. Thus, while S_2 is certainly a *qualitative* indicator of a Rb clock's status-of-health, much more study will be required in order to develop a *quantitative* understanding of S_2's relationship with $dS_1/d\Delta$ at the basic atomic physics level. In the near term, the quantitative relationship between S_2 and $dS_1/d\Delta$ can only be defined empirically, and therefore determined on a case-by-case basis. Thus, in answer to the question posed in the title of this paper (i.e., Does S_2 imply $dS_1/d\Delta$?) at present we can only reply… Maybe.

Higher-order Sideband Excitation Method for Pulsed CPT Atomic Clock

Shigeyoshi Goka, Yuichiro Yano

Tokyo Metropolitan University,
Hachioji, Tokyo 1920397, Japan
goka@tmu.ac.jp

Abstract— **We propose a higher-order sideband excitation method combined with pulse excitation to reduce power consumption of coherent population trapping (CPT) atomic clocks. Since higher-order sideband excitation enables reduction of radio frequency (RF), our method can significantly reduce switching power loss of an RF generator and its peripheral circuits. Experimental results show that 3rd-order sideband excitation can lead to narrow fringe width and high contrast. In addition, the relative light shift was less than one-third that with conventional excitation method.**

I. INTRODUCTION

Coherent-population-trapping (CPT)-based atomic clocks with vertical-cavity surface-emitting lasers (VCSELs) have been widely investigated to develop very small atomic references called chip-scale atomic clocks (CSACs). The power consumption of recent CSACs is nearly 100 mW, which is lower than conventional Rb atomic clocks but not low enough for portable applications. One of the main reasons of this power consumption is the switching power loss caused by parasitic capacitance in radio frequency (RF) circuits. The switching power loss accounts for the almost entire power dissipation of an RF circuit, especially in the microwave frequency range. For example, a miniaturized CPT atomic clock [1] has an RF oscillator and a related phase-locked loop (PLL) circuit power consumption of 43 mW, which is nearly half the total power (98 mW) in spite of the required RF output power being ~0 dBm (1 mW). Therefore, it is necessary to reduce the RF-related power consumption to develop lower-power CSACs. The switching power loss P_{sw} is estimated as

$$P_{sw} = f C V^2, \tag{1}$$

where, f is the frequency of the RF signal, C is the parasitic capacitance of the RF circuits, and V is the amplitude of the RF signal [2]. From Eq. (1), one or more parameters must be decreased to reduce P_{sw}. However, C and V values are determined using device parameters and required RF power, respectively. We propose a higher-order sideband excitation method to decrease the required frequency of the RF signal with pulsed CPT excitation. In our previous work [3], we reported on CPT-Ramsey resonances using a liquid crystal modulator for low power operation; therefore, our method can be applied to CSACs.

Experimental results show that 3rd-order sideband excitation can lead to narrow fringe width and high contrast. In addition, the relative light shift is less than one-third that with conventional excitation.

II. HIGHER-ORDER SIDEBAND EXCITATION

To excite the CPT resonance, two laser light fields whose wavelength is equal to the energy differences between two ground states and a common excite state are used. In conventional CPT-based atomic clocks, two lasers are generated as two first-order sidebands around the laser carrier by using the direct RF modulation of the VCSEL injection current [4]. The direct RF modulation consists of amplitude modulation (AM) and frequency modulation (FM). Although AM generates only first-order sidebands, FM generates higher-order sidebands including first-order depending on the modulation index [5]. Therefore, we can use the higher-order sidebands to excite CPT resonances at a relatively high modulation index and reduce the required RF frequency. The required RF frequency f_{RF} is expressed as

$$f_{RF} = \frac{f_{hfs}}{2n}, \tag{2}$$

where f_{hfs} is the hyper-fine splitting frequency of alkali atoms, and n is the sideband order number, which is an integer larger than 1. Table I lists the f_{RF} in higher-order sideband excitation using ^{133}Cs atoms. When n = 3, the required f_{RF} is only 1.53 GHz, which is one-third that of n = 1, and third-order sidebands can excite CPT resonance, as shown in Fig. 1.

TABLE I. REQUIRED RF FREQUENCY FOR HIGHER ORDER SIDEBANDE EXCITATION IN Cs^{133} ATOMS

Side-band order	***Required RF Frequency***	
n	***f_{RF}* [GHz]**	***Frequency Division***
1	4.60	f_{hfs} / 2
2	2.30	f_{hfs} / 4
3	1.53	f_{hfs} / 6

III. Experimental Results

A. Experimental Configureration

The measurement system for higher-order sideband excitation is shown in Fig. 2. A 895-nm VCSEL was used to excite Cs at the D_1 line. The Cs gas cell had an optical length of 20 mm and contained ^{133}Cs atoms and 1.3 kPa of N_2 buffer gas at a controlled temperature of 42.0ºC. The linearly polarized (lin||lin) laser beam of 6 mm in diameter was intensity-modulated using an acousto-optical modulator (AOM) to excite a CPT-Ramsey resonance. By using the linearly polarized laser, two Λ schemes can be formed with two pairs of ground-state hyperfine sublevels simultaneously: $|F=3, m=-1\rangle$, $|F=4, m=1\rangle$ and $|F=3, m=1\rangle$, $|F=4, m=-1\rangle$ coupled with the common excited state $|F'=3, m=0\rangle$ or $|F'=4, m=0\rangle$ [6]. The pulsed laser light field with a 1-kHz switching frequency was generated using the AOM. By adding the S/H circuit, it is possible to use the same lock-in detection system without changing the conventional measurement setup [3]. The sampling delay time T_m of the S/H circuit was set to 10 μs. The Cs standard (Symmetricom 5071A High performance tube) was used as a reference frequency source. In the experiment, the CPT characteristics with the sideband order n = 1~3 were measured because the CPT contrast of the $n > 3$ was small.

B. CPT resonances Excited by Higher Order Sidebands

Figure 3 shows the CPT resonance excited by the conventional continuous and pulsed laser light fields of the higher-order sidebands. The vertical axis is transmitted laser power normalized by the maximum value, and the horizontal axis is the detuning from the f_{RF}. Table II lists the contrast and the resonant full-width at half-maximum (FWHM) with the optimized RF power as the resonant contrast was maximized. With continuous excitation, the CPT contrast decreased and the Q values slightly decreased when n increased. This is because the higher-order wavelength components were generated by the larger frequency modulation index, which also causes the other unwanted wavelength components to decrease the CPT contrast. On the other hand, in pulsed excitation, Q values drastically increased and were not affected by n because the resonant FWHM was determined by CPT Ramsey free

evolution time (500 μs) [7]. The Allan standard deviation $\sigma_y(\tau)$ is expressed as

$$\sigma_y(\tau) \propto \frac{1}{Q \cdot (S/N)} \tau^{-\frac{1}{2}}, \quad (3)$$

where τ is the averaging time, and the signal-to-noise ratio (S/N) is equivalent to the contrast. Since short-term stability is determined from the contrast and Q value, the figure of merit is defined as the product of the Q value and contrast. From Table II, the figure of merit of pulsed excitation (n = 3) was 2.3 times better than that of conventional continuous excitation (n = 1).

C. RF Power

The RF power dependence of contrast characteristics are shown in Fig. 4. In both excitations, there were maximal contrast values in the RF Power range of 0.3 ~ 0.5 mW. Since this RF power range was much less than the power consumption of the RF related circuit of 43 mW [1], almost all the RF electrical power was dissipated by the switching power loss. Therefore, it is possible to reduce the RF related power to 1/n.

D. Light Shift

It is well known that the light shift effect is a major limitation to the long-term stability of vapor cell-based atomic clocks [8]. Since the RF sources for each n differ, we measured the relative frequency shifts of CPT resonances, as shown in Fig. 5. The frequency shifts were observed to have a reasonably linear relationship with laser intensity; therefore, we estimated the slope of the fitted linear lines, as shown in Table III. All relative light shifts of pulsed excitation were one-third less than that of continuous excitation of n = 1. These results indicate that the higher-order excitation of n = 3 can reduce the RF frequency and relative light shift.

IV. Conclusion

We proposed a higher-order sideband excitation method combined with pulse excitation to reduce power consumption of CPT atomic clocks. Since switching power loss of RF is proportional to its frequency, lower RF frequency can reduce the power loss of an RF generator and its peripheral circuits.

Experimental results show that 3rd-order sideband excitation can lead to narrow fringe width and high contrast. In addition, the relative light shift was less than one-third that with conventional excitation. These results indicate that the proposed excitation method can improve low-power operation and frequency stabilities in CSACs.

***Abstract*—We are developing a new Cs fountain frequency standard in NIM, and shooting for the frequency uncertainty of a few parts in 10^{16}. The new fountain will run in a lab with the temperature fluctuation of 0.3K, and no active temperature control system will be added outside the flight tube. Instead, an isothermal liner will be surrounded the flight tube. It is a special type of heat pipe, made of a thin layer of vacuum tube filled with pure water. The thermal conductivity of a glass isothermal liner is about 10 times higher than that of coppers. It also works like a low pass filter reducing the temperature fluctuations of the system. The advantage of using an isothermal liner is to make the temperature of the whole interrogation region more uniform and stable. With precision standard Pt thermometers measuring the temperatures of a few locations of the flight tube, the average temperature uncertainty is less than 50 mK. The frequency shift due to the blackbody radiation can be calculated, and the relative frequency shift due to black body radiation can reach down to 7.2E-17 of this new fountain clock.**

Key words: Fountain clock, blackbody radiation, heat pipe

I. INTRODUCTION

Atomic clocks provide the most accurate measurements of the physical observables, time and frequency. Up to date, several groups' Cs fountain clocks have achieved frequency uncertainties in the low E-16 [1-5]. These capabilities offer great opportunities in a variety of precision measurements, such as realization of the second, frequency metrology, high accuracy spectroscopy, and tests of fundamental physics [6-9]. There are four main effects which will shift the energy levels of the clock transition and consequently give frequency shifts, including the cold-atomic-collision-induced density shift [10, 11], the magnetic-field-induced quadratic Zeeman shift, the Earth-gravitational-potential-induced red shift and the black-body-radiation-induced AC Stark shift [12, 13]. Theories and several new techniques have been brought to bear on the problem of estimating the spin exchange shift and microwave-power-related frequency shifts in fountain frequency standards [11, 14]. The black-body-radiation-induced frequency shift will presumably limit the accuracy that fountain clocks can achieve. NIST built a new fountain F2, which will run in a cryogenic region at a temperature of about 80 K, with an expected uncertainty far below 10^{-16}. Another way to reduce the blackbody-radiation-induced frequency shift is to improve the temperature uniformity of the flight tube and measure the temperature more accurate to reduce the temperature uncertainty.

In this Letter, we introduce the design of our new fountain NIM6. We are planning to use an isothermal liner heat pipe outside the interrogation region to improve the temperature uniformity. Heat pipes are effective thermal control devices, have been widely applied in broad areas [15]. The performance of a mock up isothermal liner is tested, and the results show reduced temperature fluctuations and better temperature uniformity with this heat pipe.

II. DESIGN OF NIM6

Atoms exposed to electromagnetic radiation during their ballistic flight will be subject to an AC Stark shift. If the thermal radiation of the vacuum enclosure gives rise to a spectral power density distribution which is equivalent to that of a black body, according to [16], the clock transition frequency is shifted by

$$\Delta\nu_{BR} = \beta\left(\frac{T}{300\,K}\right)^4\left[1+\varepsilon\left(\frac{T}{300\,K}\right)^2\right] \quad (1)$$

Here, where T is the radiation temperature of the environment expressed in kelvin. The coefficients β and ε depends on atoms and on the considered transition; up to now the theoretical accepted value of β and ε for ^{133}Cs are β=(-1.572±0.006)×10^{-14} and ε=1.4×10^{-2}. The uncertainty of this frequency shift is:

$$\delta\nu_{BR} = \Delta\nu_{BR}\cdot\frac{\delta\beta}{\beta} + 4\Delta\nu_{BR}\cdot\frac{\delta T}{T} + (2\beta\varepsilon\frac{\delta T}{T} + \delta\varepsilon\beta)\left(\frac{T}{300}\right)^6 \quad (2)$$

In equation 2, the third term is negligible at room temperatures. Reducing the temperature can reduce both first two terms, thus reducing the frequency uncertainty due to blackbody radiation. Another way to reduce the uncertainty is to reduce δT, especially when we have better knowledge of β. In the design of new fountain NIM6, we are planning to use a heat pipe and precision Pt thermometers to reduce the temperature uncertainty down to 50 mK.

The NIM6 system design is shown in figure 1. The flight tube is surrounded by 3 layers of μ-metal magnetic shield with

This work is supported by the Chinese NSF(11174260) and 973 project (2010CB922902) (sponsors)

a measured shielding factor of more than 10^4. The shields are vertical concentric cylinders with end-caps on top and bottom, each having holes for the vacuum structure, and are thermally and electrically isolated from each other and from the vacuum system. An isothermal liner will be added outside the flight tube. It is a thin layer of vacuum tube made of the fused silica, 700 mm high, filled with pure water. Three precision standard Pt100 thermometers will be added inside the isothermal liner to monitor the temperature of the flight tube.

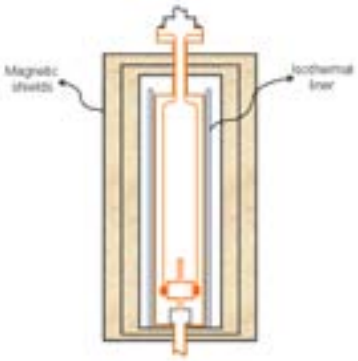

Fig.1 Schematic of the new fountain clock design. The flight tube is surrounded by 3 layers of μ-metal magnetic shield which are thermally and electrically isolated from each other and from the vacuum system. An isothermal liner will be added outside the flight tube.

The Ramsey cavity is rested on a ceramic ring. Four semi-rigid coaxial cables (one for each waveguide) connect the waveguides with vacuum feedthroughs at the top of the fountain. The Ramsey pulse power applied on the cavity is about 1 nW at the π/2 pulse. The increased temperature on the cavity due to the applied microwave was measured less than 50 mK at 100 nW input power. Thus, the temperature variations due to the Ramsey pulse are negligible at the normal running condition.

III. TEMPERATURE UNIFORMITY IMPROVEMENTS WITH ISOTHERMAL LINER

The picture of a mock up isothermal liner is shown in figure 2.

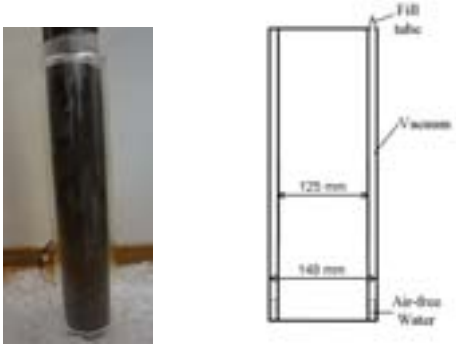

Fig.2 Picture of a mock up isothermal liner made of glass.

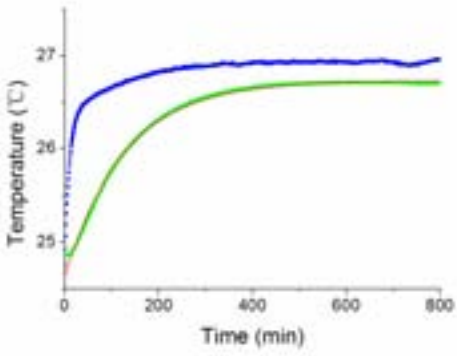
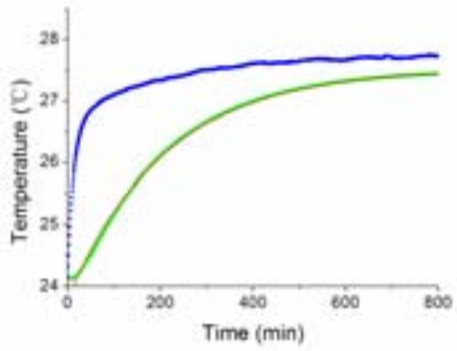
This mock up isothermal liner heat pipe is made of glass, has the same size as the one designed for NIM6. High purity air-free water is filled in glass vacuum tube. When there is a temperature gradient, liquid water around the hot part absorbs heat, transforms into vapor and flows toward the condensate section (cold part). This phase transitions inside the heat pipe redistribute the heat, block corresponding changes in the inner chamber temperature, regulate thermal transport and dampen temperature oscillations.

The performance of this mock-up isothermal liner is tested with a copper tube as shown in figure 2. A thin aluminum tube is placed outside the isothermal liner, and a heat tape is wrapped around it to generate temperature variations. The temperatures inside the aluminum tube and the copper tube are measured with precision standard Pt thermometers. The results are compared with the situations when the isothermal liner was taken out, and shown in figure 3.



(a)



(b)

Fig.3 Comparisons of the temperature fluctuations inside the copper tube with and without the isothermal liner surrounded it. (a) shows results without the isothermal liner; (b) shows results with the isothermal liner. The blue rectangular is the temperature increasing inside the Aluminum tube (environment), the green solid circle is the temperature increasing inside the copper tube, the red solid line is the theoretical fit by an exponential curve.

From the figure, we can see that when the environment temperature increased, the temperature of the copper tube which is surrounded by the isothermal liner is increased with a slower time constant. Fitted by an exponential curve $A_1+A_2(1-$

exp(-t/τ)), the time constant τ is about 127 minutes without the isothermal liner, and about 210 minutes with the isothermal liner. This suggests that this isothermal liner works like a low pass filter, reduces the temperature fluctuations inside it.

Isothermal liners also improve the temperature gradients. This is the key benefit for NIM6 fountain clock. With improved temperature gradients and precision Pt standard thermometers, the average temperature of the flight tube can be obtained with much less uncertainty. This isothermal liner is a gravity type heat pipe. The working conditions are different for the positive and negative temperature gradient along the vertical direction. The improvements of temperature gradients with the isothermal liner are tested by wrapping the heat tape on one side to generate the temperature gradient. The results are shown in Table 1.

TABLE I. RESULTS OF THE REDUCED TEMPERATURE GRADIENT INSIDE THE COPPER TUBE WITH THE ISOTHERMAL LINER.

Temperature gradient of the environment (K/cm)	*Temperature gradient inside the copper tube (with heat pipe)*	*Temperature gradient of the environment (K/cm)*	*Temperature gradient inside the copper tube (without heat pipe)*	*Improved factor with heat pipe*
0.122	***0.011***	***0.303***	***0.011***	***2.6***
-0.0487	***-0.000432***	***-0.0645***	***-0.0051***	***6.3***

From the table, we can see that with the isothermal liner, the temperature gradient of the copper tube is improved by a factor of 6.3 when the bottom part is hot, and improved by a factor of 2.6 when the top part is hot.

IV. CONCLUSIONS

To conclude, here we have reported a new method to get a more uniform and stable temperature environment around the flight tube. At normal lab conditions, the maximum temperature fluctuation is 0.3 K, and the temperature gradient in the vertical direction is about 0.3 K/m around the fountain. With 3-layers magnetic shield and thermal isolations between them, the temperature fluctuations are reduced to be less than 0.1 K. The temperature difference between top and bottom parts of the flight tube is less than 0.1 K. With an isothermal liner, the temperature gradient can be reduced by more than a factor of 2. With precision standard Pt thermometers, which have a temperature uncertainty of less than 10 mK, and will be calibrated twice a year. For NIM6, we will use MOT to collect cold atoms. The MOT coils could heat up the MOT chamber and introduce a temperature gradient on the vacuum system. How much the isothermal liner can improve this will be tested in the future. Presumably, the total temperature uncertainty will be less than 50 mK. From equation 2, the uncertainty of blackbody-radiation-induced frequency shift is 7.2×10^{-17} with 50 mK temperature uncertainty, and keeping the total uncertainty in a few parts in 10^{16}.

Abstract— **Recently, microwave phase gradients were identified as the main source of uncertainty in the continuous fountain clock. Indeed, because of its particular geometry with two interaction zones, a dedicated research effort was necessary to reduce this effect. With the help of 3D finite element simulations and ultra-precise machining, we report here on the design and realization of a new kind of low phase gradient microwave cavity. The proposed geometry based on a ring waveguide of rectangular cross-section has a theoretical spatial phase variation of 30 µrad over the interaction zones, which corresponds to a predicted relative frequency shift below 10^{-15}.**

Keywords—Atomic clock, Microwave Cavity, FE simulations, Phase Gradient, Distributed Cavity Phase Shift

I. INTRODUCTION

Fountain clocks base their measurement on time separated Ramsey RF spectroscopy [1]. A disturbance of the microwave field between the first and second interaction zones will perturb the measured frequency. Such a frequency offset $\Delta\omega$ can be expressed as $\Delta\omega = \Delta\phi/T$ with T being the free evolution time and $\Delta\phi$ a phase change in the field between the two interaction zones. Studies of this cavity-induced frequency shift started many years ago with molecular beams [2] and continued with thermal atomic beam clocks [3] and more recently with atomic fountains [4]-[10].

In pulsed atomic clocks the atomic cloud passes twice through the same micro-wave cavity [11], but nevertheless spatial phase variations in the microwave cavity result in a net phase difference and thus in a frequency shift known as distributed cavity phase shift (DCP). Recent theoretical work has shown how to model cavity phase shift in cylindrical cavities typically used in pulsed fountain clocks and how to minimize DCP [7], [12]. This work has been put to practice on a number of pulsed atomic fountains, where the DCP now has been decreased to negligible levels on the uncertainty budgets [13]-[15].

The atomic clock, which is the topic of this article, is the FOCS-2 continuous Cs fountain clock (see for example [16], [17]). In a continuous fountain clock the probed atoms follow a parabolic trajectory, passing through two spatially separated interaction zones in a microwave cavity. A first realization of such a cavity was based on the TE_{021} mode in a single coaxial cavity with the two interaction zones being in the azimuthal angles $\varphi = \pm\pi/2$ with respect to a pair of independent feeds at $\varphi = 0$ and $\varphi = \pi$. An average phase shift may exist between the two interaction zones, which produces a frequency shift known as end-to-end phase shift. It has been demonstrated that this shift can be evaluated using a reversal mechanism that exchanges the two interaction zones [17]. It was discovered though, that the DCP was too large due to the larger cavity and thus closer neighboring modes. It was estimated that the DCP had a value of about 350 µrad.

In the last year work has been done to design and build a microwave cavity better suited for use in a continuous fountain clock with a significantly smaller DCP [18]. Simulations show that with this design, phase variations across each interaction zone should be less than 30 µrad.

II. DESIGN OF THE CAVITY

The main design principle of this cavity was to reduce the mode density and the time-averaged power flow over the interaction zones. A ring waveguide cavity (L_x: 56.2 mm, L_y: 61.77 mm) has been designed with a rectangular cross-section (a: 24.9 mm, b: 14.0 mm) in which both interaction zones Z_1 and Z_2 are equidistant from the feeding ports P_1 and P_2 (see Fig.1). Its dimensions and resonance frequency $\nu_0 = 9192631770$ Hz are fixed by the atomic trajectory and the cesium clock transition. To avoid any microwave leakage out of the cavity, four cutoff waveguides parallel to the atomic beam of (9.5 mm × 58.4 mm) with more than 200 dB attenuation have been designed. Microwave power is injected through two irises (8 mm diameter) situated on the top wall of the cavity. Each feeding port, composed of waveguide sections, is excited by a coaxial line whose inner conductor acts as a coupling antenna.

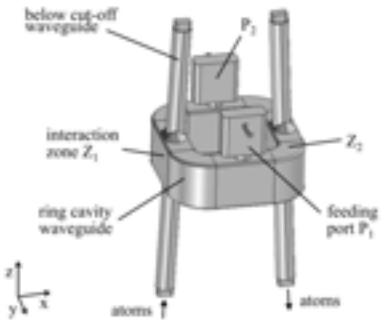

Figure 1. Scheme of the inner volume of the microwave cavity design. The ring waveguide is excited through two irises on its top wall. Two independant feeding ports P_1 and P_2 are used to balance the power flow through the interaction zones Z_1 and Z_2 (see section II and III for details).

III. Electromagnetic properties

We excite the electromagnetic mode TE_{105}, which is resonant at 9.193 GHz. Using both numerical simulations and analytical modeling (see below) we found the main characteristics of the field inside the ring waveguide. In particular, the loaded quality factor $Q_L = 6900$ was measured on the resonance curve shown in Fig.4 (-3 dB linewidth of 1.33 MHz) and the unloaded cavity factor $Q_0 = 13900$ was computed with the global coupling factor $\beta_1 + \beta_2 = 1$, which comes from the analysis of the feeding ports.

A. Finite Elements Analysis

To predict spatial phase variations of this cavity, the 3D geometry has been entirely modeled by a Finite Element Method (FEM) software. Maxwell's equations were solved numerically, assuming vacuum inside the inner volume and the boundary conditions imposed by the copper walls. The microwave field was injected through the feeding ports with a π-phase difference in between the two.

The model shows that the magnetic fields in the two interaction zones are anti-parallel. This results in an inverted Ramsey pattern with a dark central fringe [19]. The model also shows that microwave energy flows from the feeding ports to the walls along the waveguide and since the interaction regions (Z_1 and Z_2 in Fig.1) are equidistant from the ports, minimal energy will flow in these regions. Most importantly the model indicates that the phase variations across an interaction region present a saddle structure (Fig.2) with a maximum peak-to-peak phase variation of 30 µrad.

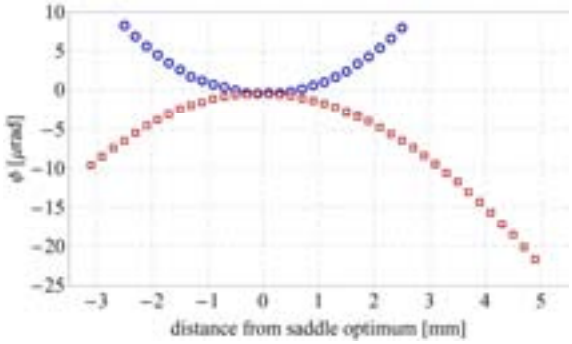

Figure 2. Modeled phase variations along the two transversal axes of the interaction zone. The circles (squares) show variations along *Oy* (*Ox*).

B. Analytical Modeling

Besides FE analysis, we developed a simple analytical model of the electromagnetic mode in the ring waveguide. We showed that the peak-to-peak phase variation over the interaction zone Δx×Δy can be computed with the following expression [19]:

$$\Delta\phi_{pp} = \sqrt{\frac{\epsilon_0}{2\sigma}}\frac{\omega^{3/2}}{4b\,c}\left(1+\frac{2\,b\,c^2\,\pi^2}{a^3\,\omega^2}\right)\left(\Delta x^2+\Delta y^2\right) \quad (1)$$

At the resonance frequency $2\pi\nu_0$ and for the waveguide dimensions (a×b) and copper conductivity ($\sigma = 5.95\times10^7$ S/m), we obtain a peak-to-peak value only limited by the losses in the walls of 30 µrad.

IV. Practical realization

The ring cavity is realized by assembling the upper and lower parts of the waveguide. All parts (cut-offs, coupling ports, half cavities) are sealed together with indium to prevent microwave leakages.

To keep phase variations close to optimum, we thoroughly studied the effect of geometric imperfections on the electromagnetic mode. We showed that mechanical tolerances on the dimensions between 5 and 10 µm and surface roughness better than $R_a = 0.025$ µm (according to ISO 4287) increase $\Delta\phi_{pp}$ less than 5%. The measurements performed on our new cavity (Fig.3) machined with state-of-the-art ultra-precise diamond milling showed that these specifications are available with a best waveguide surface roughness of $R_a = 0.012$ µm.

This work was supported by the Swiss National Science Foundation (grant 200021-141338/1).

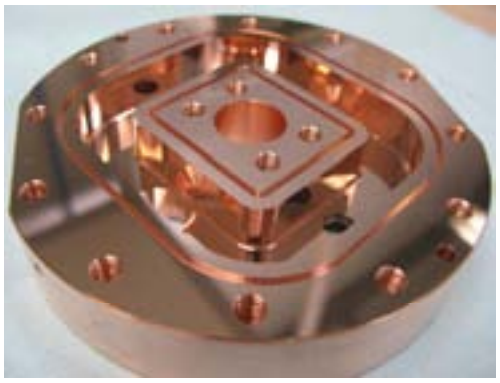

Figure 3. Picture of the inner half volume of the TE_{105} waveguide. Surfaces were machined with ultra-precise diamond miling to obtain a state-of-the-art roughness of R_a = 12 nm

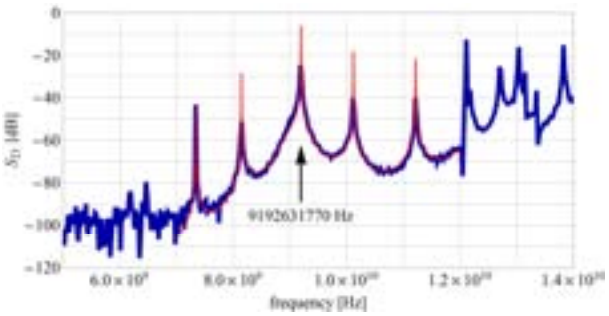

Figure 4. Cavity transmission spectrum: measurement (blue thick curve) is compared to finite element simulations (red thin curve).

V. Experimental Results

A. Frequency Spectrum

Once the cavity mounted, general properties of the waveguide (frequency spectrum and coupling and cavity factor) were measured.

The low mode density of this waveguide cavity is clearly visible on the frequency spectrum Fig.4. The closest resonances (TE_{104} and TE_{106}) are approximately 1 GHz away from the frequency of the mode TE_{105} used to interrogate the atoms. Moreover, experimental measurement (blue thick line) and numerical calculation (red thin line) of the transmission spectrum are in very good agreement.

B. Ramsey Fringes

The TE_{105} electromagnetic mode shows a π-phase difference between the two interaction zones. For this reason, Ramsey fringes exhibit a dark central fringe (Fig.5) at the Cesium resonance frequency ν_0 = 9192631770 Hz. This has been shown to have some metrological advantages [19].

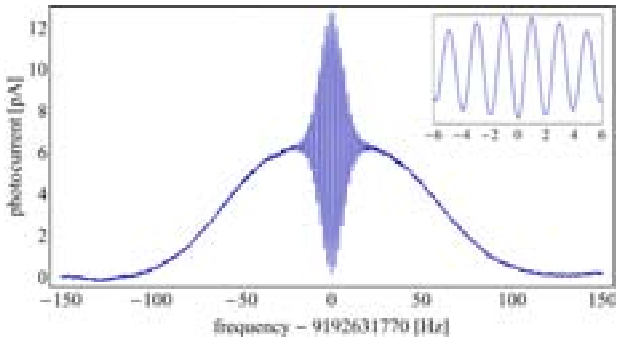

Figure 5. Ramsey fringes obtained with the new ring waveguide cavity. The inset shows the central dark fringe at 9192631770 Hz.

C. Perspectives

To evaluate the frequency shift associated with the spatial phase gradient in the microwave cavity, we are currently working on three types of experimental measurements. One experiment is to change the velocity of the cold atoms along their trajectory and thereby change where the atoms pass through the µ-wave cavities. Another experiment is to tilt the fountain in two vertical planes to probe the phase of the µ-wave field in those two directions separately. A third experiment will be to select the atomic trajectories that are being detected by blocking off part of the detection laser beam.

VI. Conclusion

We presented the design and realization of a low phase gradient microwave cavity. Numerical model based on finite elements simulation predict spatial phase variations of 30 µrad over each interaction zone. With a free evolution time of 0.52 s, both the end-to-end and distributed cavity phase shifts should be reduced to a level of 10^{-15} or below in relative units. The general electromagnetic properties of the cavity have been tested and we are currently working on the evaluation of its associated fountain frequency shifts.

Acknowledgment

We thank Dr I. Syratchev and Dr W. Wuensch at CERN for useful discussions and for their support in verifying the simulation results.

***Abstract*— The transportable microwave frequency standard based on laser-cooled $^{113}Cd^{+}$ ions is a promising to be applied in the comparison of the atomic clocks located in different places. We report the main progress of this clock including the measurements of the clock transition and the preliminary frequency stability.**

Keywords—microwave frequency standard, cadmium ions, frequency stability

I. INTRODUCTION

The frequency standards based on trapped ions were investigated by different groups and achieved great improvements in the past decades [1-6]. A project aimed at a transportable microwave atomic clock based on the laser-cooled $^{113}Cd^{+}$ ions has been carried out since 2010 in our laboratory [7]. The short-term frequency stability of this clock is expected to be $2\times10^{-14}\tau^{-1/2}$. Meanwhile, this clock can be designed to be transportable because that only one laser is needed for laser cooling, optical pump and detection. This clock is going to be applied in the comparison between the clocks located in different places, e. g. the atomic clocks at the ground stations of Beidou Navigation Satellite System. This paper reports the main progress and preliminary results of the Cd^{+} clock in the past year.

II. PROGRESS

Since the detailed description of the experimental setup can be found in [7], only a brief instruction is given here. The linear quadrupole ion trap and the technique of laser cooling are applied in this clock. The laser system is a frequency-quadrupled diode laser system from Topitca Inc. To stabilize the frequency of the laser to megahertz level, the 858 nm seed laser of this laser system is locked by comparing the frequency with an 852 nm laser stabilized to the cesium lines via a transfer cavity [8]. By the laser cooling, the velocity of ions can be slowed down and the ions can be cooled down to crystallization state. In our experiments, it is successfully demonstrated that approximately 10^4 ions are cooled to 16 mK by laser cooling [9]. Thanks to the energy level structure of the $^{113}Cd^{+}$ ions, the same laser can be used for laser cooling, optical detection, as well as optical pumping with the laser frequency blue-shifted 800 MHz by an acousto-optic modulator. During the optical pumping, the ions are prepared to the upper state of the ground-state hyperfine states. After the interaction between the microwave radiation field and the ions, the ions populated on the lower state of the ground-state hyperfine states are detected. Then the spectrum of the clock transition is obtained by measuring the population variation at different microwave frequency.

By measuring the ground-state hyperfine splitting in different magnetic fields, the clock transition in the zero field can be extrapolated. Two independent groups have measured the ground-state hyperfine splitting of $^{113}Cd^{+}$ ions [10, 11]. Based on the experimental setups, we also measure the hyperfine splitting of $^{113}Cd^{+}$ ions. On the first setup, namely JMI-1, the measured result is 15. 199 862 854 96(12) GHz [12], which precision is mainly limited by the fluctuation of the magnetic field. To solve the magnetic field problem, a box made of silicon steel is applied to shield the physics package to reduce the magnetic field fluctuation from the ambient disturbance. In the mean time, the magnetic field close to the vacuum chamber is actively controlled via a fluxgate magnetometer. On the upgraded experimental setup, JMI-2, we obtained the hyperfine splitting with better precision than previous measurement, which is 15. 199 862 855 0125(87) GHz [13]. The improvement of the measurement precision is mainly due to the following two reasons. Firstly, the magnetic field is more stable than before and measured by the $\Delta m_F=\pm 1$ transition frequencies of the ground-state hyperfine splitting, which makes the measurement error due to the Zeeman effect much smaller than the previous measurement. Secondly, the free processing time during the Ramsey interrogation is extended from 0.1 s to 2 s, which improves the measurement resolution significantly. The precision of the second measurement is limited by the frequency reference.

Recently, the preliminary stability of this clock is measured by the close-loop operation. Fig. 1 shows the schematic measurement setup. The local oscillator is an oven controlled crystal oscillator (OCXO) with an ultrahigh stability of 2×10^{-13} at 1 s. The 10 MHz output of the OCXO is feed to a microwave synthesizer to produce the 15.2 GHz microwave radiation field. The power and frequency of the microwave signal is controlled by a computer. During the detection phase, the fluorescence signal is detected by a photomultiplier tube (PMT) operating in the Geiger mode. The photon emitting rate is measured by a photon counter and the data are directed to the computer. A digital proportional-integral-derivative (PID) controller is used

This work was supported by 973 Program (Grant No. 2010CB922901) and Tsinghua University Initiative Scientific Research Program (Grant No. 20131080063).

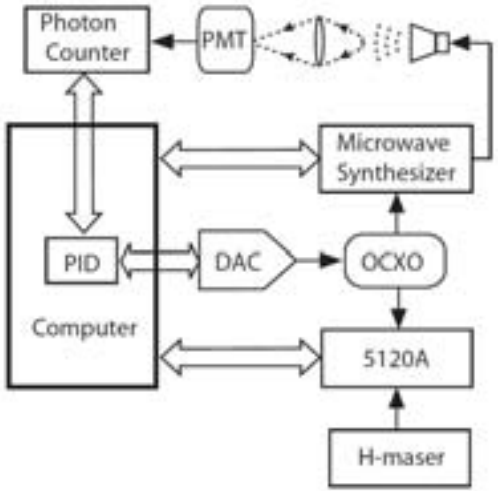

Fig. 1. Schematic experimental setup for the frequency stability measurement. PMT: photomultiplier tube, PID: proportional-integral-derivative controller, DAC: digital-to-analog converter, OCXO: oven controlled crystal oscillator, 5120A: Allan deviation test set, H-maser: hydrogen maser.

to generate the feedback signal and this signal is converted to analog signal by a digital-to-analog converter to control the frequency of the OCXO. While the clock is in close-loop operation, a part of the OCXO output is feed to an Allan deviation test set to compare with a hydrogen maser.

Fig. 2 shows the modified Allan deviation of the measurement where the linear frequency drift is removed. Because the loop time constant here is about 100 s, the stability at the averaging time less than 100 s is from the local oscillator. The stability from 100 s to 4000 s is approximately $1.5\times10^{-12}\ \tau^{-1/2}$.

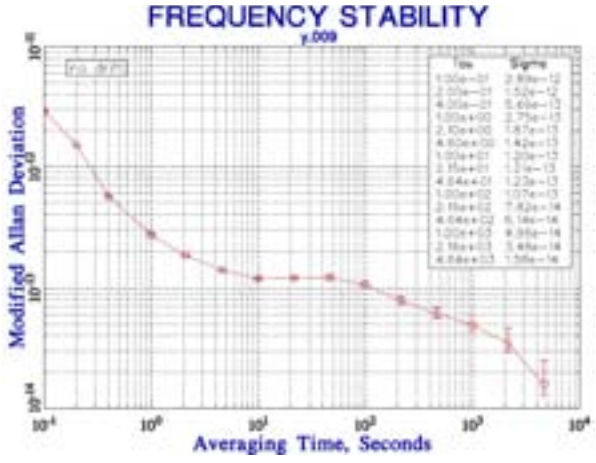

Fig. 2. Modified Allan deviation of the measured data. The period of measurement time is approximately 6 hours and the linear frequency drift is removed.

III. Conclusion and Outlook

The microwave frequency standard based on laser-cooled $^{113}Cd^+$ ions is promising to be applied in the comparison of atomic clocks located in different places. By the experimental setups at JMI, we measured the ground-state hyperfine splitting of $^{113}Cd^+$ precisely. And the preliminary frequency stability of the clock is reported. A series of upgrading of the experimental setup are planned, and an improved result is expected in the next phase.

Institute of Electronic Measurements KVARZ, Nizhny Novgorod, Russia
Email: nnipi_kvarz@sinn.ru

Abstract — **The physical model of hydrogen maser systematic frequency drift is discussed. Results of theoretical research are compared with results of experiments and long-term practical observations over drift of a hydrogen maser. One of conclusions of research is the statement that drift can change its value and a sign. The model allows to predict behavior of maser frequency with the help of maser parameters monitoring.**

Keywords - hydrogen maser; frequency drift; relaxation time; cavity auto tuning; quality factor of the spectral line.

I. INTRODUCTION

Systematic frequency change of a signal (drift) is one of the primary metrological characteristics of hydrogen maser. Minimization and prediction of drift remain an important task [1, 2]. Figures 1 shows data on long-term measurements of frequency for hydrogen maser CH1-75A. Masers are made by the Institute of Electronic Measurements KVARZ. The data show evolution of frequency of FGUP «VNIIFTRI» hydrogen clock ensemble. Drift of a hydrogen maser frequency at manufacturing does not exceed 2×10^{-15}/day, and then it decreases. In the presented plots it does not exceed 5×10^{-16}/day. It is necessary to note that drift can be of both positive and negative signs. This fact complicates understanding of a phenomenon.

Earlier a number of scientists proposed hypotheses about the drift nature, but articles had either qualitative [3] or statistical and descriptive character [2, 4]. For example, in article [2] it is considered that drift has constant linear scaling coefficient and slowly changing random component.

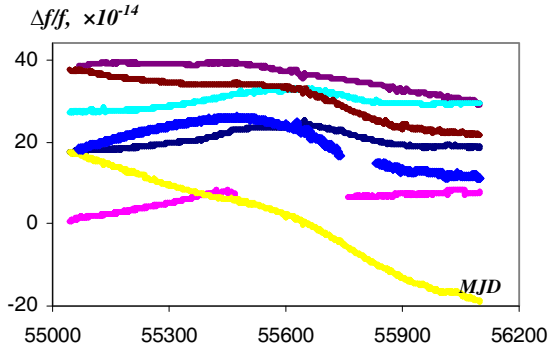

Fig1. Dependence of hydrogen masers frequency on time over four years.

II. FREQUENCY EVOLUTION OF HYDROGEN MASER

This paper presents a possibility of the theoretical description of frequency evolution for a hydrogen maser. The analysis of evolution is based on the use of the solution of the hydrogen maser differential equations in two-level approximation:

$$\begin{cases} \dfrac{d^2H}{dt^2}+\dfrac{\omega_c}{Q_c}\dfrac{dH}{dt}+\omega_c^2 H = K\dfrac{d^2M}{dt^2} & , \\ \dfrac{d^2M}{dt^2}+\dfrac{\omega_l}{Q_l}\dfrac{dM}{dt}+\omega_l^2 M = \dfrac{2\mu_B^2\omega_l\Delta N H}{\hbar} & , \\ \dfrac{d\Delta N}{dt}+\dfrac{1}{T_1}(\Delta N-\Delta N_0) = -\dfrac{2H}{\hbar\omega_l}\dfrac{dM}{dt} & , \end{cases}$$

where t – time, H – intensity of magnetic microwave field component, M – induced magnetic moment of atomic ensemble, ω_c, Q_c, V_c – angular frequency, quality factor and volume of the microwave cavity, ω_l, Q_l – angular frequency and quality factor of the spectral line, ΔN, ΔN_0 – population difference and initial population difference, η – filling factor of cavity, $K=\dfrac{\mu_0\mu_B{}^2\eta}{\hbar V_c}$ – constant, μ_B – Bohr magneton, $\hbar$ – Planck constant.

The exact solution of system is not known, therefore «a steady-state» approximation is used [4]. The importance in the solution is connected with the following parameters: T_1, T_2 – longitudinal and transverse relaxation time, $\vartheta = \phi - \psi$ – difference between oscillation phases of the microwave field and the induced magnetic moment of atomic ensemble, I – magnitude of the beam flux, $b_R = \mu_B H / \hbar$ – Rabi frequency. But this solution does not contain a drift component.

According to the approach of the articles [5, 6] as frequency evolution of a two-level quantum system being in resonant harmonic electromagnetic field, we consider the asymptotic solution of the following equation:

$$\Delta\omega_{sys} \equiv \frac{d\vartheta}{dt} = \frac{d\phi}{dt} - \frac{d\psi}{dt} \quad .$$

From the reduced equations of a hydrogen maser it is possible to derive the following time dependent equation:

$$\Delta\omega_{sys}(t) = \Delta\omega_c(t) \pm \left(K\omega_c \frac{M_0(t)}{2b_R(t)} + \Delta N(t) \frac{b_R(t)}{M_0(t)} \right) \times \sin\left(\overline{\vartheta}\right) \quad (1),$$

where $\Delta\omega_c$ – frequency detuning of cavity, $M_0(t)$ – amplitude of the induced magnetic moment of atomic ensemble, $\overline{\vartheta}$ – time averaging.

We use the ratios obtained in a «steady-state» approximation [4]. For obtaining the nontrivial solution we will consider that $\sin\left(\overline{\vartheta}\right) \approx \pm 0$. Let us specify it explicitly by using a formal small parameter ε ($0 < \varepsilon << 1$). We will derive the following solution:

$$\Delta\omega_{sys}(t) = \Delta\omega_c(t) \pm \varepsilon \left(\frac{1}{T_2(t)} + \frac{K\omega_c}{2} \frac{T_1(t)T_2(t)I(t)}{1 + T_1(t)T_2(t)b_R(t)^2} \right) \quad (2).$$

The formula shows that long-term changes of frequency are defined by slow changes of basic parameters in the course of time. The most important is dependence on a detuning of cavity. Change of frequency of the cavity directly influences frequency of a standard. Dependence on other parameters is much weaker.

To use the solution for finding of evolution of hydrogen maser frequency it is necessary to know evolution of the observable value T_1, T_2, I, b_R. If quality factor of the hydrogen spectral line Q_l at a threshold beam flux is known, it is possible to consider that $T_{2-th} \approx \frac{2Q_{l-th}}{\omega_l}$, and for a stronger beam flux to consider that $T_2 \approx \frac{1}{\chi + \beta K Q_c I}$, $T_1 \approx \frac{1}{\chi + 2\beta K Q_c I}$, where χ, β – parameters.

III. The Analysis of Solution

At correct work of automatic cavity tuning $\Delta\omega_c \approx 0 = const$ and the formula (2) appears as follows

$$\Delta\omega_{sys}(t) = \frac{K\omega_c}{2} \frac{T_1(t)T_2(t)I(t)}{1 + T_1(t)T_2(t)b_R(t)^2} + \frac{1}{T_2(t)} .$$

A. Variant

Let all parameters remain constants. Then frequency of quantum system also remains a constant.

B. Variant

On very long periods (years) polymer is not a static system, thus possessing the processes causing changes in structure and composition. It is shown in change of quality factor of the spectral line. The long-term researches made at our institute show that quality factor can change in two main directions. The first is associated with degradation of a storage bulb covering and with reduction of Q_a, the second is defined by a surface cleaning and increasing of Q_l.

Let's consider that the beam flux of hydrogen is constant, we will take value of Rabi frequency from a «steady-state» approximation:

$$b_{Rs}{}^2 = KQ_c I - \frac{1}{T_1 T_2} \quad .$$

Situation modeling at increasing (or decreasing) quality factor of the spectral line on a ratio

$$Q_l = Q_{l0} \pm a \log(t) \quad ,$$

where Q_{l0} и a – parameters, leads to the graphs represented in Fig. 2. The analysis (Fig. 3) shows that the increase in quality factor is associated with the general drift reduction.

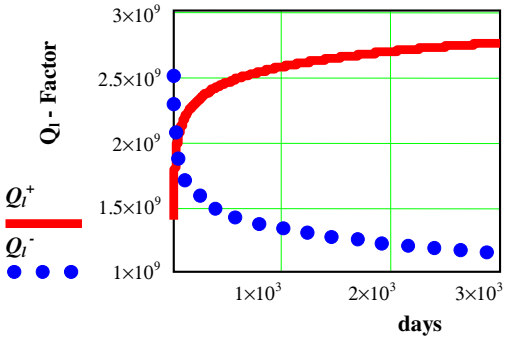

Fig.2. Modeling dependence of the spectral line quality factor on time.

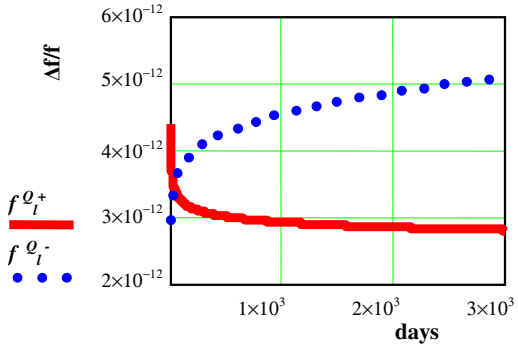

Fig.3.Modeling dependence of hydrogen maser relative frequency on time.

C. *Variant*

Let's assume that

$$b_{Ra} = z b_{Rs}, \quad z = const < 1 .$$

It means that the value of Rabi frequency differs from the value received in a «steady-state» approximation b_{Rs}. In a «steady-state» approximation it is assumed that all atoms should give energy quantum. It does not correspond to reality. In addition we will consider that the beam flux of hydrogen linearly decreases 3 times. Results of modeling at increasing and decreasing of quality factor of the spectral line are given in Fig. 4.

Sign inversion at frequency drift in variant of decreasing of quality factor is an interesting feature of Fig.4. We have drift acceleration on very long periods.

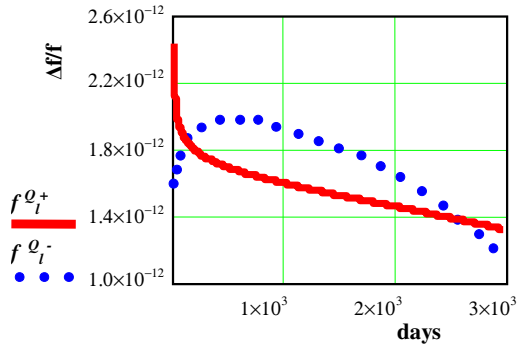

Fig.4.Modeling dependence of hydrogen maser relative frequency on time.

IV. EXPERIMENTAL RESULTS

The inner bulb surface of observable hydrogen maser is coated with fluroplastic type F-10. As experiment shows, quality factor of the line at a threshold beam flux decreases. The typical case of change of Q_l is presented in Fig.5. This phenomenon can't be presented as simple degradation of the line, because amplitude of generation increases. The fastest changes take place at the beginning.

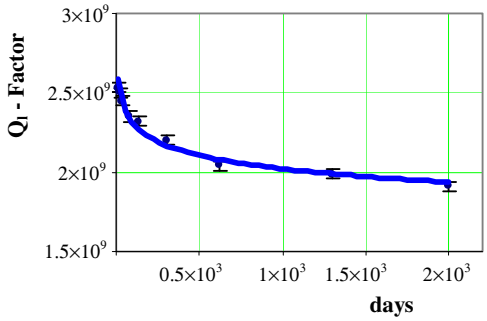

Fig.5. Change of quality factor of the spectral line at a threshold beam flux on time.

Drift decreasing at $\sin(\overline{\vartheta}) \approx \pm 0$ hypothesis examination. This hypothesis is right in a case when own frequency of the cavity is very close to the frequency of the spectral line. For hypothesis examination the CH1-75B model of new modification was used. Standard stability is presented in Fig. 6.

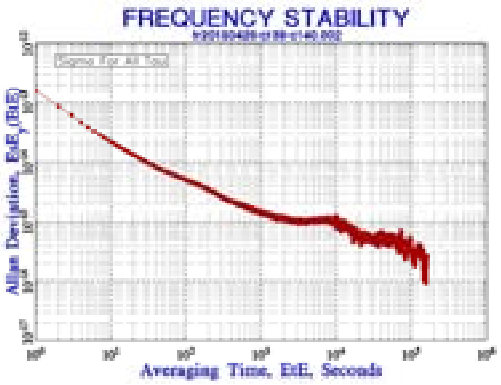

Fig.6. Hydrogen maser CH1-75B stability with removing drift.

It is possible to tune the cavity of this model with controlled accuracy. In Fig. 7 evolution of CH1-75B frequency with the microwave cavity tuned and detuned by +40 Hz are presented. After cavity detuning the frequency of a maser was compensated by $\Delta f / f = -1 \times 10^{-12}$. As the figure analysis shows, drift increased by 1.5 times from $+1.3 \times 10^{-15}$ to $+1.9 \times 10^{-15}$ per day after cavity detuning. Microwave cavity was retuned 38 days later. Frequency drift thus returned to its previous value.

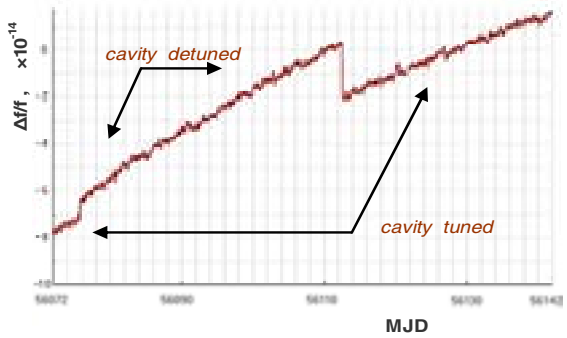

Fig.7. Evolution of output signal frequency of CH1-75B with the microwave cavity tuned and detuned by +40 Hz.

V. CONCLUSION

- The main reason for appearance of active hydrogen maser systematic frequency drift is evolution of longitudinal and transverse relaxation time of quantum system. The evolution is related to change of quality factor of the spectral line, decreasing of the beam flux of hydrogen, change of maser generation amplitude.
- Frequency drift minimization is associated with the minimization of maser operating parameters variation, for example with stabilization of hydrogen beam flux and accuracy of cavity auto tuning.
- There is a physical model helpful to predict frequency evolution on the base of maser parameters monitoring.

alejnikov@vniiftri.ru

Abstract — **To improve short-time stability the amplification of the hydrogen maser output signal due to using the single-state selection and cooling the source cell is theoretically discussed. H-maser theory basic aspects are sequentially developed in the introduction part. The results of the numerical calculation active H-maser power versus magnet parameters of specific selective system and source temperature are obtained. In conclusion, the theoretic prototype of maser, that has a short-time stability achieved 2.5×10^{-14} for one second, is represented.**

Keywords - hydrogen maser ; single-state selection ; cooled source's cell.

I. INTRODUCTION

At present hydrogen masers together with ultrahigh stability oscillators [1] are the main source of a stable microwave signals. Typical short-time stability (Allan variation [2]) of this signals is estimated to be $\sigma_y \sim (1\div2)\times10^{-13}$ for 1 second. It's necessary to possess such description, for example, in atomic fountain frequency standards [3, 4] to form interrogation process. The amplification of a synthesizer based on the increased power H - maser can improve above short-time stability and ratio Signal/Noise of interrogation waveform.

One of the first idea to create active hydrogen maser with improve short-time stability was developed in the paper [5]. The gist of idea consists in using two state-selection magnets, which are separated by spin-flip region [6], instead of conventional state-selection magnet. In the new state-selection system (single-state) proposed by the authors, all of the undesirable atoms are eliminated from the hydrogen beam and, thus, only operational atoms are present in the storage bulb. Therefore, the H-maser's output power in case of single-state selection system is increased in comparison with conventional one due to spin exchange relaxation. The quantitative estimation of specific selection system will be introduced in the further statement.

In this paper the results of numerical calculation of the atomic beam's trajectories are represented. We symbolically divided it into two parts: in one of them the H-maser's power versus choice of selective system is shown, in another one - versus temperature of the hydrogen source's cell.

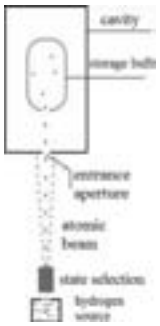

Figure 1. The design of H-maser

II. THEORY

A. General regulations

The short-time stability σ_s of hydrogen maser, which is sketchy shown in figure 1, can be written as [5]:

$$\sigma_s^2 = \frac{1}{\omega^2\tau^2}\frac{N}{S} = \frac{1}{\omega^2\tau^2}FkTB\left[\frac{1+\beta}{\beta}\frac{1}{P}\right], \qquad (1)$$

where $N = FkTB$ - equivalent noise power delivered to the receiver (F - noise figure, k - Boltzmann's constant, T - absolute temperature of the maser's storage bulb, B - equivalent bandwidth); $S = \beta P/(1+\beta)$ - the power delivered to the receiver (P - total power radiated by the hydrogen atoms in the storage bulb, β - coupling factor to the cavity); ω - circular frequency of the oscillation, τ - averaging time interval (≤ 50 s).

Here and further we suppose that hydrogen source and state selection system are the lower part of the maser and storage bulb, microwave cavity and receiver are the higher part. By-turn the maser power P in (1) can be expressed by the conventional equation [7], which contains parameters of the both maser's parts:

$$\frac{P}{P_c} = -2q^2\left(\frac{\Delta I}{I_{thr}}\right)^2 + (1-3q)\frac{\Delta I}{I_{thr}} - 1, \qquad (2)$$

where I_{thr}, P_c - threshold values of the flux and radiated power of an atomic beam, ΔI - efficient flux of the active atoms entered in the storage bulb, q - quality quantity described as:

$$q = \frac{\sigma \overline{v_r} \hbar}{2\mu_B^2 \mu_0} \frac{V_c}{V_b} \frac{1}{Q_c \eta} \frac{\Gamma_b + \Gamma_\omega}{\Gamma_b} \frac{I_{tot}}{\Delta I}, \qquad (3)$$

where σ - spin exchange cross section [8], v_r - the average relative velocity of atoms in the storage bulb, V_c, V_b - the volumes of the cavity and storage bulb, Q_c - the quality factor of the loaded cavity, η - the magnetic filling factor, Γ_b, Γ_ω - relaxation rates due to escape from the bulb and recombination on the bulb walls, I_{tot} - the total flux of atoms. The quantity q is an important parameter, which describes maser performance. If $0 \le q \le 0.17$ the oscillation will be observed. All of the quantities on the right side of (3) other than $I_{tot}/\Delta I$ can be measured; therefore, the ratio $I_{tot}/\Delta I$ determines quantity q and depends on the parameters of the lower part only. As a matter of fact, this ratio describes state selection performance.

B. Lower part of H - maser

As is well known [9], in the source hydrogen atoms are in the ground state $S_{1/2}$. The hyperfine ground state has four magnetic sublevels [$F = 1$, $m_f = 0, \pm 1$], [$F = 0$, $m_f = 0$] (F, m_f - the quantum numbers of total magnetic moment and its projection of the hydrogen atom). According to Boltzmann's temperature distribution the probability w_n of a quantum system being on level with energy E_n equals:

$$w_n \sim e^{-\frac{E_n}{kT}}$$

Since the magnetic sublevels have approximately the same energy, they are filled equally.

To create converse population in the maser's storage bulb a magnetic state-selection system is used. In the storage bulb the atoms in the state [$F = 1$, $m_f = 0$] contribute to an oscillation, but the presence of another three magnetic sublevels causes the undesirable spin exchange and the additional frequency shifts of the output waveform. To describe a state selection performance it's convenient to use parameter α:

$$\alpha = \frac{I_{10} + I_{11} + I_{1-1} + I_{00}}{I_{10} - I_{00}} = \frac{I_{tot}}{\Delta I}$$

here indices denote the quantum numbers.

This parameter is the subject of the numerical calculation of the H-maser's lower part and it describes the state-selection performance. Thus, $\alpha \ge 1$ and if the value converge to 1, there are only active atoms in the storage bulb. To calculate α we use Maxwell's velocity distribution that describes the atoms escaped from the hydrogen source [10]:

$$I(\mathrm{v}, \Theta)\, \mathrm{d}\mathrm{v}\, \mathrm{d}\Omega = \frac{2 I_0}{\overline{v}^4} v^3 e^{-\frac{v^2}{\overline{v}^2}} f(\Theta)\, \mathrm{d}\mathrm{v}\, \mathrm{d}\Omega, \qquad (4)$$

here $f(\Theta)$ - the normalized diagram of the source's direction, I_0 - the intensity of the beam at the maximum of the diagram.

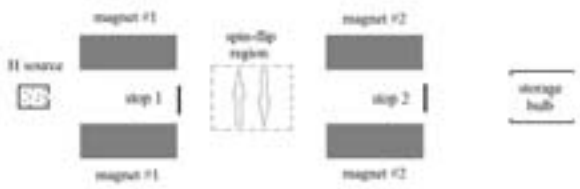

Figure 2. The H-maser's lower part with double selection

Consequently, using the equations of the atom's motion in *2N*-pole magnet [11], we may calculate atom flux $I_{F,mf}$ and, thus, α.

III. NUMERICAL CALCULATIONS

In this section we consider two problems about optimal choice of the parameters of the H-maser's lower part that is shown in figure 2. The first problem is about optimal choice of the selective system in general, and the second - source's temperature influence on the output power.

As a reference the eventual results of the numerical calculation of the conventional magnetic selective system have been discussed. Thus, let one 6-pole magnet with next parameters is used: $H_0 = (0.6 \div 0.8)$ T - field strength on the side of the gap, $r_m = (1.0 \div 2.5)$ mm - the radius of the inner magnet's hole, $l_m = (40 \div 60)$ mm - the magnet's length. The theoretical calculation of the parameter α for such selection system gives $\alpha \ge 4 \div 5$ that is insufficient satisfactory selection (there are only about (20 - 30) % active atoms in the storage bulb). For such values of the parameter α the quality quantity is $q \ge 0.07 \div 0.1$ according to the parameters of the maser's higher part. It's obvious that the output power of the H-maser with such state-selection is far from peak, and sometimes the oscillation may be complicated. So, there is a reasonable problem about improving of the state-selection efficiency.

A. State-selection system

To decrease α to 1, one should to use selective system with two magnets (Fig. 2). Usually 4-pole and 6-pole magnets are used as selective elements. The difference between 4- and 6-pole magnets consists in the magnetic field and, therefore, the force acting on the atoms, versus a radial coordinate. In the 6-pole magnet near axis the force is equal to zero, so to eliminate the undesirable atoms from the atomic beam the axis minor stops are additionally used (Fig. 2). In the 4-pole magnet this requirement is absent, because the force is not equal to zero. Thus, it's curious to compare 4- and 6-pole selective systems numerically.

Before discussing the eventual results of the calculations, a model of the hydrogen source will be described. We consider the source that consists of a system of the independent channels with the direction diagram [12]:

$$f(\Theta) = \begin{cases} \cos\Theta \left[1 - \frac{1}{2} \frac{tg\Theta}{tg\Theta_0} \right] 2\pi \sin\Theta d\Theta & 0 \le \Theta \le \Theta_0 \\ \cos\Theta \left[\frac{1}{2} \frac{tg\Theta_0}{tg\Theta} \right] 2\pi \sin\Theta d\Theta & \Theta_0 \le \Theta \le \frac{\pi}{2} \end{cases},$$

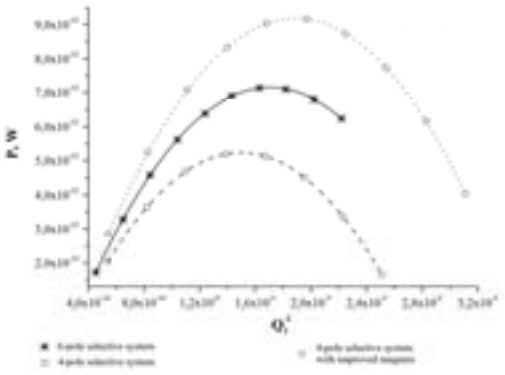

Figure 3. Atomic beam power versus inverse line Q_l

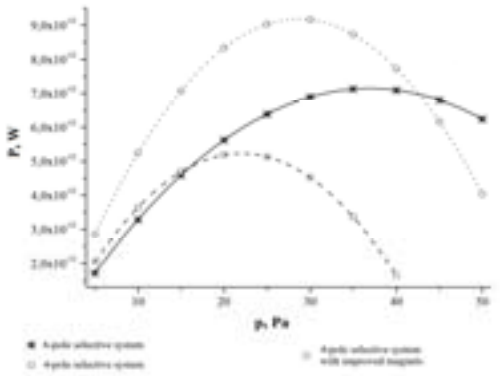

Figure 4. Atomic beam power versus pressure in source's cell

here Θ_0 = arctg(d/L) (d, L - the channel's diameter and length). The intensity maximum of the direction diagram equals $I_0 = \eta Sp\langle v\rangle/(4\pi kT)$ (η - the source's transparency, S - the source's hole cross section, p - the pressure in the source's cell, $\langle v\rangle$ - the average velocity of the atoms in the source's cell, T - the temperature of the source). Let $\eta = 0.6$, $S = \pi r^2 = \pi/4$ mm^2, $d = 40$ μm, $L = 1.5$ mm, the temperature of the source is considered to be equal 900 ^{o}K.

The relationships between atomic beam power and inverse line quality factor [13] or pressure in the source's cell are shown in figures 3 - 4. In the ordinary case the selective magnets were used with parameters: $H_0 = 0.6$ T, $r_m = 1.25$ mm for the first magnet, $r_m = 2.0$ mm - for the second, $l_m = 60$ mm. In the improved case: $H_0 = 1.0$ T, $r_m = 1.25$ mm for the first magnet, $r_m = 2.0$ mm - for the second, $l_m = 80$ mm. Parameters of the storage bulb and microwave cavity: $V_b = 3.0\times10^3$ cm^3 - the volume of the bulb, $\Gamma_{tot} = 1.15$ s^{-1} - the total density-independent relaxation rate, $T = 323$ ^{o}K - the temperature of the bulb's walls; $V_c = 17.5\times10^3$ cm^3 - the volume of the maser's cavity, $Q_c = 36.0\times10^3$ - the quality factor of the loaded cavity.

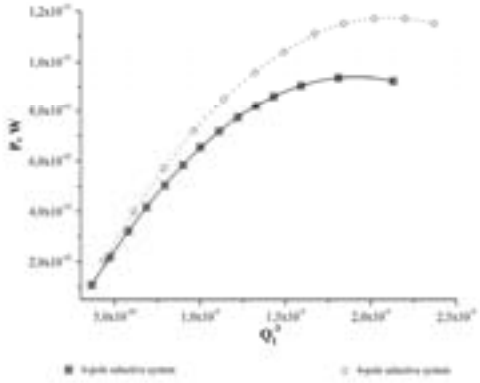

Figure 5. Atomic beam power versus inverse line Q_l

The rated values of the α for the ordinary case of the 4-pole state-selection system - 1.37, 6-pole - 1.26 and for the improved 4-pole - 1.13. The advantage of 6-pole over 4-pole state-selection in ordinary case is shown from figure 3, but in the 6-pole system stop 1 with diameter $d = 1$ mm was used and, thus, about one third of active atoms is eliminated. This fact is shown in figure 4, there 4-pole system has advantage in initial region of pressure. As a matter of fact this region (5-15 Pa) may be a principal duty of the H-maser's source. Therefore, the choice of the selective system depends on active duty of the hydrogen source. This arguments are correct in the case of the source cell's temperature $T = 900$ ^{o}K.

In the case of improved 4-pole selective system the parameter α approaches to 1 and such system eliminates practically all of the undesirable atoms. The peak power of the atomic beam is increased in 1.8 times in comparison with the ordinary case (Fig. 3-4).

B. Temperature of hydrogen source's cell

The velocity distribution (4) of atoms escaped from the source's hole represents a bell-shaped curve with essential parameter T. If the temperature T decreases, the peak of the distribution will increase and move to region of the low velocities and, thus, the state-selection performance will rise since the group of the atoms moving linearly with high velocity is absent.

The analogue of previous sections' curves represents in figure 5 with the same masers' parameters except for the hydrogen source temperature - $T = 300$ ^{o}K.

The advantage of 4-pole over 6-pole state-selection system in the case of cooled hydrogen source is shown in figure 5 (the rated values of α - 1.02 and 1.12). Moreover, the consumption of the hydrogen atoms in 4-pole system is less than 6-pole system in 1.9 times. The peak of the output waveform's power in the case of improved 4-pole system with cooled source increases in 1.3 times, than with normal source $T = 900$ ^{o}K (Fig. 3), and the consumption of the hydrogen atoms decreases in 2 times. Indeed, the improved 4-pole system with cooled source's cell is a perfect state-selection (in our case $q \sim 0.03$)

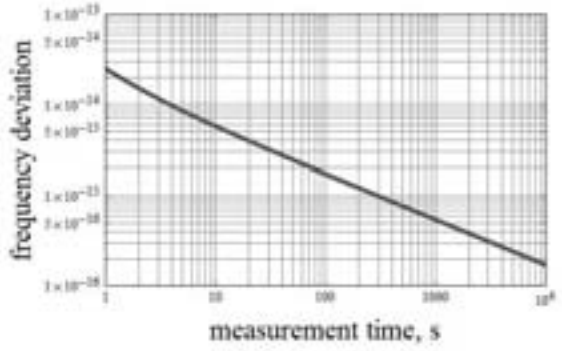

Figure 6. Predicted frequency stability versus measurement time

and in order to increase the rate of the maser's power we should vary the parameters of the H-maser's higher part.

In conclusion the conventional H-maser's frequency stability versus measurement time is lead:

$$\sigma^2(\tau) = \frac{1}{\omega^2 \tau^2} \frac{N}{S} + \left[\frac{kT}{2\tau} \right] \frac{1}{PQ_l^2} \qquad (5)$$

This relation for case of improved 4-pole selective system with cooled source is shown in figure 6 for operating point $Q_l = 1 \times 10^9$. Parameters of abstract receiver: $F = 0.8$ dB, $B = 10$ Hz.

The rated value of the short time frequency stability is 2.48×10^{-14} for one second.

IV. Conclusion

We obtained rated values of the α for various magnetic state selection system. The efficiency advantage of 6-pole using one stop over 4-pole state-selection in the case of source's temperature T = 900 ^{o}K is demonstrated, but the consumption of the hydrogen atoms in 4-pole selection is reduced by one third. In the case of source's temperature T = 300 ^{o}K the application of 4-pole state-selection is desirable. Moreover, the numerical calculation is realized: the application of improved magnets increases output power in 1.8 times, the application of cooled source - in 1.3 times.

Acknowledgment

We would like to thank Georgiy Yolkin and Fedor Rusin for many discussions. Many thanks to Igor Blinov for his contribution to the development of the project.

***Abstract*—This paper is introduced a novel waveguide cavity for Rb atomic clock. In the cavity, a coupling ring shaped semi-circle imports RF signal from electronics, a screw regulator acts as a medium coupler to transmit microwave signal into absorption cell, and the both of the two parts construct a filter to suppress useless components except 6.8GHz. The RF signal can be high effectively produced in the cavity in this way. The waveguide cavity can be used to design miniature Rb atomic clock, and spread it to design chip scale atomic clock. furthermore.**

Keywords—Rb atomic clock; Waveguide cavity; coulper and transimission chipl scale atomic cloct

I. INTRODUCTION

Rb atomic clock as a frequency standard is popularly used in the aspect of telecoms, electronic instruments, etc., although Chip-Scale Atomic Clock (CSAC) based Coherent Population Trap (CPT) has been manufactured two years ago. CSAC has tiny size and very low power dissipation, but the disadvantages of high costs and lack of batch engineer applications for CSAC can not been surpassed in short term. Alternatively, Rb atomic clock with traditional gas-cell has the ad-vantages in costs and in power dissipation, and has improvements in reducing profile recent year. The means to reduce Rb atomic clock dimension is mostly to design kinds of cavity, and some progress has been made in recent year. Nowadays, introducing waveguide to the Rb atomic clock cavity design, we have realized a novel miniature waveguide cavity, and Rb atomic clock made by the cavity is lowered by three folders.

II. STUDYING ON CAVITY

A. Rb atomic clock Scheme and Cavity

Rubidium atomic clock is based on optical pumping, microwave interrogating and light intensity detecting. Rb atomic clock consists of electronics and physics package, and the latter is the key part because it will mainly decide the stability of clock. The physics package has two parts also: Rb spectrum lamp and cavity. Rb spectrum lamp to create a population inversion between the ground state hyperfine energy levels F=2 and F=1 in absorption cell inserted into cavity [1]. If the atoms of absorption cell are interrogated with microwave radiation, the change in light transmission through the cell can be checked by optical diode, and a discriminating signal in the light is to lock OCXO in the atomic clock. According to the clock operation course, enough microwave power is important, and the realization means is popularly to use cavity in which the power can be enclosed in a definite space with special model, such as TE111 or TE011. A typical scheme of Rb atomic clock is shown in figure 1.

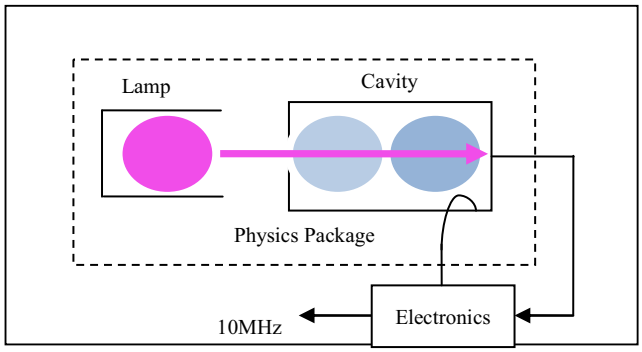

Figure 1. Cavity and Rb atomic clock diagram

In Rb atomic clock, Rb absorption cell must be enough feed with power level of microwave signal and its direction must also be parallel to the quantum axe. So, while cavity resonates at the point of 6.8GHz, the size of the cavity is a little big. Otherwise, if the no resonance occurs there, the stability of the clock will degenerate generally. Therefore, to reduce the volume of cavity is the main content of deigning miniature Rb atomic clock.

Typical means to downsize the volume is to adopt TE111 cylinder cavity. In comparison with TE011, the volume can be reduced by four folders. But the performance will worsen comparably. This cavity is popularly used in the world, and a series of Rb atomic clock have be developed and massly manufactured, including spacial high performance Rb frequency standard made by EG&G for GPS in America [2].

In order to simultaneously possess the high performance of TE011 and low size of TE111, a slot magnet cavity has been designed [3]. In the cavity, the slot and gap are respectively equivalent to capacitor and inductor according to integral parameter analysis. Therefore the resonant frequency is just decided by the size of the both part and independent on the size of cavity. Importantly, the model is approximately TE011 at an extent, and consideration of performance and volume can be realized.

A waveguide cavity, in a patent US5627497 called resonator package for atomic frequency standard by Gerold skoczen from Efratom Time and frequency Products, has been invented [4]. In the resonator package, a cylinder cavity containing absorption cell has not to be tuned and its size can not be accurately confined in a range, and a RF loop ring consisted of SRD and metal wire is shaped as a rectangle which inserts into the cavity from a hole in the profile. While to tune RF signal amplitude, the side of the loop ring must be

This work has been gotten support from National key scientific instrument and equipment development project No.2012YQ200183.

turned slowly by holding the connector, and be fixed by a screw on the optimum point where the atomic discrimination signal is maximal. The best one of the merits is that low size of cavity can be achieved, but shortage is very obvious that precession is inconvenient due to the functions of coupler and transmission are within the one loop ring. By the waveguide cavity, a kind of Rb atomic clock (model LPRO) has bee made.

B. Ttansmision-Counpler and Waveguide Cavity

Coupled strip line filters and directional couplers were presented by E. M. T. JONES and J. T. BOLLJAHN in 1956[5]. In that theory, two stripe lines are parallel each other and total effect is one of low-pass, band-pass, all-pass, or all-stop filter. Simultaneously, the signal power can been coupled and transmitted between the two strip lines. The idea from us, the combination of the stripe line filter and waveguide is to design a special waveguide cavity and reduce the cavity size more and more. While analyzing the stripe line, we found the band-pass filter could be selected to design a waveguide cavity for Rb atomic clock. The band-pass filter has the property as below.

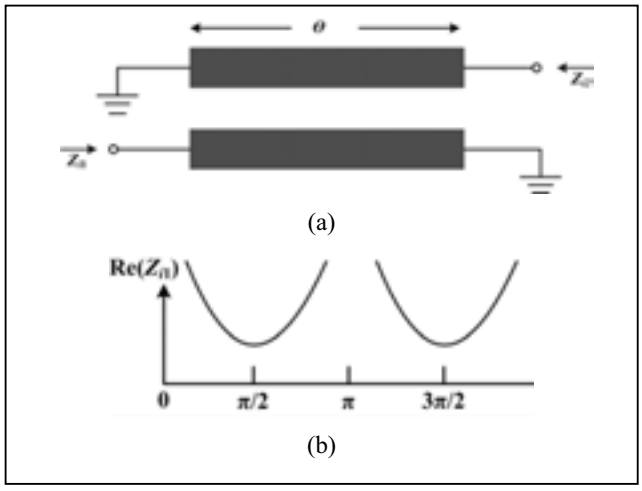

Figure 2. Coupler and transimision filter diagram. (a) abstraction construct, (b) the relation between transimission Real compoent with phase

As is known the cavity in Rb atomic clock consists of absorption cell and hole for transmitting light, which complicate the boundary condition. Therefore, computer simulation and assisting design must be used in order to achieve the optimum of mechanical parameters when we design the waveguide cavity by the above stripe line technology.

III. SIMULATING AND DESIGNING

Auxiliary computer simulation is very popularly used in researching and developing mechanical and Microwave technology and product. In this project, we will design the cavity with help of simulation, in which microwave band is about the point 6.8GHz, and the H-component been parallel to the axe of the cavity is enough strong in order to reduce the electronics power dissipation.

A. Reforming and Slimulating

The stripe line in figure 2 can not be used to design cavity for Rb atomic clock, and must be reformed. According to electromagnetic induction theory, there is alternatively transferring between H-component and E-component in space-time domain on RF signal transmitting. Regarding the cavity construct where a bottom side and cylinder profile will worsen electromagnetic field distribution from stripe lines, the one stripe line must be changed into a semicircle which is work as a coupling ring, and another one will be as a screw regulator. The both of the two lines are parallel each other also.

We have simulated the effect of the reformed construct in comparison with the stripe line in figure 2 by HFSS. The effect is in figure 3.

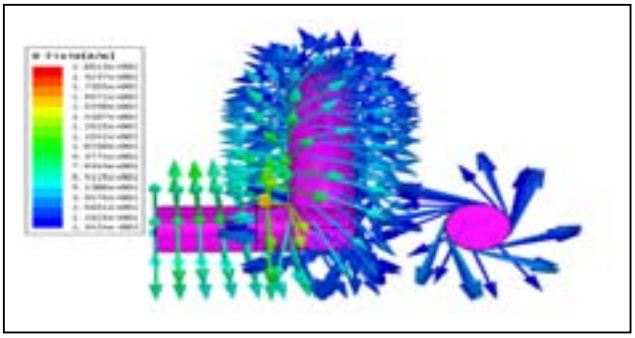

Figure 3. H-component in the Waveguide by HFSS Simulating

The above simulation is shown that H-component can transmit from the semicircle ring loop to other space, and the RF power can be coupled with the screw regulator. By this reform, big couple efficiency would be realized.

While using this construct of the reformed stripe line to design new waveguide cavity for Rb atomic clock, We have also simulated the cavity by HFSS.

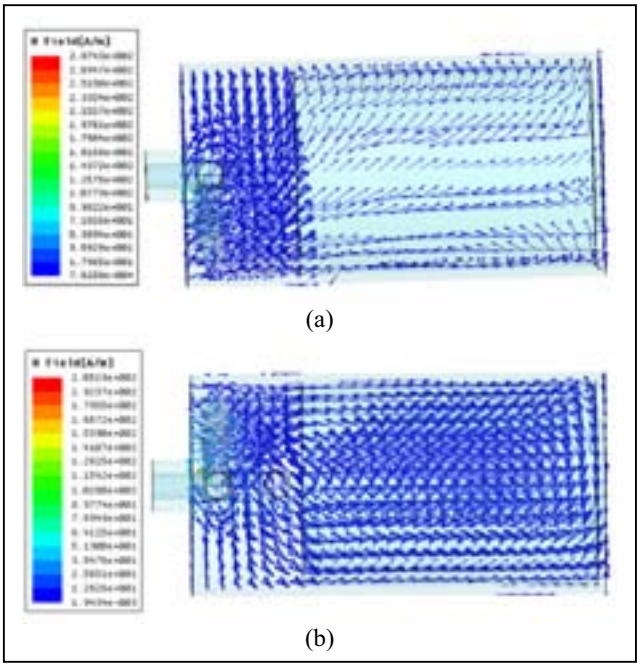

Figure 4. H-component in the Waveguide by HFSS Simulating. (a) effect without screw regulator, (b) effect with screw regulator.

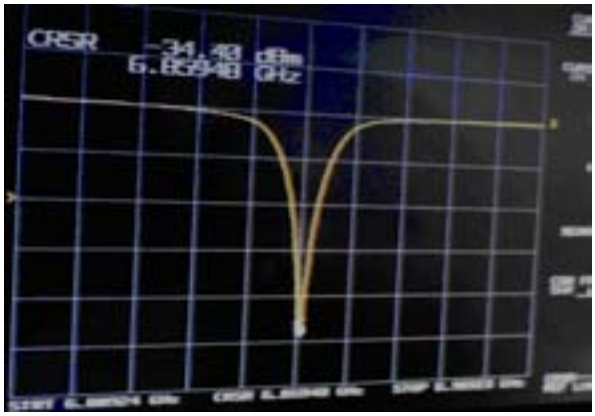
B. Manufacturing and Testing

According to the above simulation, the waveguide cavity has manufactured in Spcaon. In the cavity, the screw regulator and ring loop are made of copper by coating silver. A Step-Recovery-Diode (SRD), multiplying RF signal to 6.8 GHz, is soldered on the bottom side and ring loop simultaneously. In general, the RF signal is about 60 MHz or 90 MHz.

We have tested the reflect efficiency which represents microwave transmission into absorption cell, and the curve is as below.

(a)



(b)

Figure 5. (a) H-component in the Waveguide by HFSS Simulating, (b) cavity reflect coeffient

From the test in figure 5, the profile of the cavity is very low, and the point of the coefficient is about 6.8 GHz. If using the cavity to design Rb atomic clock, small volume must be realized.

C. Design traditional Rb atomic clock

While the cavity was made, we have developed a miniature Rb atomic clock which is compatible with OCXO in aspect of size and pin definition。In the miniature Rb atomic clock, the cavity is heated among with OCXO, the lamp is reduced correspondingly, and final demission is just 51×51× 25 cubic millimeters. Finally, the clock is one of smallest traditional cell Rb atomic clock. The cell is made by classic procession, and the power dissipation is still big. We have tested the specification parameters of the clock [6].

D. Trying in Chi-Scale Atomic clock

Except Coherent Population Trap (CPT), another one chip-scale atomic clock has been made [7]. In that clock, its absorption cell is made by MEMS procession, and the size of the cell is just several cubic millimeters. Especially, the microwave signal is directly coupled by a circle ring loop. According to the above stripe line theory and our reforming design, the high coupling efficiency will be realized. The relative try is doing in spaceon.

IV. CONCLUTIONS

Basing stripe line coupler theory, a novel waveguide cavity has been designed where the balance between low size and high performance is realized. By this cavity design, we have firstly developed a smallest miniature Rb atomic clock which can be used to compatible with OCXO; and give an idea to develop a chip-scale atomic clock.

ACKNOWLEDGMENT

The work relative to this paper got helps from our colleagues. Wang Wenjun helped us in HFSS simulation; An Fangfan tested the miniature Rb atomic clock. Importantly, Quartzlock Company has paid many efforts to expand the international market for this clock.

***Abstract*—recently we propose a lin⊥lin quasi-bichromatic laser scheme and experimentally realized the device. Through modulating two Vertical-Cavity Surface-Emitting Lasers (VCSELs) with same microwave and mutually injecting between two VCSELs, a lin⊥lin quasi-bichromatic laser with the 90% laser power on the two wanted frequency components is obtained. With the laser source the high quality CPT signal has been obtained. We also introduce the scheme which is promising to provide a lin ⊥ lin quasi-bichromatic laser source for the miniature CPT atomic clock.**

Keywords— Coherent Population Trapping; Atomic Clock; Vertical-Cavity Surface-Emitting Laser.

I. INTRODUCTION

The chip scale atomic clock (CSAC) based on coherent population trapping (CPT) has been widely studied[1-5], and has been applied in Global Position System (GPS), mobile communication, geodetic surveying and so on.

In the prevail CPT atomic clock, a Vertical-Cavity Surface-Emitting Laser (VCSEL) driven by a microwave modulated dc provides a lineally polarized multichromatic laser beam, which is turned with a quarter waveplate into a circularly polarized one to interact with atoms. Though the scheme suits for the miniature atomic clock it causes two main disadvantages: certain atoms are pumped into the leaky trap state[6, 7] thus make no contribution to CPT resonance, and except the two wanted frequency components the others contribute to background noise rather than CPT resonance.

Different schemes have been proposed and studied, among them the lin⊥lin bichromatic laser, which has no unwanted frequency components and eliminates the leaky trap state atoms, is a promising one. However, presently laboratory realized lin⊥lin bichromatic lasers, based on optical phase-locked loop (OPLL)[8], acoustic optic modulator (AOM)[9] and electro optic modulator (EOM)[10] etc are all with large volume and high power consumption, thus all of these setups are not suitable for the practical package atomic clock, not to speak for CSAC.

Previously we have presented a lin⊥lin quasi-bichromatic laser scheme based on master-slave injection locked VCSELs[11]. With this laser source, a very high contrast has been achieved, and the two disadvantages mentioned above can be both eliminated. Same as in [6], we define contrast as CPT signal amplitude divide by the amplitude of background light signal. However, an optical isolator used in this experiment setup makes the light source still too large to apply in a practical package atomic clock. In this paper we present our proposed mutually injection locking lin⊥lin quasi-bichromatic laser scheme and our experimental result.

This work is supported by the National Natural Science Foundation of China (NSFC) under Grant No. 11204351.

II. METHODS

The configuration of the mutually injection frequency locking lin⊥lin quasi-bichromatic laser source is depicted in Fig. 1. A 6.834GHz microwave generated by the microwave source (Agilent E8257D) is split with a power splitter (Mini-Circuits ZX10-2-71), and each the split microwave is mixed with a dc through a Bias-T. Driven by the mixed currents, both VCSELs emit multichromatic lasers with frequency distribution as that in Fig. 2.

The two orthogonal linearly polarized laser beams are combined at a polarized beam splitter (PBS) to form a lin⊥lin beam. A partial reflector reflects certain laser of each linearly polarized beam, while as the reflected beams go through the quarter waveplate twice their polarization directions are both rotated by 90 degree. Therefore, each the reflected beam goes through the PBS and injects into the other VCSEL. When there are the same frequency components between the two VCSELs' outputs, there appears injection frequency locking effect and the two VCSELs' output could be mutually frequency injection locked to each other.

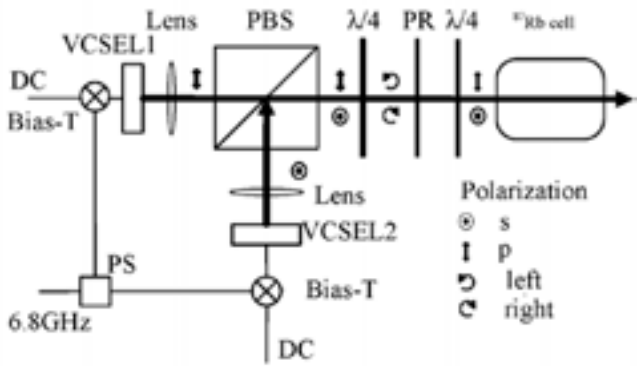

Fig. 1. Experiment setup. PBS: polarized beam splitter, PS: power splitter, PR: partial reflector.

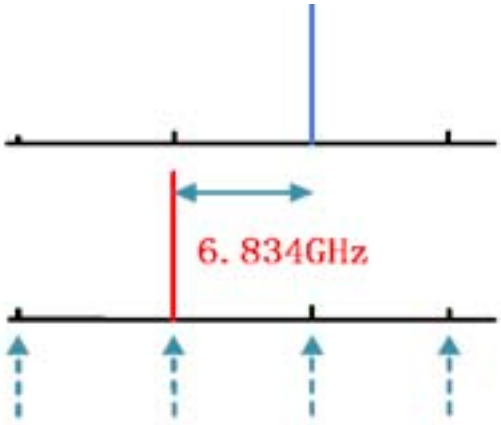

Fig. 2. Spectra of two VCSELs' outputs. The red and blue line denote the VCSELs' carriers respectively.

III. RESUALTS AND DISCUSSION

In the experiment, we used pretty weak microwave that the main power maintains in two carriers as that in Fig. 2. In order to mutually frequency lock as expected, we turned the driving current of one VCSEL to let the carrier of its output laser coincident with the first sideband of the other VCSEL's output as that in Fig. 2, and experimentally studied the mutual frequency injection locking effect[12]. With the spectral distributions of the two VCSELs's outputs are close to those of Fig. 2, and the injection ratio (defined as the laser power injected into the VCSEL divide by its output laser power), is about 0.5%, we recorded Fig. 3a, the spectrum of the mutually frequency injection locked lin⊥lin quasi-bichromatic laser, with a Fabry-Perot interferometer. From the spectrum we calculated out that the two wanted frequency components occupy about 90% of the total laser power. Under the same experimental condition, we have checked the control range by tuning wavelength of one VCSEL by changing its driving current and leaving the other VCSEL's driving current unchanged, and found that the locking range can reach 2 GHz.

It shall be mentioned that with this scheme, there will appear unwanted spectral modes from the cavity consisted of the VCSELs' high reflecting end faces when the injection is too strong. In our experiment setup, the optical length between the two VCSELs' end faces is 90 cm, therefore we recorded the cavity modes as that in Fig. 3(b) with mode spacing of 166 MHz when the injection ratio was 2.2%. According our experimental resualt, within 1% injection ratio, no obvious cavity mode was observed.

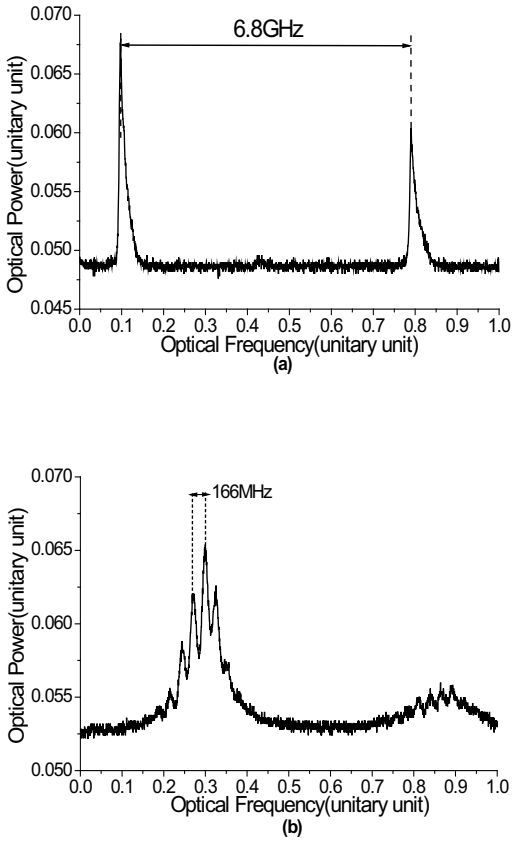

Fig. 3. The optical spectra recorded with a Fabry-Perot interferometer. The injection ratio is (a) 0.5% , (b) 2.2%.

With the experimental setup of our previous work [12], we have applied the realized lin⊥lin quasi-bichromatic laser beam to generate CPT resonance with ^{87}Rb, and obtained CPT resonance signal with contrast of 50%, while in prevail CPT atomic clock which is normally less than 5% [6].

Based on this study, we also propose a scheme as depicted in Fig. 4 for realizing a chip scale lin⊥lin quasi-bichromatic laser source. In the scheme two VCSELs are mounted on a basement such that the polarization directions of their output laser beams are orthogonal to each other, and with a birefringent crystal such as YVO4 the two laser beams are combined to form the lin⊥lin beam. With two VCSEL chips separated for less than one millimeter, according to the

refraction index a YVO4 with the thickness of less than 10 millimeter is enough to combine the two beam. Therefore, a lin ⊥lin quasi-bichromatic laser device could be integrated with about 1 cm^3. It is promising to apply this miniature laser device in the package CPT atomic clock, even CSAC.

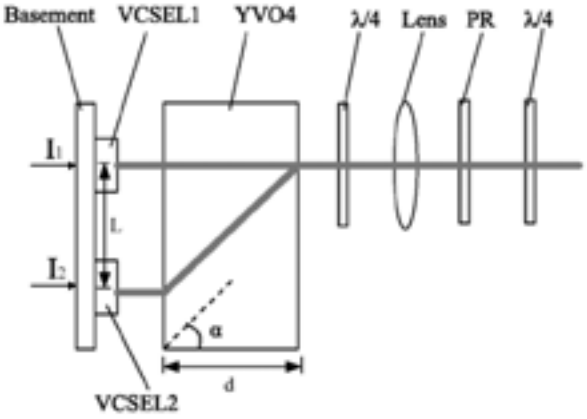

Fig. 4. The chip scale lin ⊥ lin quasi-bichromatic laser beam generator scheme.

IV. CONCLUSION

We have proposed and experimentally studied a lin⊥lin quasi-bichromatic laser beam generator scheme, and have applied the realized laser beam to obtained high quality CPT resonance signal. Based on this laser scheme, we have also proposed a miniature lin⊥lin quasi-bichromatic laser beam generator scheme, which is promising to be applied in the package CPT atomic clock even in CSAC.

***Abstract*—We have detected and analysed interesting features of sub-Doppler resonances, which are induced in absorption of the weak monochromatic probe light beam (with the scanned frequency) by the counterpropagating two-frequency pumping radiation implementing the phenomenon of the coherent population trapping (CPT) on resonant Λ-systems of atomic levels. Our experimental investigations have been carried out on example of spectral components of the Doppler broadened D_2 line of cesium atoms. Obtained results may be used for optimization of laser frequencies stabilization on atomic transitions.**

Keywords- Sub-doppler resonance, Coherent population trapping, Laser frequency stabilization.

I. INTRODUCTION

The phenomenon of the coherent population trapping (CPT is the basis of a number of important applications: ultrahigh resolution spectroscopy, atomic clocks, magnetometers, coherent population transfer among quantum states of atoms (or molecules) and also in some others described, for example in reviews [1-3]. In particular, narrow CPT resonances are detected in absorption of a two-frequency laser radiation on three level atomic Λ-systems and also in the corresponding induced fluorescence spectrum of a gas medium. Such a resonance excitation of atoms on the Λ-system scheme is realized by means of light induced optical transitions $|1> - |3>$ and $|2> - |3>$ from long-lived levels $|1>$ and $|2>$ to the excited state $|3>$. Most given Λ-systems are not closed because of possible channels of a radiative decay of the upper state $|3>$ on "exit" quantum states, which don't interact with the resonance laser radiation [4,5]. Let us consider interaction of a nonclosed Λ-system with 2 monochromatic laser fields. Frequencies ω_1 and ω_2 of given fields are close to centers Ω_{31} and Ω_{32} of electrodipole transitions $|1> - |3>$ and $|2> - |3>$ respectively. Populations of lower levels $|1>$ and $|2>$ will dwindle at intensification of this resonance two-frequency radiation because of the light induced repumping of atoms from these levels to "exit" states after the radiative decay of the opticaly excited level $|3>$. However sharp weakening of such a repumping process takes place in consequence of a strong decrease of a population of the upper state $|3>$ under the following CPT condition [1-3]:

$$|\delta_2 - \delta_1| \le W, \qquad (1)$$

where $\delta_1=(\omega_1 - \Omega_{31})$ and $\delta_2=(\omega_2 - \Omega_{32})$ are detunings of laser frequencies. The characteristic width W of the CPT resonance in Eq.(1) is determined by intensities of laser fields and by relaxation rates of populations and coherence of lower quantum states $|1>$ and $|2>$. Under definite conditions, the value W may be much less than homogeneous widths of spectral lines of optical transitions $|1> - |3>$ and $|2> - |3>$. The population of such a nonclosed Λ-system almost completely vanishes at sufficiently intensive optical pumping at a violation of the Eq. (1). However, according to the theoretical work [6], lower long-lived levels of an open Λ-system may keep about half of the equilibrium population of an initial noncoherent molecular ensemble at the exact CPT condition $\delta_1=\delta_2$ even in the case of such strong pumping. Thus narrow high-contrast CPT peaks will arise in populations of long-lived levels $|1>$ and $|2>$ of a nonclosed Λ-system versus the detuning difference $(\delta_2 - \delta_1)$.

Recently we have carried out experimental research of such CPT resonances for nonclosed three level Λ-systems formed by spectral components of the Doppler broadened D_2 line of cesium atoms [7,8]. Given CPT resonances were detected in absorption of the probe monochromatic light beam under

action of the counterpropagating two-frequency pumping radiation. In the recent work [8] we use only one diode laser, which generates the monochromatic beam with the stabilized frequency ω_1. The second coherent radiation component (with the frequency ω_2) was obtained from this initial beam by the electro-optical modulator (EOM). The frequency difference ($\omega_1 - \omega_2$) were smoothly scanned around the microwave interval (9192.6 MHz) between hyperfine sublevels of the Cs ground term (Fig.1). In particular we have established that, at definite conditions, CPT resonances in transmission of the weak probe beam may have not only more contrast but also are essentially narrower in comparison with well-known CPT resonances in transmission of the corresponding two-frequency pumping radiation (or the light induced fluorescence of the gas medium) [8].

Unlike our previous works [7,8], now we will analyze features of sub-Doppler resonances in absorption of the weak probe beam (with the scanned frequency ω_1) counterpropagating with respect to the bichromatic pumping radiation with various fixed frequency differences ($\omega_1 - \omega_2$) near the CPT condition (1).

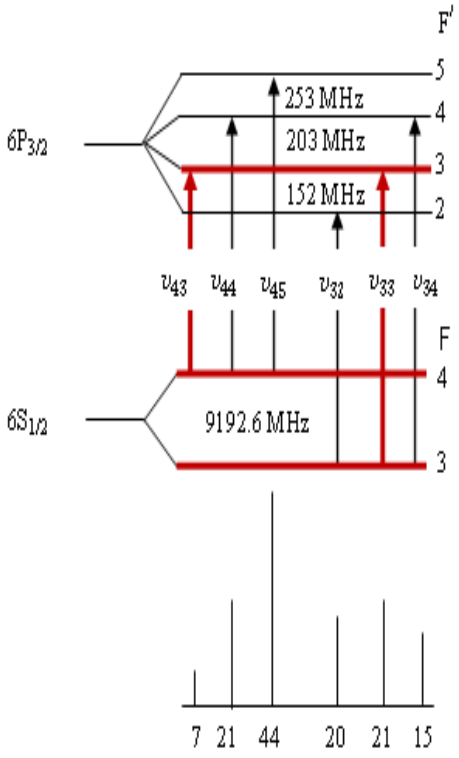

Fig. 1. Energy level scheme of the ^{133}Cs D_2 line. The relative oscillator strengths of lines, representing hyperfine transitions, are given on the bottom of the figure. CPT resonances are formed in the following 2 Λ-systems of this scheme: $6S_{1/2}(F=3) - 6P_{3/2}(F'=3) - 6S_{1/2}(F=4)$ and $6S_{1/2}(F=3) - 6P_{3/2}(F'=4) - 6S_{1/2}(F=4)$.

II. EXPERIMENTAL METHOD AND SETUP

Our experimental configuration is shown in Fig 2. The output of the external cavity diode laser (ECDL) with the frequency ω_1 was phase modulated at the ^{133}Cs hyperfine frequency 9192.6 MHz by an electro-optical modulator (EOM). The bichromatic pumping beam (with frequencies ω_1 and ω_2), which was indicated by the red color in Fig. 2, was collimated to the diameter D_{pump} = 5 mm, linearly polarized by the polarizer (P_1) and then sent to the quartz cell, containing the rarefied Cs vapor (without any buffer gas) at the sufficiently low pressure about 0.1 mPa ($3x10^{10}$ atom/cm^3). The monochromatic probe beam, which was the diameter of 1.8 mm and indicated by the green color in Fig 3., had the same parallel linear polarization after the polarizer (P_2) and propagated through the given Cs cell in the opposite direction. Both two-frequency pumping and monochromatic probe beams were overlapped in the irradiated Cs cell which was 3 cm length and diameter 2.5 cm. The cylindrical quartz Cs cell was kept at the room temperature of 22 ºC without temperature stabilization. No external magnetic field was applied on the Cs cell that was magnetically shielded. During the experiment the intensity of the monochromatic probe beam was kept constant at the sufficiently low value about 0.01 mW/cm^2 and in fact did not induce saturation and optical pumping effects in the Cs vapor. For recording of sub-Doppler resonances on different hyperfine spectral components of the Cs D_2 line (Fig.1), the laser frequency was stabilized on the transmission resonance of Fabry-perot interferometer (FPI). To avoid the amplitude fluctations of laser frequency, the FPI was modulated. Sub-Doppler resonances were recorded by using the chopper and lock-in amplifier.

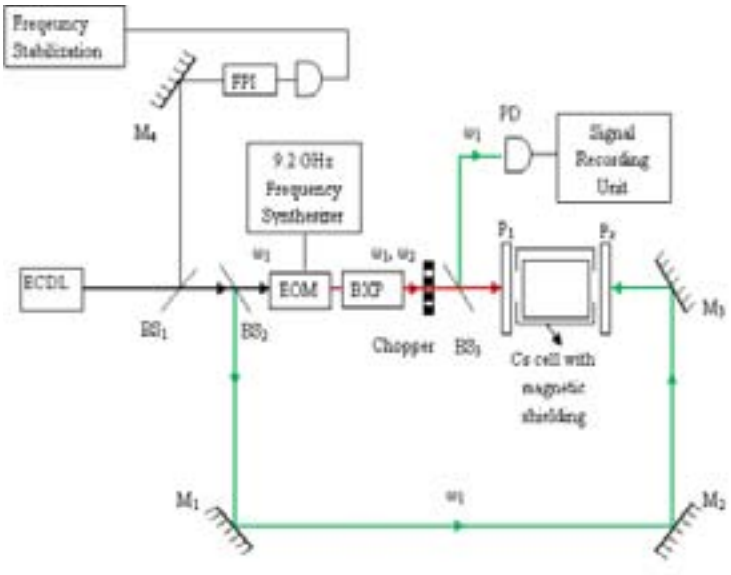

Fig. 2. Scheme of the experimental setup, which includes external cavity diode laser (ECDL), Fabry-perot interferometer (FPI), electro-optical modulator (EOM), beam splitter (BS_1, BS_2, BS_3), beam expander (BXP), mirrors (M_1, M_2, M_3, M_4), polarizers (P_1, P_2), photodiode (PD), and the Cs cell with the magnetic shielding.

III. DISCUSSION OF RESULTS

We investigated the sufficiently rarefied natural Cs vapor (without any buffer gas) where interatomic collisions were negligible. Homogeneous widths of resonance optical lines were much less than their corresponding Doppler broadening under conditions of our experiment. Then, according to the level scheme of the Doppler broadened Cs D_2 line (Fig.1), the component of the laser pumping beam with the frequency ω_1 effectively interacts with 3 various groups of atoms, whose velocity projections (along the wave vector k of this beam) are close to following values [9]:

$$V_{32} = \frac{(\omega_1 - \nu_{32})}{|k|},\ V_{33} = \frac{(\omega_1 - \nu_{33})}{|k|},\ V_{34} = \frac{(\omega_1 - \nu_{34})}{|k|}. \qquad (2)$$

We note, that narrow CPT resonances in absorption of the two-frequency pumping are formed in 2 different Λ-systems $6S_{1/2}(F=3) - 6P_{3/2}(F'=3) - 6S_{1/2}(F=4)$ and $6S_{1/2}(F=3) - 6P_{3/2}(F'=4) - 6S_{1/2}(F=4)$ (Fig.2), which correspond to atomic velocity projections V_{33} and V_{34} in Eq. (2).

The counterpropagating probe beam with the frequency ω_1 also will interact with 3 various groups of atoms whose velocity projections have opposite sign with respect to corresponding values in formulas (2). Thus 6 sub-Doppler resonances should appear in absorption of the probe beam with centers on following values of the scanned frequency ω_1: ν_{32}, ν_{33}, ν_{34}, $0.5(\nu_{32}+\nu_{33})$, $0.5(\nu_{32}+\nu_{34})$, $0.5(\nu_{33}+\nu_{34})$, in the interval between ν_{32} and ν_{34}. Fig. 3 demonstrates given saturated absorption resonances at various fixed frequency detunings $|\delta_1 - \delta_2|$ from the CPT condition (1). These detunings $|\delta_1 - \delta_2|$ are much less than the natural width γ (about 5 MHz) of the optical Cs D_2 line, however are more than the characteristic width W of the CPT resonance (1) for curves 2 and 3 in Fig.3. The curve 1 in this figure 3 corresponds to the exact CPT condition $\delta_1=\delta_2$.

The CPT phenomenon may essentially effect on the optical pumping process, which directly determines structure of saturated absorption resonances in the probe beam. Thus we directly see in Fig.3, that even small deviations $W \leq |\delta_2 - \delta_1| << \gamma$ from the equality $\delta_1=\delta_2$ lead to changes of indicated sub-Doppler resonances with the exception of the resonance with the center $\omega_1=\nu_{32}$. Indeed, the second component of the pumping radiation with the frequency ω_2 can not effect on this resonance because the dipole transition $6S_{1/2}(F=4) - 6P_{3/2}(F'=2)$ is forbidden and the CPT phenomenon are not realized on the corresponding Λ-system $6S_{1/2}(F=3) - 6P_{3/2}(F'=2) - 6S_{1/2}(F=4)$ (Fig.1). At the same time CPT leads to noticeable decrease of saturated absorption resonances with centers on frequencies $0.5(\nu_{32}+\nu_{33})$, ν_{33} and ν_{34} (Fig.3) because of the weakening of the repumping process from lower long-lived levels of corresponding Λ-systems at the CPT condition (1). However, unlike this usual situation, CPT leads to increase of the amplitude of the crossover resonance with the center $0.5(\nu_{33}+\nu_{34})$. Such nontrivial result may be caused by specific light induced redistribution of atomic populations

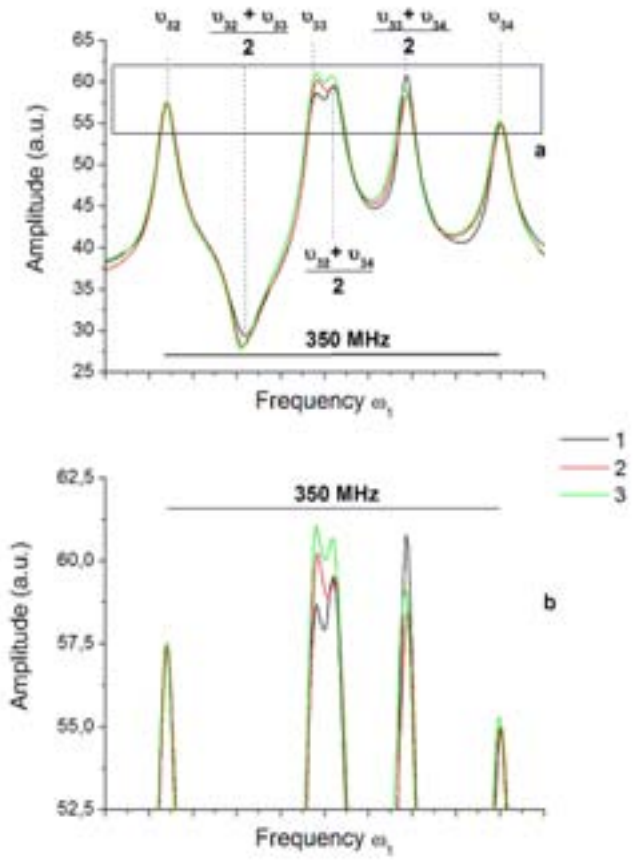

Fig. 3. Saturated absorption spectra of the probe beam versus its frequency ω_1 at the pumping intensity 7,64 mW/cm^2 and probe intensity 0.01 mW/cm^2 with corresponding beam diameters D_{pump} = 5 mm and D_{probe} = 1.8 mm for various fixed frequency detunings from the CPT condition $|\delta_1 - \delta_2|$= 0 (curve 1), 0.5 MHz (curve 2), and 1 MHz (curve 3). Figure 3b is the enlarged fragment of figure 3a enclosed in the rectangle.

between Zeeman sublevels of the ground Cs term (Fig.1) under action of the bichromatic pumping radiation.

Analyzed features of saturated absorption sub-Doppler resonances at the CPT phenomenon may be used for optimization of laser frequencies stabilization on corresponding atomic transitions.

***Abstract*— The possibility to generate simultaneously Surface Acoustic Wave (SAW) and Waveguiding layer acoustic wave (WLAW) in layered structures AlN/ZnO/Silicon was investigated. A delay line operating at 525 MHz was tested versus temperature in air and in contact with liquid. Experimental characterizations were also supported by modeling using the commercial software (COMSOL Multiphysics). The full delay line was simulated and liquid modeled by an additional layer on the top of AlN film.**

Keywords- AlN; packageless; silicon; temperature sensor; ZnO

I. INTRODUCTION

Devices based on wave guiding layer acoustic waves (WLAW) present a great interest in sensor application due to packageless structure, the possibility of extreme miniaturization and reduced sensibility to chemical environment. To generate isolated waves, the structures combining layers with low and high impedance in Bragg mirror configuration (ILAW-Isolated Layer Acoustic Wave) or acoustic confinement of the wave in a low-acoustic-velocity layer between two high-acoustic-velocity materials were used [1]. There are several requirements for the guiding layer: to be highly oriented and to have low surface roughness to ensure a good wave transmission and to avoid the increase of the acoustic propagation losses [2-4]. The isolated layer can be dielectric, piezoelectric or metallic and has to be stress- and crack-free and relatively thick for the confinement of the wave. Electro-acoustic properties of isolated wave, such as propagation velocity and electromechanical coupling are highly dependent on the nature, thickness and geometrical configuration of the materials composing WLAW device.

To this date, few studies have been reported in the literature on this type of structure [1, 5-7]. The successful confinement of WLAW in structures based on SiO_2 guiding layer was reported by Zhgoon et al. [1, 7]. However, more efforts need to be done to increase the coupling coefficient of such structures. Due to its low acoustic velocity and its high electromechanical coupling, zinc oxide was one of most promising material for the guiding layer. Our previous works have shown theoretically and experimentally, the possibility to generate Waveguiding layer acoustic wave in layered structures AlN/ZnO/diamond [8]. Such structures are of great interest because of their potential applications as packageless resonators, filters or sensors, based on WLAW, and as thermally compensated gas or liquid sensors, based on the combination of both SAW and WLAW. Because of its high acoustic velocity, the diamond appears to be the most suitable substrate for the production of containment structures for WLAW wave type, but it has major drawbacks including its high price and its poor compatibility with CMOS technology. In addition, the diamond growth occurs at high temperatures (700 °C - 1000 °C) inducing significant stress in the heterostructure. Therefore heterostructures with diamond are unsuitable for mass production.

The aim of this work is to evidence the potential of the AlN/ZnO/Silicon structure as low cost, CMOS compatible and packageless temperature sensor able to operate in harsh environments. Theoretical investigation was realized by using a finite element method (FEM) in order to define the best configuration and the optimized thicknesses of different layers. To achieve efficient confinement of WLAW, AlN layer was deposited on operating SAW device (IDT/ZnO/Si). The frequency response and thickness of AlN were monitored in real-time and during AlN film deposition. The second part of this paper is devoted to the experimental realization of the heterostructure with a comparison of results obtained by the simulation.

II. THEORITICAL DETAILS

Theoretical investigation was realized by a finite element method (FEM) using COMSOL Multiphysics [9]. The full delay line was simulated and liquid was modeled by an additional layer on the top of the AlN film.

$kh_{ZnO} = 1.25$ has been chosen i.e. (λ = 10 µm, thickness (ZnO) = 2 µm, thickness (AlN) > 20 µm).

The materials are described by their physical constants (elastic, piezoelectric, dielectric...), reported in literature [10-12].

The confinement of the wave was demonstrated by analyzing the field distribution of the wave in the structure notably the acoustic wave displacement profile.

III. Experimental Setup

2 µm thick ZnO films were deposited on Si (100) by rf magnetron sputtering. The pressure in the chamber was 0.002 mbar (1:1 of Ar: O_2) and the power injected in the plasma was 100 W. The distance target-substrate was fixed at 80 mm and the substrate temperature was 450°C. Then IDT were fabricated on ZnO/Si surface by using Aluminum sputtering followed by photolithography and wet etching processes. The number of IDT fingers, the aperture width (W) and the gap were set to 40, 0.4 mm and 200 µm, respectively. Finally, 30 µm of AlN were deposited on IDT/ZnO/Si by rf magnetron sputtering. AlN deposition process was optimized to avoid the AlN film cracking even in the case of thick layer. Following our experience, the key consists in working at relatively low deposition temperature (343 K). To perform electrical characterization, vacuum tight rf connectors were installed in the magnetron vacuum chamber. During AlN layer deposition, in-situ measurements of frequency and insertion losses of different modes were performed by a network analyzer (Agilent N5230A) and AlN thickness was monitored by interferential reflectometry method.

IV. Results and Discussion

1D-curves and 2D representation of modeling results for the particles displacement in AlN/ZnO/Si hétérostructure obtained for 2 µm and 12 µm of AlN thickness are shown in Fig.1 (a) and (b). The AlN thickness influences the confinement of the wave. Indeed, one can clearly observe that with 2 µm of AlN, the displacement of particles was reduced at the surface that corresponds to 30 % of confinement, at 12 µm of AlN zero displacement of particle was observed resulting in a total confinement of the wave. The addition of liquid on top of the AlN film in modeling induces no serious change in transmission signal that proves theoretically the confinement of the wave (Fig. 1(c)). The evolution of frequency response in transmission mode (S_{21}), obtained experimentally, related to the 0th, 1st and 2nd mode of acoustic wave, with AlN layer thickness is shown in Fig. 4. Before AlN deposition, only the 1st mode was observed due to the low electromechanical coupling of the other mode. At 12 µm of AlN thickness, the mode 1 starts to confine and the surface acoustic wave of 2nd mode appears. Frequency-Temperature characteristic shows a

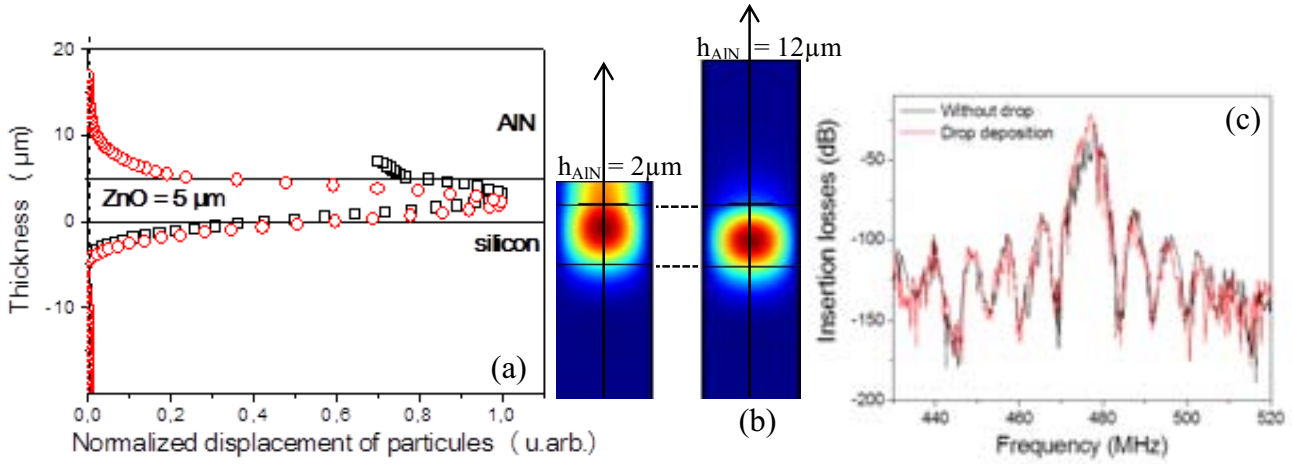

Fig.1: (a) 1D-curves and (b) 2D representation of modeling of the displacement of particles in AlN/ZnO/Si heterostructure obtained for 2µm and 12µm of AlN thickness. (c) Transmission signal of a delay-line obtained by modeling in air and with water over-layer.

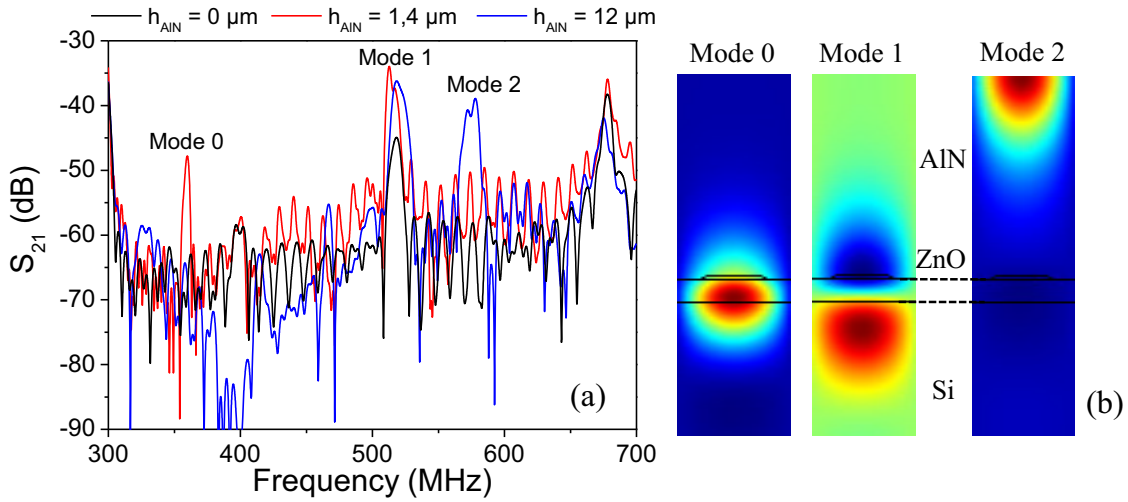

Fig. 2: (a) SAW signal (S_{21}) before and after deposition of AlN with the thickness of 1.4 and 12µm for the heterostructure AlN / ZnO / Si where kh_{ZnO} = 1.25. (b) 2D representation of modeling results for particle displacement in AlN/ZnO/Si hétérostructure obtained for 12 µm of AlN thickness for the mode 0, 1 and 2.

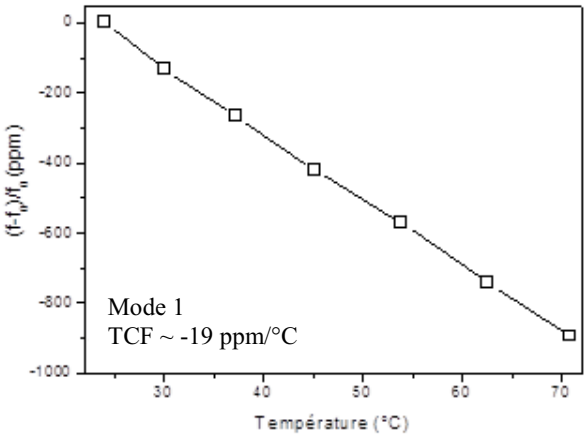

Fig 3: Relative velocity variation with temperature of AlN/ZnO/Si structure.

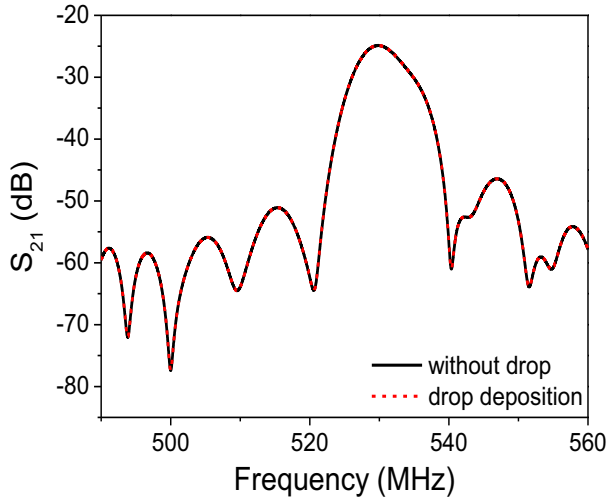

Fig. 4: Experimental test of the wave's confinement with addition of a water micro drop on the gap between the IDTs of the device.

very good linearity and a TCF value of -19 ppm/°C in air and in contact with liquid (Fig. 3). One can also observe that there is no change in transmission responses (S_{21}) collected in both conditions (Fig. 4). These results prove the total confinement of the wave in the AlN/IDT/ZnO/Si structure. Note that a Rayleigh wave on open surface is partially or completely attenuated. This study confirmed the feasibility of the AlN/IDT/ ZnO/Si structure as a packageless sensor sensitive to temperature with the ability to protect itself.

V. Conclusion

The ability to generate in the same heterostructure three propagation modes 0, 1 and 2 of the acoustic wave, the confinement of the wave in the structure and good compatibility of the results obtained in simulation to experiment have been demonstrated. The characterization of the temperature behavior of the optimized heterostructure (kh_{ZnO} = 1.25), showed its potential as a temperature sensor. The measured TCF value is - 19.1 ppm/°C. Finally the effective acoustic isolation of the wave within the heterostructure AlN / IDT / ZnO / Si has been demonstrated experimentally. Thus, this study allowed us to confirm the potential of the heterostructure AlN/IDT/ZnO/Si as the temperature sensitive device, having the ability to protect itself from air and moisture.

Abstract— **In this paper we analyze the effects of doping AlN films with vanadium and tantalum to concentrations up to 6% atomic. The structure and composition of the new compounds are assessed as a function of the dopant concentration by x-ray diffraction (XRD), IR reflectance and Rutherford backscattering spectrometry (RBS). Test devices consisting on bulk acoustic wave resonators are used to assess the piezoelectric activity of the compounds as well as other material properties, such as the acoustic velocities and the piezoelectric constant. Films doped with vanadium show an overall worsening of their main properties for acoustics applications. Films doped with tantalum show variations in their wurtzite crystal structure that suggests that an improvement of the piezoelectric activity can be achieved as long as films exhibiting good crystal quality and homogeneous dipole orientation can be grown.**

I. INTRODUCTION

Aluminum nitride (AlN) is the preferred piezoelectric material for a broad range of thin film devices and applications requiring piezoelectric actuation, such as resonators for telecommunications RF filters, sensors, or micro-electromechanical systems. Due to its good piezoelectric properties and chemical stability, AlN is especially appropriate for operating in moderately harsh environments, such as relatively high temperatures or corrosive media. However, the increasingly demanding applications require the development of new piezoelectric materials with improved properties.

Since Akiyama [1] reported a very strong variation of the piezoelectric coefficient d_{33} when scandium (Sc) atoms were introduced in wurtzite AlN films, new compound materials based on AlN films doped with different elements have been investigated in order to develop new materials with improved piezo-acoustic properties. The addition of some chemical elements to polycrystalline AlN films has been reported to cause the deformation of their wurtzite structure and, hence, of their physical properties, which makes them suitable for some applications, such as hard coatings or electroacoustic devices. Boron, chromium, manganese, copper or scandium are some of the elements investigated to date. Not all of them provide improved properties; for example, boron-doped AlN films exhibit smaller electromechanical coupling factors in electroacoustic devices due to a decrease of the piezoelectric coefficients [2,3]. However, it has been verified that the addition of scandium produces a significant increase of the overall piezoelectric activity of the Al:Sc:N alloy [1], although other parameters, such the acoustic losses or the sound velocity, worsen [4]. Manganese and copper turn AlN into a magnetic material, but we have not found data reporting on its piezoelectric behavior [5,6]. Chromium and AlN alloys have been extensively studied because Al:Cr:N films exhibit interesting magnetic properties [7]. Regarding the piezoelectric properties, AlN films containing 6% Cr atoms exhibit an increased lattice parameter accompanied by a rise in the d_{33} piezoelectric coefficient; in contrast, the stiffness and, therefore, the sound velocity, decreases [8,9]. In a previous paper [10] we showed that doping AlN with Ti increased the lattice parameters, but some inhomogeneities appeared for doping levels above 4% atomic. In all cases, the piezoelectric response and the sound velocity decreased and the dielectric constant rose with Ti content. It is important to note that, whatever the effect of the dopant in the crystalline structure of AlN, the doped films have to fulfill the essential requisite of exhibiting a definite preferred crystalline orientation with all the dipoles pointing to the same direction in order to achieve a good piezoelectric activity. This requires a careful study of the deposition conditions of the new compound, which includes the influence of the nature of the substrate, its preconditioning, and the deposition parameters, which may vary compared to those required to grow highly oriented AlN films.

In this communication we investigate the effects of adding different amounts of vanadium and tantalum in the physical properties of the doped AlN compounds. These are deposited by co-sputtering a double coaxial target in alternate current configuration under the conditions that guarantee the best pure AlN films achievable in our equipment, which do not necessarily provide the best performing doped films. We carry out the assessment of the structural and piezoelectric properties of the doped films through Rutherford backscattering spectrometry (RBS), infrared transmission, and X-ray diffraction measurements, and frequency response of bulk acoustic wave (BAW) test resonators.

II. EXPERIMENTAL

A. Film deposition

Al:M:N (M=V, Ta) 1.1 μm-thick piezoelectric films were deposited on 150 mm-Si (100) wafers covered with a simple

acoustic reflector for the BAW test resonators used to assess the piezoelectric activity of the films. The reflector was composed of three layers of thermal SiO_2, aluminum (as low acoustic impedance film), and molybdenum (as high acoustic impedance film); their thicknesses were adjusted to achieve a resonant frequency of 3 GHz. The simulated acoustic transmittance at the resonant frequency was around -18 dB, which allowed accurately assessing the electromechanical coupling factor (k^2). The 100 nm-thick (110)-oriented Mo top layer of the reflector acted as the bottom electrode of the test devices. All the films were deposited in an Endeavor-AT cluster tool from OEM Group equipped with dual-target S-gun magnetrons [11].

The S-gun consists of two ring-shaped targets (diameters of 178 and 280 mm) mounted concentrically on the same vertical axis. The inner target is made of Al and the outer of V or Ta. Each target has its own magnetic array with opposite polarities. An alternating current power of 40 kHz applied between the two targets creates a plasma discharge at the conical face of each target. The power fed to each target can be adjusted separately by a power splitter module. Due to this dual-target arrangement, where each target alternates as a cathode and an anode, the ac powered S-gun is free from parasitic arcing and disappearing anode effects. This target configuration allows obtaining films with non-uniform composition in the radial direction, which are useful to study the variations of the properties as a function of the dopant content. Before the deposition of the $Al_{0.5-x}M_xN_{0.5}$ films, the Mo bottom electrode was treated with low energy Ar ions either in a separate RF (13.56 MHz) etch module, producing a capacitively coupled plasma, or in the deposition module (in-situ etch). Deposition processes were performed either without external heating (T<300°C) or at elevated temperatures (up to 400°C) using an external IR heater before or during deposition.

B. Film characterization

The composition of the Al:M:N films was assessed by RBS measurements. Fig. 1 shows the RBS spectra of two representative $Al_{0.5-x}M_xN_{0.5}$/Mo/Al/Mo/SiO_2/Si stacks with AlN films doped either with V or with Ta. We assumed that the N content in the films was around 50% in all cases, which was confirmed by RBS measurements. The experimental RBS spectra were fitted using SIMNRA simulation program to obtain the composition of the doped AlN layer. According to the fitting, the V and the Ta content varied between 3% and 6% atomic. RBS measurements also allowed deriving the thickness of the films assuming that the mass density did not vary significantly in the range of variation of doping.

Infrared reflection was measured with a Fourier transform infrared (FTIR) Nicolet 5-PC spectrophotometer using non-polarized light with an incident angle of 30º in the 400 cm^{-1}-4000 cm^{-1} range with a spectral resolution of 2 cm^{-1}. These spectra provide information about the chemical bonding configuration of the films and allow deducing their composition after calibrating the position of the A1(LO) band around 880 cm^{-1} with the RBS data. In previous works we related the ratio of the amplitudes A1(LO)/E1(LO) measured in pure AlN films to the presence of non-c-axis-oriented grains, which were associated to microcrystals with different polar orientation [12, 13]. For the doped films this correlation also applies. The absorption bands were fitted with lorentzian curves to accurately determine their position, amplitude and width.

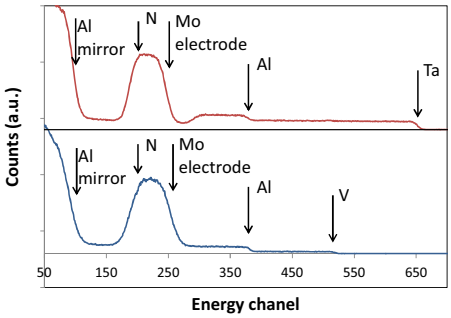

Figure 1. RBS spectra of AlVN and AlTaN representative films.

X-ray diffraction (XRD) patterns of the Al:M:N films were measured in conventional Bragg-Brentano geometry in a high intensity Supratech XPert MRD diffractometer between 2θ=10º and 2θ=80º using the Kα1,2 doublet of a β-filtered Cu anode radiation. Since all the samples were strongly c-axis oriented, the rocking curves (RC) around the (00·2) peak were also measured to assess the quality of the films through the value of their width at half maximum (FWHM).

The piezoelectric activity of the doped AlN films was assessed by measuring the electrical reflection coefficient (S_{11}) at frequencies ranging from 10 MHz to 10 GHz with an Agilent PNA N5230A network analyzer. The electrical impedance of the resonators, derived from S_{11}, was fitted with Mason's model to obtain accurate values of the material electromechanical coupling factor k_m^2. Due to the low value of the acoustic transmittance (-18 dB) the quality factor (Q) of the devices did not exceeded 20, which did not impede to achieve an accurate fitting of the impedance with frequency. Since the thickness of films, area of the resonator, dielectric constant (ε) and sound velocity (v_s) significantly influence the resonant frequency and the out-of-band response of the resonators, a careful assessment of all the geometrical dimensions of the devices was required to achieve accurate values of ε for each doped film. After the electrical characterization the thicknesses of the electrodes and the piezoelectric film were measured with a profilometer by patterning the AlN-doped films by wet etching in warm KOH using the top electrode as etching mask. The obtained values were in good agreement with those obtained from RBS measurements. The area of each device was also carefully measured with an optical microscope with accuracy better than 1% to overcome possible undercutting effects in the top electrode patterning. The method allows assessing the electro-acoustic properties of the doped-AlN films independently of the design of the test device.

III. Results and Discussion

A. Vanadium doped AlN films: AlVN

When part of the Al atoms in the AlN wurtzite structure are substituted by V atoms, the structure of the crystals changes as

a function of the V content. For low V contents the crystal structure remains being wurtzite, with slight changes in the lattice parameters. As the V content increases (above 7% atomic), the crystallinity is destroyed; the films turn from transparent to dark grey and become conductive and non-piezoelectric.

Figure 2 shows the XRD patterns of an Al:V:N layer along with that of a pure AlN film for comparison. The wurtzite structure characterized by a diffraction peak at 2θ=36º is clearly maintained in the doped layer but an additional peak at 2θ=37.52º appears. This suggests the formation of an additional phase, probably related with VN, which has the 111 XRD peak at that angle. The peaks labeled with an asterisk are the partially filtered Cuβ-components of the XRD tube.

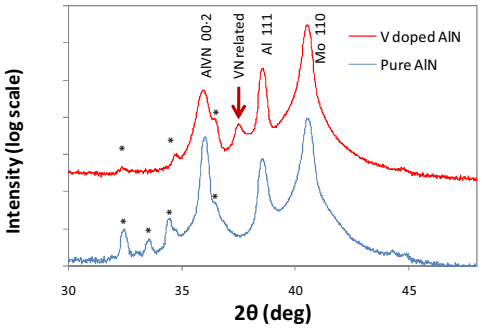

Figure 2. XRD pattern of (a) an AlVN film with a V content of 6.4% atomic and (b) a pure AlN film.

The c-parameter of the V-doped AlN films decreases from 5.02 A to 4.99 A in the composition range from 4.8% to 6.5% atomic, revealing is a very weak variation with the V content. This contrasts with the data from IR absorption that shows a shift of the LO mode to lower wavenumbers, which suggests an increase of the c-parameter of the wurtzite structure.

The electromechanical coupling factor, longitudinal acoustic velocity and dielectric constant are derived from the frequency response of the BAW devices. The best value of k_m^2 exhibited by the V-doped AlN films (2.5%) was achieved in the samples with the lowest V content (around 4.8% atomic); this value is far from the 6% routinely achieved in pure AlN films grown on identical structures. The acoustic velocity dropped from 11000 m·s^{-1} (corresponding to pure c-axis oriented AlN) to values below 9500 m·s^{-1}, as shown in figure 3.

In summary, doping AlN with V does not improve the material properties for electroacoustic devices in the range of doping studied. Both the acoustic velocity and the piezoelectric response decrease monotonously as the V content in the films increases; this is accompanied by an increase of more than 10% of the dielectric constant.

B. Tantalum doped AlN films: AlTaN

Figure 4 shows the XRD θ/2θ patterns AlN films doped with Ta contents ranging from 0% to 5% atomic. The angle of the 00·2 wurtzite reflection shifts towards lower values as the Ta content increases, which indicates an increase of the c lattice parameter.

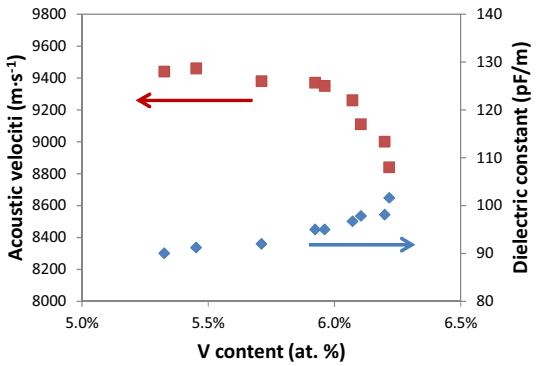

Figure 3. Acoustic velocity and dielectric constant as a function of the V content (atomic %)

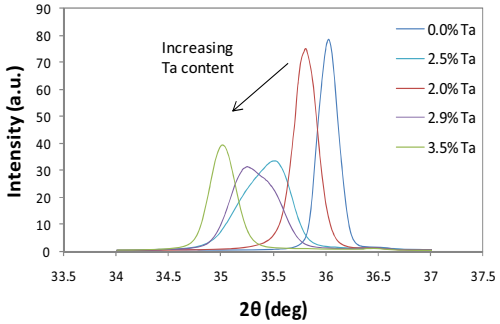

Figure 4. XRD pattern of AlTaN for various Ta contents.

It is worth noting that for intermediate Ta contents (3% and 3.2% at.) the XRD patterns show a double peak, which suggests the existence of two populations of grains with different crystal properties. This kind of inhomogeneity has also been observed in the electrical response of the test resonators that, aside from the expected main resonance around 2.8 GHz, also exhibit an additional peak at around 5 GHz, as figure 5 shows.

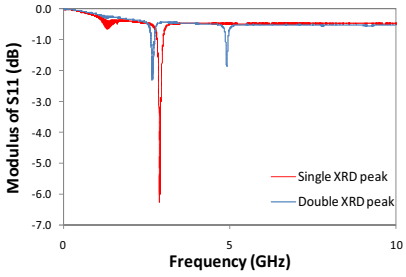

Figure 5. S11 vs frequency of two AlTaN films with and without double XRD 00·2 reflection.

The acoustic velocity and dielectric constant of the Ta-doped AlN films are represented in figure 6 as a function of the Ta content. Both tend to increase with the Ta content.

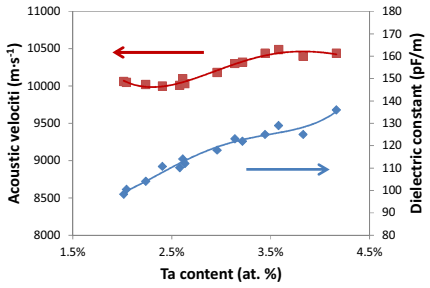

Figure 6. Acoustic velocity and dielectric constant as a functión of the Ta content (in atomic %)

Finally, the electromechanical coupling factor of Ta-doped AlN films drop dramatically from 6% to 0% as the Ta content increases. This reduction is accompanied by an significant increase of the ratio between the amplitudes of the E1(LO) and the A1(LO) modes that appear in the IR reflectance spectra, as shown in Figure 7. It has been reported in previous works [12,13] that this ratio increases significantly as the amount of grains with the c axis tilted with respect to the normal increases. This has been associated in turn to the presence of grains with opposite polarities, which accounts for the significant reduction of the piezoelectric activity.

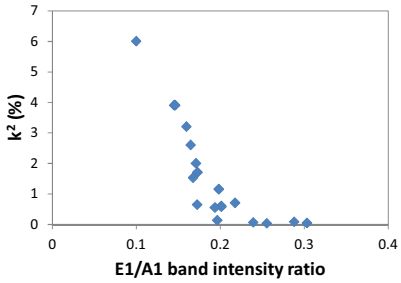

Figure 7. Electromechanical coupling factor as a function of intensity ratio of the E1(LO) and A1(LO) IR absorption bands

IV. Conclusions

We have investigated the influence of V and Ta doping on the properties of polycrystalline AlN sputtered films. In all V-doped films, new compounds with a different crystalline structure are observed. As the doping concentration increases, the relevant properties of the material for its use in electroacoustic devices worsen; the acoustic velocity and the coupling factor decrease, and the dielectric constant increases to 102 pF/m for doping levels around 6.2% atomic. At higher V contents the films become non-transparent and conductive. As for Ta doping, an increase of the *c* lattice parameter with the Ta content is observed, which suggests that an improved piezoelectric response could be achieved in this compound. However, this effect was not observed in BAW measurements that reveal, instead, a significant drop of the piezoelectric activity in most of the films. FTIR measurements reveal that this effect is very likely related to a poorly adjusted growth process (leading to grains with opposite polarities) more than to the effect of the Ta doping. Additionally, a lack of homogeneity in the crystal structure is observed at intermediate Ta content (2.5% to 3 % at.), where two kinds of compounds appear simultaneously in the films, giving rise to two resonances in BAW devices. As the Ta content increases, the sound velocity, after an initial drop, increases as well, but keeping always a value lower than that of pure AlN. The dielectric constant increases up to 140 pF/m with the Ta content. Despite the increase of the *c* lattice constant, the results so far do not allow drawing conclusions regarding the possible benefits of Ta doping. A significant improvement of the growth conditions is required in order to achieve films of better crystal quality that would allow assessing the actual effects of Ta doping.

***Abstract*—Dual layer piezoelectric transducer has been developed using an adhesive free process and characterized both experimentally and by FEM models. Our findings show an enhanced amplitude when both layers are used as a transceiver system for sufficiently large pulse width. The peak frequency obtained from Comsol modeling shows a good agreement with the experimental results.**

Keywords— Multilayer, PVDF, PEI, Ultrasonic measurements

I. Introduction

Piezo-electric transducers made from poly (vinylidenefluoride-co-trifluoroethylene) [P(VDF-TrFE)], are used in various nondestructive evaluation (NDE) and bio-medical imaging because of their broad band characteristics [1]-[5]. However, their mechanical coupling efficiency is relatively low compare to ceramic transducer. To overcome this drawback, multiple layer of piezoelectric copolymer transducer has been deployed to improve the overall performance. Conventionally, to fabricate multilayer polymer transducers from pre-polarized film, adhesive layers are used for increasing the number of layers, requiring a mechanically attaching process where the desired and a consistent thickness of each adhesive layer are difficult to achieve. Such condition, consequently, will cause a reduction of the overall acoustic response signal [4]. As far as we know, only one group has previously produced an adhesive-free multilayer transducer with few publications [5]. Therefore, there is a need for comparative evaluations on the modeling with experimental result to provide better understanding of such transducer physics, consequently improving in transducer designing. In this work, we have implemented an adhesive-free dual layer P(VDF-TrFE) ultrasonic transducer and compared our experimental results with numerical models.

II. Transducer Development and Characterization

In this section we will describe the transducer layout and the electrode structure which are common for the experimental and numerical investigations.

The proposed dual layer piezoelectric transducer was produced from two layers of P(VDF-TrFE) films (thickness 20 μm each) with intermediate conductive electrodes with thicknesses around 1 μm. The layered structure which we will refer to as a stack, are sitting on the top Polyethylenimine (PEI) backing substrate with thickness around 850 μm as shown by the schematic drawing in Fig. 1 (a). As illustrated in this figure, the acoustic wave generated by the piezoelectric film will travel down into the PEI substrate and become totally reflected when reaching the PEI/air interface. This first reflection is then detected and converted to electric signal (so-called 1st acoustic response signal) by the same piezoelectric film. To generate the wide band acoustical wave, the piezoelectric film was excited by an ultra-wide band (UWB) signal described by the 1st derivative of the Gaussian pulse expressed as

$$V(t) = \left[\frac{t - t_0}{\sigma}\right] e^{-\frac{(t-t_0)^2}{2\sigma^2}} \quad (1)$$

In this equation t_0 will be the pulse firing time while σ is the pulse width of the Gaussian distribution.

To evaluate the response from the transducer, two different modes were investigated. First, we consider sending and receiving from only a single layer (i.e. upper or lower) which we will refer to as the single layer modus. For example, if the

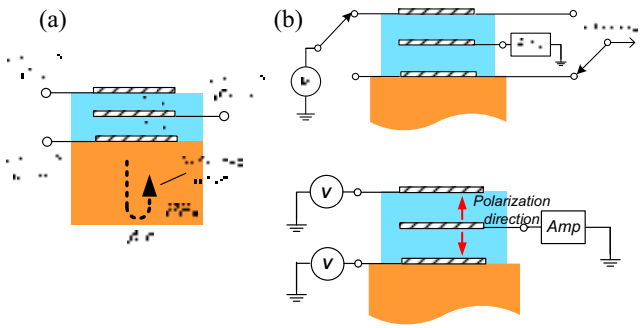

Fig. 1 Schematic drawing of transducer layout (a) and transducer evaluation mode (b).

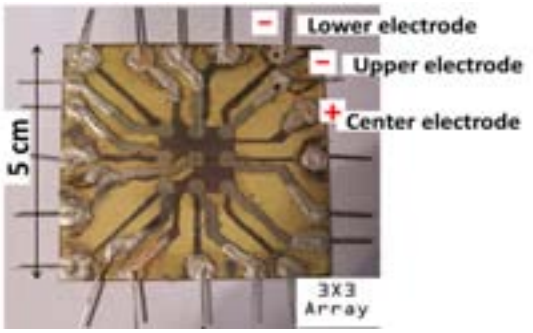

Fig. 2 Image of the prototype transducer.

upper layer is excited in single layer modus, the upper electrode will be driven by the potential given by Eq. (1), while the current is collected on the middle electrode as shown in Fig. 1(b) (Top). The lower electrode is left floating, to minimize the influence from layer that is not active.

For the second mode that we will denote as the dual layer modus, both the upper and lower electrodes are driven with the same UWB potential, while the current is detected by the middle electrode as shown in Fig 1(b) (Bottom). A number of different pulse widths σ were used in the investigation, ranging from 3.6 ns to 15 ns with a pulse amplitude of 5 Vp-p.

A. Transducer implementation

For the transducers, the P(VDF-TrFE) film was made from the fluid phase by mixing P(VDF-TrFE) powder (77:23) (in molar ration) with an appropriate amount of solvent. This solution was mixed with an ultrasonic disperser to obtain a complete dissolving of the powder**.** For the transducer conductive layer, inkjet-printable silver (Ag) ink from Sigma Aldrich was employed. The fabrication was initiated by preparing a PEI substrate with size of 5 × 5 cm. A layer of Ag ink acting as the lower electrode, was then deposited on the PEI surface by spin coating and sintered at 130 ℃ for 2 hours. The electrode was then patterned by wet chemical etching to obtain the desired electrode diameter (3 mm). The 1st layer of P(VDF-TrFE) solution was spin coated onto of the patterned electrode and degassed in 1 mbar vacuum atmosphere to vaporize the solvent. After that the sample was annealed at a temperature of 130 ℃ for 2 hours. The previous mentioned processes were then repeated to make the middle electrode, the upper P(VDF-TrFE), and the upper electrode. Then in the final step, electrical connection out of the transducer are made easy by connecting pins to the transducer edge by conductive epoxy. An image of a complete is shown in Fig. 2.

To make the P(VDF-TrFE) films piezoelectric, the sensors were polarized by applying a DC high voltage (1580 KV) between the electrodes with sample heated temperature of 100 ℃. The voltage was kept constant for 30 mins after reducing the temperature to room temperature. Dual layer transducer was polarized in opposite direction to avoid the cancellation of the acoustical signal.

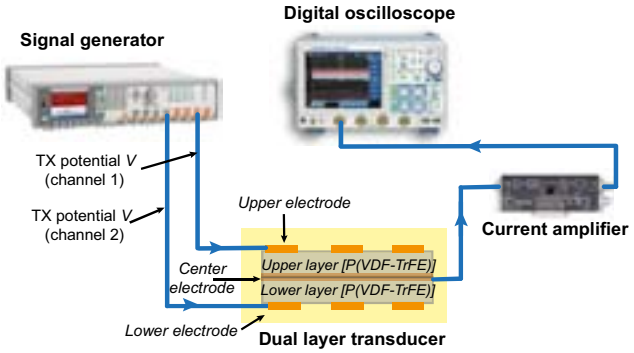

Fig. 3 Experimental setup for ultrasonic characterization.

B. Experimental Characterization

The acoustical characterization system consists of a two channel arbitrary wave generator (Agilent 81150A), a current amplifier (FEMTO DHPCA-100) and a digital oscilloscope (Yodogawa DLM 6054) as shown in Fig. 3. To generate the transmitted first derivative Gaussian signal, the time domain pulse function was specified in a Matlab program, and then uploaded on to the wave generator memory. The acoustic response signal from piezoelectric film was amplified by a low impedance current amplifier, which converts the current into output potential. Finally, this potential signal was sampled by oscilloscope capable of digitizing with up to 12-bit accuracy in high resolution.

C. Numerical Characterization

A two dimensional axisymmetric numerical simulation was developed as a time domain study in the commercial software Comsol Multiphysics. This software, which uses a Finite Element Method (FEM) to solve partial differential equations, has also previously been used to solve transducer models [6]. For our model, the elastic and piezoelectric materials are represented as linear plain strain models with loss factors 0.2 and 0.02 for PVDF and PEI, respectively, approximated by a Rayleigh damping model. A rectangular mesh with an appropriate size was chosen to solve the model. The material constant for PVDF, PEI and Silver was taken from the Comsol database and from Refs. 6 and 7.

III. Results and Discussion

In this section we have compared the experimental and numerical results, and focused on the first acoustic reflection from the backside of the PEI substrate, The acoustic response signal (ARS) from this reflection for excitation pulses with pulse widths σ=15 ns and 3.6 ns was obtained both in the experiment and in Comsol Multiphysics as shown in Fig.4. For the 15 ns pulse, the peak-to-peak voltage amplitude was found to be significant higher both in the expeiment [upper Fig. 4 (a)] and in the FEM model [upper Fig. 4(b)], when the transducer was operated in dual layer modus compared to single layer modus. However, for a 3.6 ns pulse, the opposite trend was observed as shown in the lower figures. These signals may also be transfered to the frequency domain using a Fourier transformation, yielding the responses shown in Fig. 5

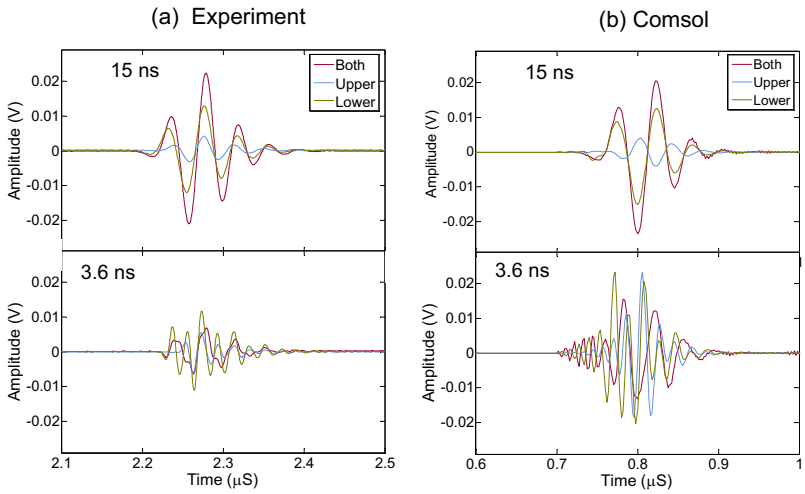

Fig. 4 The 1st acoustic response signal from experiment (a) and Comsol model (b) with pulse width 15 and 3.6 ns excitation.

(a) and (b). Here, both the experimental and numerical results yield maximum responses for the 15 ns pulse around 24 MHz. However, as the excitation pulse was shorten to 3.6 ns, the bandwidth was increased and the maximum response was splited up. The maximum response then occured around 27 MHz for the dual layer modus, and around 50 MHz for the single layer modus.

Variation in the peak-to-peak value for the ARS amplitude as a function of the pulse width was compared in Fig. 6 (a) for the experimental and numerical results. Here, we observed that the peak-to-peak amplitude obtained from the Comsol modeling was significantly higher than for the experimental results. However, both results showed similar trend in terms of the rise and fall of the ARS amplitude. Possible reasons for the observed amplitude variation can be differences in the used damping parameter of P(VDF-TrFE) and/or variation in the area of the active element for the experiment and numerical model. Moreover, a systematic study for many pulse widths has shown that the dual modus obtain the highest response for $\sigma \gtrsim 8$ ns. This behavior is most likely due to the differences in resonance frequency of the single and dual layer systems, suggesting a dual layer response frequency at around 50% of the single layer value. The estimated resonance frequencies of P(VDF-TrFE) films with thicknesses 20 and 40 μm are 15 and 30 MHz, respectively (assumng a $\lambda/4$ resonance due to rigidity of the material PEI compare to air and epoxy backing [2,3]). The speed of sound in P(VDF-TrFE) was taken as 2400 m/s in the estimate [2]. For our case, we observe that maximum amplitude of ARS for the dual layer modus was around 26 MHz and 50 MHz for the single layer modus. This indicates that the single and dual layer resonances of the developed transducer are significantly higher than $\lambda/4$, in fact closer to $\lambda/2$ resonance modes.

The variation of peak frequency of the ARS as a function of the pulse width was compared in Fig. 6 (b) for both experimental and numerical operation modes. Here, we

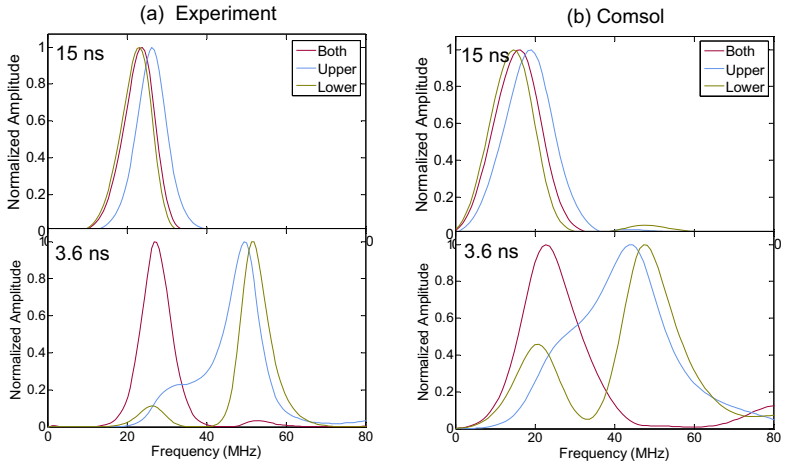

Fig. 5 Corresponding FFT of ARS from experiment (a) and Comsol model (b) with pulse width 15 and 3.6 ns excitation.

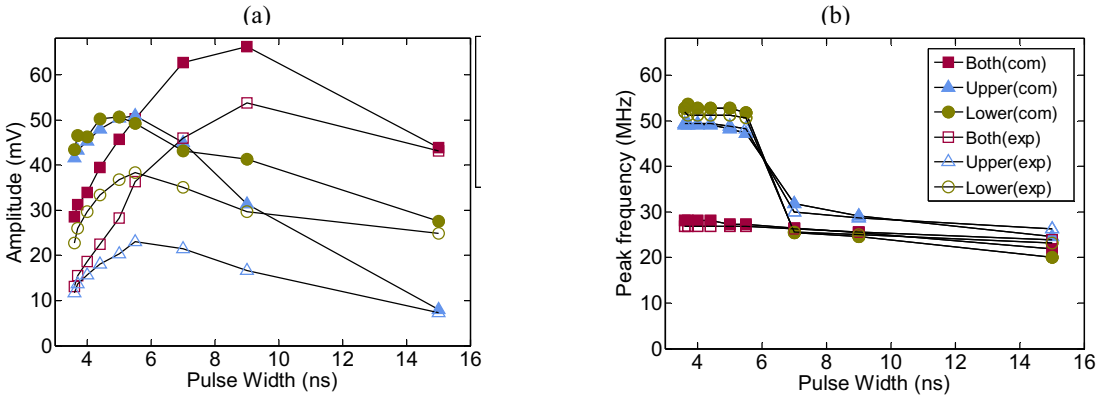

Fig. 6 (a) Relation between peak-to-peak amplitude of ARS and pulse width excitation. (b) Relation between peak frequency of ARS and various pulse width excitation. (Legends are same for fig. (a) and (b))

observed that the peak frequency obtained from Comsol modeling showed good agreement with the experimental results.

Previously, multilayer transducers produced from pre-polarized film with adhesive layers showed an increase in the sensitivity by 2.1 times (about 30 % lower than theoretically expected) when three layers of P(VDF-TrFE) were stacked and by 5 times when seven layers of P(VDF-TrFE) were stacked [4]. The dual layer transducer produced from fluid phase also showed the increase in the efficiency of the transduce [5]. The present dual transducer also showed higher efficiency (i.e. more than twice) when input pulse frequency was near to resonance frequency of the transducer.

IV. Conclusion

Adhesive free dual-layer ultrasonic transducer of P(VDF-TrFE) copolymer was developed by depositing layer by layer on the PEI polymer with the combination of different processing method from the fluid phase. The transducer was acoustically characterized by pulse/echo ultrasonic measurements and FEM models. The main findings from our study are the following:

(1) The amplitude of the acoustic response signal was higher, when transducer was operated in dual layer modus for the larger pulse widths.

(2) The frequency of the maximum amplitude of the dual layer modus was around 26 MHz and 50 MHz for single layer modus.

(3) The amplitude of the acoustic response signal shows similar trend (for rise and fall computations) but are found larger in the Comsol model than in the experimental results.

(4) The peak frequency obtained from Comsol modeling shows good agreement to experimental results.

Software Defined Radio for Passive Sensor Interrogation

J.R. Humphries and D.C. Malocha
Department of Electrical Engineering and Computer Science
University of Central Florida, Orlando, FL. 32816-2450
James.Humphries@knights.ucf.edu

***Abstract*—The software defined radio (SDR) provides a unique platform to interrogate passive, wireless sensors. The SDR platform defines many radio functions in software, rather than hardware. This allows for a very versatile interrogation platform that can be quickly reconfigured for diverse scenarios. This paper investigates the Universal Software Radio Peripheral (USRP), a commercial SDR developed by Ettus Research™, to determine its viability to interrogate passive, wireless sensors. In particular, the N200 USRP and the WBX daughterboard are considered because they allow for the greatest possible bandwidth for this platform (40MHz) and frequency tuning that is ideal for surface acoustic wave (SAW) sensor interrogation (50MHz - 2.2GHz).**

In the default operation mode, the USRP continuously streams data to and from the host computer. The host computer generates samples for transmission and processes any received samples. Synchronization of the transmit and receive chains becomes difficult due to latency in the communication medium (USB or Ethernet) between the host and USRP. While this mode is sufficient for most narrowband applications, wideband applications are more difficult to achieve because of the high sampling rates required (even in a baseband system such as the USRP). A prototype transceiver (passive tag reader) is developed by modifying the N200 FPGA to introduce new functionality to the USRP. These modifications include a custom interrogation signal generator (linear chirp) and triggering of the receiver based on the transmission state and desired listening time. These modifications are discussed and the modified transmit and receive characteristics are analyzed. Finally, a passive, wireless SAW OFC sensor is interrogated to demonstrate performance as a passive sensor transceiver.

I. Introduction

The Universal Software Radio Peripheral (USRP) is an interesting platform for a variety of wireless applications. Developed by Ettus Research™, the USRP is a versatile software defined radio (SDR) platform that can be reconfigured easily using the USRP Hardware Drivers (UHD) and software libraries such as GNU Radio. The transceiver daughterboards (RF front-end electronics) are also programmable (gain, center frequency, and port configuration) and swappable, giving the end user many options for RF characteristics.

The software radio approach has allowed the USRP to adapt to many scenarios including passive and active RADAR, cognitive radio, and OFDM [1]–[4]. Instead of an application specific design for the transceiver system, the USRP and baseband signaling approach grants the end user the ability to define the radio design using software. This approach gives access to rapid prototyping of radio systems design by quickly reconfiguring DSP, center frequencies, and sampling rates, among other specifications.

While some work has been accomplished using the USRP for RFID purposes [5], [6], little research has investigated the USRP as a platform to interrogate passive, wireless sensors. This project demonstrates modifications to the USRP which allow it to achieve the goal of communicating with passive surface acoustic wave (SAW) sensors. These functionalities are accomplished by modifying the FPGA design to introduce new functionality in the transmit and receive DSP chains. A custom chirp generator replaces the default transmit chain while a new module is implemented to synchronize timing between the transmit and receive states. These modifications are discussed and characterized in the following sections.

II. USRP and Experimental Setup

This section outlines the USRP and host computer setup that was used for this project. While many configurations are possible, the purpose of this section is to document a successful setup for the USRP platform.

A. USRP

The USRP chosen for this project is the N200 paired with the WBX daughterboard. The N (networked) series of the USRP, intended for high performance applications, is the fastest USRP in terms of sampling rates. The WBX covers this project's frequency range of interest (50MHz-2.2GHz) and has good output power (+20dBm). A brief overview of the USRP system specifications are given in Table I.

B. Host Computer and Software

The host computer used in this experiment is critical for processing high sample rates. The most important components for the host are processing speed and main memory, which prevents Ethernet packet loss. For this project, a computer was selected that utilizes a dual-core, 2.8 GHz processor with 4GB of memory and runs Ubuntu Linux, version 12.04.

Some combinations of Xilinx, FPGA source code, or UHD versions may limit performance or operation of the USRP. Xilinx 12.1 is used to build the FPGA code for the N200. Other versions of Xilinx are known to cause compatibility issues with the N200 FPGA code and can prevent the build and synthesize routines from completing efficiently. The UHD version is UHD_003.005.001-25-ge134b863. Additionally, the version of GNU Radio is 3.6.0.

TABLE I
SELECTED SPECIFICATIONS OF THE N200 USRP AND WBX DAUGHTERBOARD.

N200 USRP	
Host Interface	Gigabit Ethernet
FPGA	Xilinx Spartan 3A-DSP 1800
ADC / DAC	100 / 400 MSPS
WBX Daughterboard	
Type	Full Duplex Transceiver
Frequency Range	50MHz - 2.2GHz
Bandwidth	40MHz
Noise Figure	5-10dB
Power Output	20 dBm

III. USRP FPGA MODIFICATIONS

This section details the requirements for SAW sensor interrogation and the modifications required to achieve desired performance requirements. A custom chirp generator is implemented to replace the default transmit chain in the FPGA while another module is implemented in the receiver to synchronize with the transmit chirp. Planned updates are also discussed that will further improve the performance of the USRP.

A. Sensor Interrogation Requirements

The planned use of this transceiver is to interrogate passive, wireless SAW OFC sensors [7]. The system is based on a synchronous correlator approach using a pulsed interrogation signal [8]. The interrogator must capture the reflected signal from the target sensor and transfer the data to the host computer for post processing and data extraction. A SAW OFC sensor requires both frequency and time diversity. This leads to wideband SAW sensors (>20MHz) and time responses ranging between 1-10μs. The transmit signal must not overlap the sensor response, so the signal must be shorter than the SAW delay time. With these considerations in mind, modifications to the USRP FPGA design were implemented to transmit a 1μs linear chirp, set a listen time of 10μs, and synchronize the transmit and receive chains.

B. Modified FPGA Design

The FPGA source code is provided by Ettus and the modifications were integrated into the standard code. The existing transmit chain was removed completely since streaming TX samples are not being used and to reduce FPGA resource usage. In place of the transmit chain, a custom chirp generation module was added with outputs directly to the DAC's. Instead of replacing the whole receive chain as well, a custom module was inserted after the DDC to control the receive data flow.

1) Transmitter: A custom chirp generator was implemented to transmit a chirp of a user defined time length and bandwidth. A MATLAB script was written that allows the user to specify these parameters. The script then calculates the I and Q samples required for each clock cycle of the FPGA (assuming a 100MHz clock). Once the samples have been calculated, the script outputs the Verilog code to generate the module. The samples are output to the DAC's on the USRP in two's complement binary format.

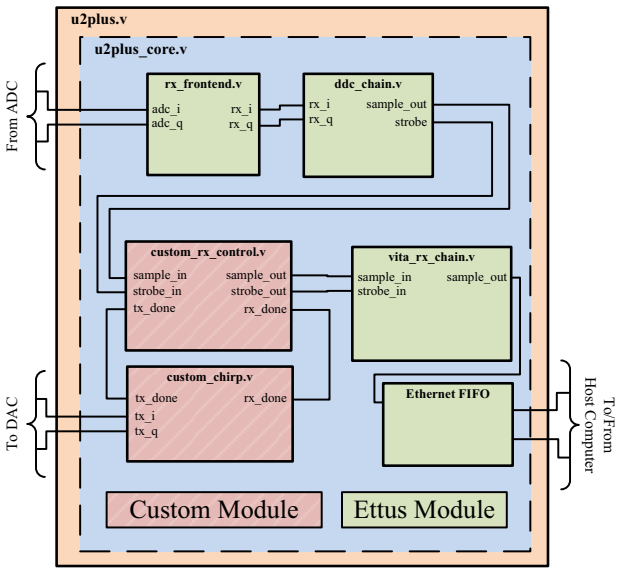

Fig. 1. Simplified block diagram of the modified FPGA design. The existing (Ettus) transmit chain was replaced by a custom chirp generator. A custom module was inserted in the receive chain to synchronize the start of the listen time with completion of transmitted chirp.

For this project, a 10MHz chirp with time length of 1μs was chosen. It is possible to generate a 50MHz bandwidth chirp in this configuration, but due to the limited sampling rate of the streaming receiver (25 MSPS), much of the chirp would be truncated from the received signal. Fig. 2 shows the I/Q samples generated for this signal.

The programmed chirp was output directly to a spectrum

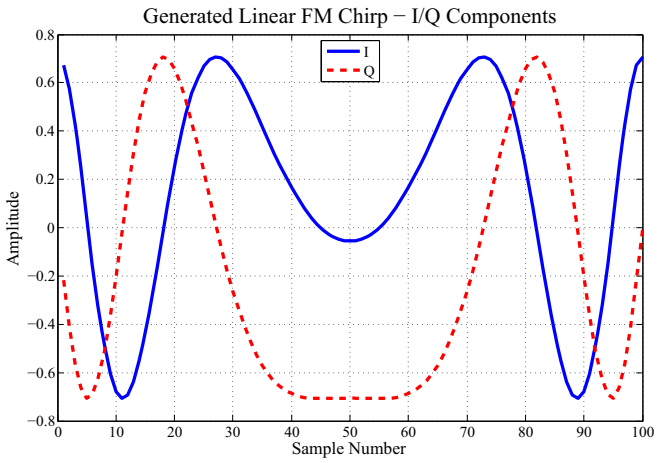

Fig. 2. A 2D representation of the generated I/Q samples for the linear FM chirp. The samples are generated at baseband and shifted up in frequency by the daughterboard. These samples are converted to binary and output directly to the DAC's.

TABLE II
CONFIGURATION OF THE USRP RECEIVE CHAIN.

USRP Receiver Configuration	
Sampling Rate	25 MSPS
T_{max} (Listen Time)	10μs
Samples per Sweep (N)	250
Δt (Resolution)	40ns
F_{max}	25MHz
Δf (Resolution)	100kHz

analyzer to compare with the predicted frequency spectrum of the signal. Fig. 3 compares the measured frequency spectrum with the predicted frequency spectrum of the generated signal. As seen in the figure, the actual transmitted signal matches well with the predicted response.

2) Receiver: A custom module was inserted between the DDC and the VITA (packet formatting) modules in the default design. Fig. 1 shows the location of this custom module (custom_rx_control.v). This module only allows samples to pass through after the transmission has completed and after a user set delay. The delay was set for 1.5μs to allow for chirp roll-off and to allow bad samples to propagate through the FPGA that were present before transmission. This module passes the strobe signal from the DDC to indicate that the output data to the VITA module is good. Fig. 4 shows an oscilloscope plot which illustrates the chirp and listening times that have been programmed. Additionally, the receiver configuration is shown in Table II. The sampling rate is currently limited by the Ethernet bus due to the constant streaming method that the default USRP configuration uses.

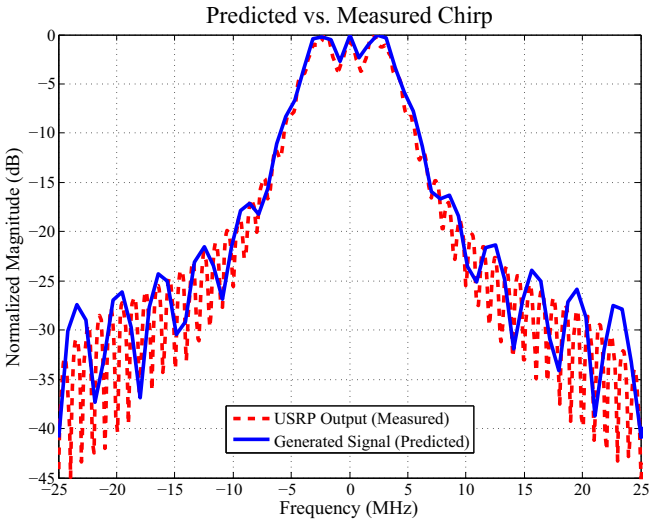

Fig. 3. Plot comparing the chirp as measured on a spectrum analyzer with the predicted frequency spectrum of the generated samples. The output at 915MHz is compared with the predicted baseband spectrum.

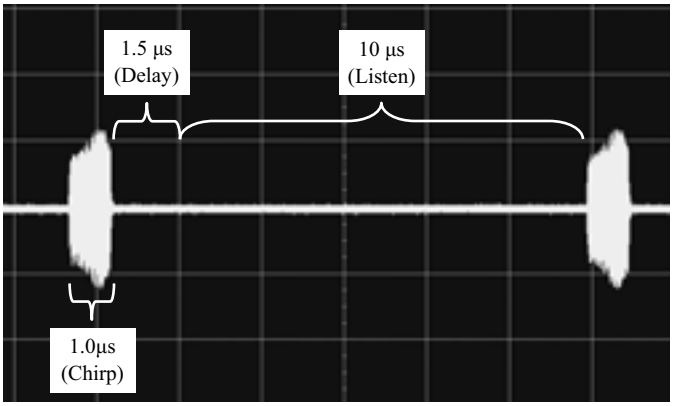

Fig. 4. Oscilloscope plot showing the chirp and listen times programmed on the N200 FPGA. Each interrogation cycle takes approximately 12.5μs to complete.

C. Planned Updates to USRP Modification

Future updates are planned to improve the functionality of the USRP as a passive sensor interrogator. These updates include improvements to the FPGA code design, better integration with the UHD, and external hardware components to improve TX/RX isolation and TX power output.

Ideally, the FPGA chirp generator would allow the user to program chirp length and chirp bandwidth. The current configuration does not allow for the chirp to be reprogrammed on the fly. Integration with the UHD drivers would allow the user programmed information to be set in the FPGA and would give run-time reconfiguration abilities.

External hardware components can be integrated with the USRP using the available MICTOR connector on the USRP mainboard. The current purpose of this connector is to connect a logic analyzer to check the FPGA logic functionality. Bypassing the current functionality would allow, for example, external TX and RX switches to be incorporated and controlled by the FPGA. This would reduce TX leakage into the RX front-end and improve extraction of sensor information. These future improvements will give a more robust transceiver that can be more easily configured for a variety of sensor designs.

IV. USRP PROTOTYPE TRANSCEIVER CHARACTERIZATION

Testing of the prototype transceiver is presented in this section. First, a wideband SAW filter was placed in-line between the TX and RX ports to test the chirp deconvolution. Finally, a passive SAW sensor is interrogated and correlated with its matched filter at 915MHz.

A. Chirp Deconvolution Through SAW Filter

A wired test was configured to test the process of deconvolving the transmitted chirp on the received signals. A wideband SAW filter was placed in-line between the transmit port and receive port on the USRP. The bandwidth of the filter is much

greater than the bandwidth of the transmitted chirp to ensure little distortion over the chirp passband.

A chirp was transmitted and 250 samples (10μs) were recorded. The chirp samples that were generated for transmission were used as the transmit signal to deconvolve and were zero padded and decimated to match the received sample number and sample rate. Fig. 5 shows the time correlation of this test. Accounting for the programmed delay on the FPGA, the time of the correlated pulse in Fig. 5 corresponds to the designed time delay of the SAW filter.

B. Passive SAW Sensor Interrogation

Characterization of the prototype system was concluded by interrogating a passive, wireless SAW OFC strain sensor at 915MHz. A single sensor is attached to a PCB dipole antenna of approximately 2dBi gain. The chirp signal is broadcast and the return signal is recorded for 10μs. The SAW delay is approximately 3μs when the system delay is taken into account.

After the samples have been saved on the host computer, the transmitted chirp is deconvolved and the sensor response is correlated with its matched filter. In this experiment, the matched filter contains only one OFC chip since the current receiver bandwidth is not large enough to capture the entire sensor spectrum. The sensor time response, frequency response, and demodulated time correlation is seen in Fig. 6. The sensor response was successfully correlated with its matched filter. Future improvements to the FPGA design will allow wider bandwidths to be utilized to improve overall sensor response with wideband designs, such as OFC.

V. Conclusion

This paper has presented the USRP as a viable platform for passive, wireless sensor interrogation. The versatility of the software radio approach allows for quick reconfiguration of many of the interrogator functions. An approach to redesign selected FPGA functions on the USRP was discussed and the modifications were detailed. The characteristics of the transmitter and receiver were shown and match well with the expected functionality. The transmitted linear FM chirp can be deconvolved using the generated signal components, which was demonstrated through a wideband SAW filter with known delay. Finally, the modified USRP was successfully demonstrated by interrogating a 915MHz, wireless SAW OFC sensor. These modifications have shown that the USRP can be adapted to function as a passive sensor interrogator platform.

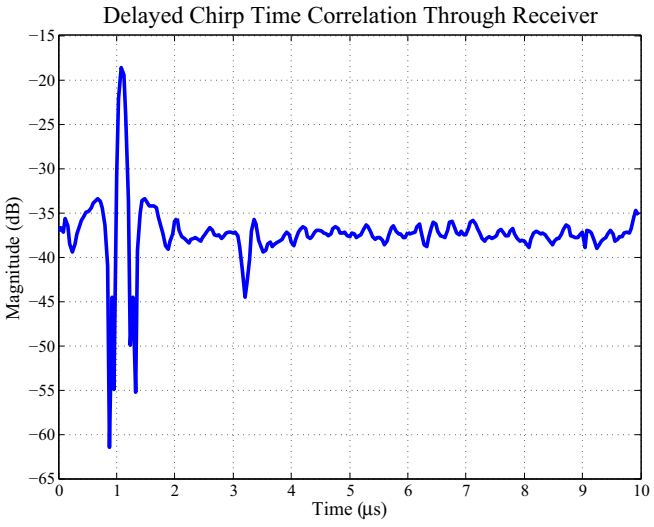

Fig. 5. Time correlation of the transmitted chirp signal through a wideband SAW filter at 915MHz. The correlation time matches the expected filter delay time of approximately 1μs when the system delay is taken into account.

***Abstract*— Two methods currently used to induce surface roughness that promotes the growth of AlN tilted grains to fabricate shear mode resonators have been investigated. The first one involves the use of a rough substrate to provide tilted facets on which the AlN grains will grow with a certain angle. The second method is based on using a thin non-piezoelectric AlN seed layer that exhibits high populations of {10·3} and {10·2} planes. The influence of the power applied to the Al target and the total gas pressure during the deposition process of the AlN seed layer has been studied and correlated with the k^2_{shear} of the resonators. The best fabricated devices show a shear mode resonance frequency at around 1.45 GHz, a k^2_{shear} up to 3.64% and a Q_{shear} above 230 when operating in air, which reduces to 108 when operating in liquid.**

Seed layer; shear mode resonator; AlN; tilted grains

I. INTRODUCTION

A serious drawback of biochemical sensors based on piezoelectric resonators is the requirement of operating in liquid environments. This can be overcome by exciting shear modes that exhibit less attenuation in liquid media than longitudinal modes. Quartz has been widely used as piezoelectric material to manufacture resonators capable of operating in liquid media, because of its natural capacity to resonate in shear mode [1], [2]. Nevertheless, the difficulties encountered in the fabrication and integration of very thin crystals for operating in the GHz frequency range have boosted the search of alternative piezoelectric materials. In the last years, AlN has revealed itself as a great substitute thanks to its high acoustic velocity [3] and piezoelectric coefficients [4], and the possibility of sputtering the high quality AlN thin films required for high frequency applications [5].

To obtain AlN polycrystalline thin films with good piezoelectric performance, it is necessary that all the grains have the c-axis parallel to a given direction and the same crystal polarity [6]. This is commonly achieved by giving enough energy to the adatoms on the growing film surface, which favors the preferential growth of the {00·2} planes parallel to the surface of the substrate [7], [8]. Under these conditions, AlN microcrystals always grow normal to the surface where they are being sputtered, even if it is vertical [9]. Shear mode resonances can be achieved by transverse excitation (by means of the d_{51} piezoelectric coefficient) in AlN with microcrystals exhibiting both homogenous tilt and polar orientation. Among the different techniques developed to achieve such tilted films [10–12], the most effective is the one based on inducing a rough structure on the surface just beneath the AlN active layer [11]. On this kind of surface, if the flux of Al atoms impacting on the different facets is uniform, the grains of AlN will grow perpendicular to the facets in different directions, therefore originating a randomly-oriented AlN layer without piezoelectric response. However, if an impinging direction is encouraged (e.g. by displacing the substrate with respect to the center of the target), the grains will grow faster on the facets most exposed to the atom flux and their mean tilt angle, fixed by those planes, will be more uniform [12]. As shown in figure 1, the best possible structure to accomplish the tilted AlN grains would be a sawtooth profile of microscopic dimensions, which is unfortunately very hard to fabricate. Instead, a layer with controlled roughness is commonly used [11], [12].

Two possible approaches to control the roughness of this layer have been proposed. The first one is based on the control of the last layer of the substrate, usually the bottom electrode if it is a resonator, or the roughness of the layer just below, usually the uppermost layer of an acoustic reflector. The other method involves using a polycrystalline film, acting as seed layer, with a controlled preferred orientation that exhibits a plane with the desired tilt angle.

In this paper we have investigated the above-mentioned methods to induce surface roughness to promote the growth of tilted AlN films for shear modes resonators. The efficacy of the process involving the use of the inherited roughness of the layers below the active AlN layer has been studied and discussed. Concerning the second method, thin AlN films have been chosen as polycrystalline seed layers, because of their proven effectiveness for this purpose [11], [12]. The deposition conditions of the seed layer and their influence on the performance (electromechanical coupling factor and quality factor) of shear mode resonators have been analyzed.

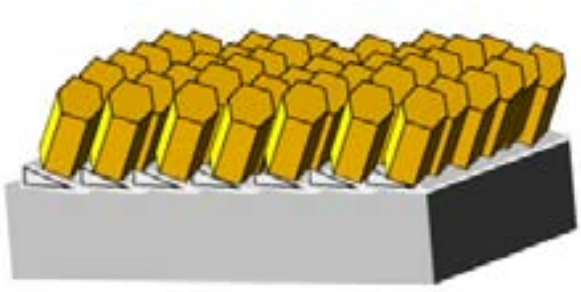

Figure 1. Sawtooth profile to promote growth of tilted grains.

II. Experimental

The deposition of AlN thin films was conducted in a custom-made ultra-high vacuum sputtering system pumped by a cryogenic pump to a base pressure of 10^{-8} Torr and provided with a transfer chamber to avoid oxygen contamination in the deposition chamber. AlN films were deposited with a 150 mm diameter 99.999% purity aluminum target located at a distance of 55 mm from the substrate holder. The 99.9999% purity gas mixture was 60% N_2 in Ar. The substrate holder could be heated to temperatures up to 600ºC and RF biased during the deposition process. The substrates consisted of (001)-oriented silicon wafers covered with an acoustic reflector made of five alternating sputtered layers of porous SiO_2 and Mo whose thicknesses were adjusted to achieve a center frequency of 2.5 GHz for the longitudinal mode and of 1.45 GHz for the shear mode. The samples selected to study the AlN seed layer had their uppermost SiO_2 layer mechanically polished with alumina slurry to a RMS roughness below 1 nm. They were covered with a 120 nm-thick iridium film that acted as bottom electrode of the resonators. Some samples were cleaned before the deposition of the AlN films by ion bombardment in a pure Ar RF discharge.

To promote the growth of AlN active layers with an effective tilt, AlN seed layers 100 nm-thick were first sputtered under the conditions that favors the growth of <10·3> or <10·2>-oriented microcrystals. The obtained tilt, combined with a good basal alignment leading to a large piezoelectric response, is the most favorable structure for shear mode generation. However, achieving in practice thick AlN films with those characteristics is a difficult task, as the energy supplied to the adatoms must be very low, which causes inevitably the appearance of inversion domains that yield, in turn, a poor piezoelectric response [13]. Therefore the strategy is based on depositing these poorly-piezoelectric polycrystalline AlN film and, without breaking the vacuum cycle, using them as a seed for the growth of the 1000 nm-thick active layer. This active layer is sputtered under a highly energetic process specially optimized to achieve the best-performing AlN piezoelectric layers in our system, which involves high power, low pressure, high temperature and substrate biasing.

After AlN deposition, a top electrode of molybdenum 150 nm-thick was deposited and patterned to fabricate resonators as test devices. The impedance of these devices as a function of the frequency (between 100 MHz and 10 GHz) was measured using an Agilent N5300 network analyzer. The resulting spectra were fitted using Mason's model to obtain the actual electromechanical coupling factor of the material (instead of the effective one, which also depends on the thickness of the other layers) [14], [15] associated to the shear mode (k^2_{shear}) and to the longitudinal mode (k^2_{long}) and their corresponding quality factors Q_{shear} and Q_{long}. The characterization of the devices and the material was conducted on samples located at 40 mm from the center of the wafer to take advantage of the abovementioned off-axis deposition.

X ray diffraction (XRD) has been used to obtain the crystal structure of the films. Conventional θ/2θ patterns and ψ scans with θ=18° (the Bragg angle for the (00·2) planes) between 80° and - 80° were measured in the radial direction of the wafer at 40 mm from the center.

Atomic force microscopy (AFM) images in contact mode were taken from selected samples to study the roughness of the substrates before the AlN deposition.

III. Results and Discussion

A. *Roughness of the uppermost layer*

To analyze the influence of the uppermost layer roughness on the orientation of the AlN grains, several deposition were made on substrates as shown in figure 2: (a) polished (RMS roughness below 1 nm) and (b) rough (RMS roughness over 12 nm). The devices fabricated on them show a clear increase of the k^2_{shear} when using the rough substrate, which indicates that higher roughness promotes the growth of tilted AlN. Polished surfaces, even when the AlN is sputtered off axis, induce a highly perpendicular growth of the grains. However, even if the same conditions are used to deposit the AlN active layer, the k^2_{shear} of the devices fabricated on different substrates varies from 1% to 2.4%, which indicates that this method is poorly reproducible and controllable, although high quality resonators have been obtained (k^2_{shear} as high as 2.4% with a Q_{shear} value of 270).

Some tests were made depositing non-oriented AlN layer, texturing it with KOH chemical etching in order to achieve a controlled surface roughness and, then, depositing an optimum AlN film again. The quality of the piezoelectric films was drastically reduced since the seed layer had to be exposed to oxygen when the vacuum cycle was broken, as already observed in previous works [16].

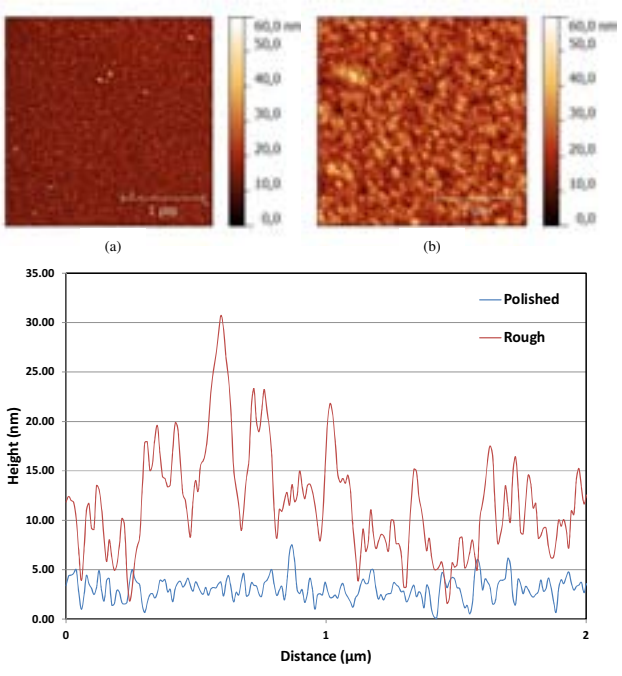

Figure 2. AFM images and profiles of (a) polished and (b) rough substrates

B. *AlN seed layer*

AlN polycrystalline seed layers with high content of <10·2> or <10·3>-oriented grains were deposited by reducing the energy supplied to the substrate during deposition through a careful control of the deposition parameters: substrate temperature (including the electron bombardment effects), ionic bombardment (caused by the self-polarization of the substrate and applied bias), cathode potential, and gas pressure. The substrate was not intentionally heated during the deposition of the seed layer and the substrate holder was not externally polarized to reduce the energy applied to the substrate. The variables tracked were the power applied to the target and the total pressure. The tilted AlN layers were grown on top of the seed layers under the sputter conditions that guarantee the best AlN films achievable in our system. The goodness of the seed layers was assessed through the value of k^2_{shear} measured in the test resonators.

Figure 3 shows the values of k^2_{shear} achieved in the test resonators for different deposition conditions of the seed layer (target power and total pressure). For the lowest pressures the k^2_{shear} values decrease when the power increases, but this tendency is reversed when the pressure rises. This behavior is due to two competitive mechanisms. A reduction in the total pressure originates an increase in the energy supplied to the substrate because the self-polarization of the substrate increases (in module), thus increasing the ionic bombardment; as a consequence the sputtered species reach the substrate with more energy as they do not completely thermalize. The energetic excess supplied at higher target power makes the AlN grains to be less tilted and the k^2_{shear} values drop because the mean tilt angle of the c-axis of the active layer is lower. At high pressures the energy supplied to the substrate is very low, due to lower substrate polarization and a complete thermalization of atoms reaching the substrate; hence, the crystallinity of the seed layer is very poor. An increase in the power applied to the target helps the crystal formation without changing the orientation tendency.

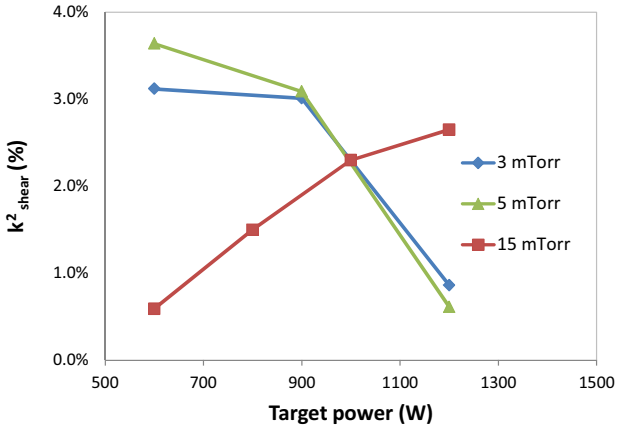

Figure 3. k^2_{shear} of the resonators as a function of the power applied to the target during the growth of the seed layer at three different total pressures.

To overcome the very demanding conditions of XRD to detect {10·2} and {10·3} we have analyzed the structure of the AlN layers by FTIR reflectance (see figure 4), which is a technique sensitive to tilt angle of the grains as we have shown in [17], [18]. The results show that the greater grain populations with orientation around <10·2> or <10·3> we get in the seed layer, the more <00·2> tilt angle we achieve in the active piezoelectric layer. Therefore k^2_{shear} increases well above the values obtained using the first method, reaching 3.64%. Figure 5 shows the longitudinal and shear resonances of a well-performing device operating in air and liquid. Notice how the longitudinal mode is strongly affected by the presence of the liquid, while the shear mode maintains Q values that still allow biosensing applications. These results are fairly reproducible and controllable compared to the results obtained in devices fabricated on rough surfaces under identical deposition conditions (see figure 6).

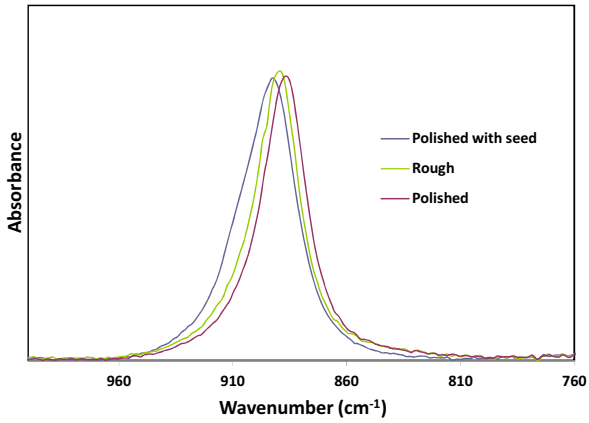

Figure 4. IR reflectance spectra of the AlN active layer deposited on top of polished substrates covered with a seed layer, polished substrates without seed layer, and rough subtrates. The position shift of the peaks towards larger wavenumbers indicates a a) 24.3°, b) 12.3° and c) 0° tilt of the AlN grains with respect to the normal to the surface.

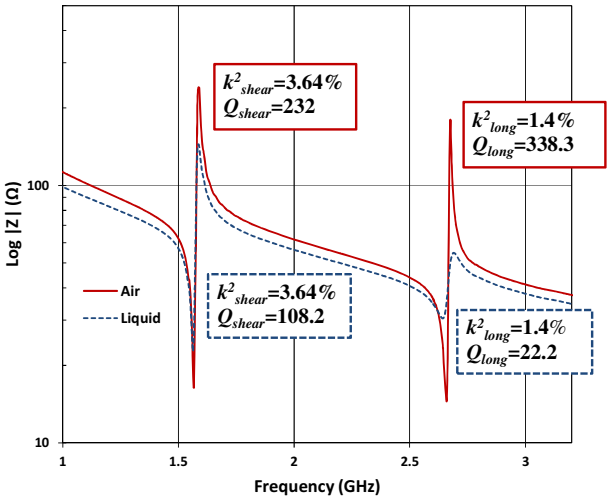

Figure 5. Impedance of the test resonator operating in air and in liquid.

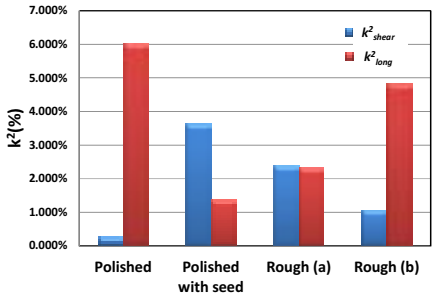

Figure 6. k^2_{shear} (blue) and k^2_{long} (red) of resonators fabricated on polished and rough substrates, with and without AlN seed layer. Notice the strong dispersion of the k^2 values of resonators fabricated on rough subtrates under the same deposition conditions.

However, the use of a non-piezoelectric seed layer generates an undesirable electrically dead layer in the resonator, which lowers its resonant frequency and worsens its performance. A metallic seed layer which could serve as bottom electrode and whose texture could be controlled like in the AlN case (e.g. W, Al or Ta) [19–21], opens the door to a promising method of new seed layers that has yet to be studied.

IV. Conclusions

We have investigated two methods to induce surface roughness that enhances the growth of tilted AlN films intended for shear mode resonators. The first method, which takes advantage of the roughness of the underlying substrates, can yield well-performing devices (k^2_{shear} up to 2.4%, Q_{shear} above 270), but in an uncontrollable way. The second method involves the use of a very thin non-piezoelectric AlN seed layer that contains inclined facets suitable for promoting the growth of tilted films; this seed layer has been achieved by sputtering at low power and moderate pressures. Combining such seed layers with an off-axis growth of the active layer we have achieved shear resonators exhibiting values of k^2_{shear} above 3.6% and Q_{shear} above 230 that have demonstrated a good performance in liquid environments.

***Abstract*—The flexibility, reconfigurability and stability of software defined radio yield an attractive alternative to the analog strategy of probing acoustic transducers acting as passive sensors probed through a wireless link or to phase noise characterization of oscillators. However, developing processing blocks is a time consuming activity, yet metrology applications require a dedicated understanding of each processing step. We consider GNURadio as a means of exploiting opensource software as an optimum tradeoff between software re-usability yet compatible with an audit for assessing performance. This signal processing environment is demonstrated on two practical examples, FMCW probing of acoustic delay lines acting as sensors, and quartz tuning fork characterization. Both examples are considered as introductory setups for training and teaching yet a suitable environment for research activities.**

I. Introduction

Digital signal processing has been identified as a significant improvement over analog signal processing for a number of reasons [1], [2], including stability, flexibility and accuracy. Respectively, digital signal processing is not prone to component aging or drift over time; is reconfigurable in order to update algorithms or parameters in order to perform new functionalities on a given hardware; and provides a pre-defined, quantitative computation accuracy given the size of the handled datasets. Digital signal processing is nowadays ubiquitous and the mostly infinite computational power available yields to the trend of Software Defined Radio [3], in which general purpose radiofrequency source and sampling hardware is used for software processing of the recorded data for multiple application on a given experimental setup. Although processing power has been increasing continuously, the extensive bandwidth needed for radiofrequency (RF) sampling often remains beyond the general purpose hardware. On the other hand, most RF signal are narrowband and do not require full bandwidth sampling, so a common trend is to use an analog frontend with an amplifier and a mixer with a local oscillator to provide a zero-intermediate frequency (IF) configuration. We consider here the use of such a configuration in the context of time and frequency metrology signal processing, and most significantly consider the software environment needed to implement the associated processing algorithm, both from application and a teaching considerations since the skills for applying these concepts are mostly lacking.

II. FMCW RADAR for passive wireless sensor monitoring

Acoustic transducers [4]have been demonstrated to be relevant alternatives to silicon-based radiofrequency identification tags (RFID) when harsh environments (temperatures above CMOS operating range) or long interrogation ranges (no threshold on the received power in the case of piezoelectric substrate) are needed. By patterning electrodes on single crystal substrates, a delay line configuration aims at providing a simple means to convert the incoming electromagnetic signal to a mechanical wave whose propagation velocity on the surface of the substrate is dependent on the physical property under investigation [5]. Through direct piezoelectric effect, the pulse reflected on a mirror patterned on the substrate generates a returned electromagnetic signal: the purpose of the readout unit is to allow for a measurement of this time of flight in order to recover the physical quantity value [6].

A classical pulsed-mode RADAR approach requires large measurement bandwidths B in order to achieve time resolution $1/B$: typical pulse widths and maximum time of flight durations are respectively 100 ns and 5 μs, so that $B > 10$ MS/s is needed. Although the pulsed mode, wideband RADAR approach provides some significant range and measurement speed advantages, a simpler approach has been favored in the literature through the use of the frequency-modulated continuous wave (FMCW) RADAR approach [7]. In the latter method, a local oscillator frequency f is linearly swept along a bandwidth B within the bandpass function of the acoustic delay line. The time delayed returned τ signal is mixed and low pass filtered with the local oscillator, so that a beat signal $\Delta f(\tau) = f(t) - f(t+\tau)$ is recorded after removal of the carrier. The resulting architecture is simple and only requires low frequency sampling rates, but also introduces multiple free parameters which are best tested in a software defined radio approach. Among the parameters are the central operating frequency f and the sweep rate T: $\Delta f(\tau)/\tau = B/T$ since the frequency band B is swept linearly over a duration T.

Recently, a tutorial has been presented on the MIT OpenCourseWare web site [8] demonstrating a basic FMCW approach: this hardware platform is used as the starting point of this experiment, although the linear RF oscillator sweep and recording a no longer performed by dedicated hardware but by a personal computer sound card running GNURadio (http:

978-1-4799-0342-9/13/$31.00 ©2013 IEEE

//gnuradio.org/). The recorded signals are Fourier transformed in real time in order to display the multiple echoes returned by the acoustic delay line $\Delta f(\tau_i)$ with i an index of the echo number. In the case of the transducer we have experimented with – available from the Carithian Tech Research (CTR, Villach, Austria), $i \in [1..8]$.

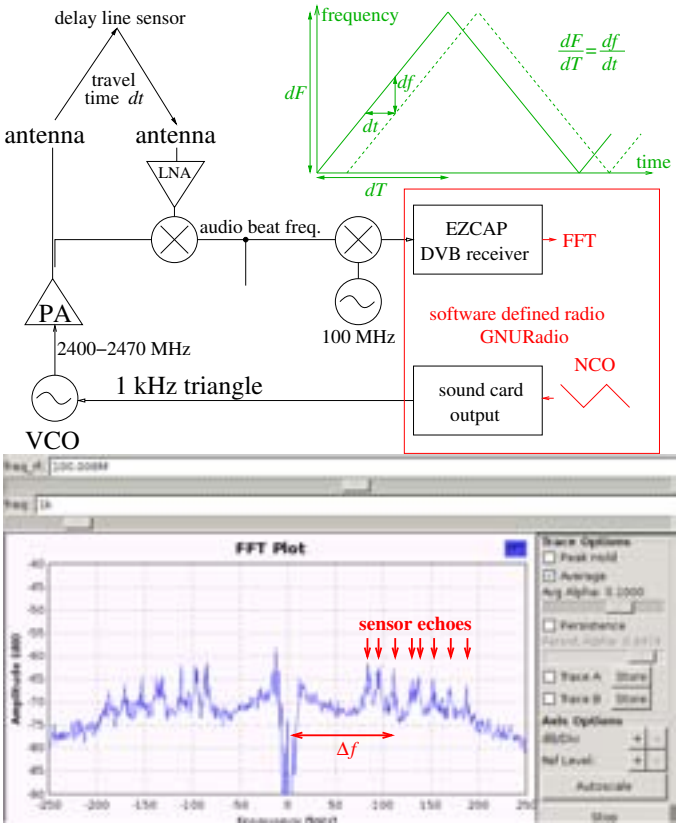

Fig. 1. Top: schematic diagram of the FMCW RADAR used to demonstrate probing a 2.45 GHz acoustic delay line acting as passive, wireless sensor. The RF hardware is based on the MIT design [8], while the signal source (triangle-shaped Voltage Controlled Oscillator – VCO – control signal) and sink (beat frequency recording and Fourier transform) are performed using the GNURadio software. Since the recording by an DVB receiver requires an input signal higher than 100 MHz, the audio beat signal is mixed with a fixed frequency oscillator to reach the requested frequency band. Bottom: real time display of the 8 echoes observed as 8 discrete frequency components of the beat signal.

Fig. 1 exhibits a screenshot of the monitored signal, in which the 8 delay line echoes are well resolved as 8-discrete beat frequencies. The software defined signal source – here a linear sweep on the output sound card – provides the flexibility to compensate for the RF oscillator non-linear frequency output with respect to the control voltage: this linearity on the whole range B is mandatory for all contributions to the beat signal to add coherently. Lack of linearity of the RF oscillator yields a given delay τ to induce variable $\Delta f(\tau)$ as the oscillator is swept and hence a broadening of the returned signal beat frequency peaks. This aspect is well demonstrated with the software defined radio as well.

For teaching purposes, the two options available to us when using widely available, commercial off the shelf analog to digital converters, are a sound card and a Digital Video Broadcast (DVB) receiver, both acting as dual I and Q channel data streams. The sound card is a high resolution analog to digital converter (typically 16 bit at least) but only provides a bandwidth up to 48 kHz (96 kHz sampling rate), while internal anti-aliasing filters prevent the monitoring of higher frequency signals. Since the CTR-delay line requires a bandwidth of at least 30 MHz and the time delay is in the 5 μs range, the sweep rate T must be $T < \frac{B \times \tau}{\Delta f(min)}$ or in this case 3.125 ms. An output frequency of 320 Hz is well within the bandpass of a soundcard output. Alternatively, higher refresh rates are achieved by sweeping the frequency source at a faster rate, hence also improving the frequency detection resolution since Δf becomes larger for a given delay τ. Since the sound card is no longer an option at higher signal frequencies and the DVB receiver only operates above 100 MHz, a frequency transposition strategy is used to bring the monitored signal in the 100 MHz range (mixing with a local quartz oscillator) before the DVB receiver demodulates the signal and provides the I/Q datastream.

III. Time & Frequency Metrology Algorithm Prototyping and Assessing Hardware Limitations

Software implementation of classical analog signal processing methods are best suited for rapid prototyping [2]. While frequency counting is intrinsically a digital method, its software implementation easily demonstrates the gains and influence on the statistics of various strategies (direct counter, reciprocal counter, sliding average functions [9], [10]). More challenging is the phase noise measurement [11]–[14], which is classically performed by mixing the test oscillator with a reference local oscillator and low-pass filtering the beat signal, possibly providing a feedback control signal for the local oscillator to track the measured oscillator frequency if long term drift is compensated for (statistics on the control signal rather than on the beat signal output itself). All these blocks are implemented as software, but the influence on the phase noise spectra as a function of the digital hardware performance often remains challenging to assess [15] .

Efficient processing of the narrowband signals considered remains a challenging aspect of the data acquisition chain: under the assumption that the oscillator under investigation is stable, sampling is not needed to meet the Shannon criteria under the hypothesis that only a narrow band around the carrier frequency holds the needed information. One such consideration yields to the fact that aliasing on purpose the measured signal to only meet the analyzed bandwidth – without the ability to reconstruct the whole signal – is enough, yet the impact on the noise level is still under consideration.

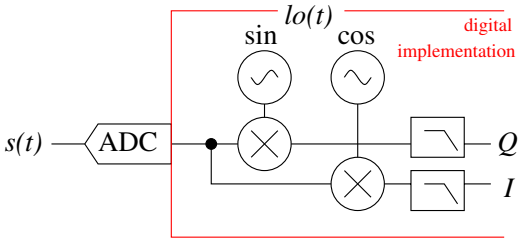

Fig. 2. Classical phase detection scheme considered here in its digital implementation.

When single sample operations are needed, such as

I/Q demodulation in which a local numerically controlled oscillator (NCO, described in the GNURadio source tree in `gnuradio-core/src/lib/general/gr_nco.h`) is mixed with the incoming signal, no stream handling functionality is needed. However, the data block size is not known and data are transmitted from one block to another asynchronously. If a minimum number of data is needed to perform a given processing step, e.g a Fourier transform, data are accumulated in a temporary array which is processed only once filled. The buffer is then freed of the processed data and the remaining values are moved to the beginning of the buffer to be processed with the next batch of data.

Phase noise analysis is the most basic processing tool for characterizing an oscillator stability. Many schemes have been devised using analog electronics, most classically mixing the oscillator output under investigation with a local oscillator assumed to exhibit better stability, low pass filtering the mixer output to get rid of the signal at the sum of the frequencies, and controlling the reference oscillator in order to keep the quadrature condition at the mixer so that $\sin(\varphi) \simeq \varphi$. In order to implement such a scheme digitally and use at best digital signal processing – flexibility in setting the local oscillator frequency, low pass filter characteristics and phase noise extraction – we assess the number of bits on which the computation has to be performed to comply with the targeted resolution. Let us assume, to justify this calculation, that we aim for phase noise resolution calculations reaching -180 dBrad^2/Hz (Fig. 3).

The phase noise S_φ defines the phase fluctuations σ_φ in a given bandwidth BW:

$$S_\varphi = \sigma_\varphi^2 / BW \text{ rad}^2/\text{Hz}$$

Considering the phase noise at carrier offset 1 to 10 MHz and 1000 points/decade, $BW = 9$ kHz in such conditions. S_φ is usually expressed in dB with $S_{dB} = 10\log_{10}(S_\varphi)$. The classical scheme of mixing the sine wave translates, in terms of digital computation [16], [17], into a product of the local numerically controlled oscillator LO and sampled signals from the oscillator under investigation s, followed by a low pass filter which we here consider to be a finite impulse response (FIR) filter with coefficients a_n:

$$I, Q = \frac{1}{N} \sum_N s_k \times LO_k \times a_{N-k}$$

where I, Q are the in-phase and quadrature coefficients obtained from two expressions of the local oscillator phase shifted by 90^o (*i.e.* expressed as cos and sin). From these two sets of coefficient, the phase is classically expressed as the argument of the complex $I + jQ$ or $\varphi = \arctan(Q/I)$.

In the low pass filter expression, the sum yields a standard deviation rising as $\sqrt{N}$ for samples affected by an additive gaussian noise, and the $1/N$ factor yields the classical decrease of the standard deviation during averaging by $1/\sqrt{N}$. This number of samples N is given by the ratio of the sampling frequency f_s to twice the maximum offset from the carrier at which phase noise is computed. Assuming a 500 Msamples/s sampling rate and a phase noise calculation at 10 MHz from the carrier, then $N = 25$.

The uncertainty of the I, Q calculation is given by the sum of the uncertainties of each term in the sum: $dI, Q = \frac{1}{N}\sum_N ds \times LO \times a_{N-k} + dLO \times s \times a_{N-k} + da \times LO \times s$. If only quantization noise is considered when representing information on M bits, then all infinitesimal terms are equal to 2^{-M} and each quantity is assumed to have been scaled to be around unity, so that this uncertainty on the computation of I and Q are dominated by $3 \times 2^{-M}/\sqrt{N}$ since the sum of the independent noise source rises as $\sqrt{N}$. We then target a given phase noise floor S_dB expressed in dB, then

$$\sqrt{BW \times 10^{S_dB/10}} = 3/\sqrt{N} \times 2^{-M}$$

$$\Leftrightarrow M = -\ln_2\left(\sqrt{N \cdot BW \times 10^{S_dB/10}}\right)/3$$

Keeping the previous assumption of $B = 500$ MHz and a targeted phase noise plot up to a 10 MHz offset from the carrier hence requiring $N = 25$, computation on 26 bits is needed to reach the targeted resolution of -180 dBrad^2/Hz. Even at -160 dBrad^2/Hz, $M = 23$ bits are needed to reach the requested computation resolution. The sum of three sources of noises rises the resolution need by 1.6 bits: if the filter can be tuned in order to prevent resolution uncertainty on its coefficients ($da = 0$) and if a square wave is used instead of the sine wave defining the NCO ($dLO = 0$), then the needed resolution becomes 25 and 21 bits respectively. However, the use of a square wave NCO brings new challenges including the rejection of unwanted harmonics and its aliases after the mixing step, while making sure than none of these aliases are brought back within the band of interest [18], [19].

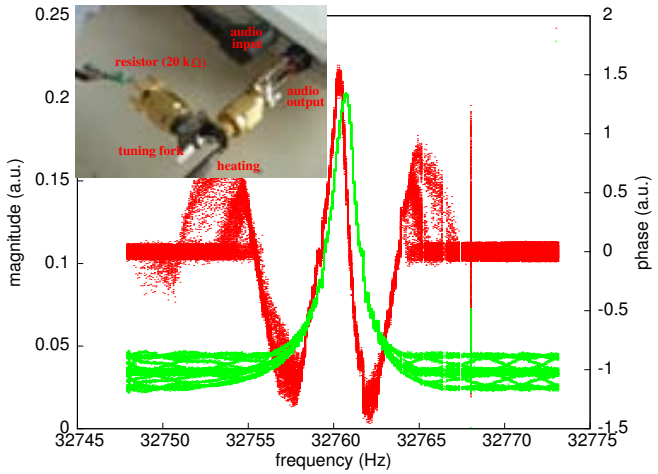

Fig. 3. Illustration of the I/Q demodulation scheme on a low frequency quartz tuning fork yielding phase (red) and magnitude (green) of the audiofrequency signal transmitted through the dipole. Notice that this experiment only requires a full-duplex sound card programmed through GNURadio as a network analyzer since the emission and recording are performed simultaneously. In this particular application, phase monitoring is used when the unpackaged tuning fork acts as a temperature sensor.

IV. Limitations of the GNURadio approach

While most digital signal processing blocks are readily available and the missing functions dedicated to time & frequency metrology are being implemented thanks to the opensource software aspect of the tool, one major limitation in terms of signal processing bandwidth is due to the software running on general purpose central processing units (CPU).

Although dedicated hardware provides FPGA-based data acquisition, the signal processing is performed on the data-flow recovered from the FPGA and not implemented on the gate matrix itself, thus reducing the processing bandwidth to the communication bus bandwidth. Hence, while this environment provides a flexible testbench for real time prototyping of signal processing algorithms, it might not be suited when large (> 100 MS/s) bandwidths are considered. Alternate solutions include on-purpose aliasing or stroboscopy [19], [20].

Nevertheless, we consider this environment best suited for getting familiar with the basics of digital signal processing of RF signals, as well as for teaching purposes since this aspect is needed to train the current and future generation of researchers interested in such a topic. The easily available hardware (sound card, DVB receiver) and the ability to add signal source blocks thanks to the opensource code makes this software most versatile.

V. Conclusion

While analog implementations of most radiofrequency signal processing schemes provide suitable results for RADAR detection of signals returned from acoustic sensors acting as passive sensors and for characterizing oscillator stability, the need to design new hardware for each new application or new frequency band is time consuming and prone to the introduction of design errors in each new hardware setup. The flexibility of software reconfigurable processing chains is well suited for such applications. However, the need for a detailed understanding of the methods implemented in each processing block is hardly compatible with the use of closed source software, and an opensource solution as offered by the GNURadio software suite is considered. Reaching the targeted resolution of low phase noise oscillator using a full software implementation in which the RF front end is solely made of a fast analog to digital converter and all further processing steps are performed by software appears challenging with current available technologies.

Modeling and Analysis of a Liquid-Level Sensor Utilizing an Evanescent Field of a Trapped-Energy Vibrator

Ken Yamada, Tatsuya Ishioka, and Naoki Aita
Department of Electronic Engineering
Tohoku Gakuin University
Tagajo, Miyagi 985-8537, Japan

***Abstract*—Equivalent-network modeling and analysis have been presented for a liquid-level sensor that utilizes an evanescent field created by a trapped-energy vibrator. The network is constructed by modifying an electric network representing the propagation of thickness-vibration mode along the piezoelectric plate. Simulation has been performed for the sensors utilizing trapped-energy vibration modes of conventional type and the backward wave type. It is revealed that the computed results show a similar trend in variation to the experimental results that have been examined so far.**

Keywords—energy-trapping; liquid-level sensor; piezoelecytric resonator;piezoelectric sensor;equivalent-network analysis

I. INTRODUCTION

A novel approach for detecting a small-scale variation in liquid level that employs a piezoelectric thickness vibrator operating in a trapped-energy mode [1] has been studied by the authors [2]-[6]. In a trapped-energy resonator, an evanescent field is created in the surrounding region in which the vibration amplitude decays exponentially. If the evanescent region is dipped in a liquid, a depth-dependent leakage of vibration energy will occur and this causes the deterioration in the mechanical quality factor *Qm* and/or the electric conductance *G* at the resonance frequency. Because the liquid level is detected easily by observing variation in *G* of the resonator, it is desirable that the sensing device should be modeled by an equivalent electric network for simulating its operation. In this paper, a sensor is expressed by modifying an equivalent electric network proposed by Nakamura and coworkers [7],[8] which could represent the propagation of a thickness-vibration mode along the piezoelectric plate, and therefore its operation is simulated.

II. EQUIVALENT-NETWORK REPRESENTATION OF THE SENSORS AND RESULTS OF THE ANALYSES

A. *Device Using Conventional Trapped-Energy Resonator*

The sensor employing a conventional trapped-energy resonator is shown in Fig. 1(a) [2],[3]. A piezoelectric plate is supported vertically by clamping its top fringe and dipped in a liquid of which the surface level is measured. The original device studied so far was composed of a piezoelectric disk having an axisymmetric configuration with circular electrodes. However, the sensor model treated in this study is supposed to have two-dimensional geometry without taking the variations in the depth (width) direction into consideration.

This work was supported in part by a Grant-in-Aid for scientific research (C) (No. 22560340) from the Japan Society for the Promotion of Science.

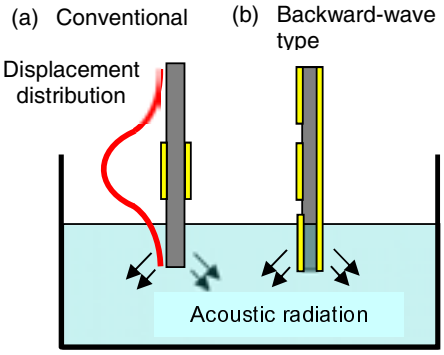

Fig. 1 Liquid-level sensors utilizing trapped-energy resonators.

Equivalent network representations for thickness vibration modes presented by Mason [9] or Krimholtz *et al*. [10] are well known and utilized widely so far. However, these networks are not applicable for vibrators operating in a trapped-energy mode. Therefore, the sensor is modeled by modifying an equivalent electric network proposed by Nakamura *et al*. [7],[8] which could represent the propagation of a thickness-vibration mode along the piezoelectric plate.

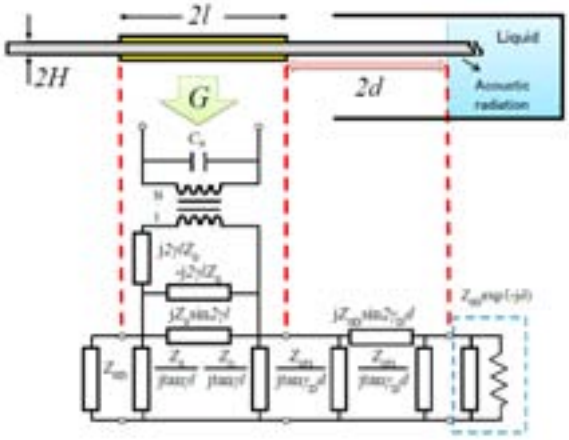

Fig. 2 Equivalent network representation for the sensor [11].

Figure 2 shows the network model [11] for the sensing vibrator with a thickness of 2*H*. Here, the sensor system is illustrated rotated by 90 ° from its original position. It has rectangular electrodes with a length of 2*l* in the direction of wave propagation and a width of unit length perpendicular to it. The central electroded region is composed of a transmission line (length: 2*l*, characteristic impedance: Z_0, wave number: γ), which is related to the electric terminal via some additional elements including a damped capacitance C_0. The section between the electrode edge and the liquid surface is expressed by a transmission line representing the unelectroded portion of length 2*d*, wave number γ_D and characteristic impedance Z_{0D}. The outermost regions are supposed to have an infinite length and are therefore expressed by the characteristic impedance Z_{0D}. In this network, Z_0 and Z_{0D} will be either real or imaginary depending on frequency. In the frequency range where energy trapping works, Z_0 is real, whereas Z_{0D} is imaginary. To take the radiation loss into account, a phase angle -δ is applied to Z_{0D} for the portion dipped in a liquid. The variation in the electric properties with the length 2*d* between the electrode edge and the liquid surface is evaluated by varying the ratio *d*/*H*.

A thickness-extensional-wave trapped-energy resonator composed of a thickness-poled $Pb(Zr,Ti)O_3$ (PZT) plate is assumed as a one-dimensional model of the sensor. Since the vibration loss is not considered intrinsically in the equivalent-network model in Fig. 2, a small amount of resistance is added at the electric port so that the resulting Q_m becomes 750. Figure 3 shows the admittance characteristic for an unloaded (free) plate computed using the network. Here, the horizontal axis is the normalized frequency Ω (=ω*H*/v_t, v_t: longitudinal wave velocity), the vertical axis is the normalized admittance $|Y|/(v_tC_0/H)$. The ratio of the electrode length 2*l* to the plate thickness 2*H* is supposed to be 9. It is noted that two inharmonic overtone modes as well as the fundamental mode are produced because the ratio *l*/*H* is large.

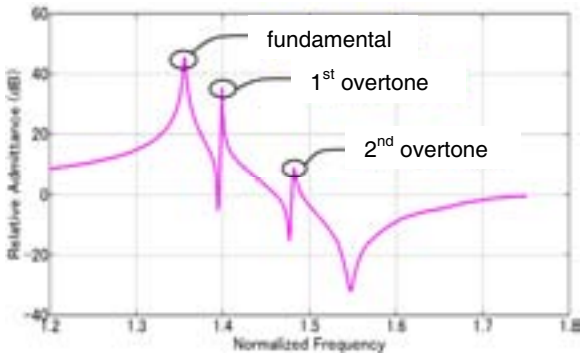

Fig. 3 Admittance characteristic computed for *l*/*H*=9.

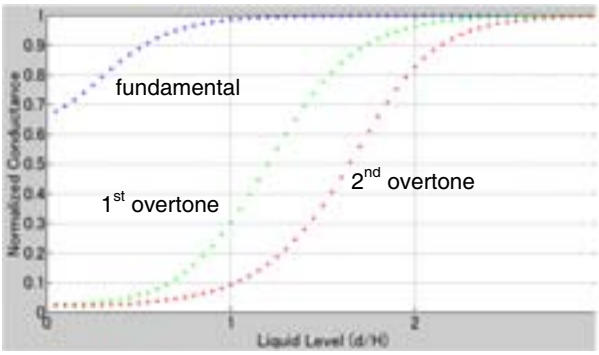

Fig. 4 Variations in *G* with the liquid level at resonances.

For sensing the liquid level, the variation in the electric conductance *G* is examined that corresponds to the variation in Q_m. Therefore, the variation in *G* with the normalized liquid level *d*/*H* is computed for the fundamental and the inharmonic modes. The result is shown in Fig. 4. Here, the vertical axis is normalized to *G* at *d*/*H*=3, and δ is assumed to be 1. It is noted that *G* decreases as the liquid surface approaches to the electrodes. The decay factor, the imaginary wave number determining the profile of the evanescent field, differs between the fundamental and inharmonic modes. For inharmonic modes, the decay factor is smaller than that for fundamental modes. Therefore, exponential decay is gentle for inharmonic modes, and the performance for liquid-level sensing is regarded as different depending on which mode is used.

B. Device using Trapper-Energy Resonator for Backward-Wave-Type Thickness Vibration

In some thickness vibration modes, the dispersion curve takes a different form, as shown in Fig. 5(a). In this case, the corresponding vibration has the cut-off regime above the cut-off frequency, and therefore it becomes a backward-wave mode. To realize energy trapping for this mode, the surrounding region should be electroded and short-circuited so that the wave number there becomes imaginary, as shown in Fig. 5(b) [5], [12]-[14]. In the trapped-energy mode of this type, spurious-free characteristics are obtained around the anti-resonance frequency rather than the resonance frequency. Therefore, the use of antiresonance may be effective for liquid level sensing.

The sensor configuration for this type of trapped-energy vibrator and the equivalent-network representation are shown in Figs. 1(b) and 6, respectively. A backward-wave-type trapped-energy resonator composed of a thickness-poled $PbTiO_3$ plate is assumed as a model. Two transmission lines representing the unelectroded gaps of the length 2*l'* are added

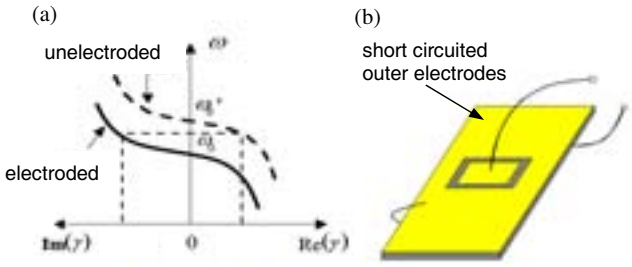

Fig. 5 (a) Dispersion curve for backward-wave thickness vibration and (b) electrode configuration for energy trapping.

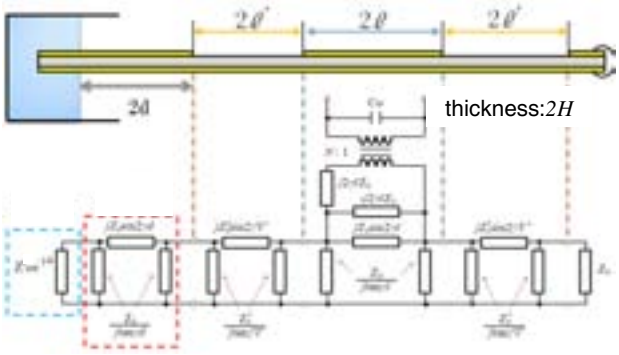

Fig. 6 Equivalent network for the sensor utilizing trapped energy vibrator of backward-wave mode.

to the network shown in Fig. 2. The outermost metallized regions are supposed to have an infinite length and are therefore expressed by the characteristic impedance Z_0. In the sensing side, however, a transmission line of the length representing the out-of-liquid portion of length $2d$, wave number γ and characteristic impedance Z_0 is added, which is terminated by $Z_0\exp(-j\delta)$.

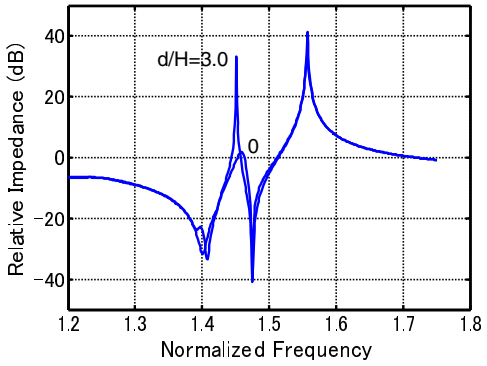

Fig. 7 Impedance characteristics computed for d/H of 0 and 3.0.

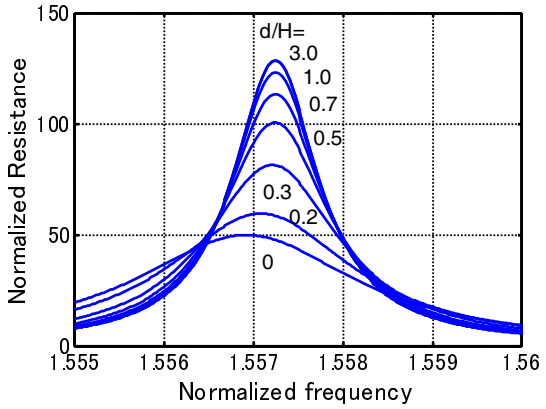

Fig.8 Variation in R with the liquid level at antiresonance.

In the trapped-energy mode of this type, spurious-free characteristics are obtained around the anti-resonance frequency rather than the resonance frequency [5], [12]-[14]. Therefore, the variations in the electric impedance characteristic are computed for d/H of 0 and 3.0. The result is shown in Fig. 7. The ratio of the center-electrode length $2l$ to the plate thickness $2H$ is supposed to be 4, and l'/H=0.5. The horizontal axis is the normalized frequency Ω (=$\omega H/v_l$, v_l: longitudinal wave velocity), and the vertical axis is the normalized impedance $|Z|/(H/v_lC_0)$. Although it is not clear enough for the fundamental mode, it is noted that smaller d/H (higher liquid level) gives a lower peak level at antiresonance frequencies.

The frequency characteristic of R, the real part of Z, is also computed for several values of d/H at the antiresonance frequency of the fundamental mode. The result is shown in Fig. 8. Here, the vertical axis is the normalized resistance $R/(H/v_lC_0)$. A gradual decrease in R is observed in accordance with the increase in the liquid level.

III. Conclusions

An equivalent network representation is presented for the liquid-level sensors operating in a trapped-energy mode thickness vibration of conventional type and backward-wave type. The variation in G and/or R with the liquid level has been computed using this network model, and it is revealed that the computed plots show a similar trend in variation to the experimental results that have been reported so far.

Abstract - **This paper deals with the formation of the ASC immunocomplex at the surface of the Y-cut $GaPO_4$ resonator vibrating in thickness-shear mode. The orientation YXl (-16.4°), with the tolerance on the rotation angle ± 0.1° of the sample is used in this study. The relevant $GaPO_4$ material constants were calculated. The biochemical affinity process can be characterized by association and dissociation kinetic rate constants, by binding between a covalently immobilized small molecule and its relative antibodies. The binding curves of series resonance frequency f_s vs. time t were measured and discussed. The following tasks were considered: activation by the cystamine, glutaraldehyde, and albumine as bioactive buffer, ASC antibody solution with phosphate buffer, and regeneration of the biosensor.**

Standard frequency response of a new biosensor was evaluated by the analyzer Agilent E5100A. However, the newly developed digital processing techniques are used to precise the measurement and to evaluate the frequency changes. The Field Programmable Gate Array circuits (FPGA) open the field of digital signal processing. Our solution uses the digital down converter (DDC) for evaluation of frequency changes. The DDC consists of three components: reference complex oscillator, low-pass filter and down sampler. Complex (quadrature) oscillator works on principle of direct digital synthesis and it provides a pair orthogonal sine and cosine waveform. The complex multiplier works as mixer, its output includes images centered at the sum and difference of input frequencies. The low-pass filter is digital FIR filter and it passes the difference frequency. The down sampler reduces the sampling rate of a signal.

The digital solution gives important advantages – digital stability, controllability and small size, that allow realize the biosensor controller unit in a smaller volume. This solution reduces the cost of the biosensor unit and brings the concept of "lab on chip". The resolution of the $GaPO_4$ biosensor remains unchanged, and biosensor sensitivity is increased.

Keywords: GaPO4 biosensor; ASC formation; FPGA circuits; evaluation of frequency changes

I. INTRODUCTION

A classical realization of a biosensor is based on the AT-cut quartz resonator, vibrating in thickness-shear mode of vibration [1-8]. A process of activation of biosensor influences the resonance frequency changes vs. time. In many experiments, the resonance frequencies of the piezoelectric resonator are measured, using classical oscillator and methods.

In the last years, the outstanding properties of the quartz homeotype gallium orthophosphate ($GaP0_4$) promise new applications of this modern representative of piezoelectric single crystals with large electromechanical coupling factor [9-11]. Its coupling factor k_{26} associated with the resonators vibrating in the thickness-shear mode is approximately two times greater than that of quartz [12]. Now, the nonlinear properties of the $GaP0_4$ and methods for determination of some nonlinear constants of $GaP0_4$ were presented [12]. The outstanding properties as remarkable frequency, temperature and chemical stability of this quartz homeotype make possible to use it such as a biosensor. The increased number of the papers indicates a significance of the $GaP0_4$ too [13]. However, the use of thickness-shear mode of vibrations of the $GaP0_4$ resonator such as biosensor is relatively rare. The biosensor´s functions are closely connected to the signal processing. The field of digital signal processing is now open for modern microelectronic circuits such as FPGAs [15-16]. They are the reasons to develop our studies on $GaPO_4$ biosensors and to prepare the miniaturized sensible biosensor.

II. ROTATED Y-CUT GAPO4 RESONATOR IN OUR STUDY

In order to measure the important parameters of the $GaP0_4$ Y-cut resonators, sample plates of the orientation (YXI)-16.4° were prepared and electroded by AVL of Graz, Austria, and measured in our laboratory. The plates were 10 mm in diameter and 0.3 mm thick. The gold electrodes of 5 mm diameter were deposited on the major surfaces of the plates. The orientation of the plates was measured to ± 0.1°. The basic material parameters were calculated and transformed to the orientation (YXl)-16.4° Y-cut [12].

III. EXPERIMENTAL

A. Activation Process

Affinity interaction describes usually the formation of specific supramolecular complexes between two affinity partners. The surface of the gold-electroded resonator was firstly treated 30 min with 100 ml of acetone, and dried. Using cystamine solution (200 mg) in water, applied on the gold

TUL – Institute of Mechatronics and Computer Engineering.

electrode surface (100 µl), incubated 2 hours, then crystal unit was washed with water and air dried. Alternatively, the glutaraldehyde 3% solution 3mg/97mg in phosphate buffer with pH=7.0, applied on the gold electrode surface (100 µl), incubated 1 hour was used, then crystal unit was washed and air dried. In the third case, the albumin solution in phosphate buffer 500 µg/l ml, applied on the gold electrode surface (100 µl), incubated and stored at 4 °C 12 hours was used, then crystal unit was washed air dried. The piezoelectric unit with bio-complex as biosensor is prepared to bind with its covalent layer the antibody liquid. The frequency shifts caused by activation process are given in Table I.

TABLE I. CHANGES IN RESONANCE FREQUENCY CAUSED BY DIFFERENT MODE OF THE ACTIVATION. $GaPO_4$ RESONATOR YXL (-16.4^0).

Mode of activation	$GaPO_4$ Resonator YXl (-16.4^0)	
	fs [Hz] in the measuring cell	fs [Hz] without measuring cell
Without active surface	4 057 182	4 058 959
After treatment by acetone	4 057 663	4 059 184
After activation by cystamine	4 057 502	4 059 124
After activation by gluterdehyde	4 057 868	4 059 662
After activation by albumine	4 058 033	4 059 965

B. GaP0$_4$ Resonator´s Affinity Interactions

An important issue affecting sensor performance is the proper attachment of a biological film to the sensor surface. Several immobilization techniques have been developed and its properties studied [2], [8] to create an affinity sensor. For an affinity sensor, receptor molecules have to be immobilized on surface on the gold electrodes of the $GaPO_4$ disc. The area of the electrodes dimensions is characterized by maximum vibrations (trapped energy case). The corresponding binding molecule, if present in the sample solution, will bind specifically to the receptor of the surface. In this case the sensor directly responds to the formation of the receptor-ligand complex. When the ligand and receptor are an antigen and the relative antibody their interaction will lead to an immunocomplex. We analyzed the binding between a covalently immobilized small molecule and its relative antibodies. Formation of immunocomplex AB at the surface of the $GaPO_4$ resonator vibrating in thickness-shear mode can be characterized by association k_a and dissociation k_d kinetic rate constants. The binding curves of series resonance frequency f_s vs. time t were derived in [8]. The typical characteristics $f_s(t)$ of immunosensor shown fifth phases:

a) Relative stable background frequency $f_s(t)$ caused by presence of buffer (with their loading effect). This phase typically lasts five minutes.

b) Then, sample solution containing a mixture of antibody and analyte is injected (association phase). The antibodies with free binding sites interact with the immobiliyed ligand. A decrease of frequency *fs* is observed when a surface mass on the crystal increases (the equilibrium change *feq* is achieved eventually). This phase typically lasts about 30 minutes.

c) Reaction of biosensor with phosphate buffer. Buffer is injected again and the dissociation of immunocomplexes is observed. From this phase, the dissociation constant *kd* can be obtained. The frequency *fs* represents the amount of surface-bound irnmunocomplex at the beginning of dissociation. This phase typically lasts about 30 minutes.

d) Area of regeneration of biosensor after application of the formic acid. This phase typically lasts five minutes.

e) Terminal phase of resonator regeneration. The process of the regeneration of all covalent bonds between molecules of antibody and molecules of bioactive layer is observed. About 5 minutes.

The reaction time depends on the concentration of antibody and analyte. These results are consistent with [1] and [2].

The series resonance frequency f_s, has been determined using the standard IEEE method and Network Analyzer AGILENT E5100A in accordance to the [14]. The affinity process is presented by Fig. 1 and 2, which describes the affinity reactions of the antibody solutions ASC with phosphate buffer 1:250, or 1:100 respectively.

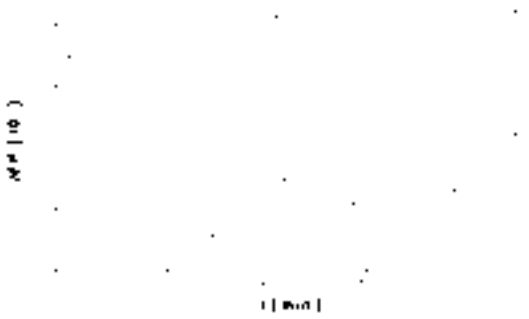

Figure 1. Affinity reaction of the biosensor with the antibody ASC 1:250. GaP0$_4$ piezoelectric resonator YXI (-16.4°).

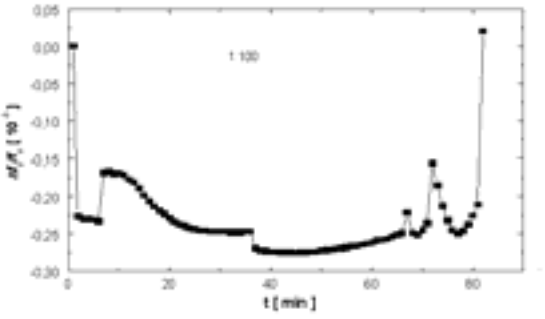

Figure 2. Affinity reaction of the biosensor with the antibody ASC 1:100.

IV. AFFINITY ELECTRONIC EVALUATION

The standard frequency response of a new biosensor was evaluated by the classical analog techniques – using analyzer Agilent E5100A (see Figure 3).

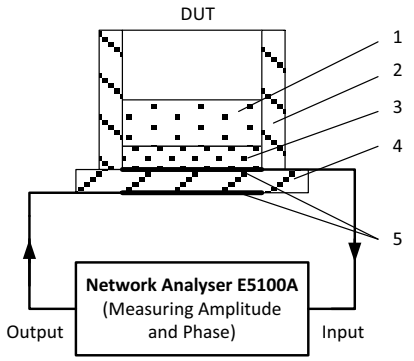

Figure 3. Block diagram of a laboratory biosensor measuring systems. 1 – Bioactive liquid, 2 – Teflon cell, 3 – Buffer, 4 – AT quartz resonator in measuring π-network, 5 – Au electrodes.

With the advent of newer larger and faster semiconductor devices has opened up the field of digital signal processing. Therefore we are made an evaluation of the signal processing (changes in resonance frequency) using digital down conversion (DDC). DDC is a technique that takes a band limited high sample rate digitized signal, mixes the signal to a lower frequency and reduces the sample rate while retaining all the information. The basic arrangement shows the Figure 4.

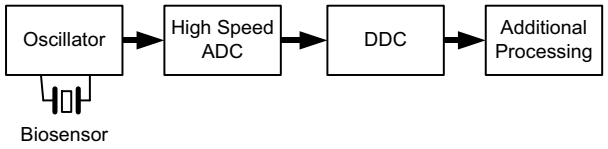

Figure 4. The basic arrangement of frequency evaluation

The signal from oscillator with biosensor (frequency about 5 MHz) is converting using fast analog-to-digital converter (ADC) to digital signal. The sample rate of an ADC must be at least twice the signal rate (the Nyquist theorem). 12-bit ADC was used for good dynamic range.

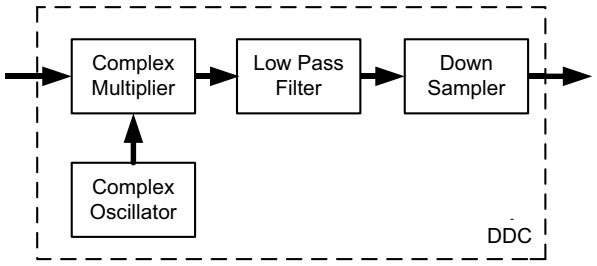

Figure 5. Block structure of DDC

Principle of the DDC is a fundamental part of many communication systems and consists of three basic subcomponents: complex numerically controlled oscillator (NCO), low-pass filter (LPF) and down-sampler (which may be integrated into the LPF). Figure 5 illustrates the block structure of the DDC.

The NCO is a digital signal generator which creates a synchronous, discrete-time, discrete-value representation of a waveform, usually sinusoidal. In our case the NCO has quadrature output (generates sine and cosine waveforms) and consists of two parts: phase accumulator (PA) and phase-to-amplitude converter (PAC) – see Figure 6. The frequency control register keeps generally N-bit word FCW. A binary phase accumulator consists of N-bit binary adder and phase register. Each clock cycle produces a new N-bit output consisting of the previous output obtained from the register summed with FCW which is constant for a given output frequency. The resulting output waveform is staircase with step size FCW (a modulo-2^N sawtooth waveform). These outputs are converted by the PAC to a sampled sinusoid or cosinusoid. PAC is designed as a memory (look-up table) - PA output word represents address.

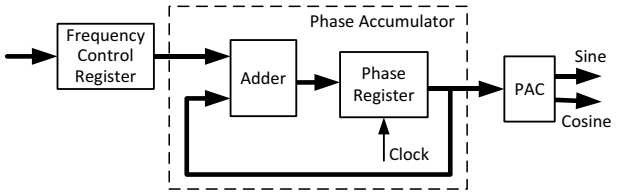

Figure 6. NCO with quadrature output

The function of the complex multiplier (mixer) is to multiply the incoming signal (from ADC) by the generated sinusoid to shift the spectrum of signal – generates sum and difference frequency. An implementation uses two multipliers, one each for the sine and the cosine. If frequencies of received signal and local tunable NCO are near, difference frequency draw to zero (spectrum centered at zero). Therefore frequency changes can measure very precisely.

The LPF pass the difference frequency while rejecting the sum frequency spectral image. LPF was implementing high speed finite impulse response (FIR) filter (4^{th} order) using registered adders and hardwired shifts. The following down sampler reduces the sampling rate of a signal for additional slower processing.

The implementation of all electronic blocks is testing on development kit which consist fast ADC, FPGA circuit (family Altera Cyclone III) and crystal reference oscillator.

V. CONCLUSION

The characteristics frequency-time correspond to the experimentally values obtained by AT-cut quartz resonator, but increasing sensitivity of the $GaP0_4$ resonator, based on the large coupling factor k_{26}, was found. The small differences in the characteristics described as a), c) and e) are caused by the process of regeneration, realized previously. The attention should be devoted to the viscoelastic interaction of liquid and resonator surface, roughness of resonator surface, controlling electronic circuit, surface tension, and different chemical interaction of resonator surface - liquid.

The digital solution gives important advantages – digital stability, controllability and small size, that allow realize the biosensor controller unit in a smaller volume. This solution reduces the cost of the biosensor unit and bringing it closer to the solutions "lab on chip". However, a resolution of the biosensor remains.

Frequency Stability Estimation of Compass On-Board Clock Based on Smoothed Broadcast Ephemeris

Hang Gong, Wenke Yang, Hai Sha, Xiangwei Zhu, Feixue Wang
College of Electronic Science and Engineering, National University of Defense Technology,
Changsha, Hunan, P.R. China, 410073
gonghang@nudt.edu.cn

***Abstract*—For Compass and Galileo systems which are currently in their stage of construction, it is difficult to obtain precise on-board clock short-term stability for common users. In this paper, a simple estimation method based on smoothed broadcast ephemerides is proposed, which only needs observation from one single receiver. The principle of this method is discussed, followed by performance evaluation using GPS data. We conclude that the relative error of short-term stability estimated with this method is less than 10% for average time of 1~800 seconds. Short-term stability estimation of all the current 14 Compass on-board clocks are presented, with the result of approximately 6×10^{-12} at average time of 1s and 2×10^{-13} at 1000s.**

Keywords-BeiDou Navigation Satellite System (BDS/Compass); on-board clock; short-term stability estimation; precise ephemeris; smoothed broadcast ephemeris;

I. INTRODUCTION

On-board clock performance evaluation is of great significance for satellite navigation system. In the application such as satellite clock offset modeling, simulation and prediction, not only characteristics determined by the medium- and long-term stability need to be known, short-term stability parameters of satellite clock also need to be obtained.

Stability estimation of GPS satellite clock is usually implemented using IGS precise clock data, which is derived from post-processing using complex orbit determination and time synchronization (ODTS) method [1]. The sampling interval of 30s typically, even the sampling interval of 5s provided by Center for of Orbit Determination in Europe (CODE), cannot satisfy the need of shorter average time (e.g. 1s) frequency stability estimation. On the other hand, IGS products are only available for GPS and GLONASS system currently, not for BeiDou (BDS/ Compass) or Galileo system. In addition, due to limited access permission for monitoring networks observation data, there are certain difficulties for Compass and Galileo common users to obtain precise satellite clock parameters presently.

In this paper, based on the analysis of the single station estimation method of satellite clock stability in Section II, Section III proposes a method based on smoothed broadcast ephemeris. Compared with IGS clock products, the method are validated using GPS data in Section IV. Using this simple method, the short-term stability of present Compass on-board clocks is presented at the end.

II. SINGLE STATION ESTIMATION METHODS OF SATELLITE CLOCK STABILITY

For satellite *i*, the carrier phase observation equations of receiver *j* on the frequency *k* are shown as follows:

$$\varphi_k^{ij} = d^{ij} + c\left(\Delta t_S^i - \Delta t_R^j\right) + T_k^{ij} - N_k^{ij}\lambda_k + \varphi_{k0}^{ij} + s^{ij} + t_k^i + r_k^j + m^{ij} + \varepsilon_{\varphi k}^{ij} \quad (1)$$

Where φ_k^{ij} is carrier phase observation; d^{ij} is geometric distance of satellite and receiver; Δt_S^i and Δt_R^j are satellite and receiver clock offset; T_k^{ij} is atmospheric propagation delay; $N_k^{ij}\lambda$ and φ_{k0}^{ij} are integral and fractional ambiguity of carrier phase; s^{ij} is error caused by the Sagnac effect; t_k^i is transmission delay of satellite; r_k^j is receive delay of receiver; m^{ij} is multipath error; $\varepsilon_{\varphi k}^{ij}$ is measurement noise of carrier phase.

Because only relative clock offset is needed to estimate satellite clock short-term stability, we can determine the on-board clock offset with respect to receiver clock [2]. In this case, satellite clock stability can be obtained as long as the stability of receiver clock is better than that of satellite clock, which can be achieved easily.

Equations (1) show that, several errors should be corrected before the computation of satellite clock offset [2]. It should be noted that the ionospheric delay has greater impact among these errors, thus the residuals will significantly increase estimation error of frequency stability for large average time if it cannot be corrected accurately. Dual-frequency combination is one of the most effective methods, but the noise variance will be magnified when using this method.

For carrier phase observations, general dual-frequency ionosphere-free combination is as follows:

$$\varphi_{if}^{ij} = \frac{\left(\varphi_2^{ij} + N_2^{ij}\lambda_2\right) - \gamma\left(\varphi_1^{ij} + N_1^{ij}\lambda_1\right)}{1-\gamma},\ \gamma = \frac{f_1^2}{f_2^2} \quad (2)$$

Equation (2) shows that the noise variance of φ_{if}^{ij} will be larger than $\varepsilon_{\varphi 1}^{ij}$ or $\varepsilon_{\varphi 2}^{ij}$, so although estimation error of frequency

stability with large average time is improved, but the estimation error of short-term stability will correspondingly increase.

Let ionospheric delay correction on the frequency f_1 be:

$$\Delta\varphi_1 = \varphi_1^{ij} - \varphi_{if}^{ij} + \frac{N_2^{ij}\lambda_2 - \gamma N_1^{ij}\lambda_1}{1-\gamma} = \frac{\varphi_1^{ij} - \varphi_2^{ij}}{1-\gamma} \tag{3}$$

Then revise dual-frequency ionosphere-free combination to [3]:

$$\varphi'_{if} = \varphi_1^{ij} - smooth\{\Delta\varphi_1\} \tag{4}$$

Where smooth {•} is a smoothing operator.

By equations (3) and (4), carrier phase integer ambiguity solutions could be avoided, but cycle slips should be detected and repaired. On the other hand, since the ionospheric delay will not dramatically changes, smoothing $\Delta\varphi_1$ will greatly reduce the error introduced by the dual-frequency combination, so that φ'_{if} will get same noise variance as single-frequency observation, and then both short- and long-term frequency stability estimation error introduced by ionospheric delay can be reduced to minimum.

After all the errors are corrected, the satellite on-board clock offset with respect to receiver clock is as follows:

$$\Delta t_k^j = \frac{1}{c}\left(\varphi_k^j - d_k^j\right) + \Delta\varepsilon_\varphi^j \tag{5}$$

Where $\Delta\varepsilon_\varphi^{ij}$ is residual error. Receiver can obtain carrier phase observation φ_k^{ij} with high sampling rate, and then satellite clock offset with the same sampling rate can be obtained. As long as geometric distance between satellite and receiver is determined beforehand, the short-term stability of on-board clock can be estimated consequently.

Since receiver position can be accurately calibrated, the main problem to determine the geometric distance is how to obtain precise satellite position. There are three approaches to reduce calculation errors of geometric distance: Firstly, we can obtain accurate satellite position through IGS precise ephemeris products [4]; Secondly, we can accurately determine the geometric distance, such as using satellite laser ranging [5]; Thirdly, we can try to eliminate the effect of geometric distance error by two-way ranging [6] or observation fitting [7], etc. For common users, using precise ephemeris is a relatively simple method, but for Compass and Galileo systems there is no precise ephemeris available but broadcast ephemeris for the moment.

III. Estimation Methods Based on Smoothed Broadcast Ephemeris

A. *Errors of Broadcast Ephemeris*

Broadcast ephemeris is predicted results based on the post-processed satellite position data using ODTS method. The prediction error of the satellite orbit both in cross-track and along-track direction normally is 5~10m [8], but in radial direction is much smaller for it is fully observed, with only 1/3 to 1/4 of the error in cross-track or along-track directions [8], and it also changes relatively slowly, which affects the estimation of the short-term stability of the satellite clock very slightly. The error projected to receiver's line of sight direction (LOS) exhibits similar characteristic.

Taking GPS Satellite PRN14 as an example, its ECEF coordinate error of broadcast ephemeris compared with precise ephemeris on September 10, 2011 is shown in Figure 1, and its LOS direction error observed by U.S. Naval Observatory (USNO) station is also shown.

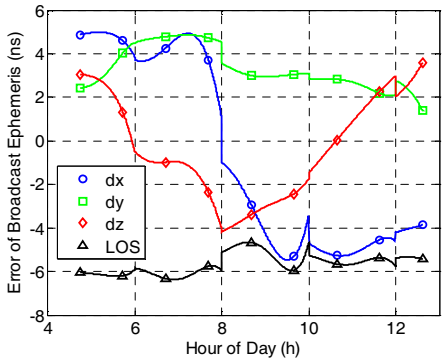

Figure 1. Broadcast ephemeris error of GPS PRN14

As shown in Figure 1, although the broadcast ephemeris absolute errors in x, y, and z-direction show marked variation up to ±6ns (approximately ±2m), but the variation of relative error in receiver's LOS direction is only 2ns. And there are much orbit jumps at the time of ephemeris update (TOE) for all direction.

Figure 2 and Figure 3 show statistical mean and standard deviation of prediction error of GPS broadcast ephemeris from September 9 to 12, 2011. It can be seen that the backward or forward prediction error within 2 hours is very small and stable, but increases radically beyond 2 hours.

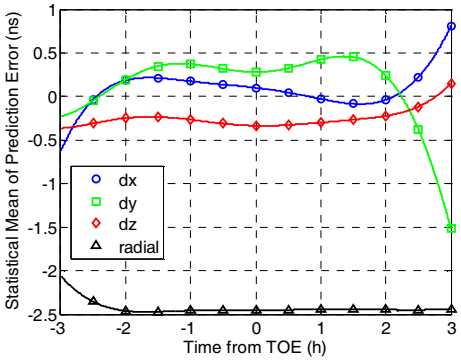

Figure 2. Statistical mean of prediction error of GPS broadcast ephemeris

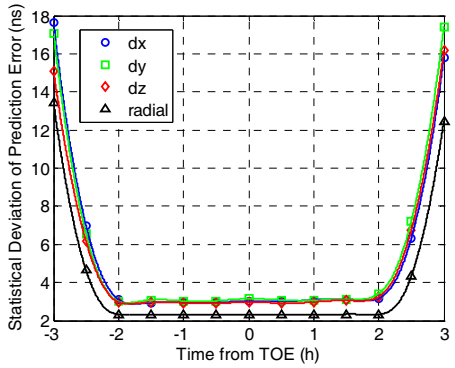

Figure 3. Statistical deviation of prediction error of GPS broadcast ephemeris

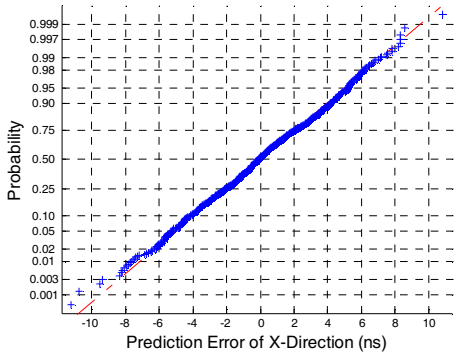

Figure 4. Lognormal probability plot of x-direction prediction error

Figure 4 shows lognormal probability statistical of x-direction prediction error within 2 hours of GPS broadcast ephemeris, which indicates that the backward and forward prediction errors are nearly normal distribution, so the prediction error of broadcast ephemeris can be modeled as:

- The prediction errors of x, y and z direction within 2 hours are distributed as $N(0,\sigma_x^2)$, $N(0, \sigma_y^2)$ and $N(0, \sigma_z^2)$ respectively;
- They are irrelevance with prediction time;

B. Smoothing Method of Broadcast Ephemeris

There are two groups of ephemeris parameters available for each observation epoch t, the TOE of the two adjacent groups of broadcast ephemeris are denoted as t_b and t_f respectively, and satellite positions calculated from the above two groups of broadcast ephemeris for t as $\mathbf{P_b}$ and $\mathbf{P_f}$, the prediction errors of $\mathbf{P_b}$ and $\mathbf{P_f}$, as $\mathbf{w_b}$ and $\mathbf{w_f}$, the actual satellite position as $\mathbf{P}$, then we have:

$$\mathbf{P_p} = \mathbf{H}\cdot\mathbf{P} + \mathbf{w} \tag{6}$$

where,

$$\mathbf{P_p} = \begin{bmatrix}\mathbf{P_b}\\ \mathbf{P_f}\end{bmatrix} = \begin{bmatrix} x_b & y_b & z_b \\ x_f & y_f & z_f \end{bmatrix},\ \mathbf{H} = \begin{bmatrix}1\\1\end{bmatrix} \tag{7}$$

$$\mathbf{P} = \begin{bmatrix} x & y & z \end{bmatrix},\ \mathbf{w} = \begin{bmatrix}\mathbf{w_b}\\ \mathbf{w_f}\end{bmatrix} = \begin{bmatrix} w_{bx} & w_{by} & w_{bz} \\ w_{fx} & w_{fy} & w_{fz} \end{bmatrix} \tag{8}$$

So the covariance of $\mathbf{w}$ is

$$\mathbf{C_w} = \mathrm{E}\left\{[\mathbf{w}-\mathrm{E}(\mathbf{w})][\mathbf{w}-\mathrm{E}(\mathbf{w})]^{\mathrm{T}}\right\} = \left(\sigma_x^2+\sigma_y^2+\sigma_z^2\right)\mathbf{I} \tag{9}$$

Then the minimum variance unbiased estimation of $\mathbf{P}$ is

$$\hat{\mathbf{P}} = \left(\mathbf{H}^{\mathrm{T}}\mathbf{C_w^{-1}}\mathbf{H}\right)^{-1}\mathbf{H}^{\mathrm{T}}\mathbf{C_w^{-1}}\mathbf{P_p} = \frac{1}{2}\mathbf{P_b} + \frac{1}{2}\mathbf{P_f} \tag{10}$$

$$\mathbf{C}_{\hat{\mathbf{P}}} = \left(\mathbf{H}^{\mathrm{T}}\mathbf{C_w^{-1}}\mathbf{H}\right)^{-1} = \frac{1}{2}\left(\sigma_x^2+\sigma_y^2+\sigma_z^2\right) \tag{11}$$

Taking GPS as an example, the broadcast ephemeris is updated every 2h. Each group of ephemeris parameters is a combination of forecasted fitting results using data of a specific time range. Thus the calculated satellite orbit parameters according to each group of ephemeris parameters jump at the time of ephemeris parameters update. A clock phase jump with amplitude of x_0 will introduce an additive overlapping allan variance as follows:

$$\sigma_y^2(\tau) = \frac{x_0^2}{(N\tau_0 - 2\tau)\tau} \approx \frac{x_0^2}{N\tau_0}\tau^{-1},\ (2\tau << N\tau_0) \tag{12}$$

where τ_0 is sampling interval and N is total sampling number.

Equation (12) shows that phase jumps will introduce additive white frequency modulation (WFM) noise, thus the orbit jumps will impact short-term stability estimation, but equation (10) could not weaken the transition, so it is needed to smooth the broadcast ephemeris in order to reduce this impact.

The prediction error model indicates that the predicted error of each group of broadcasted ephemeris is roughly the same, so it is suggested here to revise equation (10) to smooth broadcast ephemeris using linear weighted method according to the ephemeris age, namely:

$$\hat{\mathbf{P}}' = \frac{t_f - t}{t_f - t_b}\cdot\mathbf{P_b} + \frac{t - t_b}{t_f - t_b}\cdot\mathbf{P_f} \equiv k_b\cdot\mathbf{P_b} + k_f\cdot\mathbf{P_f} \tag{13}$$

Then we have:

$$\mathrm{E}\left(\hat{\mathbf{P}}'\right) = \mathrm{E}\left(k_b\cdot\mathbf{P_b} + k_f\cdot\mathbf{P_f}\right) = \mathbf{P} \tag{14}$$

$$\mathbf{C}_{\hat{\mathbf{P}}'} = \left(\mathbf{H}^{\mathrm{T}}\mathbf{C}^{-1}\mathbf{H}\right)^{-1} = \left(k_b^2+k_f^2\right)\left(\sigma_x^2+\sigma_y^2+\sigma_z^2\right) \tag{15}$$

We can see that $\hat{\mathbf{P}}'$ is still an unbiased estimation of $\mathbf{P}$, and although the estimation variance increases a bit, the satellite orbit will be smoothed.

Still taking USNO stations as example, Figure 5 shows smoothed results of GPS PRN14 broadcast ephemeris during the same time as Figure 1. It is shown that the smooth method eliminates the jumps of calculated satellite orbit, which will help to reduce the error of short-term stability estimation.

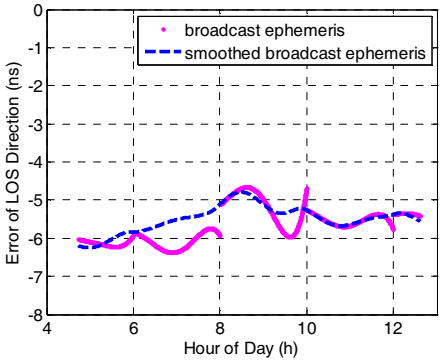

Figure 5. Smoothed broadcast ephemeris error of GPS PRN14

C. *Principle of Estimation Method*

Based on the above discussion, as shown in Figure 6, the estimation method based on precise ephemeris, broadcast ephemeris and smoothed broadcast ephemeris (denoted as PE method, BE method and SBE method respectively for the sake of simplicity) is carried out as follows:

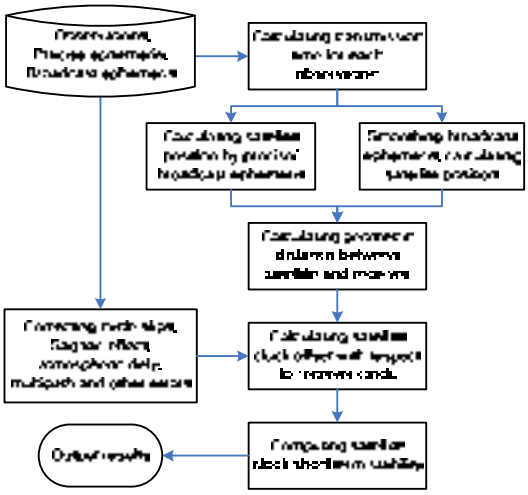

Figure 6. Principle of PE, BE and SBE method

IV. Experiments and Analysis

In this section we will use USNO station's GPS carrier phase observations published by IGS to verify these methods. This station provides GPS measurements at the rate of 1 Hz, and its receiver clock refers to a hydrogen maser which is disciplined by UTC(USNO), so that both short-term and long-term frequency stability of the receiver clock are much better than satellite on-board clock.

As a comparison of SBE method, the stability of GPS PRN14 on-board clock obtained by PE method is shown in Figure 6 firstly, along with the results of CODE precision clock product with 5s sampling interval in the same period. The experimental period is from GPST 2010-9-10 06:00:00 to 2010-9-10 12:00:00.

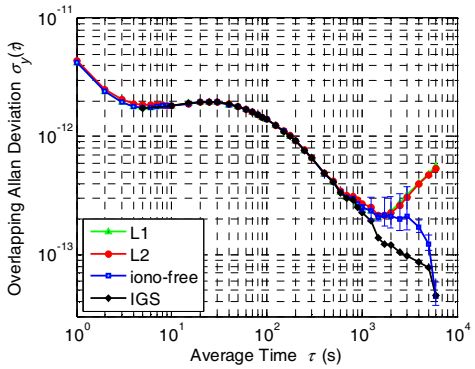

Figure 7. Frequency stability of GPS PRN14 by PE method

'L1' and 'L2' in Figure 7 are results with ionospheric delay corrected by Klobuchar model, 'iono-free' is corrected by dual-frequency ionosphere-free combination using equation (4). The above result shows that, ionosphere-free combination result is better than L1 and L2 for average time above 1000s due to correcting ionospheric delay effectively, and its short-term stability does not deteriorated within 10s average time due to noise variance smoothed. For the sake of simplicity, only dual-frequency ionosphere-free combination results will be presented in the following discussions.

Based on the same observation data of USNO station, the short-term stability estimations of GPS PRN14 on-board clock by BE and SBE method are shown in Figure 8.

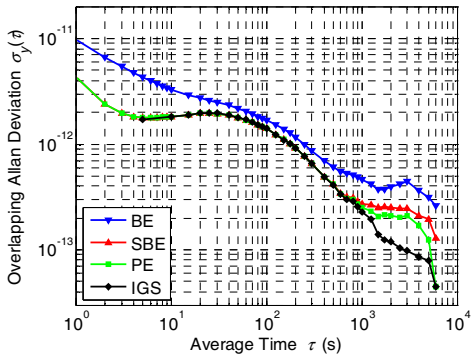

Figure 8. Frequency stability of GPS PRN14 by BE and SBE method

Taking the frequency stability calculated by IGS precise clock as true value, and the relative deviation between PE, BE and SBE method results and the corresponding true value as their estimation error. The three methods are compared with each other in Table 1 in four aspects: maximum applicable average time, maximum estimation error, and applicable GNSS systems at this stage. In which the maximum applicable average time is evaluated as the maximum average time with error less than 10%, and the maximum estimation error is evaluated as the maximum relative deviation within average time of 1000s.

TABLE I. PERFORMANCE COMPARISON OF THE THREE METHODS

	PE method	**BE method**	**SBE method**
maximum applicable average time	900s	/	800s
maximum estimation error	10.6%	148.7%	20.9%
applicable GNSS systems at this stage	GPS GLONASS	GPS GLONASS Compass Galileo	GPS GLONASS Compass Galileo

From the above table, we can draw the following conclusions:

- Orbit jumps introduced by broadcast ephemeris have a greater impact on the stability estimation, with WFM noise was introduced, leading that the results of BE method deviate from true value for all the average time, and the maximum estimation error is up to 148.7%;
- Since the influence of orbit jumps are eliminated by smoothed broadcast ephemeris, the estimation error of SBE method is greatly reduced. The result of SBE method is very close to PE method, and remarkably consistent with the true value. Its relative error is less than 10%, and even two order of magnitude less than the true value for the average time of 10~500s in particular.

V. COMPASS RESULTS

As for Compass system, precise clock is not available for validating the estimation results, and none of the results of on-board clock short-term stability is released until now, except for the stability of some satellite clock for the average time of above 100s presented by the literature [9], which is obtained from observation during February 2012 by ODTS method (denoted as ODTS results in the following discuss). In this paper, the observation data obtained from two monitoring stations (station 01 and station 03) within the same observation period are employed to estimate the short-term stability of satellite clock, and the results of the two stations are compared to validate themselves to another. As the receivers of the two stations refer to hydrogen masers which are synchronized with BDT (Compass System Time), the frequency stability of the receiver clock are better than satellite on-board clock, so the results can be used as a estimation of satellite on-board clock. In addition, ODTS results are also presented as a comparative reference.

Firstly we will compare the SBE method and ODTS results for Compass. The estimation results of SV07 on-board clock (rubidium) are shown in Figure 9, in which dual-frequency ionosphere-free combination of B1 and B3 carrier phase observations from BDT 2012-12-02 00:00:00 to 2012-12-03 00:00:00 are used. It should be noted that the frequency drift of satellite clocks are eliminated in literature [9], in order to compare with it the results of BE and SBE method in Figure 9 also eliminated frequency drift.

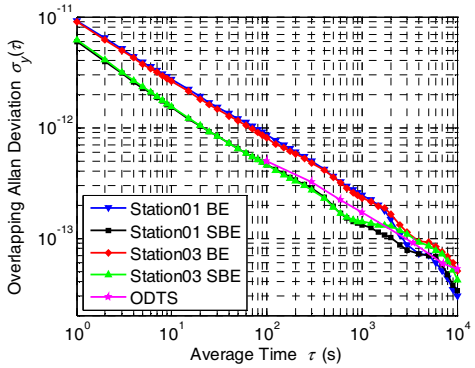

Figure 9. Frequency stability of Compass SV07 by SBE method

Figure 9 shows that the estimation results of the stations 01 and 03 by SBE method are consistent with each other, and agree well with ODTS results within the average time of less than 10000s. Since Compass broadcast ephemeris is updated once every 1 hour, orbit calculated by the broadcast ephemeris jumps frequently, but estimation error is greatly reduced after smoothing broadcast ephemeris.

Figure 10 shows stability estimation of all the 14 Compass satellite on-board clocks, in which the observation period is from BDT 2012-12-02 00:00:00 to 2012-12-04 00:00:00, but frequency drift is not eliminated in order to reflect the actual characteristics of space rubidium clock.

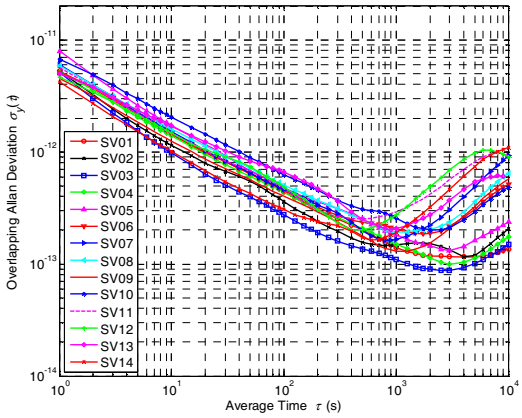

Figure 10. Frequency stability of all the current Compass on-board clocks

As can be seen from Figure 10, the stability of all the 14 on-board clocks are basically consistent for the average time of less than 1000s, and agree with ODTS results for 100~1000s, with statistical results shown in Table 2. Clocks of GEOs (SV01~SV05) are little better than that of IGSOs (SV06~SV10) or MEOs (SV11~SV14) for the average time of above 1000s.

TABLE II. FREQUENCY STABILITY ESTIMATION OF CURRENT COMPASS ON-BOARD CLOCKS

Average time (s)	SBE method	ODTS method
1	5.8×10^{-12}	/
10	1.5×10^{-12}	/
100	4.5×10^{-13}	6×10^{-13}
1000	1.7×10^{-13}	2×10^{-13}

VI. CONCLUSION

This paper proposed a simple estimation method based on smoothed broadcast ephemeris. Compared to IGS final clock product and other two methods namely PE and BE method, the performance of this method is validated using GPS observation. Experimental results indicate that the relative estimation error of this method is less than 10% for the average time of less than 800s, which is consistent with the results of PE method using precise ephemeris. Finally, the short-term stability of all the current 14 Compass on-board clocks are estimated by the proposed method, the results show that the stability of all the satellite clocks are basically consistent and agree with ODTS results. The short-term stability of current Compass on-board clocks is approximately 6×10^{-12} at average time of 1s and 2×10^{-13} at 1000s.

The proposed method in this paper provided some meaningful suggestions of short-term stability estimation and simulation of on-board clock for Compass and Galileo civil users. When the satellite on-board clock stability is better than receiver clock, the method also provides a receiver clock stability estimation approach.

***Abstract*—In satellite navigation system, the main time-frequency equipment of space segment is on-board clock, and its performance directly related to the pseudo code ranging and doppler effect observation precision, then affects the satellite navigation system orientation, velocity measurement and time service, so the test and evaluation of the on-board clock is very important. The methods and indicators used to evaluate the on-board clock in this paper. The performance of GPS on-board clock is evaluated based on the GPS on-board clock time difference data released by the IGS. Using Hadamard variance to evaluate the stability, the results show that the stability a day of most GPS on-board atomic clocks can reach 2×10^{-14}, in the time interval of 5 days, the stability reaches the highest level.**

I. INTRODUCTION

The satellite navigation system is based on time measurement, the main equipment depended by the time measurement is atomic clock. Master control station, all kinds of monitoring station, satellite are equipped with different amount of atomic clocks, all of the atomic clocks are synchronized to the system time. To the system, the On-board clock performance directly related to the pseudo code ranging and doppler effect observation precision, then affects the satellite navigation system orientation, velocity measurement and time service[1], so the test and evaluation of the on-board clock attach much importance. The on-board clock performance evaluation experiment had been done many times in the GPS, GALILEO and GLONASS satellite navigation systems. The similar research and experiment are carrying out in Chinese satellite navigation system.

II. THE BASIC CRITERIA FOR TESTING AND EVALUATION

In the time and frequency measurement, the frequency standard or clock to be measured is called the device under test. The measurement is a process to compared the device under test and the standard (or reference), two elements must be paid attention to as follows:

1) Reference selection

The accuracy of the reference must be at least 3 times higher than the object being measured, one order of magnitude is the best.

2) Measurement method selection

Some time comparison method is need to measure the object being measured, the error of the time comparison links must be less than the object being measured 3 times. There are two methods to meet that requirement.

(1) Choose high-precision time comparison method, to meet the requirements of testing and evaluation

(2) Optimizing the measurement method, accumulating measurement data, and use mathematical method to process the measurement data to reduce various types of errors.

III. EVALUATION METHODS OF ON-BOARD CLOCKS

1) Basic principle

According to the basic principles of testing and evaluation, the IGS precise clock difference data is used. Take the IGS integrated clock as the reference, the atomic clocks onboard as the object under test to evaluate the performance of the atomic clocks onboard.

Integrated processing the atomic clock data from all the IGS monitoring stations, more accurate and stable time scale can be obtained. Post-processing time comparison data of the atomic clock and atomic clocks onboard, the time delay error in the path used for time comparison can be well corrected to meet the requirement of the testing and evaluation of the atomic clocks onboard.

2) Testing and evaluation index analysis

The accuracy of the IGS precise satellite clock difference is better than 0.1ns[2].

To compare the uncertainty of on-board clocks using IGS precise satellite clock difference with accuracy better than 0.1ns, about $\approx 1\times10^{-15}$ frequency uncertainty will be brought one day. According to the standard of measurement uncertainty an order of magnitude higher, the index of atomic clocks onboard frequency is lower than 1×10^{-12} which meet the evaluation requirement.

The index of on-board atomic clocks frequency is lower than 1×10^{-14}(d). To evaluate the stability using IGS precise satellite clock difference with accuracy better than 0.1ns, about 1×10^{-15} stability will be brought one day. According to the standard of measurement uncertainty an order of magnitude higher, it will meet the requirement to evaluate the stability of atomic clocks onboard more than one day.

3) Index calculation model

(1) Accuracy and calculation model

Frequency accuracy refers to the consistency degree between the output frequency of device under test and the nominal frequency, it indicates the correctness of the oscillator output. The method to calculate the frequency accuracy by time difference comparison is called time difference method. The details to calculate are as follows:

$\hat{x}(t)$ is the compared atomic clocks onboard time differences, after gross error elimination of the those data, least squares linear fitting is used, and the fitting method is:

If

$$\bar{t}_i=\frac{1}{N}\sum_{i=1}^{N}t_i\ ,\quad \bar{x}_i=\frac{1}{N}\sum_{i=1}^{N}x_i(\tau)\ ,\quad \text{i=1, 2, 3……..N}$$

Draw a straight line through the point $(\bar{t}_i,\bar{x}_i)$, the equation is:

$$x(t)=\bar{x}_i+k(t-\bar{t}_i) \tag{1}$$

While

$$k=\frac{\sum(x_i-\bar{x}_i)(t-\bar{t}_i)}{\sum(t-\bar{t}_i)^2}$$

Taking zero result noted as $\hat{x}(t)$ after fitting. The atomic clocks onboard time difference data is affected by the frequency drift rate, so the data for fitting should not be too long. Make $\tau=1$, one data $\hat{x}_i(t)$ one day is obtained by fitting, i=1,2,3……N (day).

Calculating frequency accuracy by comparing the time difference data, the formula is[3]:

$$A=f(offest)=\frac{-\Delta t}{T}$$
$$=\frac{\hat{x}(t_2)-\hat{x}(t_1)}{t_2-t_1}=\frac{\hat{x}(t+\tau)-\hat{x}(t)}{\tau} \tag{2}$$

$\hat{x}(t)$ is the time difference data after processing, τ is the sampling time. A number of frequency accuracy can be obtained by using τ as sampling interval to calculate. The average of these frequency accuracy is taken as the final evaluation result.

(2) stability and calculation model

Stability characterizes the ability of the atomic clock to generate the same time and frequency within a certain time, and describes the random fluctuations of atomic clock output frequency. It does not indicate the time or frequency accuracy or not, only on whether the same value. Standard deviation of the data group is used to represent the stability in some occasions, but standard deviation can only used for stationary data. Because frequency offset contains time-varying noise, oscillator data are usually non-stationary[4][5]. For stationary data, the number of measurements increases, the mean and variance converge to the same value; for non-stationary data, the mean and variance does not converge to a certain value. Conversely, when increasing the number of measurements, the average value will be slidably changed. For this reason, some non-classical methods are used to represent time domain stability of time frequency signal. That statistical properties is called Allan variance, and it is the variance calculated by the time difference dada sampled for the second time. To overcome the linear frequency drift of the atomic clocks onboard, in this paper, Hadamard variance is used to evaluate the stability of atomic clocks onboard, it is the variance calculated by dada sampled for the third time[6]. Hadamard variance is defined as follows for the phase data:

$$H\sigma_y^2(\tau)=\frac{1}{6\tau^2(N-3)}\sum_{i=1}^{N-3}[x_{i+3}-3x_{i+2}+3x_{i+1}-x_i]^2 \tag{3}$$

The square root of the Hadamard variance is usually used to represent frequency stability, denoted as HDEV or $H\sigma_y(\tau)$.

3) Results

Using the IGS precise clock difference data from July 29, 2012 to October 27 to evaluate the performance of GPS atomic clocks onboard, the calculation result are as follows:

Table 1. The accuracy of GPS on-board clocks

Time	Satellite number	Frequency accuracy
2012.7.29~2.12.10.27 （MJD56137~56227）	G01	1.56464E-12
	G02	1.14443E-12
	G03	4.99104E-12
	G04	-2.95511E-11
	G05	-3.02479E-12
	G06	6.09588E-11
	G07	4.2496E-12
	G11	-3.90698E-12
	G12	2.04061E-12
	G13	-2.57309E-12
	G14	9.2923E-13
	G15	-6.66093E-13
	G16	-8.05873E-13
	G17	-3.25988E-12
	G18	1.82247E-12
	G19	-3.5291E-12
	G20	8.0625E-13
	G21	-2.41403E-12
	G22	5.34598E-13
	G23	-3.91266E-12
	G25	1.27853E-12
	G26	1.28926E-11
	G28	3.74722E-12
	G29	4.12023E-12
	G31	2.5029E-12
	G32	-4.07605E-12

The results of accuracy are shown as table 1, the highest accuracy is -6.66093E-13, the minimum is 6.09588E-11. Excluding the three poor clocks, as figure 1 shows, the accuracy of most GPS on-board clocks can reach the magnitude of $\pm 5\times10^{-12}$.

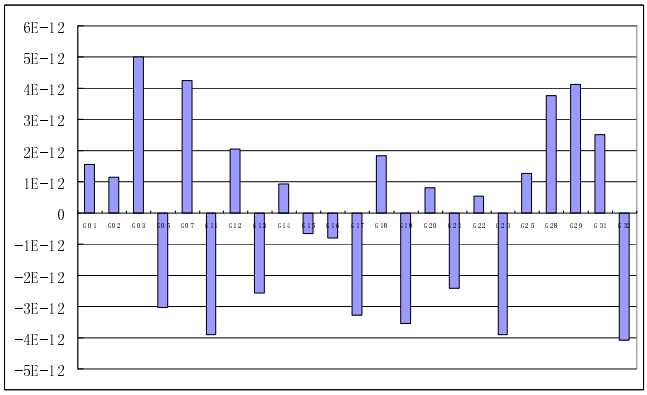

Figure 1. The accuracy of GPS on-board clocks

The results of stability of 4 on-board clocks representatively are shown as figure 2~ figure 5, their Hadamard Variance show that the stability of most GPS on-board clocks reach a level of 2×10^{-14} in one day and reaches the highest level of 6×10^{-15} in five days time interval.

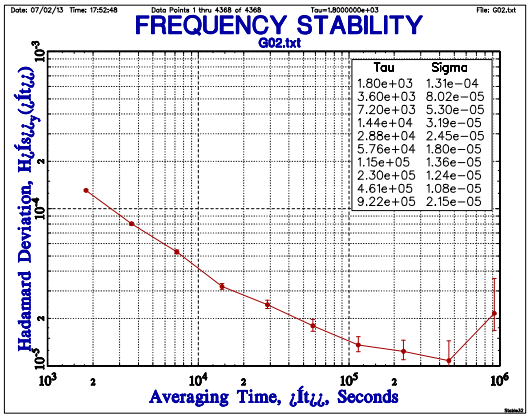

Figure 2. G02 stability (Hadamard Variance)

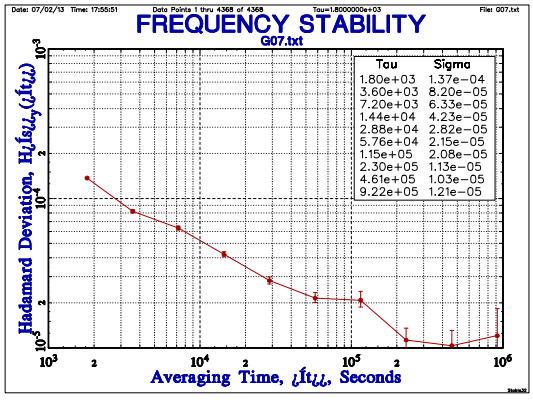

Figure 3. G07 stability (Hadamard Variance)

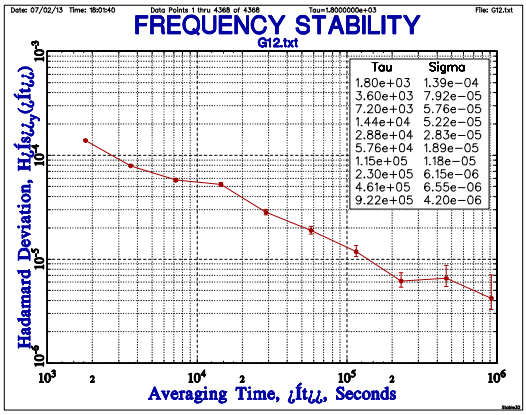

Figure 4. G12 stability (Hadamard Variance)

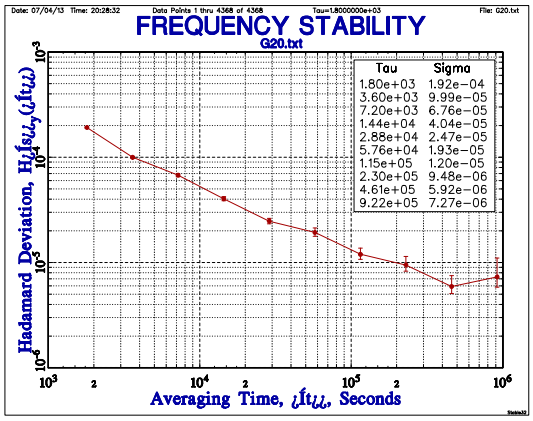

Figure 5. G20 stability (Hadamard Variance)

IV. CONCLUSIONS

Based on IGS precise clock difference data, the GPS on-board clocks performance evaluation methods used in this paper meet the basic criteria for testing and evaluation.

The evaluation results show that the accuracy of most GPS on-board clocks can reach the magnitude of $\pm 5\times10^{-12}$. The stability results evaluated by Hadamard Variance show that the stability of most GPS on-board clocks reach a level of 2×10^{-14} in one day and reaches the highest level of 6×10^{-15} in five days time interval.

An FPGA Implementation of the Distributed RF Over White Rabbit

Pedro Moreira, Izzat Darwazeh
Department of Electronic & Electrical Engineering
University College London, London, UK

***Abstract*—Distributing radio frequency signals is a requirement needed in various systems such as telecommunications systems, to synchronise base stations, or in factory control floors to distribute a clock reference from the main control unit to the acquisition and actuation hardware. However, most of these distribution RF systems require dedicated links and custom-made hardware to achieve a specified performance in terms of jitter and latency. In this paper, an FPGA implementation of a distribution RF system running over the White Rabbit network is described. The White Rabbit network is a non-dedicated timing network with sub-nanosecond timing specification that uses Ethernet as communication network.**

I. Introduction

Several applications require the delivery of a stable clock reference from a central station to spatial disperse base stations. Other applications require the distribution of modulated radio frequency (RF) signals throughout several network nodes in the site. A common solution that addresses these issues is the Radio-over-Fibre (RoF) technique [1], where electro-optical modulators are used to convert a RF signal from the electrical to the optical domain that is transmitted over large distances using optical fibres. The RoF technique is normally preferred for high bandwidth applications; it also has the advantage of not requiring any sort of hardware computation. Another solution technique is the Digitized RF-over-Fibre (DRoF) [2], which uses ADCs to convert the analogue signal to the digital domain. The digital signal is then processed, typically in an FPGA, and transmitted to the receivers nodes using off-the-shelf optical transceivers optical fibres. Both RoF and DRoF are used for very high bandwidth applications using dedicated optical links at a relative high price. Recently, we have proposed a system architecture that aims to distribute RF signals over a non-dedicated Ethernet link [3], using ADCs and DACs components.

After this introductory section, this paper continues in section II with an overview of the White Rabbit network. Next, in section III, the Distribution RF architecture is outlined. Section IV describes the FGPA implementation of the proposed distributed RF system. In addition, it shows the performance, by analysing phase-noise spectra and Allan Deviation measurements, of the proposed implementation for a couple of reference RF signals. Finally, section concludes this paper with a discussion of the obtained results.

II. The White Rabbit Network

The White Rabbit (WR) project is nowadays a mature multi-lab multi-company project [4], started at European Organization for Nuclear Research (CERN). The WR project aims to use a general purpose link, Ethernet, as a network to deliver both data and timing, the WR network. It is designed for gigabit Ethernet (GbE) where general-purpose and control/timing traffic are multiplexed and managed to allow uninterrupted messages delivery. The network timing specification is to delivery sub-nanosecond timing accuracy between the master and the slave nodes. This timing specification has been reach and shown in previous works [5] [6]. Typically, the WR network is synchronised to an UTC time reference delivered from a GPS source or a Cs clock.

The WR network employs for the timing distribution two standardised protocols. The Synchronous Ethernet (SyncE), defined by ITU-T G.8261 [7], is physical layer based synchronization implementation for packet networks requiring frequency synchronization. The IEEE 1588, Precise Timing Protocol (PTP) [8], specifies a set of messages and timing stamping capabilities to synchronise the timing slaves to the grandmaster clock, previous work have shown performance of approximately 10us timing accuracy when implementing PTP [9]. In addition, WR network employs a phase measurement mechanism, the digital dual mixer time difference (DDMTD) [10], that continually measures the phase different between the master clock and the recovered clock link coming from the slave. These measurements are used to compensate the phase drifts between the transmitted master clock and recovery network clock which occur in the network link due to external environment variables. A block diagram that illustrates the WR ecosystem is shown in Fig. 1.

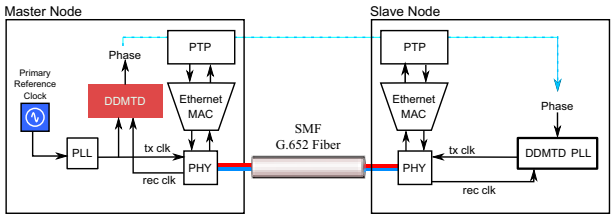

Fig. 1. WR Network System Architecture

III. Distributed Radio Frequency Architecture

The Distributed RF over white rabbit (DRF_WR) is a system architecture that takes advantage of the WR network timing specification to distribute RF clock references between nodes. An example of such system can be found at the Large Hadron Collider (LHC) where the frequency reference generated by the RF cavities is distributed to the various particles detectors to synchronise the beam with the triggering of the detectors among other functionalities. The RF frequency

generated by the cavities is not stable at a centre frequency, instead the RF frequency increases during the acceleration of the beam. The distribution of the RF signal generated by the RF cavities is realised by a dedicated and custom-made optical link with strict specification in terms of RMS jitter and latency. On the other hand, other systems require the distribution of very stable clock source such as Caesium (Cs) or Rubidium (Rb) standards over the factory control floor to synchronise its front-end equipment. In most cases this system requirement is implemented using dedicated and custom-made pieces of hardware and links that increases the cost of the system both in deployment and maintenance. For these types of applications the distributed RF over WR network has been designed as a solution leading to a more cost effective solution, as it relies on available hardware resources and on non-dedicated links. The distributed RF architecture employs a set of signal processing techniques to reduce the network bandwidth required to transmit the RF over the WR network which are detailed below.

In the transmitter (Tx) node the RF signal is digitized by means of an ADC. The ADC uses the bandpass sampling technique to directly down-convert the RF signal between DC and the Nyquist frequency without the need for passive mixers. This increases the frequency range operation of the system, which is limited by the frequency response of the ADC. To ensure that the spectrum does not overlap and corrupts the desired signal, the bandpass sampling requires that the ADC sampling rate is at least twice the bandwidth of the bandpass signal and twice the highest frequency in the bandpass signal. The digitised signal is then converted to the complex domain using a digital IQ demodulator.

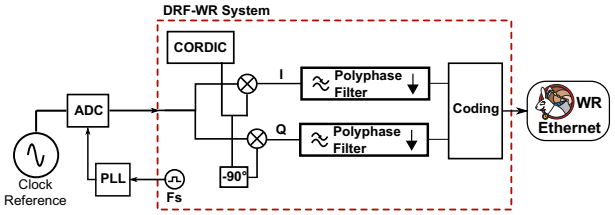

Fig. 2. Tx Architecture

The mixing frequency of the IQ demodulator is generated using the CORDIC algorithm. The CORDIC algorithm is a computationally efficient iterative arithmetic algorithm, introduced by Volder [11] in 1956.

The CORDIC algorithm relies on basic shift and adds operations which can be implemented very efficiently in hardware based designs, such as FPGAs. The CORDIC algorithm has a long latency time due it is recursive nature. However, implementing the CORDIC using pipeline architecture mitigates this issue.

The IQ demodulator down-converts the digitized signal to baseband, however, in the process it also generates a high frequency tone in the IQ signals. This high frequency tone can be removed using a digital low-pass filter (LPF). The data-rate of complex signal can be reduced to minimal specified by the Nyquist theorem, which is dependent on the bandwidth of the digitised signal. The decimation process results in savings in the bandwidth required to transmit the IQ signals to the receivers. Implementing the LPF in its direct form structures requires expensive hardware resources. To implement the filtering and decimation process in a combined and more efficient way polyphase structures are used [12]. A polyphase structure is composed by a set of filter banks each one running at the decimated frequency rate. Thus reducing the required hardware needed to implement the filtering process as each filter can share the same set of hardware resources. The decimated signal is then coded and added to an Ethernet frame. A block diagram illustrating the flow of the data processing in the Tx node is shown in Fig. 2.

In the Receiver (Rx) node, the Ethernet received data stream of the distributed RF system is decoded into the corresponding IQ components. These signals are then interpolated to restore the initial sampling rate of the sampling frequency in the Tx. The interpolated IQ components are modulated to passband by digital mixing them with the same frequency as the one applied in the Tx demodulation process. Then the up-converted IQ components are summed together to complete the modulation process. The reconstructed modulated digital signal is an identical image of the signal sampled at the Tx node. Finally, the RF signal is converted to the analogue domain by means of a DAC. An analogue LPF is added next to the DAC to remove the high frequency components generated by the conversion process. A block diagram showing the different operations realised in Rx system is shown in Fig. 2.

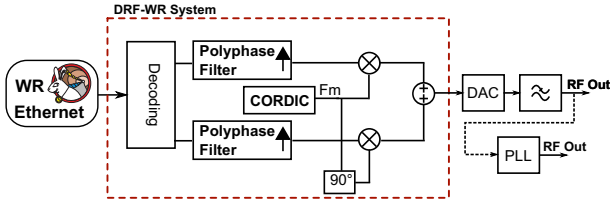

Fig. 3. Rx Architecture

For applications which require very low jitter in the reconstructed RF signal a PLL can be added in series with the analogue LPF to remove even more the remaining spurious frequency components.

IV. FPGA Implementation

To analyse the performance of the Distributed RF over White Rabbit system an FPGA implementation of the system was realized. The testing scenario aims two distribute two types of RF signals; one generated by a 10 MHz Cs clock source while the other test is to distribute a 40.078 MHz RF signal generated by a signal generator. The performance of the system is analysed by means of measuring both phase-noise spectra and Allan Deviation of the reconstructed RF signal. To realise this implementation we have used two SPEC boards plus ADC+DAC FMC cards. The SPECS are connected by 2.5 km of optical fibre (SMF G.652). The SPEC carrier card, depicted in Fig. 4, has a Xilinx SPARTAN-6 FPGA (XC6SLX45T), a FPGA Mezzanine Card (FMC) slot with low pin count (LPC) plus additional hardware [4]. The SPEC is WR compatible and it was design under open-hardware licensing.

The FMC daughter card provides a ADS62P49 dual channel 14-bit 250Msps ADC and a TI's DAC3283 dual channel

Fig. 4. The SPEC Board

TABLE I. RESOURCES REQUIRED FOR THE TX AND RX DRF CORES

Device Utilization Summary (estimated values)			
Logic Utilization	Used	Available	Utilization
Slice Registers	9133	54576	16%
Slice LUTs	14008	27288	51%
Fully used LUT-FF pairs	3022	27951	14%
Block RAM/FIFO	33	116	28%
DSP48A1s	64	58	93%
PLL_ADVs	2	4	50%

16-bit 800Msps DAC which can be clocked by an external reference, in our system it is the WR clock. The clock management and fanout is performed by TI's CDCE72010 clock synthesizer chip. Due to a hardware limitation in the FMC card we are only able to operate the DAC at 62.5 MHz; however, this limitation can be mitigated by using a PLL in series with the DAC to up-convert the signal.

The CORDIC algorithm, implemented in Tx and Rx cores, has 16 pipelined stages to achieve higher accuracy. The Tx has a decimation factor of 10, which results in using approximately 20% of the available network bandwidth. However, the selection of the above decimation factor is due to the requirements of the system which are to transmit modulated signals with a bandwidth of 2MHz. For applications that require the distribution of RF signals generated by stable clocks the required network bandwidth can be less than 0.01%. A 70-tap FIR low-pass filter with a cut-off frequency set to 2 MHz designed by the Parks-McClellan algorithm [13] was implemented in the Tx node. The implementation of the LPF and the decimation was realised with a polyphase structure. Each filter bank in the polyphase filter is composed by a 7-tap FIR. To reduce the effects of quantisation, the implementation of the filters has done using a 24-bit fix-point representation. At the Rx node the interpolation processes are designed as 70-tap FIR filter realised with a polyphase structure with 7-tap filter banks, identical to the Tx node. The current RTL implementation for the Tx and Rx DRF_WR core uses the FPGA's hardware resources as shown in Table I. The resources listed in Table I include not just the DRF_WR core but also an instantiation of the LM32 uC plus wishbone interfaces between the uC and the DRD_RF core. Nonetheless, there is further room to optimise the resources required to implement the DRF_WR core, e.g. by reducing the fix-point representation of the filters. Both Tx and Rx designs run at the required frequency of 62.5 MHz.

A. Measurements

The first set of measurements presented show the distribution of an RF clock signal generated by an Cs atomic clock, the Symmetricom Cs4000 [14]. We measured the phase noise spectrum of the RF clock signal with the Agilent's E5052B Signal Source Analyser. Fig. 5 and 6 show the phase noise spectra of the Tx input RF signal, and the reconstructed RF signal at the Rx node, respectively.

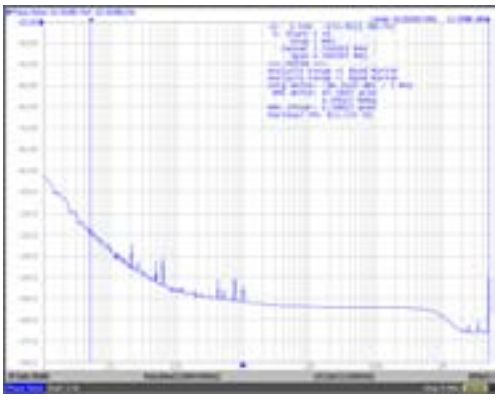

Fig. 5. Phase Noise Spectrum of the 10 MHz Tx Signal

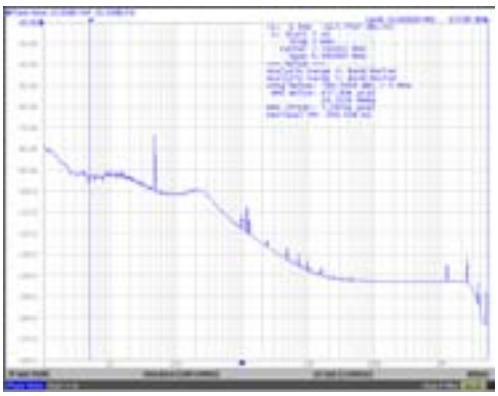

Fig. 6. Phase Noise Spectrum of the 10 MHz Rx Signal

The RMS jitter calculated in the E5052B by integrating the phase noise between the frequencies 5 Hz to 5 MHz is ~1.3ps for the Tx signal and ~7.2ps for the reconstructed signal at the Rx node. The measured phase-noise spectrum on the Rx node was done in the output of the analogue LPF, this means that the RMS jitter of the output signal can be even further reduced. This can be done by adding a PLL with narrow bandwidth in series with the LPF.

Fig. 7 and 8 show the Allan Deviation of the Tx signal the reconstructed Rx signal. The Allan Deviation is a simple and efficient measurement to verify random drift error as a function of averaging time. It can be used to determine the characteristics of different random processes.

The second set of measurements shows the distribution of a 40.078 MHz clock signal generated by a signal generator. Due to the limitation in the FMC Hardware we are not able to correctly reconstruct the 40.078 MHz. Nonetheless, this limitation is overcome by adding a PLL into the output of the DAC which up converts the RF signal to the wanted frequency.

The RMS jitter calculated between the frequencies 5 Hz to 5 MHz is ~37.9ps for the Tx signal and ~8.2ps for the reconstructed signal at the Rx node. These set of measurements indicates that the reconstructed clock signal at the Rx node is

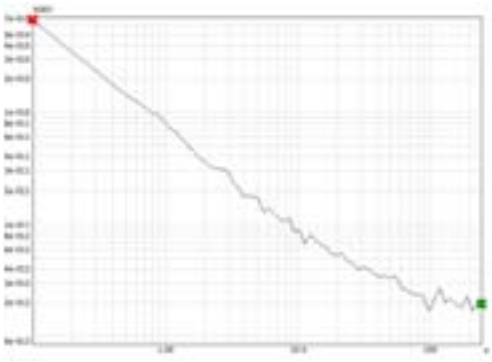

Fig. 7. Allan Deviation of the 10 MHz Tx Signal

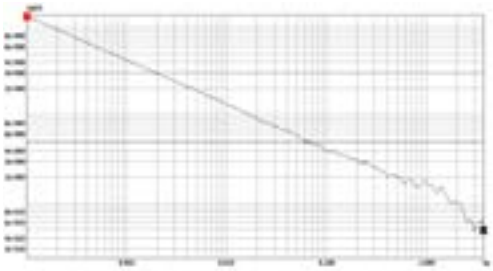

Fig. 8. Allan Deviation of the 10 MHz Rx Signal

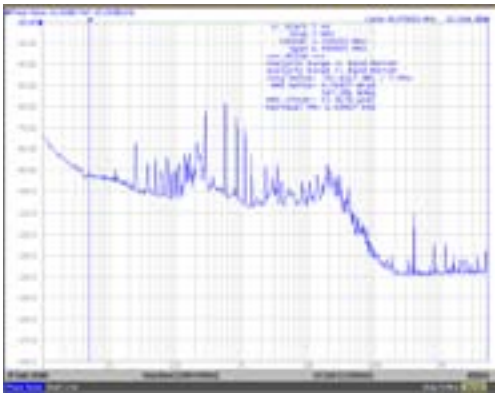

Fig. 9. Phase Noise Spectrum of the 40.078 MHz Tx Signal

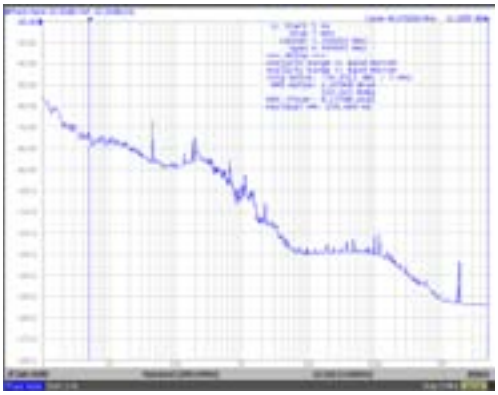

Fig. 10. Phase Noise Spectrum of the 40.078 MHz Rx Signal

more stable than the original signal sampled at the Tx. By analysing Figs. 9 and 10 it is noticeable that the high RMS jitter in Tx signal is mainly due to the frequency spurs that start ~20 Hz. These frequency spurs are filtered in the Rx signal, because of the narrow bandwidth of the PLL added.

V. Conclusion

In this paper, we have presented an FPGA implementation of the Distributed RF architecture over the White Rabbit network, a non-dedicated timing network that runs over an Ethernet link. The measurements made on the distributed signal have shown that the proposed distribution RF architecture achieves excellent performance in terms of RMS jitter and Allan Deviation.

***Abstract*—The influence of Sagnac effect in time transferring system over optical fiber is explained. Mathematical expression of the time deviation is deducted between any two points on the surface of the earth based on the analyses of the actual propagation path of the optical signal. To investigate the magnitude of the time deviation, we make theoretical calculation using the deducted equation when time is transferred from Prague to other four Europe cities with different directions through spherical circumference fiber links. It is demonstrated that the magnitude may reach 10^{-9}s when the transfer distance is longer than hundreds of kilometers and it is also decided by practical route of the fiber links. So accurate time compensation or calibration should be committed for the purpose of reaching subnanosecond accuracy in long-haul optical fiber time transferring system.**

Keywords—Time transfer ; Optical fiber ; Sagnac Effect ; Time Deviation

I. INTRODUCTION

In recent years, accurate time and stable frequency transfer have been studied since the existing optical communication networks can provide an alternative and complementary method to already established satellite-based ones[1-3]. Two-way time transfer is generally used to compare two geographically separated clocks with high accuracy, on the condition that the propagation time between two clocks is reciprocal [4] or the unequal propagation time can be accurately measured and compensated. However, in real fiber links, the propagation time in both directions differs due to different wavelength, temperature variation, stress and phase noise from fiber. As a result, the accuracy of the time transfer system, to a great extent, depends on the accurate measurement and compensation of the unequal propagation time including Sagnac effect.

The Sagnac effect[5,6] can be described by the following example. Two light beams sent in opposite directions around the circumference of a stationary disk using optical fibers will take the same time intervals to travel the path. If the disk is rotated with a certain angular velocity, the propagation time becomes different consequently. It is the same to the time transfer system over optical fiber of which the local clock and the remote clock are together rotating with the earth, accounting for the difference of the propagation time in both directions even if neglecting the disturbances mentioned above. In order to figure out and finally compensate this difference, we illustrate the principle of the time deviation caused by Sagnac effect and then give a mathematical expression for accurate calculation. The result of this paper will be required to be taken into consideration with the further development of the terrestrial time transfer system.

II. SAGNAC TIME DEVIATION

The Sagnac effect in optic fiber time transferring system can be illustrated as Fig.1. A and B are any two points on the earth. The former is the local end and the latter is the remote end. The dashed line AB (A_1B_1, A_2B_2) denotes the original optical fiber link between A and B. Simultaneous propagation processes are separated into two sequential processes to explain the phenomena more clearly as following: In time t, an optical signal is sent out from the local end A to the remote end and it arrives at B in time t_1. Then, the signal starts immediately in the opposite direction from B to A and reaches A in time t_2. So the actual bidirectional paths are A-B_1 and B_1-A_2 instead of A-B since the optical fiber is moving with the earth rotation. It is evident than bidirectional propagation times between two stations are unequal due to Sagnac effect, so calculation and compensation are needed to achieve accurate synchronization.

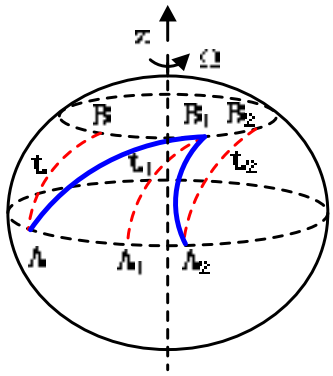

Fig. 1. The actual propagation path of the optical signals considering Sagnac effect.

If we take the travel time of A-B as the forward propagation delay, neglecting the path asymmetry analyzed above, the time compensation delay should be $(t_2-t)/2$. But in fact the forward optical signal should be delayed by t_1-t_2. That introduces a time deviation and will finally lead to a clock offset $(2t_1-t-t_2)/2$. Even though we can assert that this deviation will be very small, it may be unbearable for some applications.

To meet such demands, accurate calculation and time delay compensation is needed to modify the deviation to achieve synchronization. Besides, it is necessary to make it out that this time deviation is invariable with time for a certain time transfer system and will not affect the stability and the frequency transfer.

III. CALCULATION

To calculation the clock offset, we start from an infinitesimal of the fiber link. As is showed in Fig.2, dl is an

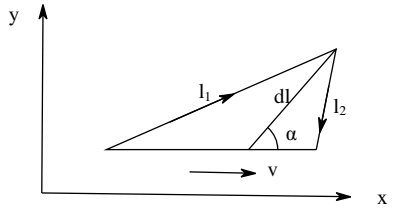

Fig. 2. The infinitesimal of the beam propagation path.

infinitesimal. l_1 is the real forward path and l_2 is the backward path. They are short enough to be thought of as linear. The vector v is the rotation speed of the earth, making an angle α with dl. If the earth is stationary, the optical signal propagates in the fiber with a speed of c/n in both directions. c, the velocity of light beam in vacuum, is 299792458 m/s. n is the index of refraction of silica optical fiber. When the earth is rotating with a linear velocity of v, the speed of the forward light and backward light no longer equals. Based on the Lorentz- Einstein transformation of speed , the modified speed of forward light is

$$u_{1x}=\frac{\frac{c}{n}\cos\alpha+v}{1+\frac{v\frac{c}{n}\cos\alpha}{c^2}}=\frac{\frac{c}{n}\cos\alpha+v}{1+\frac{v\cos\alpha}{nc}} \tag{1}$$

$$u_{1y}=\frac{\frac{c}{n}\sin\alpha\sqrt{1-\frac{v^2}{c^2}}}{1+\frac{v\frac{c}{n}\cos\alpha}{c^2}}=\frac{\frac{c}{n}\sin\alpha\sqrt{1-\frac{v^2}{c^2}}}{1+\frac{v\cos\alpha}{nc}} \tag{2}$$

and the modified speed of backward light is

$$u_{2x}=\frac{\frac{c}{n}\cos\alpha-v}{1-\frac{v\cos\alpha}{nc}} \tag{3}$$

$$u_{2y}=\frac{\frac{c}{n}\sin\alpha\sqrt{1-\frac{v^2}{c^2}}}{1-\frac{v\cos\alpha}{nc}} \tag{4}$$

We notice that the forward light and the backward light travel the same distance in the direction of the y axis. Then the difference between their propagation delays can be expressed as

$$\begin{aligned}\Delta t&=\frac{dl\cdot\sin\alpha}{u_{1y}}-\frac{dl\cdot\sin\alpha}{u_{2y}}\\&=dl\cdot\left(\frac{1+\frac{v\cos\alpha}{nc}}{\frac{c}{n}\sqrt{1-\frac{v^2}{c^2}}}-\frac{1-\frac{v\cos\alpha}{nc}}{\frac{c}{n}\sqrt{1-\frac{v^2}{c^2}}}\right)\\&=\frac{2v\cos\alpha\cdot dl}{c\sqrt{c^2-v^2}}\end{aligned} \tag{5}$$

Where v^2 is negligible compared to c^2. So the time deviation contributed by the infinitesimal is given by

$$dt=\frac{1}{2}\times\frac{2v\cos\alpha\cdot dl}{c^2}=\frac{v\cos\alpha dl}{c^2} \tag{6}$$

If the track of the fiber link L is already known, the total time deviation can be obtained by integrating Eq.(6)

$$\Delta T=\int_L dt=\int_L\frac{v\cos\alpha}{c^2}dl \tag{7}$$

From Eq.(7) we can see that the time deviation caused by Sagnac effect is independent of the fiber's refraction index. Similar conclusion has been proved by experiment [6].

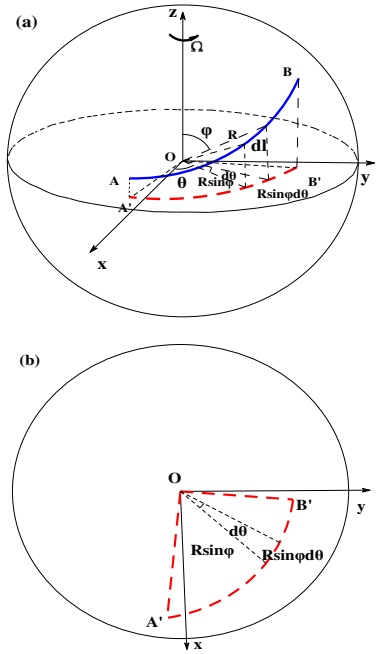

Fig. 3. The fiber link and its projection (a) on earth in spherical coordinates, (b) on the equatorial plane.

Fig 3 is the fiber link and its projection on the equatorial plane in spherical coordinates. Taking the earth as a standard sphere, we build up spherical coordinates as Fig. 3(a) shows. O is the earth's core and xoy plane corresponds to the equatorial plane. The x-axis points to the prime meridian and the z-axis points to the arctic pole. θ is azimuth angular and

φ is polar angular in spherical coordinates through the fiber link. R is the mean radius of the earth and Ω the angular velocity, R=6371 km, $\Omega=7.292\times10^{-5}$ rad/s. The curve AB denotes an arbitrary fiber link. A is the local end and B the remote end. Projecting curve AB on the equatorial plane, we get Fig. 3(b). By contrasting Fig. 2 and Fig. 3, we can reify some variables of Eq. (7) in spherical coordinates. $v=R\Omega\sin\varphi$, $\cos\alpha\cdot dl= R\ \sin\varphi\cdot d\theta$. Then the mathematical expression can be rewritten as

$$\Delta T = \int_L \frac{(R\sin\varphi)^2\Omega}{c^2} d\theta \qquad (8)$$

Eq. (8) can be used to calculate the time deviation of any time transfer system over optical fiber as long as we find out the mathematical expression of the fiber link L in spherical coordinates. Even if the course of the fiber is too irregular to denote by a definite mathematical expression, Eq. (8) still works just using numerical computation method.

It should be note that Eq. (8) can be written as

$$\Delta T = \frac{2\Omega}{c^2} \int_{L_{AB}} \frac{1}{2}\cdot(R\sin\varphi)\cdot R\sin\varphi\, d\theta \qquad (9)$$

Since $\int_{LAB} \frac{1}{2}\cdot(R\sin\varphi)\cdot R\sin\varphi\, d\theta$ equals to the pie slice area occupied by curve A′B′ and O on the equatorial plane in Fig.3 (b) which can be denoted by S, Eq. (8) can be written as

$$|\Delta T| = 2\Omega S / c^2 \qquad (10)$$

ΔT is positive if the local clock lies to the west of the remote clock, or else ΔT is negative.

TABLE I. TIME DEVIATION FROM PRAGUE TO OTHER CITIES DUE TO SAGNAC EFFECT

City	Distance(km)	Offset(ns)
London	1024.1	-3.2903
Rome	1189.3	-0.6357
Moscow	1667.3	4.7355
Stockholm	1054.3	0.6856

Table.1 shows Sagnac time deviations calculated by Eq. (8) when time is transferred from Prague to other four Europe cities with different directions through spherical circumference fiber links. It is noticeable that an east-west fiber link has a larger time offset compared to the north-south one which implies that the time deviation is also decided by practical route of the fiber links. It is showed that the time offset may reach 10^{-9}s when the transfer distance is longer than hundreds of kilometers.

IV. CONCLUSION

In this paper, the influence of Sagnac effect in time transferring system over optical fiber is explained and analyzed. Accurate equation is deducted for calculation of the Sagnac effect induced time deviation. It is showed that the time offset may reach 10^{-9}s when the transfer distance is longer than hundreds of kilometers. The result of this paper advances the time compensation mechanism in the independent terrestrial time transfer system.

Abstract — **In 2011 and 2012, ACCREDIA DT (the Calibration Laboratories Department of the Italian accreditation body) and the Time and Frequency Laboratory of the Istituto Nazionale di Ricerca Metrologica (INRIM) organized two Interlaboratory Comparisons for the Italian Accredited Calibration Laboratories, aiming to experimentally assess their calibration measurements capabilities (CMC). Two sets of instruments, preliminarily calibrated by INRIM, were circulated among the laboratories following a multi-lateral scheme with INRIM acting as pilot laboratory. The measurement results and an overall critical assessment of this exercise is provided and suggestions on possible improvements are discussed.**

Keywords: interlaboratory comparisons, frequency calibration, accreditation, GPS disciplined oscillators.

I. Introduction

In 2011 and 2012 the Calibration Laboratories Department of ACCREDIA, the Italian accreditation body, and the Optics Division of the Istituto Nazionale di Ricerca Metrologica (INRIM) organized two Interlaboratory Comparisons (ILCs) for the Italian Accredited Calibration Laboratories (ACLs).The scope of these ILCs was to experimentally assess the metrological capabilities of the ACLs in the field of frequency calibration, as requested by ACCREDIA rules and according to the ISO/IEC 17025:2005 [1].

About 80% of the ACLs accredited in this field were involved in the two ILCs, with calibration measurement capabilities ranging from 10^{-9} to 10^{-12} for the 10 MHz value, and proved to be the first successful national measurement campaign in this field and maybe also in Europe. Indeed, the instability and the limited reproducibility of the travelling frequency standards resulted in unsatisfactory results in previous experimental trials [2].

Both ILCs implemented a multi-lateral scheme having INRIM as the pilot laboratory and fulfilled the requirements of the related EA guide [3]. A set of instruments, calibrated by the Time and Frequency Laboratory of INRIM, was circulated among the ACLs. Each ACL kept the instruments for one week while performing the measurements requested by the calibration protocol before shipping them to the next one. During each circulation, that lasted about 6 months, the instruments were sent back to INRIM for an intermediate calibration. A closure calibration was also performed by the pilot laboratory at the end of each campaign to assess the consistency of instruments performances in terms of stability and repeatability.

The paper reports all the technical and logistical details of these ILCs (e.g., instrument specifications, measurements requested by the protocol, faced problems and lessons learned), together with an evaluation of the normalized errors E_n.

II. Involved Accredited Laboratories

Fig. 1 shows the geographical distribution of the eight ACLs involved in the 2011 campaign (left side) and the ten ACLs of the 2012 campaign (right side). Two ACLs were included in both campaigns, resulting then in 16 laboratories out of 20 accredited by ACCREDIA. The majority of the ACLs is equipped with a GPS-disciplined rubidium oscillator and all of them are traceable to the national time scale UTC(IT) by remote calibrations.

All ACLs were accredited for frequency calibrations and some of them also for time interval (phase/time) measurements. Their calibration measurement capabilities for the 10 MHz value are summarized in Table I.

In the 2011 ILC the ACLs were assessed in the range from 1 Hz to 1 GHz while in 2012 the measurement range was from 1 Hz to 10 MHz.

Figure 1. ACLs involved in the 2011 and 2012 ILC campaigns.

TABLE I. ACLs CALIBRATION MEASUREMENT CAPABILITIES

Quantity	Direct frequency measurement	Phase/Time measurement
Frequency	$1{,}2{\cdot}10^{-9}$ to $1{,}0{\cdot}10^{-12}$	$1{,}0{\cdot}10^{-12}$ to $2{,}0{\cdot}10^{-13}$

III. TRAVELLING INSTRUMENTS

The set of travelling instruments for both campaigns included a GPS Disciplined Oscillator (GPSDO) with a 10 MHz output frequency used as a reference standard. A signal splitter allowed for connecting the GPSDO to the same antenna already used in the ACL for its GPSDO-based frequency reference. Besides, a netbook was used to collect the travelling GPSDO relevant internal data for remote monitoring during the campaign. The sets of travelling instruments for both campaigns are shown in Fig. 2. The expanded uncertainties of both GPSDOs are reported in Table II.

In the 2011 campaign the travelling standard Fluke 910R (hereafter simply named as "GPSDO 1") provided the external reference to an Agilent 33120A function generator up to 15 MHz (sinusoidal and square waves) and to an Agilent E4428C frequency synthesizer up to 3 GHz (sinusoidal waves). Both devices were used to generate the signals to be measured by the ACLs according to the measurement protocol provided by ACCREDIA (section IV).

The two generators and the reference oscillator were replaced in 2012 by a new disciplined oscillator, the Spectra Time GPS Reference-2000 ("GPSDO 2"), also providing synthesized square waves signals in the 1 Hz to 20 MHz range. An external INRIM digital divider was also used to provide a more stable square wave signal up to 10 MHz.

Figure 2. Travelling instruments in the 2011(top) and 2012 (bottom) ILC campaigns.

TABLE II. TRAVELLING GPSDOs PERFORMANCES

ILC (GPSDO)	Frequency meas. (Tg = 100 s)	Phase/Time meas. (Tg = 1 d)
2011 (GPSDO 1)	$U_{REF} = 1{,}0{\cdot}10^{-12}$	$U_{REF} = 0{,}8{\cdot}10^{-12}$
2012 (GPSDO 2)	$U_{REF} = 5{,}0{\cdot}10^{-12}$	$U_{REF} = 0{,}7{\cdot}10^{-12}$

The characterization of the GPSDO 1 used in the 2011 ILC was performed in the pilot laboratory before starting the circulation as well as remotely during the measurement campaign. Each ACLs was asked to extract from the GPSDO 1 the time offset of its internal oscillator versus GPS Time and then send these data to INRIM by e-mail to compute its daily normalized frequency deviations versus UTC(IT). Fig. 3 graphically reports these evaluations, exhibiting a very good reproducibility of the travelling GPSDO frequency with an absolute value of its deviation versus UTC(IT) below $6{\cdot}10^{-13}$ during the whole campaign.

In the 2012 campaign, the characterization of the GPSDO 2 was made at the pilot laboratory only, as this equipment doesn't provide the data needed to remotely trace its internal oscillator to UTC(IT). The calibration results of the GPSDO 2 before the ILC are shown in Fig. 4, while Table III reports the mean frequency deviations of the GPSDO 2 as obtained from the hourly measurements performed at INRIM during the calibration sessions occurred before, in the middle and at the end of the ILC, respectively.

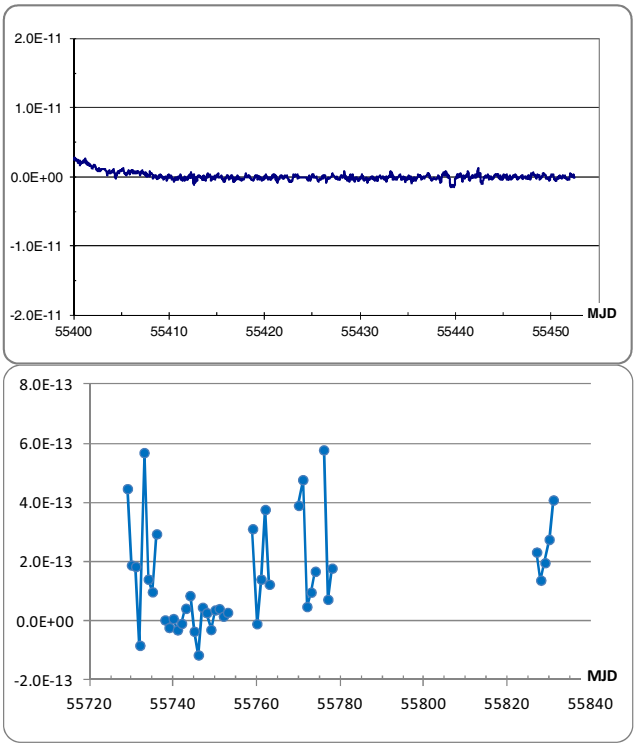

Figure 3. Normalized frequency deviation of the GPSDO 1 versus UTC(IT) during preliminary characterization in INRIM (top) and during 2011 circulation (bottom).

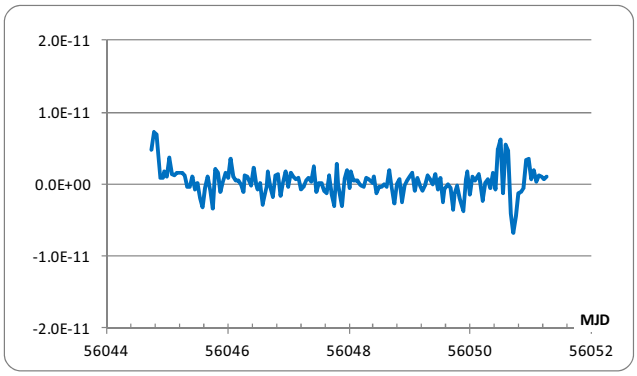

Figure 4. Normalized mean frequency deviation, over 1 hour, of the 10 MHz output of the GPSDO 2 (April 2012).

TABLE III. TRAVELLING GPSDO 2 CALIBRATION RESULTS

Period (MJD)	Frequency deviation versus UTC(IT)
56044 – 56051	$(0,3 \pm 2,0)\cdot 10^{-12}$
56142 – 56170	$(0,0 \pm 2,0)\cdot 10^{-12}$
56226 – 56238	$-(0,1 \pm 2,0)\cdot 10^{-12}$

IV. MEASUREMENT PROTOCOL

For both ILCs, ACCREDIA DT supplied a document [4] reporting the rules and the measurement protocol to be followed by the pilot laboratory and by each ACL. This document reported also all the logistical information as the travelling equipment verifications, preliminary controls and operative checks, measurements to be performed, templates for measurement reporting and communication rules with the pilot laboratory through e-mail.

Every ACL was asked to estimate the normalized frequency deviation of the 10 MHz provided by the travelling GPSDO versus its frequency standard, applying its accredited calibration procedures and in agreement with the measurement protocol. In a few cases, both direct frequency and time interval (phase/time) measurements were performed by ACLs to evaluate the frequency deviation. In addition, the measurement protocol required the calibration of the travelling generators by measuring the decimal values of the signals frequency in the range from 1 Hz to 1 GHz (ILC 2011) and from 1 Hz to 10 MHz (ILC 2012).

At the end of each ILC, the pilot laboratory and the ACCREDIA DT technical assessors analyzed the calibration results supplied by the ACLs according to the templates specified by the ILC protocol. As requested by ISO Standard [5] and EA related guide [6], the normalized errors E_n were computed:

$$E_n = (y_{ACL} - y_{REF})/(U_{ACL}^2 + U_{REF}^2)^{1/2}$$

where y_{REF} are the reference values supplied by INRIM as pilot laboratory, y_{ACL} are the values provided by the involved ACLs in their calibration certificates, while U_{REF} and U_{ACL} are the related expanded uncertainties (2σ).

The outcomes of the calibration results analysis were included in a final report drew up by ACCREDIA DT following an international guideline [7]. This final report was sent to each ACL, where every participant was identified with an anonymous code known to both ACCREDIA DT and the pilot laboratory only [8].

V. EXPERIMENTAL RESULTS

The E_n values distributions, for all the requested calibrations, are reported in Fig. 5 for both ILCs.

The distributions show a good symmetry, only slightly biased towards the negative values in 2011, indicating an overall reliability of the two ILCs. A further analysis on the data of the 2011 campaign revealed a significant asymmetry of the E_n distribution in case of low frequency signals measurements (both sine and square waves) generated by the function generator. This might be due to the Direct Digital Synthesis (DDS) technique implemented by the generator used, since it typically implies a significant short-term noise. This short-term noise could also be the reason of the higher dispersion of E_n values observed in 2012 for the measurements on the signals generated by the GPSDO 2, but not noticed on the INRIM digital divider output signals.

In spite of these minor anomalies, the computed E_n values were found always smaller than 1 except in the case of one ACL that adopted the necessary corrective actions.

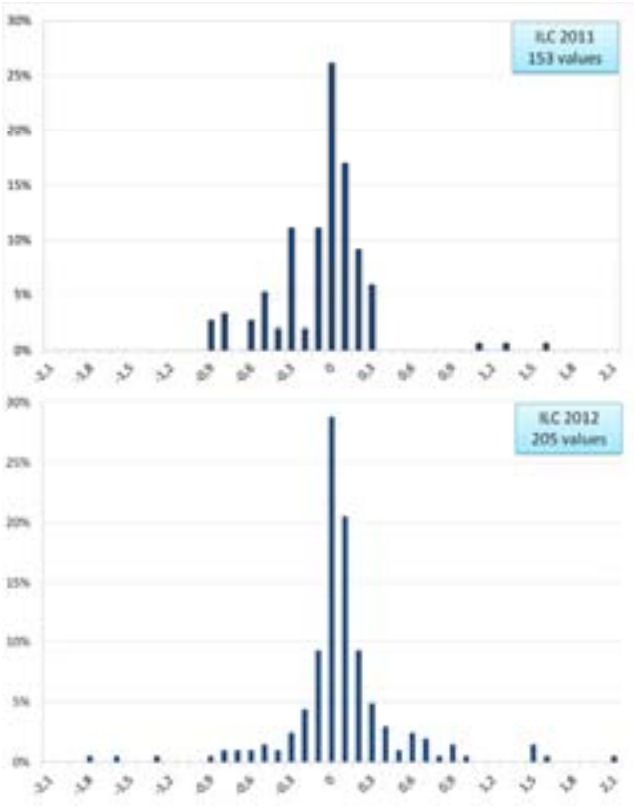

Figure 5. E_n values distribution for the 2011 ILC (top) and for the 2012 ILC (bottom).

VI. Problems Experienced

During the two ILCs no major technical problem were met, but in 2012 sudden frequency changes (of the order of 10^{-10}) of the GPSDO 2 output frequency were detected by a few ACLs. In all cases, the problem was temporary and was overcome simply by waiting one day for a new stabilization of the GPSDO frequency.

In practice the GPSDO 2 behaved as if it had been temporarily unlocked to the GPS signals, reaching again the lock condition 12 – 24 hours later. In one of these events this seemed to be related to the influence of a metallic mass set nearby the GPSDO. Investigations performed when the equipment came back to INRIM for the ILC closure, confirmed a relationship between a sudden change in frequency and a magnetic field variation. This frequency change was clearly not related to temperature changes, as a temperature effect should reflect the thermal time constant of the rubidium oscillator. Indeed, the sudden frequency jump is recovered as soon as a new steady condition is reached for the magnetic field, and the locking process gets back the nominal frequency according to the time constant of the servo system.

The sensitivity to the magnetic field was experimentally tested at INRIM moving magnetic plates close to the GPSDO 2 and continuously recording its output frequency. These operations simulated magnetic static field perturbation, changing the concentration of the Earth magnetic lines of force in proximity of the GPSDO.

While the value of the natural magnetic field, measured with a magnetic sensor for five days on the top of the workbench hosting the GPSDO and with the laboratory in quiet environmental conditions, has a mean value around 50 μT, and is stable at some μT level, when the metallic plates are set nearby the GPSDO, the magnetic sensor can detect variations of the order of more than 30 μT. But, even the metal structure of the workbench can modify locally the magnetic field. Indeed, it was observed that moving a magnetic sensor on the support plane, variations of the order of 20-30 μT could be detected.

The maximum magnetic sensitivity of GPSDO 2 showed frequency variations of the order of $1 \cdot 10^{-11}$ /μT. This results is quite in agreement with the frequency deviations of some parts in 10^{-10} observed during the campaign.

VII. Conclusions

The first successful national campaigns - and maybe one of the first in Europe - demonstrated the feasibility of an ILC to assess the metrological capabilities of accredited laboratories for frequency, at the level of 10^{-12} and below.

Some operational and logistic issues affecting similar previous experimental trials (e.g., the installation of the GPS antenna feeding the travelling GPSDO) have been overcome without significant overhead for the involved ACLs. The potential of remote monitoring the travelling equipment performance (especially the GPSDO providing the frequency reference standard) has been also successfully assessed, relying on the Fluke 910R capability to measure and archive the time offset of its internal oscillator versus the GPS Time.

Conversely, some critical points arose during the two years experience and some suggestions on possible future improvements were identified. According to the experimental analysis detailed in Section VI, the GPSDO 2 used as travelling standard in 2012 seems to be particularly sensitive to magnetic field variations, while similar devices calibrated at INRIM showed 5 to 10 times lower sensitivities. As the manufacturer specification on this subject were not supplied, it is not clear if it is an anomaly of the device used or not.

The lesson learned is that while the absolute level of the magnetic field nearby the GPSDO is not critical, since the locking mechanism compensates for this effect, what matters is the overall stability of the environment close to the device itself. According to these findings, for future exercise it is therefore strongly recommended to avoid both any movement of metallic masses in proximity of the GPSDO and occasional displacement of the GPSDO itself especially if located close to a metallic structure.

Acknowledgment

The authors wish to acknowledge the collaboration provided by the ACCREDIA DT personnel, namely its Director Mario Mosca and the Technical Officers Rosalba Mugno and Giuseppe La Paglia. Special thanks to Roberto Costa of the INRIM Time and Frequency Laboratory for the metrological support and to the staffs of all the ACLs for the outstanding effort.

The experimental contribution from Guido Pellici supporting the assessment of the magnetic field effects on the GPSDOs are also acknowledged.

***Abstract*—Simplified Dual-Mixer Time-Difference Measurement system is proposed using discrete Fourier transformation (DFT) where no sinusoidal-pulsed converter, nor zero-cross detector are necessary. The phase meter integrating the proposed method with a dead time needed to process the time difference was demonstrated with an high resolution of $\sigma_y(t=1\ s)=7x10^{-14}$ and $\sigma_y(t=10000\ s)=1x10^{-16}$. The expected truncation error due to the usage of DFT was in good agreement with the observed one. Moreover, the multi-phase meter for five oscillator was easily demonstrated where three corner hat measurement was executed, and Allan deviation of more stable oscillator that two other ones was observed at an averaging time of approximately less than 30 s.**

Keywords- component; frequency stability; noise measurement; DMTD; three-cornered hat method

I. INTRODUCTION

Precise oscillators have been contributing to the development of modern science and technology, such as the establishment of high-speed communications, navigation systems, and fundamental physics. Atomic clocks play an important role in the reliable implementation of time and frequency standards [1]. The Dual-Mixer Time-Difference(DMTD) is the most appropriate way to measure the time difference between precise oscillators with a typical standard reference signals of 5, 10, and 100MHz [2-4].

In the DMTD method, two input signals with the same nominal frequency f_0, which are usually generated by a reference signal and device under test (DUT) signal, are mixed with a common oscillator that is synchronized to the reference signal. The common oscillator has a frequency f_{beat} as an offset from f0. The output signals from two double-balanced mixers give two beat signals with a frequency typically set at a value from 1 to 100 Hz. Two sinusoidal-pulsed converters (SPCs) increase the slew rates of the two beat signals. A zero cross detector(ZCD) built in the time interval counter (TIC) determines the time interval Δt between the two beat signals with a measurement cycle of $1/f_{beat}$. Consequently, the time difference Δx between the reference and DUT signals is obtained by

$$\Delta x = \Delta t \ \mathrm{x}\ f_{beat} / f_0. \quad (1)$$

The measurement resolution of Δx, which is limited by Δt in the TIC, is enhanced by a factor of f_{beat} / f_0, and the system noise floor reaches the order of 10^{-14} at an integration time of 1s[3].

Previously, the new technique of DMTD was developed [5,6] by Anritsu CORPORATION, which is designed so that two beat signals are acquired with a par of analog-digital converters (ADCs), and digital-signal processing (DSP) to determine the time difference between tow input signals. This technique has an advantage in that the measurement system has fewer components than the conventional DMTD, as there is no need for SPCs and ZCDs in the TIC. The noise floor of the DMTD using ADCs is comparable to that of the conventional DMTD, which are expressed in terms of Allan deviation as $\sigma_y(\tau=1\ s)\sim10^{-14}$, and $\sigma_y(t=10000\ s)\sim10^{-16}$. The Anritsu group discussed in detail the degradation of the system noise floor by measuring the Allan deviation, mainly considering the hardware configuration.

For the above the new DMTD system, we propose the use of discrete Fourier transformation (DFT) as a DSP technique to determine the parameters of the precise clock. Generally, DSP is a versatile technique and helpful in many different areas where analysis of time series data is required; however, there is a truncation error to consider that can significantly affect the accuracy of the result. Most practical signals digitized by ADC are time-limited and non-periodic, and calculated results involve truncation errors.

Recently, we formulated the truncation error that causes serious error with larger frequency difference between two oscillators, while noting the specification of precise oscillator such as atomic clocks [7]. In this paper, the phase meter integrated DMTD with proposed method is demonstrated. Moreover, this method has greatly extensibility for realization of the multi-phase meter to determine the time difference during many oscillators. We also demonstrate the time difference measurement during five oscillators as well.

II. PRINCIPLE OF DMTD USING DFT

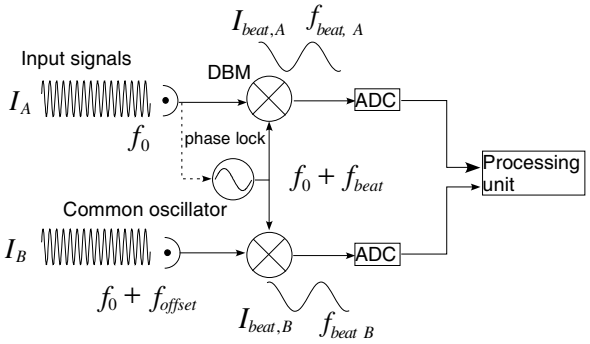

Fig. 1. Configuration of DMTD using DFT: Contrast to a conventional DMTD, SPCs and TICs are not required. Instead, two ADCs and processing unit for the DFT are used.

Figure 1 shows the configuration of the DMTD using ADCs and the DFT. The process containing the generation of two beat-down signals $I_{beat,A}(t)$ and $I_{beat,B}(t)$, using the common oscillator signal is the same as the one in the conventional DMTD. Two signals are expressed as

$$I_{beat,A}(t)=\sin(2\pi f_{\text{beat}}\, t+\theta_{\text{A}}), \tag{2}$$

$$I_{beat,B}(t)=\sin(2\pi(f_{\text{beat}}+f_{\text{offset}})t+\theta_{\text{B}}), \tag{3}$$

where $\theta_{\text{A}}=2\pi\ f_{\text{beat}}\ x_{\text{A}}$, and $\theta_{\text{B}}=2\pi\ f_0(x_{\text{A}}-x_{\text{B}})+\ 2\pi\ f_{\text{beat}}\ x_{\text{A}}$ is replaced with x_{A}, x_{B} being the time deviation of the input signal A and B respectively. Any setting of notation in this paper is the same as that defined in [7].

In order to determine $\Delta x(=x_{\text{A}}-x_{\text{B}})$, the personal computer proceeds the application the DFT to the obtained two signals through two ADCs. Two parameters are basically important: Sampling length T in a data acquisition, and sample size n. Then the Fourier spectrum $P_{\text{X}}(k)$ is obtained as a complex expression from the DFT algorithm:

$$P_{\text{X}}(k)=\Sigma_{\text{j=0}}I_{\text{beat},X}(j/n\ T)\exp(-2\pi ij/n\ k)\quad (X=\text{A, B}) \tag{4}$$

where k is the order of the harmonic spectrum, ranges from 0 to $n/2$, and can be converted into a Fourier frequency by replacing it with k/T. In the case of k=1, the frequency is the fundamental frequency of the DFT and expressed as

$$f_{\text{DFT}}=1/T \tag{5}$$

The phase $\theta_{\text{DFT},X}$ is obtained in terms of $P_{\text{X}}(l)$ as

$$\theta_{\text{DFT},X}=\tan^{-1}(\text{Im}[P_X(l)]/\text{Re}[P_X(l)])\ (\text{X=A,B}) \tag{6}$$

where k is substituted with l in Eq. (4), and l is the integer that is the nearest to the wave number of the signal acquired in the ADCs. The truncation error to be solved is closely related with this wave number, being discussed in the next section. Finally, the time difference Δx_{DFT} between two signals is calculated using the DFT from Eqs. (4), (6) as

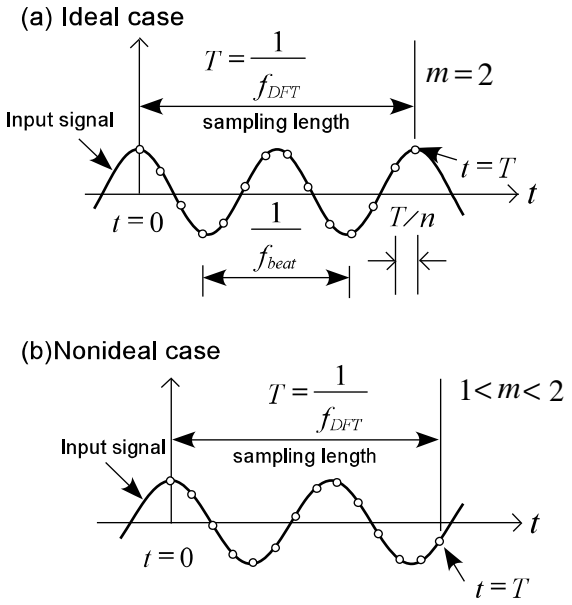

Fig. 2. Two cases of DFT (a) Ideal case and (b) non-ideal case. T(=1/fDFT): Sampling length in a data acquisition. N: Sampling number in a data acquisition. T/n: Sampling interval.

$$\Delta x_{\text{DFT}}=(\theta_{\text{DFT,B}}-\ \theta_{\text{DFT,A}})/(2\pi f_0). \tag{7}$$

III. TRUNCATION ERROR INCLUDED IN THE FOURIER SPECTRUM

Figure 2 shows a concept on the truncation error. When the signals are acquired from t=0 to T, as is drawn in two cases, DFT generally assumes that the signals continue from t=-infinity to + infinity with the acquired waveform repeated periodically. If the ratio of f_{beat} to f_{DFT} is an integer larger than or equal to 1, as an ideal case (a),

$$f_{\text{beat}}/f_{\text{DFT}}=m\ (m=1,2,\ldots..)\ , \tag{8}$$

the spectrum $P_{\text{X}}(k=m)$ gives exact information of the phase of the signal. In this ideal case, there is no discontinuity on periodical boundaries, and the real signal corresponds to the signal assumed in the DFT. If the ratio in Eq. (8) is not an interger, as non-ideal case, the information of the phase calculated from the spectrum $P_{\text{X}}(l)$ includes a truncation error due to the discontinuity on the boundaries.

Here, two beat-down signals $I_{beat,A}(t)$ and $I_{beat,B}(t)$ in Eqs. (2) and (3) is applied to DFT, then $\theta_{\text{DFT,A}}$ and $\theta_{\text{DFT,B}}$ are given by

$$\theta_{\text{DFT,A}}=\pi/2+\theta_{\text{A}}, \tag{9}$$

and

$$\theta_{\text{DFT,B}}=\pi/2+\theta_{\text{B}}+f_{\text{offset}}\{\pi T+T\sin(2\theta_{\text{B}})/(2l)\}\ , \tag{10}$$

respectively. For a detailed calculation, an appendix in [7] described. The term of the function f_{offset} originates from the truncation error, as the $(f_{beat}+f_{offset})/f_{DFT}$ is no longer an integer. By substituting Eqs. (9) and (10) for Eq. (7), the time difference that could include the truncation error is obtained:

$$\Delta x_{DFT}=\Delta x+f_{offset}/f_0\{T/2+T\sin(2\theta_B)/(4\pi l)\}. \quad (11)$$

In Eq. (11), the first term gives the exact solution, and all terms that are a function of foffset originate from the truncation error, which depends on f_{offset}, T, l, and θ_B. This behavior of the truncation error is consistent with the fact that the above four parameters change the discontinuity on all boundaries.

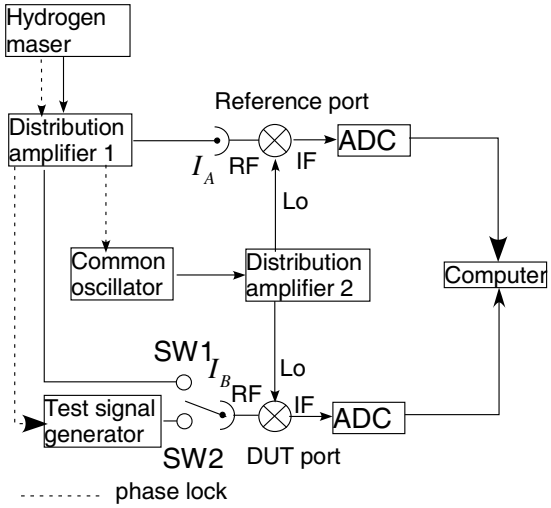

Fig. 3. Schematic diagram for experimental set up

IV. Test of Capability to Measure the Time Difference

We have demonstrated the performance and usability of the DMTD using DFT. The experimental set up is shown in Fig. 3. The Hydrogen maser reference signal I_A of 10 MHz(=f_0) passes through the distribution amplifier-1 having several output ports. The DUT signal I_B can be changed by switching SW1 and SW2. SW1 is used to investigate the system noise floor. In the use of SW2, DUT signal I_B is connected to the output from the test signal generator phase locked to the signal I_A. The test signal generator is set to produce the normalized frequency offset f_{offset}/f_0 between the two signals to simulate the signal of an atomic clock.

The common oscillator is phase locked to the signal IA and detuned by f_{beat} (62.5Hz). This signal is duplicated using distribution amplifier-2, and introduced into the local inputs of two DBMs. The two signals of $I_{beat,X}$ are obtained and simultaneously converted into digital data at a sampling length of T=0.8 s, a sampling number of n=40,000, and a time difference measurement cycle of 1 s. Two or more ADCs are supplied by NI-PCI 6143(National instruments), operated simultaneously for acquisition of multi waveform. The dead time of 0.2 s between phase measurements is reserved for processing time of the DFT on a computer, and enable us to use custom-made ADCs to easily obtain. The fundamental frequency of f_{DFT} is 1.25 Hz(=1/T), and the wave number l is 50(=f_{beat}/f_{DFT}).

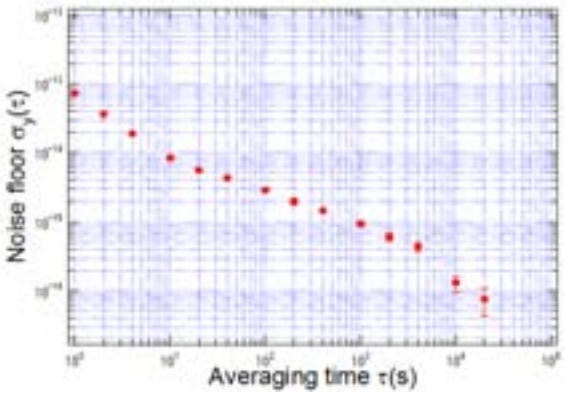

Fig. 4. System noise floor

System noise floor was observed in the case of SW1 up to an averaging time of approximately 10,000 s, which is exhibited in Fig. 4. The Allan deviation shows the performance of $\sigma_y(\tau=1\ s)=7\times10^{-14}$, and $\sigma_y(\tau=10000\ s)=1\times10^{-16}$, which is comparable to the conventional DMTD.

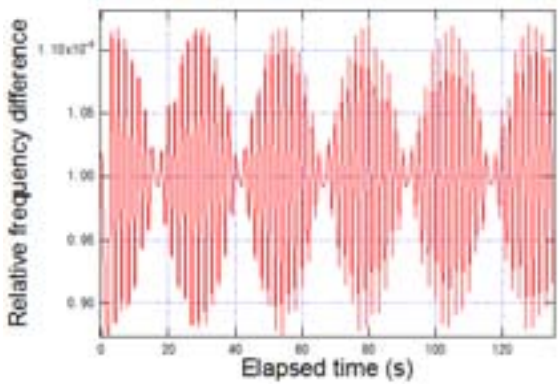

Fig. 5 Observed truncation error

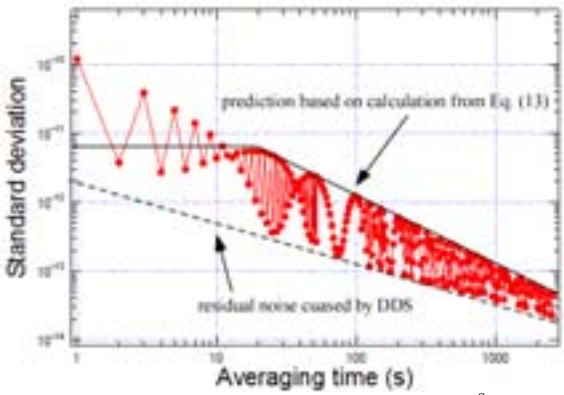

Fig. 6 Allan deviation for $f_{offset}/f_0=10^{-9}$

V. TRUNCATION ERROR APPEARED WHEN A LARGER FREQUENCY OFFSET BETWEEN TWO OSCILLATORS HAPPEN

As discussed in Sec. III, the truncation error is dependent on f_{offset}/f_0. For $f_{offset}/f_0=10^{-9}$, test signal generator was intentionally detuned so that the relatively larger truncation error occurred(Fig.5). The phase (or frequency) modulated data were observed with the center line corresponding to $f_{offset}/f_0=10^{-9}$, which should be intrinsically observed. This behavior can be explained using an error function $\Delta x_{E.F.}(T,f_{offset},l)$:

$$\Delta x_{E.F.}(T,f_{offset},l)=(T f_{offset})/(2 f_0) +\{ T f_{offset} \sin(2\theta_B)/(4\pi f_0 l)\},(12)$$

although this equation does not consider the dead time. So, the Eq. (12) does not perfectly predict the data experimentally observed. However, in perspective, the Allan deviation derived from Eq. (12) explains well the experimental result shown in Fig. 6, as is expressed by

$$\sigma(\tau)=(f_{offset}{}^2 T)/(\mathrm{sqrt}(2) l f_0), f_{offset}\tau<<1/(2\pi), \text{ or}$$

$$\sigma(\tau)= (f_{offset} T)/(2\mathrm{sqrt}(2) l\pi f_0 \tau), 1/(2\pi)<< f_{offset}\tau \qquad (13)$$

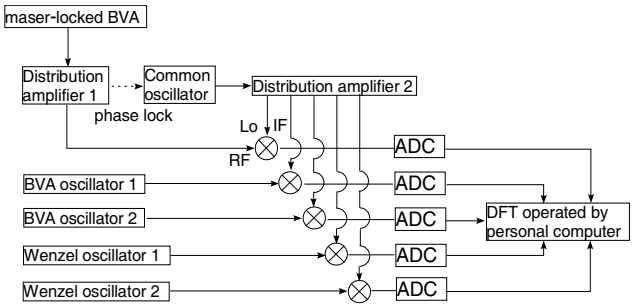

Fig. 7 Set up for multi-phase meter

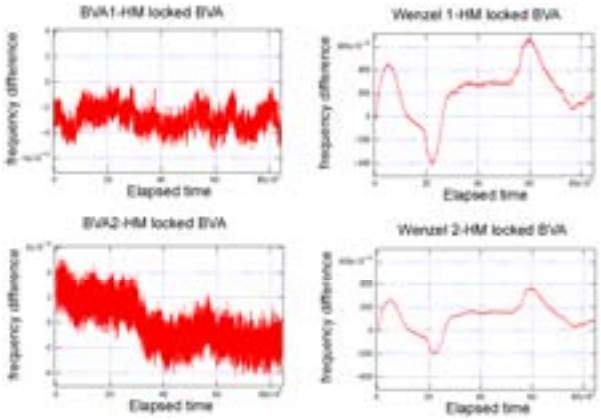

Fig 8 Observed data as a function of elapsed time

The detailed explanations, and consideration of the truncation error for the phase measurement were discussed in [7].

VI. DEMONSTRATION OF MULTI-PHASE METER

The DMTD using DFT has greatly extensibility for multi-phase meter, because the simultaneous ADCs are commercially available to easily be implemented. NI-PCI 6143 has eight ADCs so that we could measure the time difference during eight oscillators at most. Figure 7 shows a diagram of the multi-phase meter using DFT. Not so special preparation was needed comparing the DMTD measurement of two oscillators. Figure 8 is the raw data collected as the time difference during five oscillators. The two oscillators produced by Wenzel Associates, Inc. behaves similarly each other. We used three BVA oscillators, one of which is phase-locked to the Hydrogen maser, for three cornered hat measurement (Fig. 9)

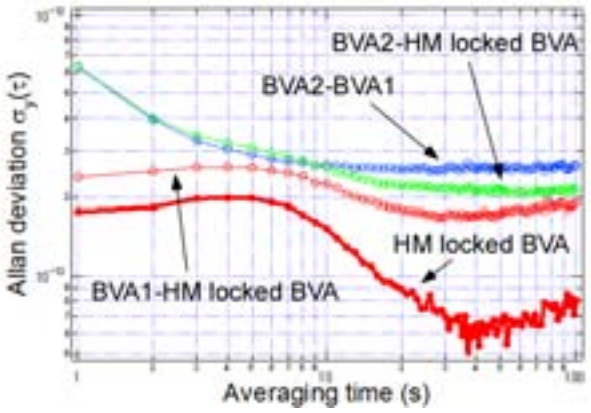

Fig. 9 Result in three cornered hat measurement

VII. CONCLUSIONS

Simplified DMTD method was proposed using Discrete Fourier Transformation, where no SPCs, nor ZCDs were needed. Truncation error was formulated to determine the time difference between two oscillators. The phase meter using DFT was implemented with not so high sampling rate by introducing dead time. The expected truncation error was in good agreement with the observed one. The multi-phase meter for five oscillators was easily demonstrated. Three corner hat measurement was also demonstrated where Allan deviation of more stable oscillator than two other ones was observed with less than approximately 30 s.

Frequency Transfer Over Optical Fiber Based on Photonic RF Phase Shifter

Jianguo Shen, Guiling Wu*, Weiwen Zou, Ruihao Chen, and Jianping Chen
State Key Laboratory of Advanced Optical Communication Systems and Networks, Shanghai Jiao Tong University, Shanghai, 200240, P. R. China
*wuguiling@sjtu.edu.cn

***Abstract*—In this paper, an active phase drift cancellation scheme based on a photonic RF phase shifter for frequency transfer over optical fiber is proposed. By this scheme, a linear and stable photonic phase shifter, which is implemented with a dual parallel mach-zehnder modulator and an optical filter, is used to compensate the phase drift induced by the fiber transmission. A 1GHz reference signal transfer over 20 km single-mode fiber with sub picosecond timing jitters measured at the remote site is experimentally demonstrated using the proposed scheme.**

Keywords-photonic RF phase shifter; frequency transfer; phase compensation.

I. INTRODUCTION

Frequency transfer via optical fiber is considered to be a promising method to realize ultra-stable reference frequency remote transfer and has attracted an intensive research in recent years [1-5]. Compare to traditional satellite-based method, the stability of frequency transfer over fiber can be improved more than three orders of magnitude [1]. However, the phase drift induced by the temperature variation and mechanical perturbation during optical fiber transmission degrades the frequency stability, especially the long-term stability. Therefore, the cancellation of those phase drifts from fiber transmission is one of the critical issues in frequency dissemination via optical fibers.

Throughout the years, varieties of schemes of phase drift cancellation for frequency transfer via optical fiber have been developed. Generally, a tunable optical delay line, typically consisted of a fiber stretcher and a temperature controlled fiber spool to obtain a large range and faster respond, is adopted to compensate delay fluctuation [2-3]. Such kind of optical delay line has a large bandwidth, but is considerably bulky and power consumption. Moreover, mechanical stress on the fiber in fiber stretcher will increase the effect of the polarization mode dispersion. Additionally, a microwave phase shifter [4] or voltage control oscillator (VCO) working as a phase integrator [5-6] is employed, which features a fast tuning speed. However, VCO is band-limited while the electrical phase shifter exits nonlinear phase shift and power variation as the phase shifting.

In this letter, a novel phase drift cancellation scheme based on a linear photonic RF phase shifter for frequency transfer over optical fiber is proposed, where the phase drift originating from fiber transmission is compensated by tuning the phase of the transmitted RF signal through a linear photonic RF phase shifter. The proposed phase drift cancellation scheme is validated experimentally by a 1GHz reference signal transfer over 20 km single-mode fiber with the timing jitter less than 1ps.

II. THE PRINCIPLE OF THE PROPOSED SCHEMATIC

Fig.1 illustrates the proposed phase drift cancellation based on a photonic RF phase shifter schematically. At local site, the reference signal is applied to a well-designed photonic RF phase shifter to generate a phase-shiftable RF modulated optical signal, of which the phase can be fast tuned by simply controlling the bias voltage of the photonic phase shifter. Then, this modulation optical signal is transmitted to a remote site through an optical fiber link. At the remote site, a part of the modulated optical signal is returned through the same optical fiber link to get the phase noise induced by the fiber transmission. The phase compensation is realized by control the bias voltage with the phase error signal, which is generated by a special phase detecting sub-system and pass through the loop filter (LP).

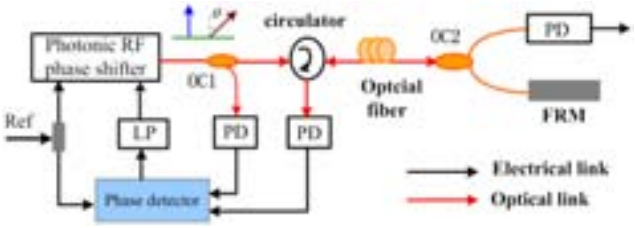

Fig.1 the schematic of the proposed phase compensation schematic

The key component in the proposed phase compensation system is a photonic RF phase shifter, which is implemented by a dual parallel mach-zehnder modulator (DPMZM) and an optical filter and shown in Fig.2. The light wave from a laser is launched into an integrated x-cut DPMZM, which is composed of two parallel sub-MZMs lying on two arms of the parent MZM, respectively. A local microwave signal from a local oscillator is applied on the sub-MZM on the top arm, and an electric up-converter (U-C) to up-convert the reference signal from a reference clock at the same time. The up-converted signal is applied to the other sub-MZM on the bottom arm. The bias voltages of the sub-MZM on the top arm and the bottom arm (DC1 and DC2) are biased at the minimum transmission point to perform optical carrier-

suppressed double sideband (CS-DSB) modulation. One sideband of the CS-DSB signal is suppressed by an optical band-pass filter (OBPF) to generate a single sideband (SSB) signal, which is detected by photo detectors to produce a phase-shifted reference signal by beating of the two signals in the same sidebands. The phase shift value of the recovered reference signal can be set by simply tuning the bias voltage of parent MZM (DC3). An EDFA is added between the DPMZM and OBPF to compensate the insert loss.

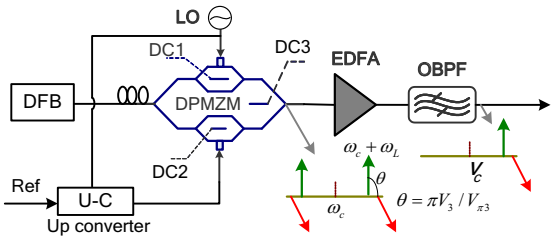

Fig.2 Schematic of the proposed photonic RF phase shifter

Under small-signal modulation, the optical field at output of the DPMZM can be expressed as follows:

$$E_1(t) = A_1 \exp[j(\omega_c t + \omega_L t - \frac{\theta}{2})] + A_1 \exp[j(\omega_c t - \omega_L t - \frac{\theta}{2})] + A_2 \exp[j(\omega_c t + (\omega_L + \omega_r)t + \frac{\theta}{2})] + A_2 \exp[j(\omega_c t - (\omega_L + \omega_r)t + \frac{\theta}{2})], \quad (1)$$

where A_1 and A_2 are the amplitude of the first sideband on the top and bottom arm, respectively; ω_c , ω_L and ω_r are the frequency of the optical carrier, local microwave and reference signal respectively; θ is the relative phase difference between the optical first sidebands on the top and bottom arm, which can be expressed as follows.

$$\theta = \pi V_3 / V_{\pi 3}, \quad (2)$$

where $V_{\pi 3}$ is the half-wave voltage of the parent MZM, V_3 is the bias voltage of the parent MZM (DC3). Assuming that the lower sidebands from the top and bottom arm are suppressed by the OBPF, we have

$$E_2(t) \propto A_1 \exp[j(\omega_c t + \omega_L t - \frac{\theta}{2})] + A_2 \exp[j(\omega_c t + (\omega_L + \omega_r)t + \frac{\theta}{2})], \quad (3)$$

Where $E_2(t)$ is the optical field of SSB signal at the output of the OBPF. A phase-shifted reference signal produced during photo detection process can be described as

$$i(t) \propto E_2(t) \times E_2^*(t) = A_1 A_2 \cos(\omega_r t + \theta) \quad (4)$$

As can be seen from Eq. (4), the optical phase is introduced to the reference signal directly and one can easily control the phase shift of the reference frequency signal linearly and continuously by tuning the bias voltage of DC3.

It is worth to note that the additional LO is used to enlarge frequency gap between the upper and lower sidebands to ensure one sideband can be suppressed completely by the optical filter. Thus, the proposed phase shifter can be for low frequency application, which corresponding to the large time delays compensation range. In fact, the LO can be replaced by the ground and the bias voltage of DC1 works at the maxim point for the high frequency application, which is realized in our previous work [7].

III. Experiment Results

A proof-concept experimental system over 20 km optical fiber based on the presented scheme is built. The optical carrier from a DFB laser with an optical power of 16 dBm is injected into a DPMZM (Photline, MXIQ-LN-40) with a usable bandwidth of 20 GHz. The bias voltages corresponding to the minimum transmission points of the two parallel sub-MZMs are 9.4 V and 9.3 V, respectively. The frequency of the local microwave signal is set at 9 GHz to ensure that the lower sideband can be suppressed completely by the consequent tunable optical band-pass filter (TOBPF, Alnair, BLV-200CL). The reference signal needed to be transferred is set at 1 GHz. Three PDs (Thorlabs, DEC010FC) with a bandwidth of 2.5 GHz is used to recover the reference signal.

Firstly, the performance of the proposed phase shifter is evaluated by testing the recovered reference signal at the PD1. Fig.3 shows the measured phase shift and power variation of the recovered reference signal as the tuning of the bias voltage (V3). A continuous and linear phase shift over 3600 is achieved when the bias voltage (V3) is tuned from -15 to 15V.

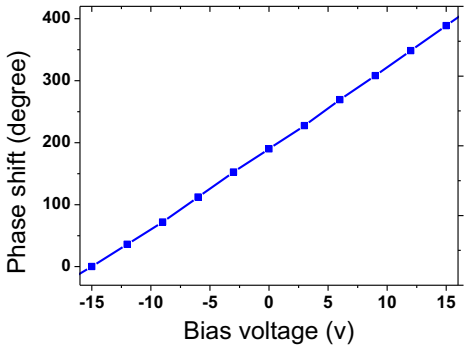

Fig.3 measured phase shift as the bias voltage tuning.

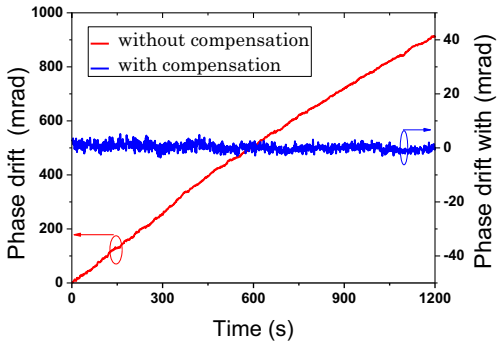

Fig.4. Phase drifts without and with phase compensation

Fig.4 shows the phases drift without and with compensation when transferring a 1GHz reference signal over 20km optical link. As can be seen, the phase drift without compensation is up to 900 mrad within 20 minutes, which mainly results from the temperature change. With the compensation based on the photonic RF phase shifter, the phase drift is less than 6 mrad or timing jitter less than 1ps (RMS).

IV. CONCLUSION

In conclusion, we proposed and experimentally demonstrated a novel phase drift cancellation scheme based on a photonic RF phase shifter for frequency transfer over optical fiber. A linear and stable photonic RF phase shifter is implemented with a DPMZM and an optical filter, which can realize phase compensation through simply tuning the bias voltage of the DPMZM. A proof-of-concept experiment of transferring a 1 GHz reference signal over 20km optical link was carried out. The timing jitter of less than 1ps is achieved with the proposed phase compensation scheme.

***Abstract*— The OPTIME project creates a long range dissemination system for transfer ultraprecise time scale and the references frequency signals in telecommunication networks. The highest accuracy signal is available only on fiber optical networks, but other type of networks can be used to transfer of signals with lower accuracy to adapt it to the needs of different user groups. Article also describes experience gained during an over-a-year experiment of connection between Central Office of Measures (GUM) in Warsaw and the Astrogeodynamic Observatory (AOS) in Borowiec.**

Keywords- Atomic clock, fiber optical network, high precision dissemination of time and frequency reference signals, time transfer.

I. INTRODUCTION

Access to ultra-precise time and frequency signals is very important for many groups of users like scientific and research communities, business or government users. Devices, which can provide such a signal (e.g. atomic clock) are not available for all of these groups of users. To ensure access high-accuracy signals other methods as satellite systems (GPS, GALILEO, GLONAS) must be used.

Next very important issue is a problem of comparison and synchronization of remote clock devices. There are only a few methods (Two-Way, PPP, L2T2) with the expected results in terms of accuracy. One of the main advantages of using fiber optical network to compare and synchronize remote devices is a very short time of receiving measurement results.

The OPTIME project proposes solution to achieve both of these issues: compare remote devices with very high accuracy and provide ultra-precise frequency and time signals to end-users. Fiber optical networks are now widely prevalent amongst research and development centers, universities, hi-tech industries or public administration so it seems to be obvious to use it as a transmission medium for time and frequency signals.

II. OPTICAL LINK GUM – AOS BOROWIEC

The idea of the OPTIME project arose as the natural consequence of the experience gained during an over-a-year operation of 421,4 km-long fiber-optic connection between Central Office of Measures (GUM) in Warsaw and the Astrogeodynamic Observatory (AOS) in Borowiec near Poznan. After some successive laboratory experiments of the time and frequency long-haul fiber-optic transfer in which the idea of the active propagation delay stabilization was evaluated the experimental link between GUM and AOS was established, basing on fiber optic infrastructure provided by PSNC – PIONIER and TPSA. The link was launched on the 27th January 2012 and as compared to other reported experimental and rather short-term installations [1], [2], [3] since that day it is in continuous operation enabling a permanent comparison of the UTC(PL) and UTC(AOS) time scales [1]. The concept of the active propagation delay in the fiber optic link was described in [5], whereas the method of joint time and frequency transfer is presented in [6]. The problem of extending the reach of the link has been discussed in details in [7] and [8].

Herein, for the first time, we are reporting on over a year comparison of UTC(PL) and UTC(AOS) atomic timescales with this system, and we refer it to the results of comparisons performed by GPS-based methods, and we also address some practical aspects of maintaining time and frequency dissemination over fiber optical network.

In Figure.1 the results of direct comparison of the UTC(AOS)-UTC(GUM) carried with usage of fiber link, the GPS PPP based on BIPM calculations and Common View (CV) C/A methods are shown. For better readability the curves for both GPS methods are shifted by ±15 ns. It is clear, that all curves are very similar and the differences between them are rather small.

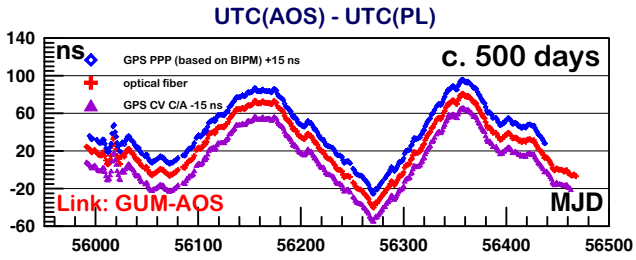

Figure. 1 Results of comparison of UTC(AOS) and UTC(PL) using: fiber optic link (middle/red), GPS PPP based on BIPM calc.(upper/blue) and GPS CV C/A (bottom/violet) methods

In Figure. 2 the differences between results obtained with the use of the fiber link and GPS PPP (BLUE) and respectively the fiber and GPS CV C/A (VIOLET) are shown.

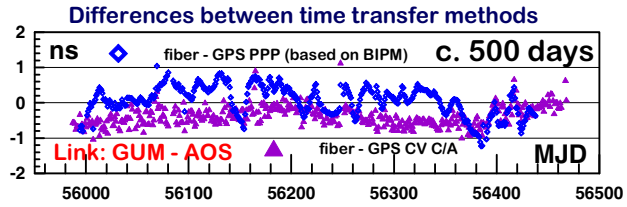

Figure. 2 Differences between time transfer methods

During the operation period in the fiber-optic link some specific events occurred. All of them are collected and listed in Table. 1. There are two types of events. One of them specified as "DLL correction" comes from the method of the time transfer stabilization [6] and may be planned. This type of event could be eliminated in the nearest future by use of automatically switched optical delay lines. The second accidental one specified as "Optical fiber break" or any type of "Breakdowns" are typical and quite commonly occurring in long-haul fiber-optic links. In our application it may be troublesome by triggering the need for new link calibration.

TABLE 1. TABLE OF EVENTS

	MJD	Event Description	Remarks
0	55963	System calibration	$\tau_{GUM-AOS}$ =2047574,25 ns
2	56080-56084	Optical fiber break	new calibration $\tau_{GUM-AOS}$ =2047351,05 ns
4	56096-56097	Optical fiber break	new calibration $\tau_{GUM-AOS}$=2047751,05 ns
5	56120-56121	Optical fiber break	no calibration required
6	56229-56230	2-hrs breakdown – unknown reason	no calibration required
7	56249-56250	Measurement breakdown at AOS	no comments
8	56330-56331	Fiber replacement	no calibration required
9	56345	Dispersion checking	OK
10	56365	Measurement reorganization	no comments
13	56464	Power supply breakdown at GUM	no comments

Nevertheless after more than one year exploitation of the link and a series of metrological experiments, it may be stated that the link is capable of transferring the highest-quality and stable 1 PPS and 10 MHz atomic reference signals for quite long distances and the technology used in the link may be used to build the wide network for time and frequency dissemination.

III. OPTIME ARCHITECTURE

The OPTIME architecture bases on three main elements. The first one is reference laboratories with reference clock devices. Each of these laboratories can provide time-frequency signals for the entire system. These reference laboratories must be leading centers with high reliability of deliver signals. The parameters of the whole system are strictly dependent on the accuracy of these laboratories.

The second element includes local repositories. Local repositories will be equipped in less precise devices like rubidium or cesium clock, which will be synchronized with references laboratories. During connection failure to reference laboratories, local repository will provide time and frequency signals until the failure will be removed. Such solution will increase the reliability of the system and minimize the effects of potential failures to end-users. Present work aims to elaboration of repository structure which enables the automatic detection of network failures and the reliable switchover to redundant and backup source of time and frequency. In order for switchover mechanism to work properly and optimally synchronization of a local repositories clock to reference laboratories is required. A concept diagram of the repository is presented in Figure 3

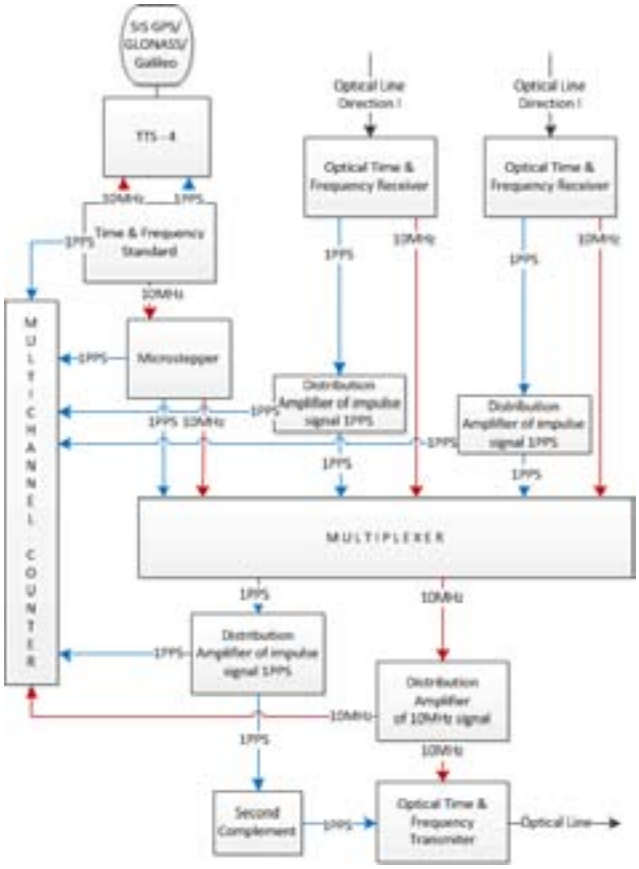

Figure. 3 Local repository diagram

The last main element of the system is dissemination network. As a backbone the OPTIME uses a fiber links provided by TPSA and PSNC – PIONIER network. All reference laboratories, local repositories and the most advanced users must be connected by optical fiber network to ensure the highest accuracy of signals. However, the OPTIME architecture also allows to use IP networks for users with less requirements.

The project plans to offer an application in the IP networks. The local repositories are going to provide 1PPS signal to a nearby located client via short distance fiber link. In the client site, 1PPS signal is going to be transformed to the RS-232 standard and supply NTP Stratum 1 server. In that way, problem of unknown time offset due to the round time trip asymmetry in IP networks is reduced. Client receives the timestamps with the time accuracy of 5us.

The project OPTIME develops the concept of national system architecture, the distribution of time and frequency. User's needs analysis was the demand for such service. Table 2 provides a first estimation of the potential needs of the division into groups of users and their requirements on the accuracy of the signals and the need for synchronization with the legal time.

TABLE 2. REQUIREMENTS FOR TIME & FREQUENCY PATTERNS

Users	Synch.	Freq. Stab.	Legal Time	Market size
SCIENCE				
T&F Lab	1ns	1.00E-15	NO	100
Opt. Astro Lab	1ns	1.00E-14	NO	100
Phys. Lab	10 ns	1.00E-17	NO	100
INDUSTRY				
Telecom.	< 3 µs	1.00E-12	YES	100 M
Mobility	< 3µs	1.00E-12	YES	100 M
Transport.	1 ms	1 µs/DAY	YES	100 K
SECURITY				
Bank/Final.	1-20 ms	-	YES	10 K
Data transfer	-	-	YES	100 K
Cryptology	1 µs	-	YES	100 K

Based on requirements analysis it is planned in future to implement national, distribution network taking advantage of the PIONIER structures – fibers. The plans assume a deployment of the local repositories in at least 21 main cites which will play the role of time and frequency distribution centers. The repositories will be supplied with at least two directions and UTC(PL) and UTC(AOS) time scales will be available in these repos.

IV. First phase of OPTIME

The first phase will focus on creation of connection between two reference laboratories and two local repositories. The first of reference laboratory will be AOS located in Borowiec with UTC(AOS), the second one will be GUM located in Warsaw with UTC(PL). Two local repositories will be created in Poznan - PSNC, and Torun - FAMO. The whole system will have fiber link more than 700 km long (see Figure 3).

Figure 3. National time and frequency distribution system – first phase.

The choice of location of local repositories was dictated by practical considerations. Poznan is a major academic center, and PSNC is an operator of PIONIER - Polish Optical Internet - a nationwide broadband optical network for e-science. Torun is a strong center of atomic, molecular and optical physics, and radio astronomy. There is one of the greatest radiotelescope located in Piwnice near Torun.

V. Opportunities for OPTIME project

The OPTIME project is planned as a demonstrator of time and frequency dissemination service. However further opportunities to develop service to include more users will be investigated. It also considers international cooperation both the exchange experiences and creates optical links to foreign partners.

Acknowledgment

The OPTIME project is co-funded be the *National Center for Research and Development* from Poland in the *Applied Research Programme*.

***Abstract*—This paper presents the design, operation and test results of an interpolating time counter with a multi-edge coding principle implemented in the second stage of interpolation. The counter is implemented in an FPGA device (Spartan-6, *Xilinx*) and provides a 2.7 ps resolution, 8 ps precision and 1 s measurement range. The development of such a high performance instrument needs to solve several design problems. The main of them are an implementation of a pattern generator and elimination of bubble errors. We designed and tested two pattern generators based respectively on look-up tables and fast carry chains. The former one is simpler for implementation while the latter allows to control parameters of the pattern signal. This control feature is especially important for the quality of T/D conversion that depends, among others, on the complexity of the pattern signal. We tested three variants of TDC based in turn on coding of three rising, three falling or six alternated edges.**

Keywords—time-to-digital conversion; time counter; multi-edge coding; two-stage interpolation

I. INTRODUCTION

Precise integrated time-to-digital converters (TDC) are typically based on the use of discrete delay lines built as chains of delay buffers [1, 2]. Due to technological spread and changes in ambient conditions, the delays of involved buffers are non-uniform. This manifests in different widths of quantization steps of TDC transfer function and ultimately deteriorates the linearity and precision of conversion. The ultra-wide steps, especially observed in FPGA-based TDCs, may be reduced in the process of conversion by detecting not a single but multiple signal transitions in a delay line [3]. This method is later called the multi-edge coding. In an integrated TDC with multi-edge coding, the leading edge of the START signal, that represents the beginning of the measured time interval, triggers the pattern generator that generates a signal with certain amount of edges. Next, this signal propagates through the time coding delay line (TCDL) that contains a tapped delay line and associated flip-flops [4]. Upon arrival of the leading edge of the STOP signal, that represents the end of the measured time interval, output states of taps of delay line are stored in flip-flops. The ordinal numbers of delay cells of TCDL, in which the transitions of pattern signal were hold, are then added up (fig. 1). The obtained total sum determines the number of the quantization step in an equivalent coding line (ECL), which is virtually created by overlapping quantization steps of the TCDL segments.

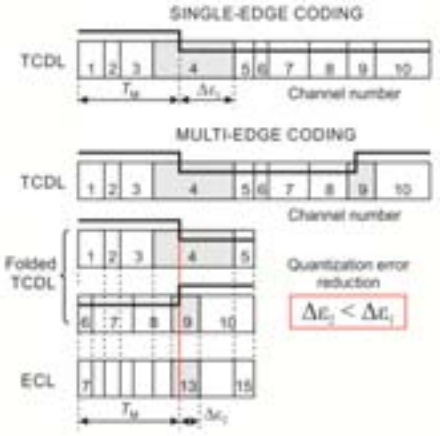

Fig. 1. The idea of multi-edge coding.

The value of measured time interval (T_M) can be calculated as:

$$T_M = \sum_{i=k}^{l} \tau_i \text{ where } l = \sum_{j=1}^{m} n_j$$

while k is the first quantization step of the ECL, n_j is the number of quantization step in the j-th segment of delay line in which the pattern signal transition is observed, τ_i is the width of the i-th bin in the ECL and m is the number of pattern transitions. In a single-edge coding method wide bins can cause a large quantization error (e.g. $\Delta\varepsilon_1$ in fig. 1). The multi-edge coding reduces such errors ($\Delta\varepsilon_2 < \Delta\varepsilon_1$) by narrowing the widths of quantization steps of TCDL. These widths, and consequently the widths of quantization steps of the ECL, are precisely evaluated during the calibration process based on a statistical code density test (SCDT) [5].

II. PATTERN GENERATORS

The multi-edge coding method requires generation of the pattern signal that is a model square signal with a certain amount of edges and possibly minimal delays between them. The shortness of the pattern is an important requirement because any increase in its length causes need for lengthening of the TCDL. This should be avoided due to larger sensitivity of longer delay lines to drifts of supply voltage and ambient temperature. Two types of pattern generators that meet the mentioned requirements are proposed.

A. LUT-based pattern generator

As the first approach we designed a pattern generator consisting of four delay buffers and a Look-Up Table (LUT) that implements the function y(a, b, c, d, e) = Σ [1, 7, 31] (fig. 2).

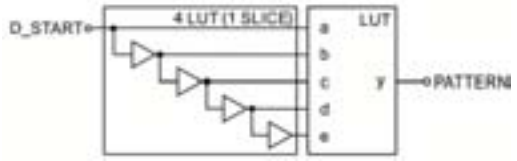

Fig. 2. Pattern generator based on Look-Up Tables.

The rising edge of the signal D_START reaches the consecutive inputs of the LUT with an incremental delay due to delays of subsequent buffers. In accordance with the implemented function, the LUT produces a square waveform with transitions that follow successive rising edges at the LUT inputs coming from the active D_START signal propagating through the chain of buffers. For the function presented above the pattern generator creates an output signal containing five edges (three rising and two falling). An important advantage of this generator is its simplicity and saving of FPGA logical resources (only two slices of *Xilinx's* Spartan-6 involved), while the main drawback is that delays between following pattern edges cannot be shorter than the delay of an elementary delay buffer.

B. Carry chain-based pattern generator

The second pattern generator has been built with the use of the carry chain structure typically implemented in modern programmable devices (fig. 3).

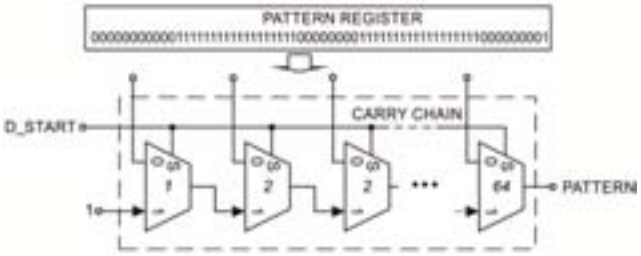

Fig. 3. Pattern generator based on carry chain structure.

The generator consists of 64 fast carry multiplexers (16 Slices in Spartan-6, *Xilinx*) connected in series and a 64-bit pattern register. Outputs of the register containing the pattern are connected to the inputs '0' of multiplexers. However, the pattern can start propagating toward the output of the carry chain only when the input signal D_START changes its state to high ('1'). The main advantage of this generator is the possibility of changing the shape of pattern by the control software without necessity of reprogramming the FPGA device.

III. BUBBLE ERRORS

The carry chains built in programmable devices together with associated flip-flops are often use for fast T/D conversion [1, 2, 4]. During tests of such a carry chain structure implemented in the Spartan-6, it has been observed that the increase in delay along the carry chain does not match the order of multiplexers, which would be expected from the schematic diagram provided by the manufacturer [6, 7]. The lack of monotonicity is a result of non-uniform propagation delays between elements of the carry chain and flip-flops. It also comes from not equal delays in the clock distribution net and from metastability effect in flip-flops. These properties can lead to appearance of bubble errors in the output code of TCDL (fig. 4).

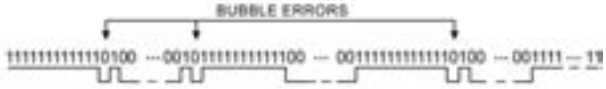

Fig. 4. An example output code with bubble errors.

In a TDC with single-edge coding such errors can be eliminated by virtual rearrangement of delay buffers in the coding line. However, in the multi-edge coding TDC both edges of the pattern signal are coded and such approach does not give proper result because the appearance of bubble errors depends also on the type of signal transition (rising/falling edge).

In order to eliminate the bubble errors an additional circuit has been developed that detects excess logic transitions in the output word of coding line and corrects them as errors (fig. 5). The circuit consists of LUTs that realize the following function y(a, b, c, d, e, f) = Σ [14, 22, 26, 38, 42, 44, 50, 52, 56].

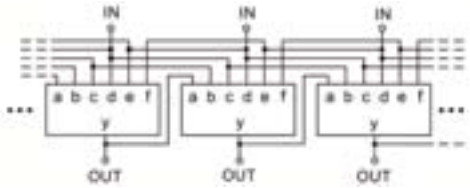

Fig. 5. Bubble error correction circuit.

The developed circuit corrects both single bubble errors (01**0**111) that may appear at the beginning and end of a coded pulse and double ones (01**00**11) at the end of the pulse. Error correction is done by swapping these '1's and '0's, which diverge from their groups.

IV. COUNTER DESIGN

Interpolation methods are typically used in time counters to obtain a high-resolution and wide measurement range [1, 4, 8]. Recently, the two-stage interpolation method, being an advanced version of the classical Nutt method [9], is the most popular. In this method the measured time interval is split into five parts. The longest one is measured by an ordinary binary counter as the integer number of the reference clock periods, which appear between leading edges of START and STOP pulses. The time intervals remaining between the leading edges of START and STOP pulses and the nearest edges of the reference clock are measured by the two-stage interpolators in respective channels START and STOP [4].

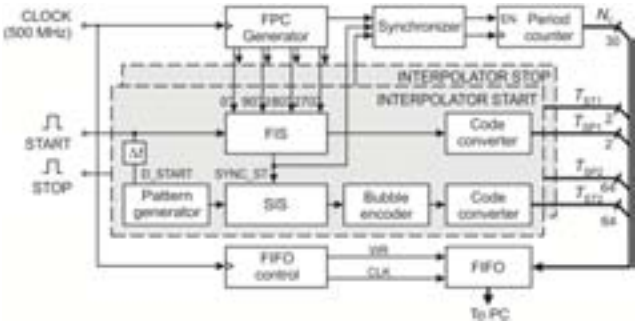

Fig. 6. Two-stage interpolation time counter.

Simplified block diagram of the designed time counter is shown in fig. 6. The first interpolation stage (FIS) has been built with the use of four double synchronizers. The main aim of the FIS is to detect the segment of four-phase clock (FPC), in which an input pulse (START or STOP) appears, and then to synchronize this signal with the nearest FPC edge. Next, this synchronized signal (SYNC_ST or SYNC_SP) is used for enabling the period counter and for further precise conversion in the second interpolation stage (SIS). Since the synchronization process takes some time (τ_{PSI}) then the input pulse (START/STOP) has to be delayed by adequate amount of time $\Delta t \approx \tau_{PSI} - \tau_G$, before it gets the pattern generator (D_START/D_STOP), while τ_G is the time needed for reliable generation of a pattern. The appearance of the active edge of D_START/D_STOP signal triggers the pattern generation and propagation of the created pattern in the SIS of corresponding channels (START/STOP). After the SYNC_ST/SYNC_SP pulse has appeared, the state of the delay line in SIS is stored in associated flip-flops.

Raw data from FIS is converted directly from the ring code to the natural binary code. Data from SIS is first corrected in the bubble encoder, and then it is appropriately converted and twofold compressed in the code converter. Finally, all measurement data from the period counter, FIS and SIS of both START and STOP channels are stored in the fast FIFO memory and then asynchronously uploaded to the computer for further analysis.

V. TEST RESULTS

A. Test setup

The experimental tests of the developed time counter were carried out in the test setup presented in figure 7, with the use of power supply voltages typical for Spartan-6 (*Xilinx*) [6] and at the room temperature of 22 ^{o}C.

To generate the reference time intervals, three generators were used consecutively, i.e.: GFT1004 (*Greenfield Technology*), 81130A (*Agilent*) and T5300U (*Vigo System*). The 10 MHz rubidium generator FS725 (*Stanford Research Systems - SRS*) and GPS-stabilized quartz generator E8-Y (*Quartzlock*) were used as the reference clock sources for the tested counter and for all time interval generators, respectively. The time counter was powered with the use of precise power suppliers 6624A (*Agilent*) and RS-75-5 (*Mean Well*). The test board with the integrated time counter and the

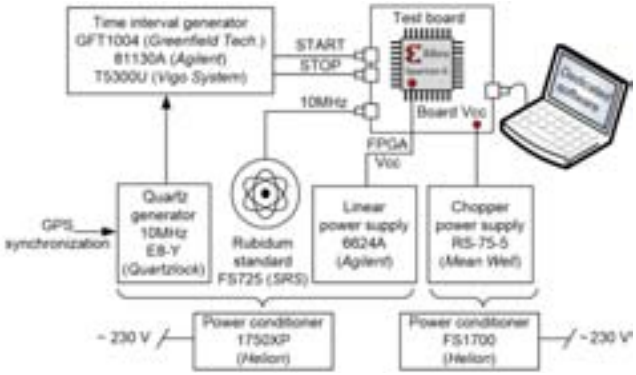

Fig. 7. Time counter test setup.

entire measurement session was controlled via USB interface with the dedicated application installed on the PC computer. Two power line conditioners FS1700 and 1750XP (*Helion*) were involved to filter deformations and noises out of the main voltage.

B. Resolution and transfer function

The first test effort was aimed at evaluation of the influence of the number of pattern edges on the counter resolution (fig. 8).

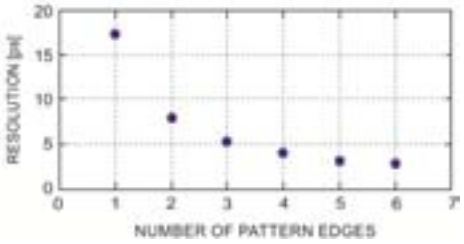

Fig. 8. The influence of the number of pattern edges on the counter resolution.

As it could be expected the resolution increases with increasing the number of pattern edges but the increase is not linear and the number of transitions larger than three gives negligible effect on the resolution (a 1.3 ps increase for 6 transitions in comparison with 4 ones). Despite the fact that any increase in the number of edges results in need of extending both the pattern and time coding lines, we decided to use a pattern consisting of six edges for further studies. It was justified by the highest resolution provided (2.7 ps). Generation of such a pattern has been done with the aid of carry chain structure (fig. 3).

Figure 9 shows bin widths, differential (DNL) and integral nonlinearity (INL) characteristics of the START interpolator. Bin width characteristic is composed of four segments corresponding to the four phases of FPC clock. A 747 quantization bins were distinguished as a result of the SCDT. Since the period of the FPC equals 2 ns then the obtained mean resolution is 2.68 ps. The extreme values of DNL and INL are 4,38 LSB (11,74 ps) and 10,40 LSB (27,87 ps), respectively. Characteristics of the STOP interpolator are similar to those presented START channel.

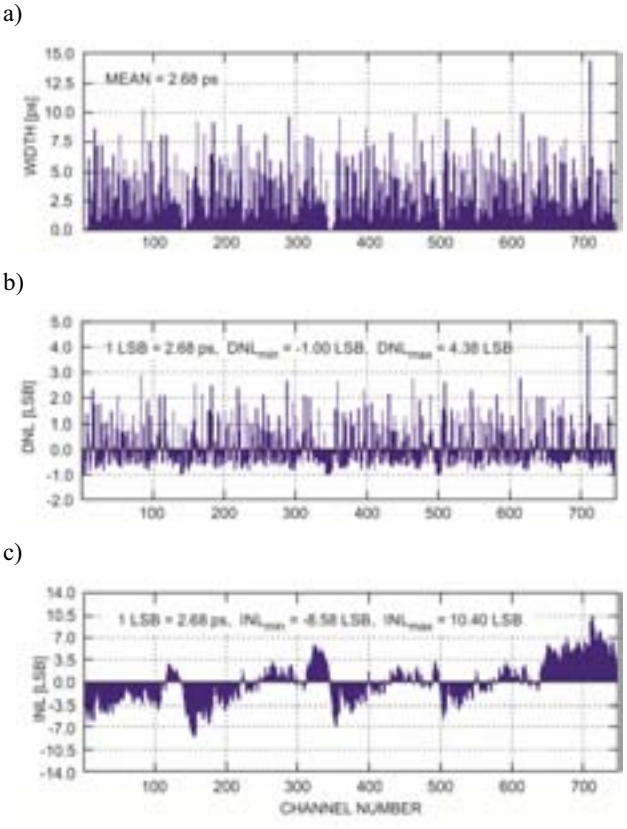

Fig. 9. Bin widths (a), differential (b) and integral (c) nonlinearities of the START interpolator.

C. Standard measurement uncertainty

In order to verify the precision of the developed time counter in its full measurement range, we first tested the precision of sources of reference time intervals. For this purposes we use a high precision oscilloscope DSA90804A (*Agilent*, noise floor < 2 ps) and evaluated characteristics of timing jitter of each time interval generator involved. Based on results of these tests, time intervals from 1 ns to 200 ns were generated by GFT1004, from 500 ns to 5 µs by 81130A, and from 10 µs to 1 s by T5300U. Measurement precision of the time counter was calculated as a standard deviation of results of 2000 measurements performed for each time interval. Figure 10 shows the measurement uncertainty achieved with and without filtration of power supply voltage. The use of power line conditioners (fig. 7) helped to lower the uncertainty level by about 0.5 ps within the range from 1 ns to 100 ns and by about 4 ps for the rest of measurement range.

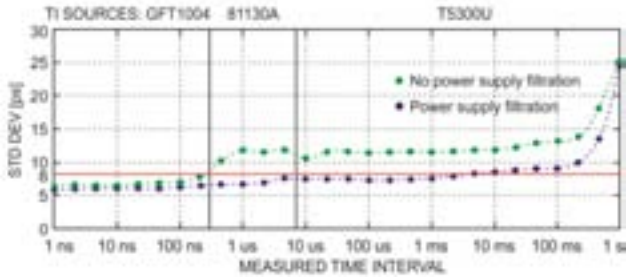

Fig. 10. Standard measurement uncertainty of the time counter.

VI. Conclusion

The use of the multi-edge coding method for T/D conversion allows to obtain a resolution value much lower than the propagation time of a single delay element in delay line. This overcomes a microelectronic technology limitation, reduces the quantization error and improves linearity of conversion. The improvement in resolution is achieved easily by increasing the number of edges of the pattern that propagates through the coding line. By applying six edges the average resolution of 2.7 ps and precision better than 8 ps for measured time intervals up to 2 ms were obtained. The high performance of the developed time counter stems also from the effective removing of bubble errors and carefully designed layout of the counter.

Abstract — Continues operation of ultra-precise time and frequency transmission requires special monitoring, calibration and management procedures to ensure high functionality, safety, and quality of the time and the frequency dissemination. The system must deliver information to administrators, end-users, and equipment manufacturer about current state of the fiber link. In the paper a description of the essential elements of the management system and data transmission methods, based on the Internet standard protocols and preliminary test results, are presented.

Keywords— Atomic clock, fiber optical network, management and monitoring, high precision dissemination of time and frequency reference signals, network management system.

I. INTRODUCTION

The idea of design the management layer came into sight as effect of the experience carried out during an over-a-year operation of 421,4 km-long fiber-optic connection between Central Office of Measures (GUM) in Warsaw and the Astrogeodynamic Observatory (AOS) in Borowiec near Poznan. The concept of the active propagation delay in the fiber optic link used to joint time and frequency transfer was widely discussed in [1,2,3,4,5]. This optical link consists of many programmable elements (amplifiers, endpoints) and classical optical fibers belonging to PIONIER backbone and spread over many kilometers. This paper focuses on out-of-band in-fiber management of EDFA (Erbium Doped Fiber Amplifier), normally installed in locations without reliable and stabile network access. Activation and a further system monitoring require robust and safety methods of management, which are based on the telecommunication standards.

A typical network management system covers the activities, methods, procedures, and tools that assure realization of special function. It is possible to find several way of their characterization. The most common is operation, administration, maintenance, and provisioning of networked systems [6].

In the Network and Management System (NMS) the operation means all activities to improve the efficiency of network and to provide defined net services. It includes monitoring, used to remark problems as soon as possible, preferably before end users are affected. The next is *administration*, which deals with tracking of resources in the network. It uses dedicated protocols and tools to keep the network under control. The *maintenance* guarantee repairs and upgrades mechanism, when equipment must be replaced. It also involves corrective and preventive measures increasing the quality of services provided by managed network, such as adjusting device configuration parameters. The last one is *provisioning*, concerned with configuring network resources to support a given service.

Network management system collects data using several mechanisms:

- agents running in infrastructure,
- logs of activity,
- sniffers,
- monitoring on demand, executed by users.

Formerly network management was worked as network status monitor, because devices were characterized only by two states: up or down. Now a crucial part of the IT team's role is delivering services on defined level, so the performance management has become a great challenges - especially for organizations of national or international range. Several access methods supporting network and network device management exist. The well-known are CLIs (Command-Line Interface), SNMP (Simple Network Management Protocol), NETCONF (Network Configuration Protocol), custom XML (Extensible Markup Language), CMIP (Common Management Information Protocol), WMI (Windows Management Instrumentation), CORBA (Common Object Request Broker Architecture) and JMX (Java Management Extensions).

The next important thing in management is an organization of a data channel for devices maintenance. Out-of-band management (OOB), called also lights-out management (LOM), needs to use a dedicated transmission channel, what makes it robust and efficient. On the contrary, in-band management is based on software and must be a part of managed system, so it is installed on the remote sites and can work transmission device operates. This solution is simply, but it does not allow access to deep system settings (system updating, reinstallation, or fix problems that prevent the system failure during booting).

In the following paragraph standard network management system (NMS) implementation, dedicated to Optical Network for Time and Frequency Transfer is presented.

This work was co-financed with the financial resources for Research and Development from Poland in the Applied Research Program (no. PBS1/A3/13/2012).

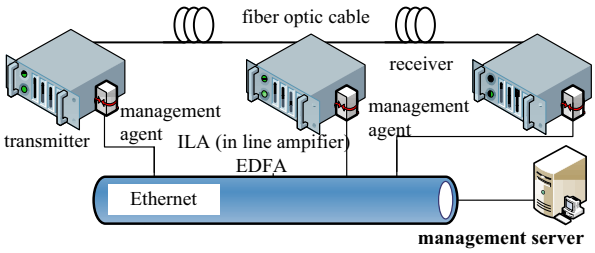
II. Optical Network Management Architecutre for Time and Frequency Transfer

A complete remote management system of ONMTFT (stand for Optical Network Management for Time and Frequency Transfer) should manage EDFA amplifiers, reference clock transmitter and receiver from remote server (Fig.1.). Requirements for monitoring, calibration and management of the transmission line, to ensure high functionality, safety, and quality, make possible the ONMTFT functions defining:

- safe access to all active system nodes;
- reading the unit status (e.g.: name, programmable parameters);
- remote reprogramming the unit parameters (e.g.: gain)
- continues/real time and on demand monitoring node performance parameters (e.g.: temperature TEMP, input power of direction West-East P_{IW}, output power of direction West-East P_{OE}, input power of direction E-W P_{IE}, output power of direction E-W P_{OW}) (Fig. 3) [1] ;
- communication with end user (e.g.: information about system status).

Delivering necessary management data is organized by CLI protocol and out-of-band technique.

a)



b)

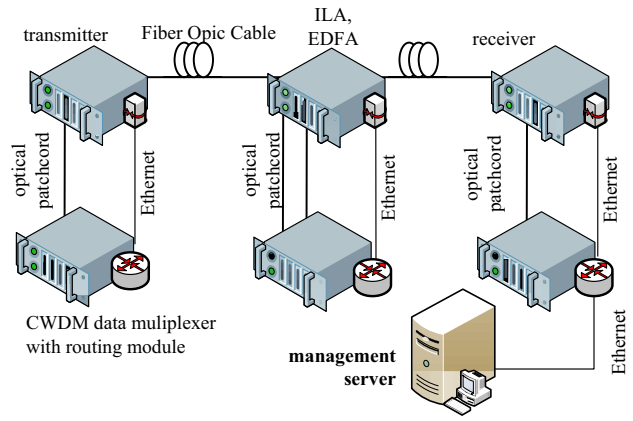


Fig. 1. Solution of out-of-band ONMTFT architecture: a) Ethernet based approach, b) "in-fiber" technique.

Implementation of the out-of-band management is usually realized, based on the Ethernet connections (Fig.1a). It is simply way of access to managed elements, but it requires additional network infrastructure. In real realization of backbone network is impossible to deliver dedicated Internet connection to ILA (In Line Amplifier) nodes. The GPRS access to network very often causes difficulties too, additionally for security reason some private network (e.g.: VLAN, VPN) is strongly recommended. Moreover management channel needs to be stable in time which is hard to achieve in GSM networks.

To eliminate this problem the remote OMTFT elements can be accessed through the time transfer link via CWDM multiplexers and routers, as shown in Fig.1b. In this case a fiber optic line is shared between time transfer link and management using in-fiber technique. A comparable solution implementing nonstandard network management procedures and dedicated to management of optical fiber link for frequency metrology was described in [8].

III. In-Fiber techniques - Nodes Arcitecture

The system of time and frequency dissemination consists of endpoints (transceiver, receiver) and regenerating nodes, included EDFA. Implementations of basic management procedures require additional management subsystem. This infrastructure (ONMTFT) contains: internal routing module (it is necessary to data exchanging between nodes and more flexible than programmable switches), Ethernet copper to fiber media converters, dedicated optical CWDM filters and optical diplexer (for physical separation of data transmission channel). The proposed hardware solution multiplexes time signal and management data using only one fiber for two functions. It is called *in-fiber* management techniques. The block diagram in Fig. 2 shows typical architecture of regenerating node. Control and status data coming from dedicated EDFA are formatted into Ethernet packet and distributed according routing table by internal routing module to media converters or local external Ethernet port. The CWDM module combines two control links (with λ_{M1} and λ_{M2} wavelengths) with time transfer carrier (λ_{C1} and λ_{C2} wavelengths) in one common fiber.

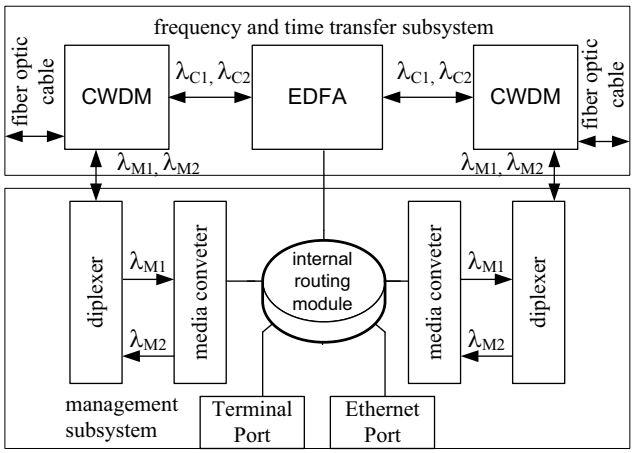

Fig. 2. Regenerating node (ILA) of fiber optic system for time and frequency transfer with management subsystem

IV. EXPERIMENTAL RESULTS

In order to verify the designed management method, presented in preceding sections, a series of measurements were arranged in the laboratory, using real telecommunication fiber link (Fig.3). The measurement results should give answer to two questions: Does a common transmission of precise time signal and management data in one optic fiber link degrade time accuracy? Does logged data of each component in the time and frequency transfer link (EDFAs, endpoints) carry information about link behavior and this information could be useful to improve time stabilization?

Answering to those problems, the test system of Time and Frequency Dissemination System with Optical Network Management for Time and Frequency Transfer, according block diagram in Fig.3, was arranged. To take closer real application of designed system, in the experiment the fibers deployed in optical cable and located in the field running along the motorway near Krakow and being the part of the TP S.A. telecommunication infrastructure, was used.

The fibers were looped-back, thus both ends of each line were accessible in the Optical Network Laboratory at AGH University of Science and Technology in Krakow. In whole line SC/APC (Angled Physical Connector) mechanical connectors were used.

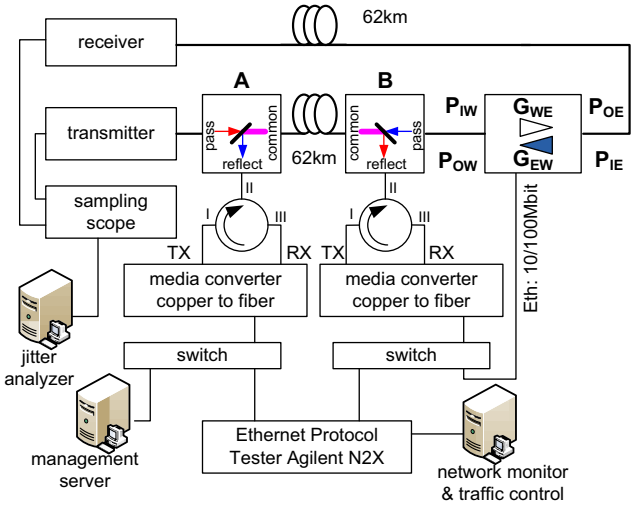

Fig. 3. Test system of Optical Network Management for Time and Frequency Transfer

In the experiments, EDFA amplifier was continuously controlled and data was recorded to the server. Managed amplifier was inserted between two 62 km long fiber spans (referred as B on Fig.3) with total attenuation equal 19.2 dB and 19.5 dB respectively. A control and status data coming from EDFA is formatted into Ethernet packets and then are transmitted over fiber by media converter. The standard small form-factor pluggable module of 1510 nm (λ_{M1}) and link budget 20 dB was applied. The optical circulator separate TX and RX signals transmitted together in circulator port II. Optic filter allows combining management wavelengths λ_{M1} and λ_{M2} (near 1510nm) with time transfer carrier (λ_{C1} and λ_{C2} wavelengths close to 1549ns) in one common fiber.

The EDFA remote pooling was executing concurrently with simulation of background 50Mbit/s network traffic, generated and measured by AGILENT N2X Network Protocol Analyzer (see Fig. 4). The maximum measured throughput between point A and B was 80Mbit/s, and this boundary is consequence of switches limitations.

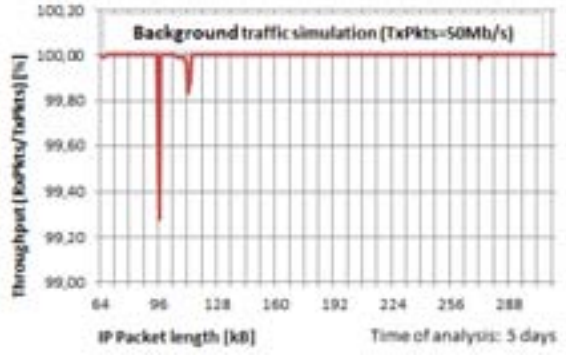

Fig. 4. Packets size test used as background traffic simulation

A set of EDFA parameters: the temperature TEMP, input power of direction West-East P_{IW}, output power of direction West-East P_{OE}, input power of direction E-W P_{IE}, output power of direction E-W P_{OW}, have been logged for 5 days, with 1 minute resolution. The behavior of EDFA gain stabilization reports graphs in Fig. 6 and in Fig.7.

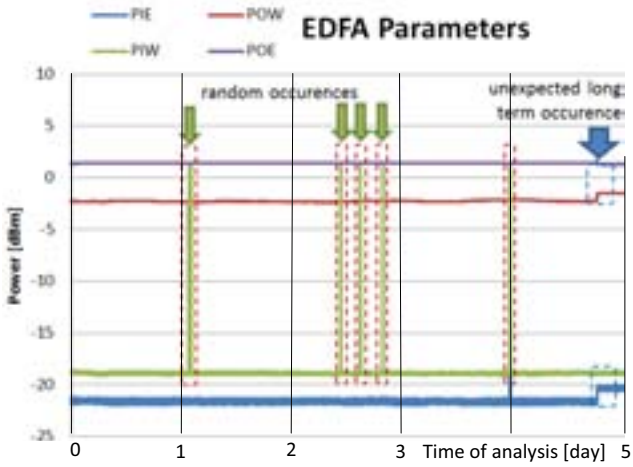

Fig. 5. Power changes in input and output of EDFA during test experiments

A short random occurrence of P_{IW} fluctuation and changes of P_{OW} and P_{IE} was observed, but its nature and its influence to time stability have not be well characterized yet.

In Fig. 7 the strong correlation between temperature and output power can be observed, however analyzes in [5] suggest that it is possible to compensate influence of temperature variance to output power. This discovery should be better investigated in future, because is related to transmitted time stability.

The time transfer accuracy was evaluated by means of Overlapping Allan Deviation (ADEV, measured using methods described in [3,7].

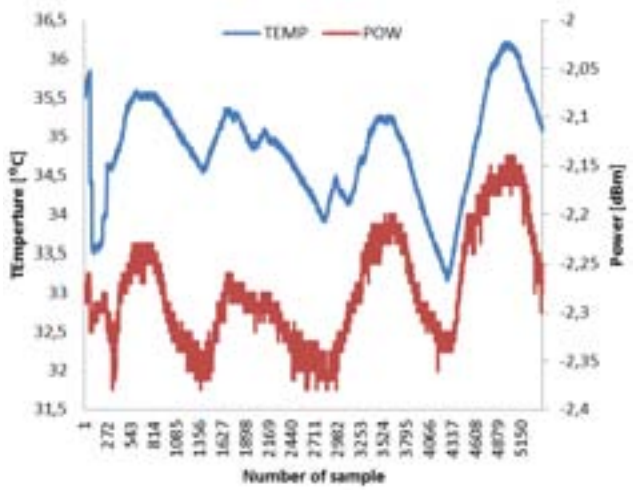

Fig. 6. Discovered correlation between output power POW and temperature TEMP

Time transfer stability with (red line) and without (blue line) management system data traffic (Fig.4.) gives similar results. It allows draw a conclusion that management facilities and in-fiber transmission do not affect time transfer accuracy.

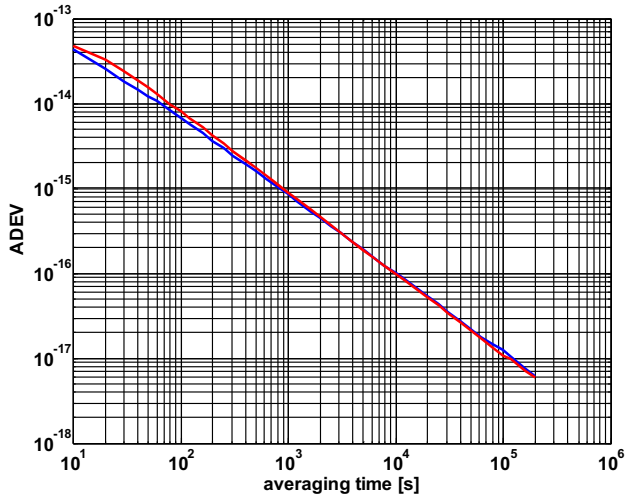

Fig. 7. Allan deviation (ADEV) with (red line) and without (blue line) running of management layer

SUMMARY

Access to ultra-precise time and frequency signals are very important for many user groups include scientific and research communities and business or government users. It requires not only infrastructure for time transfer, management layer is important too. An activating the link spread over many kilometers and keeping on its high accuracy of time transfer is impossible without reliable management system. Presented out of band in-fiber solution fulfill user expectation and could be developed in the future. The management system doesn't change *Allan deviation* of transmitted clock and allows provide additional analysis to improve performances of time transfer.

ACKNOWLEDGMENT

The authors would like to express deeply gratitude to prof. Marcin Lipiski, prof. Przemsylaw Krehlik and prof. Lukasz Sliwczynski for their valuable advices and support.

***Abstract*—A system based on self-made modems and off-the-shelf fiber-optic devices aiming at achieving precise fiber-optic time and frequency transfer based on radio frequency (RF) carrier phase tracking and pseudorandom noise code correlation is demonstrated. The RF carrier phase and the pseudorandom noise code are both used through the fiber-optic link in the two-way mode. The two-way transfer asymmetry caused by the different optical wavelengths for both directions, which is the case in DWDM system, is avoided by the Code Division Multiple Access (CDMA) system here. The first result of the common clock experiment shows that the measurement noise characterized as modified Allan deviation of $6.5\times10^{-11}\tau^{-3/2}$(1s to 1000s) and $2\times10^{-15}\tau^{0}$ (1000s to 10000s) with carrier phase and $2.5\times10^{-11}\tau^{-1}$ (1s to 10000s) with code.**

Keywords-RF carrier phase; pseudorandom noise code; fiber-optic; CDMA

I. INTRODUCTION

Many literatures have been reported on stable frequency transfer via optical fibers, both in optical domain [1] and RF domain [2, 3]. As to time transfer over fibers, frame detection in SDH or SONET network [4], timing code including 1PPS signal transferred using two-way Dense Wavelength Division Multiplexing (DWDM) [5] and two-way time transfer over fiber link based on commercial modems [6] have been reported.

A system based on self-made modems and off-the-shelf fiber-optic devices aiming at achieving precise fiber-optic time and frequency transfer based on radio frequency (RF) carrier phase tracking and pseudorandom noise (PRN) code correlation is proposed and the first result of common clock experiment is shown. It is different from the previous work on time transfer over fibers, for that the RF carrier phase information and PRN code are both used through the fiber-optic link in the two-way mode.

II. SYSTEM AND EXPERIMENT DESIGN

The setup of the fiber-optic time and frequency transfer system for common clock experiment is shown in Figure 1. It works like two-way satellite time and frequency transfer (TWSTFT), but the signal propagation path is replaced with optical fiber and the up and down frequency converting process for satellite transmit is replaced by the intensity modulation and the corresponding direct detect of the optical wave.

The self-made modem is composed with a transmitter unit (TU) and a receiver unit (RU). The RF carriers modulated by different PRN codes are transmitted by TU and go through the fiber-optic link with intensity modulation of 1550nm optical wave by E/O unit, and are direct detected by O/E units at both sites in two-way mode. Optical waves in both directions share the same fiber between site 1 and site 2 thanks to the optical circulators, which avoid the transmitted signals get back to the local site.

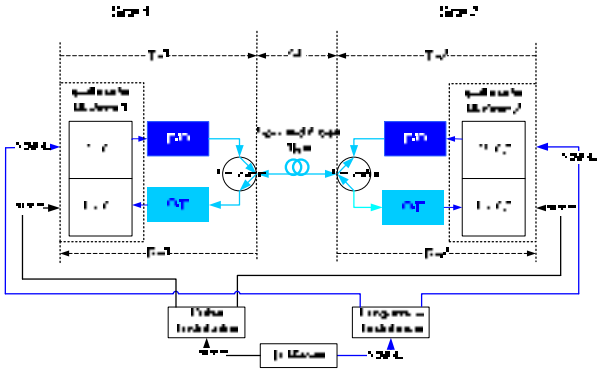

Fig. 1 The setup of the fiber-optic time and frequency transfer system for common clock experiment.

The time scale at site 1 is T_1 and the time scale at site 2 is T_2, defined at the reference end of the modems at both sites. The transmitting path delay is Tx_1 for site 1 and Tx_2 for site 2, the receiving path delay is Rx_1 for site 1 and Rx_2 for site 2. The fiber link signal path delay is SP and it is the same for both directions.

The time difference measured with PRN code correlation is shown as Eq. (1) and Eq. (2) at site 1 and site 2 respectively.

$$t_{12} = T_1 - T_2 + Tx_2 + Rx_1 + SP \tag{1}$$

$$t_{21} = T_2 - T_1 + Tx_1 + Rx_2 + SP \tag{2}$$

The time scale difference T_1- T_2 can be calculated as

$$T_1 - T_2 = \frac{1}{2}(t_{12} - t_{21}) + \frac{1}{2}(Tx_1 - Rx_1) - \frac{1}{2}(Tx_2 - Rx_2) \tag{3}$$

The carrier phase is estimated by Phase Lock Loop (PLL) which tracks the input carrier phase of RU01 and RU02 as φ_{12} and φ_{21} in circle respectively and can be written as

$$\varphi_{12} + N_{12} = \varphi_2 + (Tx_2 + Rx_1 + SP)\cdot f \tag{4}$$

$$\varphi_{21} + N_{21} = \varphi_1 + (Tx_1 + Rx_2 + SP)\cdot f \tag{5}$$

where N_{12}, N_{21} are the unknown carrier-cycle integer ambiguities of the input carrier phase of RU01 and RU02, and φ_1, φ_2 are the transmitted signal phase in circle of TU01 and TU02 respectively. f is the carrier frequency.

The time scale difference measured by carrier phase can be written as

$$\begin{aligned}(\varphi_1 - \varphi_2)/f &= (\varphi_{21} + N_{21} - \varphi_{12} - N_{12})/f \\ &+ (Tx_2 - Rx_2) - (Tx_1 - Rx_1)\end{aligned} \tag{6}$$

The experiment setup in Figure 1 is housed in a temperature controlled room with the temperature within 24±0.3°C.

III. First Result

The first result of common clock experiment is shown without calibration and the knowledge of carrier-cycle integer ambiguities. But it indicates the measurement noise of the proposed setup by PRN code correlation and carrier phase tracking.

There is no carrier cycle slips during this experiment. A continuous carrier phase measurement together with code measurement results with offset removed is shown in Figure 2.

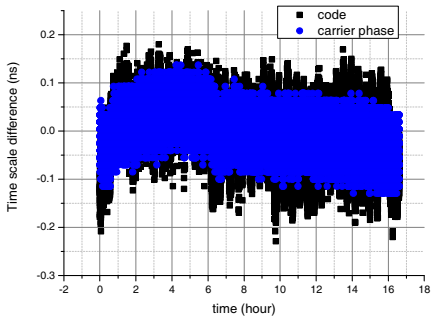

Fig. 2 Time scale difference measured with PRN code correlation and carrier phase tracking.

The code measurement result has the frequency stability as the black solid square real line, and it can be fitted as $2.5\times10^{-11}\tau^{-1}$ for averaging time 1s to 10000s as the red hollow circle dashed line in Figure 3, which shows that the flicker phase modulated noise is dominate.

The carrier phase measurement has the frequency stability as the blue solid triangle real line, and it can be fitted as $6.5\times10^{-11}\tau^{-3/2}$ for averaging time 1s to 1000s and $2\times10^{-15}\tau^{0}$ for averaging time 1000s to 10000s as the magenta hollow triangle dashed line in Figure 3, which implies that the white phase modulated noise and flicker frequency modulated noise are dominate for averaging time 1s to 1000s and 1000s to 10000s respectively.

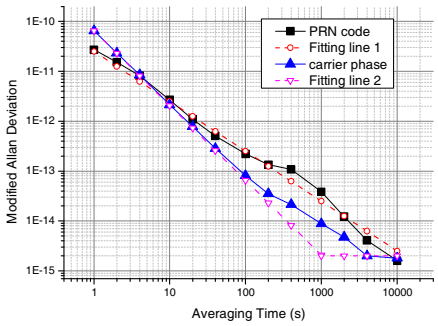

Fig. 3 The measurement noise frequency stability with PRN code and carrier phase characterized as modified Allan Deviation.

IV. Conclusions

A system based on self-made modems and off-the-shelf fiber-optic devices is proposed for time and frequency transfer with PRN code correlation and RF carrier phase tracking. The first result of common clock experiment shows the measurement noise frequency stability is $2.5\times10^{-11}\tau^{-1}$ (1s to 10000s) for code, $6.5\times10^{-11}\tau^{-3/2}$ (1s to 1000s) and $2\times10^{-15}\tau^{0}$ (1000s to 10000s) for carrier phase.

Future work will focus on the carrier-cycle integer ambiguity resolution or the combination of the code and carrier phase results, and the calibration. The noise floor for carrier phase is possibly affected by the carrier phase resolution which is limited by the hardware, which also needs more investigation.

***Abstract*—Constellations autonomous operation capability of the satellite navigation system is one of the primary ways for improving system's survivability. It is unrealistic obviously that the satellites do not update the data to test and verify the constellations autonomous operation capability under the condition of satellite navigation system can support by the ground-monitoring system. The study of measuring and estimating constellations autonomous operation time synchronization's accuracy in condition of the satellite navigation system operate normally is so little. This paper discusses the importance of testing and verification for diffident working mode, it provides one kinds of method of measuring and estimating the time synchronization accuracy under constellations autonomous operation based on the ground testing system. In the paper, it gives the basic principle and the computational model, verifying and analysing the method by simulation data. This method provides technical support for building global satellite navigation system 's inter-satellite link.**

Keywords- Constellations autonomous operation; Measuring and Estimating; Time synchronization; Ground Testing System

I. INTRODUCTION

With the development of satellite navigation systems and navigation warfare concepts proposed, the capability of autonomous survival and operation of the satellite navigation system has become an important part of the research in the field[3]. Making the inter-satellite link to achieve the autonomous function of constellation is one of the primary means to improve the viability of the satellite navigation system[6].

GPS system has been installed the inter-satellite distance measuring equipment and on-processor in BLOCK Ⅱ R and follow-on satellite, these satellites could measure the inter-satellite distance and communicate with each other by TDMA, and autonomous computing the satellite orbits and satellite clock hourly to achieve the autonomous orbit determination and autonomous timekeeping. The indicators of GPS system on autonomous navigation is that the GPS system could make the user ranging error (URE) less than 6m on the situation of that the satellite ephemeris and satellite clock parameters couldn't be modify by the information from the injection stations on the ground[2].

The index proposed by the GPS system is derived after the processing of inter-satellite measurement data[5], which means that this index is only an estimate indicators, while the main purpose of the autonomous operation of the satellite navigation system is to improve the viability to face the extreme situation that the injection stations on the ground were destroyed in the war or other special period. It's clearly unrealistic that in order to verify the autonomous operation capability of constellation, we don't inject the revelation information to the satellite for a long time even if we have the ground-base monitoring system when we design and construct the satellite navigation. How to testing and evaluating the autonomous operation capability of navigation constellation without any affection on normal conditions is an important issue should be considered before we design and construct the satellite navigation system.

In this paper, to the above problem, a testing and evaluation method of constellation autonomous run time synchronization accuracy was put forward which based on the ground test validation system, including the basic principles and the calculation model, and the analysis is verified by simulation data, providing technical support to our construction and evaluation of global navigation satellite system inter-satellite link.

II. THE ANALYSIS OF THE MODE OF AUTONOMOUS RUNNING OF NAVIGATION CONSTELLATION

The mode of autonomous running of navigation constellation is that: without the support of ground, navigation constellation determinate orbit precisely and keep time with satellite orbit prior information by inter-satellite two-way ranging and data changing. There are two kinds of working mode[3], one is the distributed processing mode: each satellite observes all the satellites in the visible range and exchange observation data according to the sampling interval which is set by the each satellite. Each satellite determines the clock error by the latest observation data and update the navigation

message. The advantage of running mode: each satellite is relatively independent, does not affect the other satellites if someone is wrong, the disadvantage is no uniform star time reference, the absolute deviation becomes larger and hard to remove with the time pass by. Moreover, the uncertainty of ISLs link, not all the satellite can compare data with other satellites, so the deviation is larger between some satellite and other satellites.

Another is the centralized processing mode: selected one satellite as the main star, other satellites send the observation data to the main star, finishing the timekeeping calculation uniformly by the main star. The advantage of this method can easily get uniformly time benchmark, but put much dependence on the main star, selection and backup of the main star is difficulty, some satellite can not complete the comparison because of the uncertainty of the ISLs link, so it can decrease the availability of satellite.

Regardless of which processing mode, there exists the uncertainty of autonomous running of constellation of the inter-satellite links, so it is important which based on the evaluation of ground testing and without relying on the atomic on-board clocks.

III. THE METHOD OF MEASURING AND ESTIMATING THE TIME SYNCHRONIZATION ACCURACY

Constellations autonomous operate mainly based on the inter-satellite links to achieve the comparing of the satellites, and broadcast the clock error forecast. The satellite atomic clock is the main participant when the constellations autonomous operating. So, it needs a kind of technique which is not dependent on satellite clock to test and estimate the time synchronization accuracy. And the ground testing system is a system based on such a technology.

3.1 The working principle of the method of measuring and estimating the time synchronization accuracy

The ground testing system is based on a satellite transponder transmit the signal. It generates high-precision atomic clock signal on the station, and modulates to pseudo-code signal, and transmits to the all satellites on the visible range by the same carrier frequency，and transmit to the diffident satellite ground station by satellite transponder. Each station receives all time signals from diffident ground station, and determines the delay of the signal path. Thereby, it can determine the distance between the ground station to the satellite. Now, the ground testing system mainly used for time synchronization between the satellite high precision orbit determination and long-distance stations and other satellite navigation test assessment. The ranging accuracy is better than 1 cm, and the orbit determination accuracy is better than two meters, and time synchronization accuracy is better than 1 nanosecond[4].

The method of measuring and estimating the time synchronization accuracy under constellations autonomous operation based on the ground testing system is worked under the mode of transmitting and receiving signal itself. It transmits signal to the all satellites on the visible range by the same carrier frequency, and transmits to the same satellite ground station by satellite transponder, and trigger satellite local time to broadcast signal by the special carrier frequency (to make a difference from the transponder signal). The ground station receive broadcast signal and transponder signal. It can determine the deviation between the satellite time and ground standard time by comparing the deviation between the receive broadcast signal and transponder signal. Thereby, it can measure and estimate the time synchronization accuracy under constellations autonomous operation. The figure of working principle is shown in figure 1.

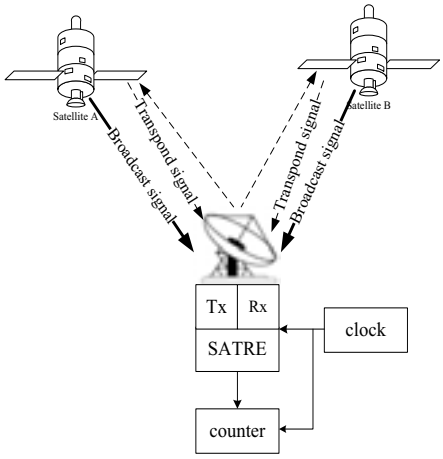

Figure 1. The figure of working principle

The ground testing system based on the satellite transponder transmit signal generate the time signal by the ground atomic clock in each satellite station. The signal of transmitting and receiving and calibrating are operated on the ground. So, it can avoid the satellite atomic clock deviation because of constellations autonomous operation, and can estimate the time synchronization accuracy under constellations autonomous operation by comparing the time deviation.

3.2 The fundamental observation equation

Assumed that the ground testing system has two ground stations, they are i and j. If the signal transmitted from i station is received successfully by the j station receiver, the time relationship formula of the signal is[4]:

$$R_{ji} = R_i^t + O_{iu} + T_i + \tau_s + R_{ji}^r + O_{jd} + I_{ji} - \Delta T_{1i} + \Delta T_{1j} \quad (1)$$

R_{ji} is j station receiver receives the i-station transmission signals delay.

R_i^t is signal delay from the i station antenna phase center (the signal transmission time) transmitted to the satellite antenna phase center (satellite receiver to signal time) .

R_{ji}^r is signal delay from the satellite antenna phase center (satellite transponder signal time) to j station antenna phase center(received i station signal time).

O_{iu} is i station signal on row ionospheric delay correction.

O_{jd} is j station signal downstream ionospheric delay correction.

T_i is i station transmitter instrument delay.

I_{ji} is j station receives the i station signal receiver instrument delay.

ΔT_{1i} is the clock offset between i station master clock relative and the ground time standard.

ΔT_{1j} is the clock offset between j station master clock relative and the ground time standard.

τ_s is the satellite transponder delay.

Assumed that the above formula has corrected the delay caused by the ionosphere, and corrected the instrumental errors. And it has taken off the effect of the earth autobiography. After the above corrections, the formula (1) can become to:

$$R_{ji} = R_i^t + \tau_s + R_{ji}^r - \Delta T_{1i} + \Delta T_{1j} \qquad (2)$$

Assumed that all the stations emit the time signal and all the stations can receive the signal transmitted from all stations. Therefore, each station can obtain N independent observation value, and the N stations have N×N observation value. If considering a pair of observation: Let i station receives j station transmitted signal, and the j station receives the i station transmitted signal. According to the equation (2), the two observation equation added to :

$$R_i^t + \tau_s + R_{ji}^r = \frac{1}{2}(R_{ji} + R_{ij}) \qquad (3)$$

The formula (3) is the pseudo distance observation equation of the i station and j station. And it is suit for any i and j (i can be equal to j).

When i is equal to j, it mean that $R_i^t = R_{ji}^r$, $R_{ji} = R_{ij}$ and it mean that each station receives only own station transmitted signal, that is the mode of transmitting and receiving signal itself. It is not difficult to obtain:

$$R_{ji}^r + \frac{1}{2}\tau_s = \frac{1}{2} R_{ii} \qquad (4)$$

The formula (4) is the pseudo distance calculation equation of ground testing system based on the transponder signal.

When satellite transponder transmit the signal from the ground station, it can design a method to trigger a signal to make satellite broadcasting the special carrier signal based on the satellite atomic clock. The time relationship formula is :

$$R_j = R^j + \tau_s^i \qquad (5)$$

It should be noted that formula (5) has been to correct the delay caused by the ionosphere and the correct instrument error, and it has taken off the effect of the earth autobiography.

R_j is j station receives the i station transmitting the signal to trigger the delay of the signal broadcast by the satellite transponder;

R^j is the delay that the Satellite broadcast signal from the satellite antenna phase center (satellite transponder i-station signal moment) to j station antenna phase center (j station receive the signal moment). It can be known that $R^j = R_{ji}^r$.

τ_s^i is the delay of i station signal to the satellite transponder to the time of the satellite broadcast signal. Let $\tau_s^i = \frac{1}{2}\tau_s$,

That formula (5) can became to :

$$R_j = R_{ji}^r + \frac{1}{2}\tau_s \qquad (6)$$

Comparing the formula (4) and (6), it can know that:

$$R_j = \frac{1}{2} R_{ii} \qquad (7)$$

In other words, the delay of the satellite broadcast signal to the receiver on the ground is equal to one half of transmitting time to receiving time under the mode of transmitting and receiving signal itself based on the ground testing system. Therefore, as long as the accurate measurement of the delay of the transmitter system to receiver system, it can calculate the starting time of the satellite broadcast signal. To compare the time offset between the satellite and the ground time standard can further analysis and estimate the time synchronization accuracy under constellations autonomous operation.

3.3 Simulation verify

To verify the validity and feasibility of the method, the paper take analysis based on the GPS data from IGS with some random errors.

Firstly, it should obtain the atomic clock data of GPS from IGS that on Taiwan station of December 20, 2010. The satellites should be observed at the same period on Taiwan station. The paper selects four satellites which are PRN4 and PRN10 and PRN17 and PRN23. The clock offset data figures are shown in figure 2.

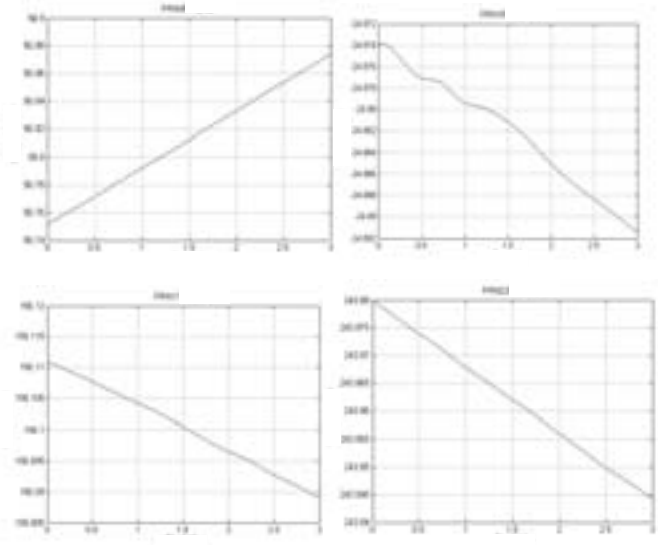

Figure 2. GPS satellite clock offset data

To use the satellite orbit data and the station coordinate, it can obtain the satellite-ground distance of the four satellites on each epoch-wise, and can convert to time offset. Because of the error less than 1 ns in the data transmission of the ground testing system, it should add a random error in simulating the satellite-ground delay. After data processing，the clock offset figure is shown in figure 3.

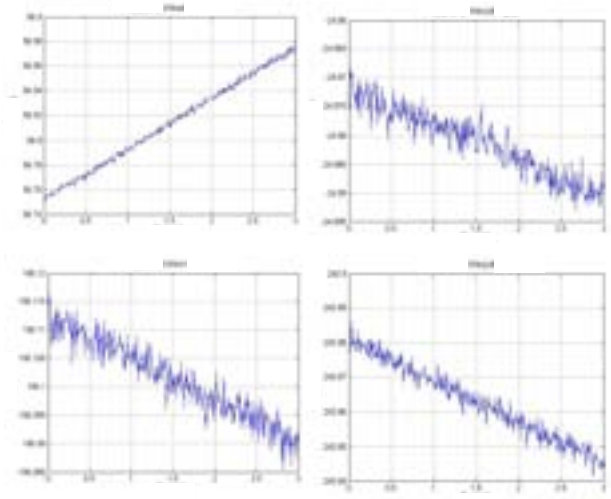

Figure 3. The clock offset after data processing

Let the above satellite data subtract the GPS system time standard data, it can obtain the figure shown in figure 4.

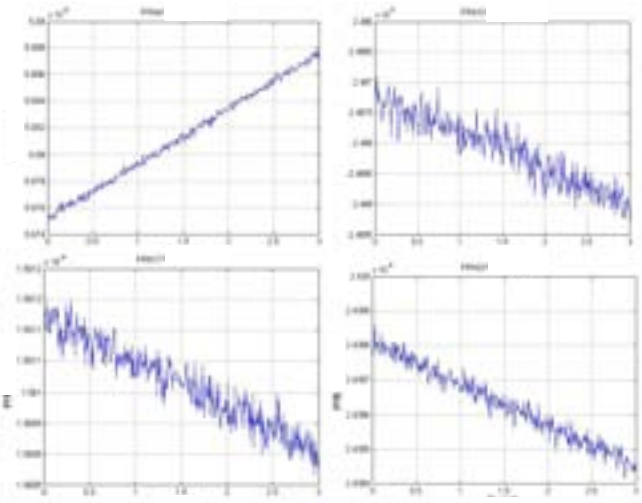

Figure 4. The data figure after subtracting the GPS time standard

The result shows that the data of PRN4 after processed have an offset of 3.57 ns (standard deviation), PRN10 is 5.53 ns, PRN17 is 6.64 ns, PRN23 is 10.5 ns. That can declare the time synchronization accuracy is less than 10 ns among the four satellite atomic clock. And it can verify the validity of the method.

3.4 The analysis of application

Now the correlative indexes of autonomous running mode of constellation of satellite navigation system are simulated or are designed by the measured data of the inter-satellite links. Which building the construction of the satellite navigation system, it is impossible not to inject the ephemeris and clock error in order to evaluate autonomous running ability, so it reduce system application. In order to cope with the extremeness of destroying ground-based monitoring system, it is necessary for evaluating the ability of autonomous running mode of constellation.

It is too high with the cost of doing experiment on the whole satellite navigation system, it is feasible for validating ability of constellation running experiment with 4-5 satellites .Choose 4-5 satellites of the same area as the simple system, cut the links between theirs and other satellites, autonomous orbit determination and time maintaining only by inter- satellite links of star-star. Evaluating it with the method, it provides the reference for answering the extremeness.

IV. CONCLUSION

With the purpose of autonomous running of navigation constellation, this paper analyses the necessity of experimenting and evaluating different working modes, advancing one kind of evaluating method of time synchronization of autonomous constellation which based on the ground-validation system. Giving the working principle , calculation model and simulation result, analysis the application value with the angle of experiment, which given the reference of building of inter-satellite links of navigation system.

Abstract—**Based on the principle of two way satellite time transfer, a time synchronization system with master-slave sturcture is established. In the system, slave sites compare their clock time with the master clock in turn. After one comparison, the slave clock offset is estimated and predicted until the next comparison period. In the paper, three clock offset prediction algorithms are discussed in detail. Their performance is evaluated and validated using measured clock offset data. The results show the linear fitting algorithm has an obvious good performance in ultra-short term prediction than quadratic polynomial method. And it's quite simple than grey system model prediction algorithm. The time synchronization system use the linear fitting algorithm for clock offset prediction in practice and has a good practical effect.**

Keywords-Two-Way Satellite Time Transfer（TWSTT）;Clock Offset Prediction; Grey System Model; Time Synchronization

I. INTRODUCTION

Two-Way Satellite Time Frequency Transfer (TWSTT) is a very high precise time & frequency remote comparison technique, which is widely used in time metrology, satellite navigation and radio measurement, etc. It is more precise than GPS common view method in time transfer, and more independent than GPS carrier phase time transfer method. Nowadays, most of the time metrology laboratories in Europe and America established the TWSTTT links. There is a TWSTT network in east Asia for remote time transfer, which is centered at NICT[1]. By means of the modem, the one pulse per second (1PPS) is modulated onto the station's intermediate frequency (IF), which is usually at 70MHz. The signal is then up-converted to the radio frequency (RF), amplified, and transmitted to the satellite. At the receiving site the RF signal is again amplified, down-converted to the IF, and demodulated by means of the modem. In TWSTT system, spread spectrum signal PN modulation is usually used, and the pseudorange of the two-way signal propagation paths are measured. Because of the reciprocity of two paths, the difference of the two measurements is the clock offset of the two stations [2].

In this paper, a high precise time synchronization system is established using TWSTT technique, which includes a master station and several slave stations. The master clock is compared with the each slave clock for a while circularly by the TWSTT system. The slave station collects and processes the comparison data, and estimates the precise parameters of the slave clock as to the master clock. Then the estimated clock parameters are used to predict the slave-master clock offset in the near future. Clock offset precise prediction with finite clock offset measurements is a very important research aspect in satellite navigation area. Considering the frequency drift of rubidium atomic clock, quadratic polynomial is used to fitting the clock offset measurements, and then to predict the clock offset after the measurement completed [3]. Cui Yongqiang, etc. [4] firstly introduced the grey system model for the satellite clock offset prediction. It's illustrated that the grey system model has better performance than the quadratic polynomial method in long term prediction. Furthermore, Lu Xiaofeng, etc. [5] presents a optimized algorithm for GM(1,1) model, which selects the grey model parameters with minimum errors by iteration method and improves the clock offset prediction performance. Zhu Xiangwei, etc. [6] presents a Kalman algorithm for satellite clock offset prediction based on GPS space based rubidium clock measurements, which improves the short term prediction performance. Zhang Qinghua, etc. [7], based on the quadratic polynomial and grey system model algorithm, furtherly put forward wavelet and ARMA methods to predict the random components. The new algorithm is quite complex and more precise. In satellite navigation field, clock offset is usually predicted on the scales of several hours to several days. However, in this paper, the clock offset algorithms are discussed on the scales of tens of minutes according to the practical requirements of the designed time synchronization system. We call them ultra-short term prediction algorithms. Several prediction algorithms are discussed and validated in practice in this paper. One of them is used in the practical synchronization system and behaves good performance.

II. TWSTT BASED TIME SYNCHRONIZATION SYSTEM

In TWSTT system, the local 1PPS signal is modulated and transmitted by the Modem & the satellite earth station facilities, and also the transmitted signal from the remote station is received and demodulated by the earth station facilities & Modem. Fig. 1 illustrates the principle of the TWSTT system. The 1PPS signal from the atomic clock in station A is splitted into two paths. One of them is to the spread

spectrum Modem A, which is transmitted to the satellite by VSAT earth station A. The other path is used as the start of a local time interval counter A. It just has the same setup in station B as station A. When the transmitted signal from B is received and demodulated, a 1PPS signal is reconstructed, which stops the time interval counter A. The readings of time interval counter at station A and B are denoted as ΔT_A and ΔT_B , and if the bidirectional propagation delay differences are ignored, then the clock offset between station A and B is given by(1),

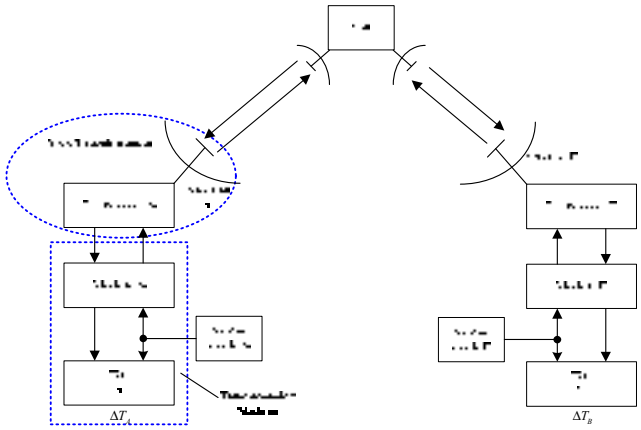

Fig. 1 Basic setup of two way satellite time frequency transfer system

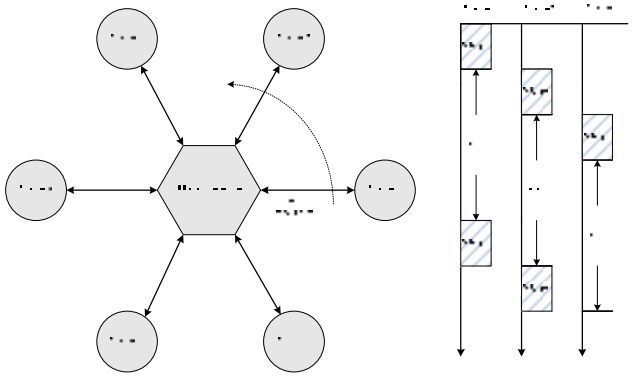
$$\Delta T_{AB} = \frac{1}{2}\left(\Delta T_A - \Delta T_B\right) \qquad (1)$$

Where, ΔT_{AB} is clock offset between station A and B, ΔT_A , ΔT_B are the readings of time interval counter at station A and B, respectively.

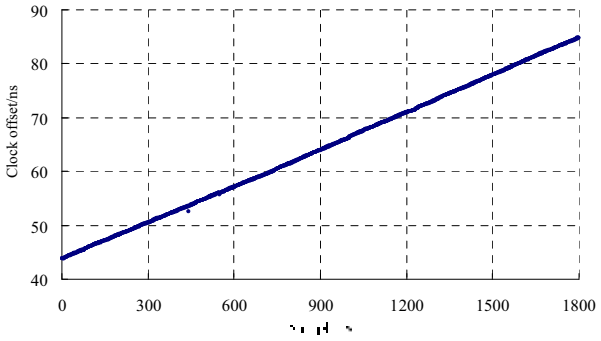
The two way satellite time synchronization system is based on the above time transfer scheme, in which the master clock compares with the slaves in turn, as shown in Fig. 2(a). When a slave clock is comparing with the master clock, their offset is measured directly. When it is not in comparison with the master, the previous the comparison data is used to estimate the current clock offset. So the slave clock offset is gotten uninterrupted, which is informed to the user for offset compensation or synchronization, as shown in Fig. 2(b). This kinds of time division time comparsion mode reduces the master complexity and the system cost. In order to guarantee the time scale stability in the system, a hydrogen atomic clock is used as the master frequency reference. Furtherly, in order to ensure the appropriate clock offset prediction accuracy, a rubidium atomic clock is used as the slave frequency reference. Fig. 2(c) shows a segment of two-way time transfer data between the master station and a slave station, which indicates that there exists some initial clock offset and a very obvious linear drift between the two clocks.

III. ULTRA-SHORT TERM CLOCK OFFSET PREDICTING METHOD

In contrast to the clock offset predicting method in traditional satellite navigation application, this paper dicussed the predicting algorithm with shorter time and less observation data, which typically is about 10min observation data and 30min prediction length.



(a) time comparison process of the system (b) time synchronization flow



(c) TWSTT measurements between the master and a slaver

Fig. 2 Time synchronization system based on TWSTT method

A. *Quadratic Polynomial Clock Offset Predicting*

Considering the rubidium atomic clock frequency characteristics, it's time offset can be described by quadratic polynomial as (2),

$$\Delta T_k = a_0 + a_1 t_k + a_2 t_k^2 + e_k, k = 1,2,\mathrm{L}\ ,N \qquad (2)$$

Where, ΔT_k is clock offset measurements between a slave and the master, a_0, a_1, a_2 为 re initial offset, fractional clock speed and fractional clock drift, e_k is the total term of measurement noise and the random phase of atomic clock. Using those measuremets and the least square method, the fractional parameters of the slave clock can be estimated as (3),

$$\hat{\mathbf{a}} = \left(\mathbf{A}^{\mathrm{T}}\mathbf{A}\right)^{-1}\mathbf{A}^{\mathrm{T}}\mathbf{X} \qquad (3)$$

Where, $\hat{\mathbf{a}} = \begin{bmatrix} a_0 \\ a_1 \\ a_2 \end{bmatrix}$, $\mathbf{A} = \begin{bmatrix} 1 & t_1 & t_1^2 \\ 1 & t_2 & t_2^2 \\ \mathrm{L} & \mathrm{L} & \mathrm{L} \\ 1 & t_N & t_N^2 \end{bmatrix}$, $\mathbf{X} = \begin{bmatrix} \Delta T_1 \\ \Delta T_2 \\ \mathrm{M} \\ \Delta T_N \end{bmatrix}$.

Those estimated a_0, a_1, a_2 can be used to predict the clock offset for the next time segment.

B. Grey System Model Predicting[5]

GM (1,1) model is most commonly used in grey system theory. It's a differential equations model containing only a single variable, which essentially use an exponential function to fitting the clock offset cumulative time series, and uses the fitting parameters to do offset predicting. If the original data sequence of the clock offset is as (4)

$$\mathbf{X}^{(0)} = \left\{x^{(0)}(1), x^{(0)}(2), \mathrm{L}\ , x^{(0)}(k)\right\}, k = 1,2,\mathrm{L}\ , N \tag{4}$$

Do first order accumulating on data sequence $x^{(0)}(k)$, then we get (5)

$$\mathbf{X}^{(1)} = \left\{x^{(1)}(1), x^{(1)}(2), \mathrm{L}\ , x^{(1)}(k)\right\}, k = 1,2,\mathrm{L}\ , N \tag{5}$$

Where, $x^{(1)}(k) = \sum_{i=1}^{k} x^{(0)}(i), k = 1,2,\mathrm{L}\ , N$. In terms of the grey system predicting model, the clock offset predicting equation is gotten as (6),

$$x^{(0)}(k) = \left[1 - \exp(a)\right]\left[x^{(0)}(1) - u/a\right]\exp\left[-a(k-1)\right] \tag{6}$$

Where, a, u are model parameters, which satisfy (7),

$$\hat{\mathbf{a}} = \left(\mathbf{G}^{\mathrm{T}}\mathbf{G}\right)^{-1}\mathbf{G}^{\mathrm{T}}\mathbf{Y} \tag{7}$$

Where, $\hat{\mathbf{a}} = \begin{bmatrix} a \\ u \end{bmatrix}$, $\mathbf{G} = \begin{bmatrix} -\frac{1}{2}\left[x^{(1)}(1) + x^{(1)}(2)\right] & 1 \\ -\frac{1}{2}\left[x^{(1)}(2) + x^{(1)}(3)\right] & 1 \\ \mathrm{M} & \mathrm{M} \\ -\frac{1}{2}\left[x^{(1)}(N-1) + x^{(1)}(N)\right] & 1 \end{bmatrix}$,

$\mathbf{Y} = \left[x^{(0)}(2) \quad x^{(0)}(3) \quad \mathrm{L} \quad x^{(0)}(N)\right]^{T}$, $[\mathrm{g}]^{T}$ is matrix transpose.

C. Linear Fitting Predicting

Using the linear function to fit the atomic clock parameters and predicting clock offset gains little attention in satellite navigation area. However, in the short term clock offset predicting application, due to the observation time is short, clock drift may not be accurate estimated in such a short time. Linear clock offset predicting equation ignores the second order term of the clock drift as (8)

$$\Delta T_k = a_0 + a_1 t_k + e_k, k = 1,2,\mathrm{L}\ , N \tag{8}$$

According to the least square method, clock parameters are estimated as (9)

$$\hat{\mathbf{a}} = \left(\mathbf{A}^{\mathrm{T}}\mathbf{A}\right)^{-1}\mathbf{A}^{\mathrm{T}}\mathbf{X} \tag{9}$$

Where, $\hat{\mathbf{a}} = \begin{bmatrix} a_0 \\ a_1 \end{bmatrix}$, $\mathbf{A} = \begin{bmatrix} 1 & t_1 \\ 1 & t_2 \\ \mathrm{M} & \mathrm{M} \\ 1 & t_N \end{bmatrix}$, $\mathbf{X} = \begin{bmatrix} \Delta T_1 \\ \Delta T_2 \\ \mathrm{M} \\ \Delta T_N \end{bmatrix}$.

D. Experiments and Analysis

In order to verify the performance of the above-mentioned clock offset predicting algorithms, four groups TWSTT data are selected randomly, each of them is 40min length. The previous 10min data is used to estimate the fractional clock parameters, and to predicting the next 30min clock offset. The later 30min TWSTT data is used to validate the performance of the algorithms by compare the difference of predicting offset and the TWSTT data. Fig. 3 show the predicting results of quadratic polynomial algorithm, grey system model and linear fitting algorithm. It can be seen that the grey system model and the linear fitting algorithm have very good consistency of predicting trends. In the previous three plots, the quadratic polynomial algorithm presents obvious larger predicting error than the other two algorithms. Only in the fourth plot, the quadratic polynomial algorithm shows quite good performance. But the grey system model and the linear fitting algorithm always present predicting errors in the same order of magnitude and behave very good performance for predicting.

In order to quantitative analyzing the predicting performance of the three algorithms, mean prediction error (Avg.), standard deviation (Std.) and maximum prediction error (Max.) of the 30min differnces between predicting data and the measurement data are used. Tab.1 list the quantitative evaluation of the three algorithms in the four experiments. The prediction error of quadratic polynomial is basically on the magnitude of several nanoseconds, and the maximum prediction error is close to 10ns. Grey system model and linear fitting prediction algorithm have very similiar forecast accuracy, which present very stable performance in the four set of experiments.

Considering the above experimental results, in the actual time synchronization system, linear fitting algorithm has better performance than quadratic polynomial algorithm, and are more concise than the grey system model algorithm.

IV. CONCLUSION

Two way satellite time transfer technique can provide remote high precision time synchronization independent of GPS, which has an important role in radio detection, navigation and other fields and cannot be replaced. Based on the two-way satellite time transfer principle, a master-slave synchronization system is established. The system includes a master station and several slave stations. Through master-slave comparison in sequence and clock offset predicting, uninterrupted time synchronization is realized. This paper expounds the principle of two-way satellite time synchronization system, time synchronization process and scheme. Emphatically, three offset predicting algorithms are discussed in basic principles, and

validated by four sets of experiments using measured data. In conclusion, linear fitting clock offset predicting algorithm has better performance than widely used quadratic polynomial algorithm in ultra-short term prediction, and has lower complex degree than the gray system model algorithm. The linear fitting algorithm is ultimately applies in the actual synchronization system, and has very good practical effect.

***Abstract*—In recent years, Two-Way Satellite Time and Frequency Transfer (TWSTFT) method has been accredited as the most effective and high precision system. But as the frequency stabilities of today's sophisticated atomic-level clocks improve, so must the stability of a Two-Way system's method of time and frequency transfer. Carrier-phase information holds the promise of improving the stabilities of TWSTFT measurements, because of the great precision at which frequency transfers can be achieved. Many years ago, some scientists try to use carrier phase in TWSTFT, in the trial of time and frequency transferring between USNO and NIST station, some excited results proved the theory and showed the promise of carrier-phase measurement. But because of the poor stability of telecommunications GEO satellite local oscillator and some other factors, the result didn't review in other trial station. Then no further research reference was published. Based on TWSTFT system, a method for measuring the satellite oscillator frequency is presented. The radial velocity of the satellite relative to the main control station can be estimated from the relationship between the Doppler frequency shift and the frequency difference between the two stations. Then the satellite oscillator frequency can be calculated after one of the two Doppler frequencies has been measured. According to the results, the influence of transponder local oscillator can be relieved by pre-adjusting the transmitter clock. Two solutions are described to calculate the two stations velocities and satellite local oscillator. By present TWSTFT link, test campaign has been conducted with 10MChip/s PN code signal between Shanghai and Shaanxi.**

Keywords-satellite local oscillator measuring;TWSTFT; doppler frequency

I. SCOPE

Independent of GPS, TWSTFT, as one of the most accurate and precise techniques for remote time and frequency transfer, is the second widely used technique. In order to improve TWSTFT precise further, some researchers have attempted to use carrier phase observation in TWSTFT and have shown some potential [1]. For transponders onboard commercial communication satellites simply convert the input carrier with a non-coherent local oscillator, carrier phase information between transponder input and output is jammed in this process. To ensure the higher precision, the influence of satellites transponder local oscillator (STLO) should be considered. Method to measure the STLO is presented in the paper. A compensation scheme has been developed to solve the two stations velocities and satellite local oscillator.

II. THEORY

A. *Satellite Transponder*

In TWSTFT system, the GEO satellite payload is a bent-pipe signal transponder or a repeater which converts the Ground Station (GS) uplink signal to downlink signal. The bent-pipe signal transponder structure can be seen in figure 1.

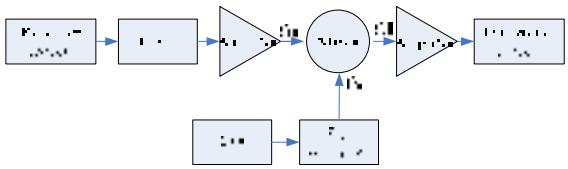

Figure 1. Satellite transponder structure

As shown in the above figure, the STLO frequency is f_{LO} , then:

$$f_s = N \cdot f_{LO} \tag{1}$$

$$f_d = f_u - f_s \tag{2}$$

In which, f_s is the transponder transforming frequency, f_u and f_d is the transponder input and output frequency separately.

B. *Frequency Transfer theory*

By the transponder, traditional TWSTFT ground station receives the signal from each other, then, space factors such as ionosphere, troposphere errors can be canceled. To enhance the system precision and use carrier phase in TWSTFT, we use the new system structure to eliminate or calculate the satellite influence. Two Way Carrier Phase (TWCP) measurement set-up is shown in figure2, in which each ground station receives the signal from the remote site and its own signal via the same

Project is sponsored by a West light Foundation of The Chinese Academy of Science (Grand No: 2012YD04) and the National Natural Sciences Foundation of China (Grand No: 11073022)

transponder. Relative to the traditional TWSTFT, TWCP has one more receiver to receive its own signal. STLO frequency can be measured by the accessorial receiver Rx2.

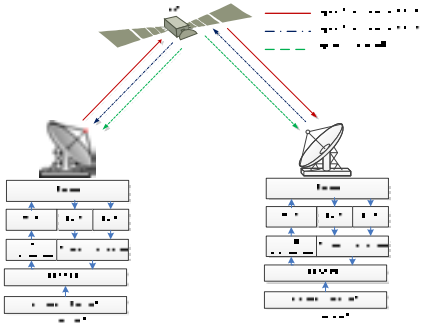

Figure 2. System frames of carrier-phase-based TWSTFT

In TWSTFT, the modem to be synchronized is equipped with a low-phase-noise hydrogen atom clock or with a Rb reference. The built-in clock, which can be controlled using a computer-based control algorithm, is synchronized to the clock on the other site of the Two-Way time link.

To achieve implementation, the one pulse per second (1 pps) is modulated onto the station's intermediate frequency (IF) by the Two-Way modem, which is usually at 70 MHz. Then the signal is up-converted to the radio frequency (RF), amplified, and transmitted to the satellite. In the satellite transponder it is retransmitted by the so-called satellite translation frequency. At the receiving site the RF signal is amplified, down-converted to the IF, and demodulated by modem.

III. MEASUREMENTS AND RESOLUTIONS

A. *Measurement equations*

Shown as Fig.2, station 1 is transmitting a signal to Station 2 and receiving its own signal relayed by a satellite. Then the signal is subject to the Doppler effects resulting from the slight motion of the satellite. The first-order Doppler coefficients are described by the following two equations.

$$k_1 = \frac{V_1}{c}\ ,\ k_2 = \frac{V_2}{c} \tag{3}$$

where V_i is a projection of the velocity vector of the satellite in the direction of Station $i(i=1,2)$ and c is the speed of light. Suppose that Station i transmits a signal with a frequency f_{txi}. At the satellite, the frequency of the received signal is centered at the Doppler-shifted frequency $\mathrm{f_{txi}} + \mathrm{k}_i \mathrm{f_{txi}}$, which is then mixed with the satellite's carrier frequency which is up-converted from the satellite's local oscillator (SLO), denoted as $\mathrm{f_s}$, and retransmitted at the carrier frequency given by the following equation:

$$\mathrm{f}_{SV} = \mathrm{f_{txi}} + \mathrm{k}_i\ \mathrm{f_{txi}} - \mathrm{f_s} \tag{4}$$

The carrier frequency is then observed Doppler-shifted at the downlink station $j(j=1,2)$ as:

$$\mathrm{f_{11}} = (\mathrm{f_{tx1}} + \mathrm{k_1 f_{tx1}} - \mathrm{f_s}) + \mathrm{k_1}(\mathrm{f_{tx1}} + \mathrm{k_1 f_{tx1}} - \mathrm{f_s}) \tag{5}$$

$$\mathrm{f_{21}} = (\mathrm{f_{tx2}} + \mathrm{k_2\ f_{tx2}} - \mathrm{f_s}) + \mathrm{k_1}\ (\mathrm{f_{tx2}} + \mathrm{k_2\ f_{tx2}} - \mathrm{f_s}) \tag{6}$$

$$\mathrm{f_{22}} = (\mathrm{f_{tx2}} + \mathrm{k_2\ f_{tx2}} - \mathrm{f_s}) + \mathrm{k_2}\ (\mathrm{f_{tx2}} + \mathrm{k_2\ f_{tx2}} - \mathrm{f_s}) \tag{7}$$

$$\mathrm{f_{12}} = (\mathrm{f_{tx1}} + \mathrm{k_1\ f_{tx1}} - \mathrm{f_s}) + \mathrm{k_2}\ (\mathrm{f_{tx1}} + \mathrm{k_1\ f_{tx1}} - \mathrm{f_s}) \tag{8}$$

The formulas can be rewritten as:

$$\mathrm{f_{11}} = \mathrm{f_{tx1}} \cdot (1 + 2k_1 + k_1^2) - \mathrm{f_s} \cdot (1 + k_1) \tag{9}$$

$$\mathrm{f_{21}} = \mathrm{f_{tx2}} \cdot (1 + k_2 + k_1 + k_1 k_2) - \mathrm{f_s} \cdot (1 + k_1) \tag{10}$$

$$\mathrm{f_{22}} = \mathrm{f_{tx2}} \cdot (1 + 2\mathrm{k_2} + k_2^2) - \mathrm{f_s} \cdot (1 + \mathrm{k_2}) \tag{11}$$

$$\mathrm{f_{12}} = \mathrm{f_{tx1}} \cdot (1 + k_2 + k_1 + k_1 k_2) - \mathrm{f_s} \cdot (1 + k_2) \tag{12}$$

Where f_{ij} is used to denote a frequency that has been transmitted by Station i and measured by Station j.

B. *Resolution of* f_s

From the formulas above, we can get the f_s related to k_1 or k_2, which is shown as follow:

$$f_s = \frac{f_{tx1}(1+k_1)^2 - f_{11}}{1+k_1} \tag{13}$$

$$f_s = \frac{f_{tx2}(1+k_2)^2 - f_{22}}{1+k_2} \tag{14}$$

$$f_s = \frac{f_{tx2}(1+k_1)(1+k_2) - f_{21}}{1+k_1} \tag{15}$$

$$f_s = \frac{f_{tx2}(1+k_1)(1+k_2) - f_{12}}{1+k_2} \tag{16}$$

C. *Resolution of* k_1 *and* k_2

With the formulas (9)-(12), to solve k_1 and k_2 is an extremely complex task. In order to reduce the resolution process and makes it easy to be implemented, a simplified method is presented. The self-closed-loop back delay of the station can be measured by receive the station itself transmitting signal. The pseudo-orange, denoted as ρ, between the station and satellite is half of the self-closed-loop back delay multiplied by the speed of light.

The Doppler can be converted to a pseudo-range rate observation given by the following:

$$V_i = \dot{\rho} = \frac{c(\Delta t_1 - \Delta t_2)}{2} \tag{17}$$

In which, $\Delta t_i (i = 1, 2)$ is the instantaneous measurement value of self-closed-loop back delay. For most TWSTFT users are national standard laboratories, each link has been installed by owners of highly accurate clock, so the station clock drift is neglected.

According to the formulas (17), k_1 and k_2 can be obtained by combined with formula (3).

D. Resolution of the difference frequency between two stations

With TWSTFT system, the two stations employ a code division multiple access (CDMA) scheme to lock onto each other and establish communication. Usually, the same uplink and downlink frequency is expected. But in fact, there is Clock offset between the two stations by a value df for the different local oscillator is used in the two stations, which can be expressed as:

$$f_{tx2} = f_{tx1} + df \tag{18}$$

By the formula (9) and (10) or (11) and (12), we can get the offset when adopted k_1 and k_2 calculated above.

$$df = \frac{f_{tx1}(1+k_1)^2 - f_{tx1}(1+k_1)(1+k_2) + f_{21} - f_{11}}{(1+k_1)(1+k_2)} \tag{19}$$

IV. TEST AND RESULTS

Measurements have been carried out at Shanghai and Shaanxi to verify function and performance. 10MChip/s PN-modulated signals on C-band have been used.

A. Observations

During the test campaign, the transponder was available continuously and transmissions were interrupted 10 to 15 minutes per hour only when the equipment is calibrated. In figures, station 1 is in Shaanxi, station 2 is in Shanghai. Here, what we concerned is the measurements of $f_{11}, f_{12}, f_{22}, f_{21}$ and ρ, which are shown in Fig.3 to Fig.6 respectively.

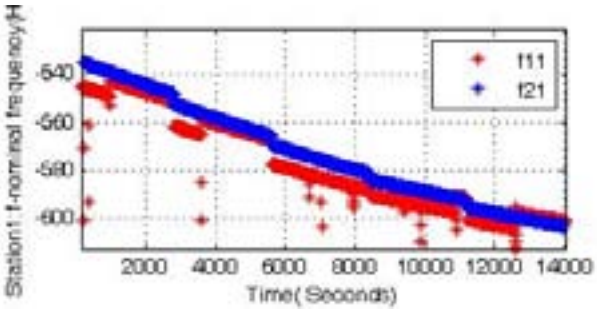

Figure 3. Frequencies received by station 1

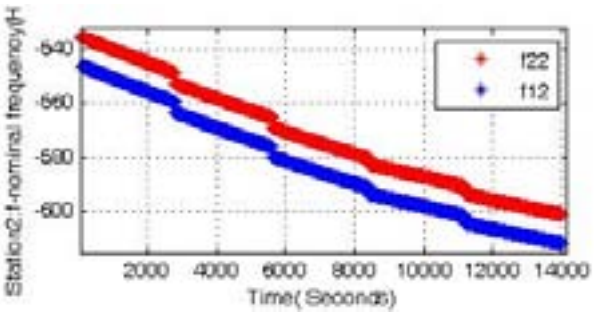

Figure 4. Frequencies received by station 2

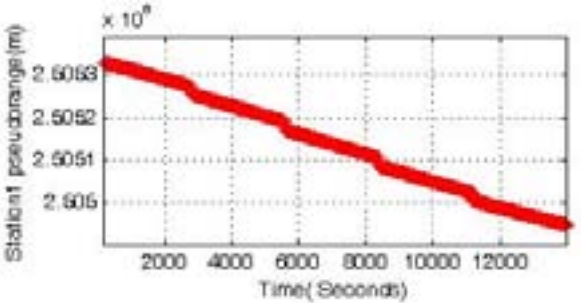

Figure 5. Pseudorange of station 1

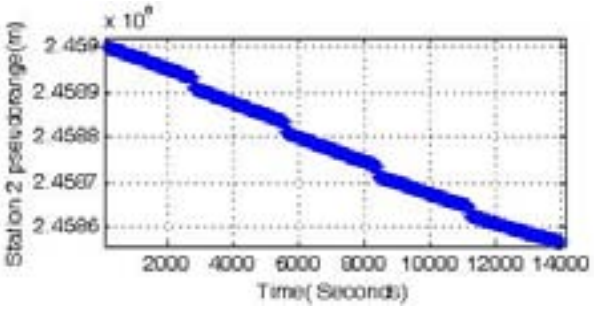

Figure 6. Pseudorange of station 2

From the figures above, we can see that the data is interrupted by the station calibration work and there are 5 hours data in the figures seen from the broken ends. About 4700 km distance difference between the station 2 and station 1 to satellite shows in the figure 5 and figure 6..

B. Resolutions

Adopting the instantaneous sample data of $f_{11}, f_{12}, f_{22}, f_{21}$ and ρ, we can draw the figures of V_i, f_s, the mean value of f_s and other calculation parameters calculated by the accordingly formulas above, which are shown in Fig.7 to Fig.10 respectively.

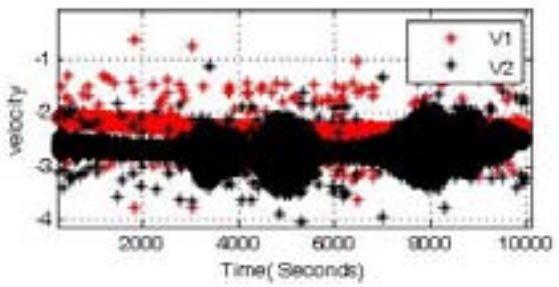

Figure 7. V_1 and V_2 calculation value

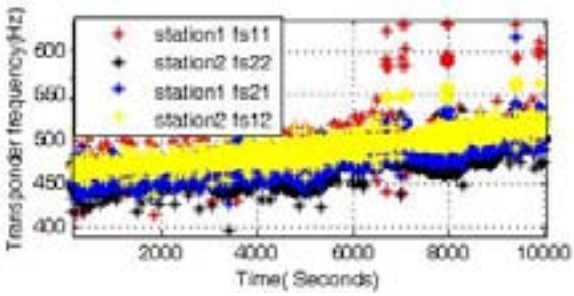

Figure 8. f_s values of formula (13) to(16)

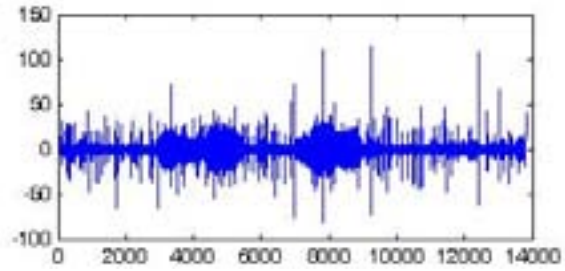

Figure 9. Stability of f_s

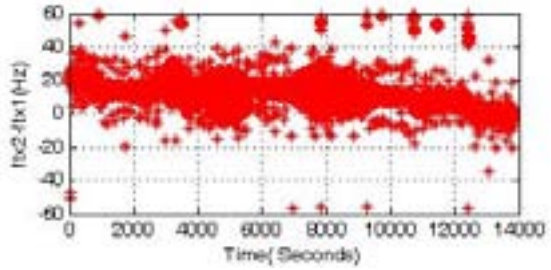

Figure 10. The frequency difference between station 1 and station 2

As the Fig.7 shows, V_1 and V_2 is surrounding 3m/s. as is consistent with the result of precise orbit method. From the figure we can see that circumstance around the station 2 is vitiated but which of station 1 is clean.

f_s values of formula (13) to(16) is shown in figure 8 which display the consistency of the results and the frequency offset 450Hz more than the nominal frequency and the offset in an upward tendency, as means the positive aging rate of the STLO. Many users calculate the Doppler by differentiating the received frequency and native nominal frequency, at this time, the STLO offset is subjected to the Doppler value, as will lead a mistake in the velocity. When knowing the STLO offset, we can pre-adjust the accordingly frequency by transmitter modem.

The figure 9 shows the stability of f_s and the figure 10 shows the frequency offset of about 20Hz between the two stations.

V. CONCLUSION

The paper suggests a simplified method of solving the satellite local oscillator and the velocity vector of the satellite in the direction of Station. The results can be used at all circumstance where there is a bent pipe transponder, such as TWSTFT, WAAS (Wide Area Augmentation System), CAPS (China Area Positioning System), and the self-closed loop link is needed. Our bench tests and live experiments have verified the coherence of the results and the experience values. For easy to calculate, the clock drift of the station, frequency offset subject to gravity and other propagation path frequency perturbations are neglected. All these would have some affects to the results which should be well understood and studied next.

ACKNOWLEDGMENT

The authors would like to thank Mr. Xiaohui Li and ZhiGang Li for their ongoing assistance with this project, and Hui Lei for his contribution to the article.

***Abstract*—TWSTFT is one of the most precise technique of time and frequency transfer. We research on the calibration technique of NIM TWSTFT Link by GPS time transfer system which have been calibrated. We did time and frequency transfer experiment between PTB and NIM use both TWSTFT and GPS time transfer system, process the experiment data of both system and get the time difference of them. The calibration result shown that the time difference of TWSTFT and GPS is about 1648ns, the calibration uncertainty is 5ns.**

I. INTRODUCTION

Two-way satellite time and frequency transfer (TWSTFT) is one of the most precise technique of time and frequency transfer[1,2], it has been developed into a widely used technique of time and frequency transfer between laboratories that contribute, with their atomic clocks and, in some cases, with their primary frequency standards, to the realization of International Atomic Time[3]. At present, TWSTFT is performed operationally in at least two laboratories in the United States, twelve in Europe, and seven in the Asia Pacific region[4,5]. The cooperation is organized by the CCTF Working Group on TWSTFT.

The NIM01 TWSTFT earth station was established in year 2008. National Institute of Metrology (NIM) and Physikalisch-Technische Bundesanstalt (PTB) have signed the cooperation agreement of TWSTFT in year 2009. After May of year 2009, NIM participated the Europe-Asia TWSTFT link which is organized by National Institute of Information and Communications Technology(NICT), the geostationary satellite is IS-4, and the participant laboratory include PTB, NICT, NMIJ, KRISS, NIM, NTSC, TL, OP. But the IS-4 satellite has equipment failure which is irreparable in 2010 February[6,7]. In order to continue the Europe-Asia TWSTFT link, the satellite was changed to AM2 which belongs to RUSSIA Intersputnik. After the communication experiment in 2010 August, NIM restarts the TWSTFT work. At present, the participant laboratories of Europe-Asia TWSTFT link include PTB, TL, NICT, NIM, NTSC, SU and NPLI. The results of laboratories should be processed to a specified format which follows the agreement of ITU-R SG4 [8,9,10], and be reported to BIPM.

In this paper, We research on the calibration technique of NIM TWSTFT Link by GPS time transfer system which have been calibrated. We did time and frequency transfer experiment between PTB and NIM use both TWSTFT and GPS time transfer system, process the experiment data of both system and get the time difference of them. The calibration result shown that the time difference of TWSTFT and GPS is about 1648ns, the calibration uncertainty is 5ns.

II. THE OPERATION OF NIM TWSTFT SYSTEM

TWSTFT is based on the exchange of timing signals through geostationary telecommunication satellites. It involves the transmission and reception of radio frequency (RF) signals carrying binary phase-shift keying (BPSK) modulations containing pseudorandom noise (PRN) codes. Modems generate the modulation at the intermediate frequency (IF) level which are then transmitted after up-conversion to the RF band (Ku-band or X-band are currently used). The received RF-signal is down-converted and the modem detects the modulation at the IF level. The phase modulation is synchronized with the local clock, and the modem generates a one-pulse-per-second (1PPS) output, synchronous with the BPSK sequence and named 1PPSTX. This signal represents the realization of a time scale. Each station uses a dedicated PRN code for the BPSK sequence in its transmitted signal. The receiving equipment generates the BPSK sequence of the remote station and reconstitutes a 1PPS tick from the received signal, named 1PPSRX. The difference between PPSTX and PPSRX (in general plus a constant) is measured by a time-interval counter (TIC). Following a pre-arranged schedule, a pair of stations lock on the code of the corresponding remote station for a specified period, called a session, measure the signal's time of arrival, and store the results. After exchanging the data records the difference between the two clocks can be computed.

The difference of the time scale between the laboratories is determined as follows:

$$
\begin{aligned}
TS(1)-TS(2) = &+0.5[TI(1)] \\
&-0.5[TI(2)] \\
&+0.5[SPT(1)-SPT(2)] \\
&-0.5[SCD(1)-SCU(1)] \\
&+0.5[SCD(2)-SCU(2)] \\
&+0.5[SPU(1)-SPD(1)] \\
&-0.5[SPU(2)-SPD(2)] \\
&+0.5[TX(1)-RX(1)] \\
&-0.5[TX(2)-RX(2)]
\end{aligned} \tag{1}
$$

Where,

TS(i) is Local time scale

TI(i) is Time interval reading

SPT(i) is Satellite path delay through the transponder

SCD(i) is Sagnac delay for a signal propagating from the GEO satellite to station i

SCU(i) is Sagnac delay for a signal propagating from station i to the GEO satellite

SPD(i) is Signal path downlink delay

SPU(i) is Signal path uplink delay

TX(i) is Signal delay in the transmit path of the TWSTFT station i

RX(i) is Signal delay in the receive path of TWSTFT station i

NIM earth station uses the SATRE modem which is made by Timetech Company; it has 1 transmission channel and 2 receiver channel. The diameter of antenna is 1.8 meter. The power of signal transceiver is 8W.

Figure 1. the TWSTFT earth station of NIM

There are many parameters that influence the stability of two-way time transfer system must be considered, such as transmission frequency, power level, carrier-to-noise density, and so on. For Europe-Asia TWSTFT link, NIM earth station need to arrange the transmission power close to PTB station, so that we can get a better RMS for data. The BPSK code rate of Europe-Asia TWSTFT link is 2.5Mch/s, the carrier-to-noise density reach to 55dBHz, 1pps jitter is lower than 500ps. Figure 1 shows the TWSTFT earth station of NIM.

At present, according to the pre-determined schedule, the laboratories of Europe-Asia TWSTFT link communicate once per-hour, and work 12 hours everyday. When the communicate work finish, we will process the raw data, recorded by modem, to a quadratic fit results and report to BIPM. The purpose of this format is to reduce the amount of data to be exchanged and to be able to report in one data file session results of one laboratory involving different partner stations and different satellite links. Data from more than one day may be reported in a single file. Such files allow clock differences to be calculated in an easy way.

Figure 2. the GPS antenna of NIM

There are several GPS time and frequency transfer receiver in NIM, such as septentrio, EURO160, NovAtel and so on. We also have an self-devoloped GPS time and frequency transfer receiver which has been proved to have a good performance. The TWSTFT and GPS time and frequency transfer receiver both contribute to the UTC calculate and submit compative data to BIPM everyday.

Figure 2 shows the GPS antenna array of NIM.

Figure 3. the TWSTFT and GPS control system of NIM

Figure 3 shows the TWSTFT and GPS control system in NIM laboratory.

III. THE COMPARATIVE RESULT OF NIM TWSTFT SYSTEM

The time reference of the NIM earth station is UTC(NIM). According to the schedule, the Europe-Asia TWSTFT link works from 10:30 to 22:59(UTC time) everyday. At first, from 10:30 to 10:40, the clean carrier will be transmitted, and after that, the time modulation signal will be transmitted. Every laboratory will communicate with each other once per-hour, the length of the period is 5 minute.

Figure4 shows the time difference(by TWSTFT) and frequency stability of NIM and PTB, NIM and TL, NIM and NICT, respectively. The experiment date is from MJD55930 to MJD56200. It is shown that Europe-Asia TWSTFT link is stable.

Figure5 is TWSTFT and GPS time transfer experimental result of PTB and NIM, include GPS PPP and TWSTFT techniques. It is shown that the two time transfer techniques results are consistent.

IV. THE CALIBRATION RESULT OF TWSTFT

As we introduced before, the time and frequency transfer GPS receiver and transfer link was calibrated. We did time and frequency transfer experiment between PTB and NIM use both TWSTFT and GPS time transfer system, process the experiment data and get the time difference of them, so the TWSTFT Link is calibrated by GPS at NIM. The time difference between PTB and NIM was shown in Fig 6. The calibration result is shown in Fig 7, the experiment period is from MJD56143 to MJD56166. It is shown that the time difference of TWSTFT and GPS is about 1648ns, the calibration uncertainty is 5ns.

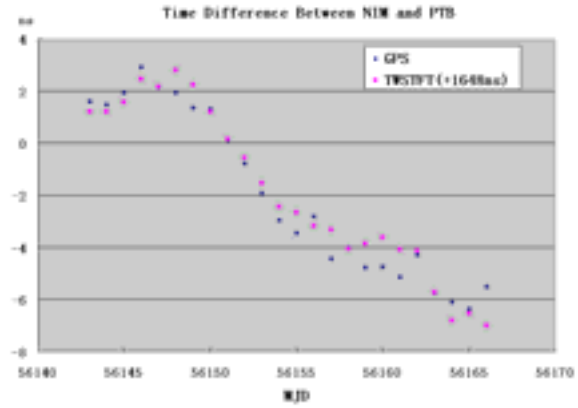

Figure 6. The time difference between PTB and NIM

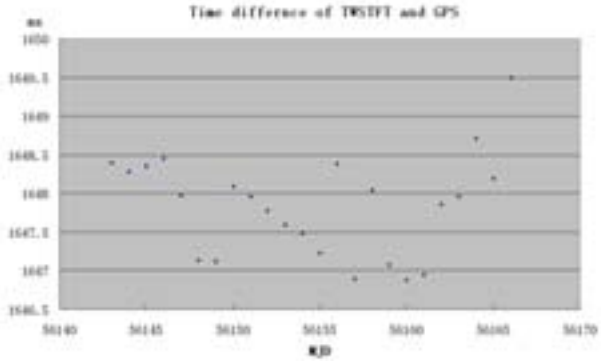

[11]

Figure 7. The calibration result of TWSTFT by GPS, the experiment period is from MJD56143 to MJD56166

V. CONCLUSIONS

The NIM01 TWSTFT earth station was established in year 2008, and participate the Europe-Asia TWSTFT link. But the TWSTFT system of NIM was not be calibrated, We research on the calibration technique of NIM TWSTFT Link by GPS time transfer system which have been calibrated. We did time and frequency transfer experiment between PTB and NIM use both TWSTFT and GPS time transfer system, process the experiment data and get the time difference of them. The calibration result shown that the time difference of TWSTFT and GPS is about 1648ns, the calibration uncertainty is 5ns.

Abstract—**As one of the high accuracy time comparison methods, Two-way Satellite Time and Frequency Transfer (TWSTFT) is one of the important methods for Bureau International des Poids et Mesures (BIPM) to organize international comparison, calculation of the International Atomic Time (TAI) and Coordinated Universal Time (UTC). Due to the interference of emitting device of TWSTFT to co-located devices of Very Long Baseline Interferometry (VLBI) or International GNSS Service (IGS) and the limitation of satellite transponder resources, the comparison is not proceed continuously. Ten consecutive days of data from C-band TWSTFT Network of National Time Service Center (NTSC) was used for analyzing the precision of non-continuous TWSTFT. The raw data of non-continuous TWSTFT was dealt with linear interpolation method. Then the result was compared with continuous TWSTFT which was seen as the true value. Finally, the influence of interval to the precision of non-continuous TWSTFT was analyzed. The comparison shows that: when the interval time is less than 2.5 days, the RMS of the difference between non-continuous and continuous TWSTFT is better than 1 ns; when the interval time is 0.5 day, the RMS is better than 0.5 ns.**

Keywords- TWSTFT; accuracy; stability

I. INTRODUCTION

As a kind of high-precision time comparison method, Two-Way Satellite Time and Frequency Transfer (TWSTFT) is the primary technique of time and frequency transfers which is used by Bureau International des Poids et Mesures (BIPM) for international time comparison [1]. Due to the symmetric signal transmission path, important sources of error such as the atmospheric delay effect can be counteract, therefore high accuracy can be obtained.

In this method, the atmospheric delay effect can be naturally eliminated since the transmit path is symmetric, thus increase the overall system accuracy. Currently, TWSTFT may be performed with 0.5 to 0.75 ns in accuracy and 0.2 ns in stability [2].

Since early 1999, TWSTFT has been used for Coordinated Universal Time (UTC) and International Atomic Time (TAI) generations. United States, Europe and Asia have formed TWSTFT networks. National Time Service Center (NTSC) participated in the Asia-Pacific TWSTFT network [3], and establishes TWSTFT links with PTB, VSL, IEN, OP, and other European timing laboratories. Moreover, NTSC formed C-band TWSTFT (TW(C)) network for continuous TWSTFT between five stations in China.

TWSTFT need to rent satellite transponders, but the transponder resource is limited, and the cost is expensive. Recently, co-locational observations with multi-methods become a trend. To construct the Very Long Baseline Interferometry (VLBI) station, International GNSS Service (IGS) station, TWSTFT station co-locationally has many advantages, such as saving the atomic clock resources and management costs. But TWSTFT need to emit signal to satellite, it will interfere the electromagnetic environment of other co-locational devices.

Due to the above reasons, the international TWSTFT is generally not consecutive. Such as the link between NTSC and National Institute of Information and Communications Technology (NICT), the official convention comparison runs 30 min, twice a week. The clock difference is obtained through interpolation [3]. In order to improve the accuracy of TWSTFT, BIPM runs TWSTFT more and more frequently: before 2004, the number of measurements was 3 points per week; since 2004, the number of measured points increased to 4 points per day; since October 2005, it increased to12 points per day in Europe-Asia area; since November 2005, it increased to 24 points per day in Asia-Pacific area [4].

TWSTFT organized by BIPM runs between timing laboratories. However, for Cs clocks or H clocks using in general engineering, the study on the difference between non-continuous and continuous TWSTFT is still on open discussion.

This work was carried out with the support of the National Natural Science Foundation of China (Grant Nos. 11033004 and 11173026).

Cs clocks and H clocks was used as time source for TWSTFT in this paper to determine the reliability of non-continuous TWSTFT in general engineering application. Interpolated results of different intervals non-continuous TWSTFT was compared with continuous TWSTFT.

For above reasons, this paper has analyzed the main error sources of TW(C), and then carried out experiment using data from TW(C) network.

II. MAIN ERROR SOURCES OF TW(C)

Fig. 1 shows the principle of TWSTFT. Station A and Station B are at the same level. The clock signal of Station A is modulated and emitted to the satellite. After receiving the signal transferred by the satellite transponder, B station demodulates the signal, and then compares with the local clock to measure the time difference between Station A and B. The process of Station B is same with Station A [1].

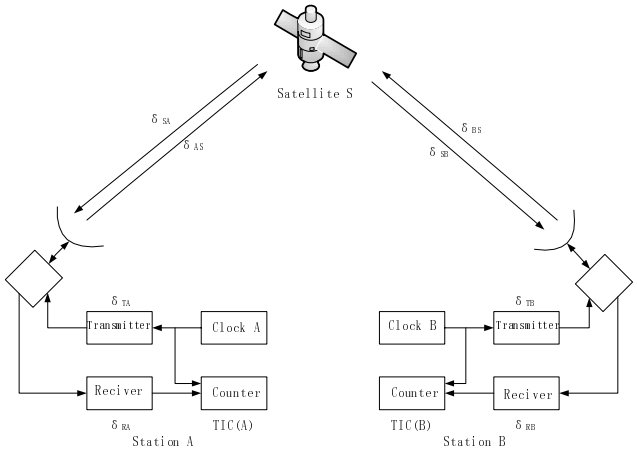

Figure. 1 Principle of TWSTFT.

TWSTFT is calculated as follows [5]:

$$TIC(A)=t_A-t_B+\delta_{TB}+\delta_{BS}+\delta_{SBA}+\delta_{SA}+\delta_{RA}+S_B \quad (1)$$

$$TIC(B)=t_B-t_A+\delta_{TA}+\delta_{AS}+\delta_{SAB}+\delta_{SB}+\delta_{RB}+S_A \quad (2)$$

Where t_A and t_B are time-scales, *TIC(A)* and *TIC(B)* are time interval readings, δ_{TA} and δ_{TB} are transmitter delays (including the modem delays), δ_{RA} and δ_{RB} are receiver delays (including the modem delays), δ_{AS} and δ_{BS} are signal path uplink delays, δ_{SA} and δ_{SB} are signal path downlink delays, δ_{SAB} and δ_{SBA} are satellite path delays through the transponder, S_A and S_B are Sagnac corrections.

Geometric path delay, ionospheric delay, tropospheric delays are included in up and down link delay [6]:

$$\delta_{AS}=(|\boldsymbol{r}_S-\boldsymbol{r}_A|)/c+\delta^{ion}_{AS}+\delta^{tro}_{AS} \quad (3)$$

$$\delta_{SB}=(|\boldsymbol{r}_B-\boldsymbol{r}_S|)/c+\delta^{ion}_{SB}+\delta^{tro}_{SB} \quad (4)$$

$$\delta_{BS}=(|\boldsymbol{r}_S-\boldsymbol{r}_B|)/c+\delta^{ion}_{BS}+\delta^{tro}_{BS} \quad (5)$$

$$\delta_{SA}=(|\boldsymbol{r}_A-\boldsymbol{r}_S|)/c+\delta^{ion}_{SA}+\delta^{tro}_{SA} \quad (6)$$

Where $\boldsymbol{r}_S$, $\boldsymbol{r}_A$ and $\boldsymbol{r}_B$ are the position vectors of satellite and stations, δ^{ion}_{AS}, δ^{ion}_{SB}, δ^{ion}_{BS} and δ^{ion}_{SA} are the ionospheric delays, δ^{tro}_{AS}, δ^{tro}_{SB}, δ^{tro}_{BS} and δ^{tro}_{SA} are the tropospheric delays, c is the speed of light in vacuum.

Herein transmission path is considered as symmetrical. So it can be considered that the geometric path delay and tropospheric delay of SA and AS, SB and BS are the same, satellite path delays through the transponder are also same. There are:

$$(|\boldsymbol{r}_S-\boldsymbol{r}_A|)/c+(|\boldsymbol{r}_B-\boldsymbol{r}_S|)/c=(|\boldsymbol{r}_S-\boldsymbol{r}_B|)/c+(|\boldsymbol{r}_A-\boldsymbol{r}_S|)/c \quad (7)$$

$$\delta_{SAB}=\delta_{SBA} \quad (8)$$

$$\delta^{tro}_{AS}=\delta^{tro}_{SA} \quad (9)$$

$$\delta^{tro}_{BS}=\delta^{tro}_{SB} \quad (10)$$

Herein that Sagnac corrections of uplink and downlink have equal value but opposite sign [7], so there is:

$$S_A=-S_B \quad (11)$$

From (1) to (11), we can obtain:

$$t_{AB}=t_A-t_B=[(TIC(A)-TIC(B))+\delta_{ion}+(\delta_{TA}-\delta_{TB})+(\delta_{RB}-\delta_{RA})]/2+S_A \quad (12)$$

Where t_{AB} is the clock difference between Station A and B which is unknown; *TIC(A)* and *TIC(B)* are time interval readings which can be obtained; δ_{TA}. δ_{TB}, δ_{RA} and δ_{RB} can be measured in advance; ionospheric delays δ_{ion} and Sagnac correction S_A can be calculated.

$$\delta_{ion}=\delta^{ion}_{AS}+\delta^{ion}_{SB}-\delta^{ion}_{BS}-\delta^{ion}_{SA} \quad (13)$$

S_A can be by accurately calculated by (14) [7,8]:

$$\delta_{Sagnac}=(\omega_e/c)R(r+h)cos(LA(e))cos(LA(s))sin(LO(s)-LO(e)) \quad (14)$$

Where ω_e is the Earth's rotation angular velocity, r is the radius of the Earth, R is the radius of the satellite orbit, *LA(e)* is latitude of the station, *LO(e)* is longitude of the station, h is height of the station, *LA(s)* is latitude of the satellite, *LO(s)* is longitude of the satellite.

Commonly, the GEO satellite is assumed to be stationary to the Earth. However, the trace of its nadir is actually changed cyclically, which affects the Sagnac correction calculation. Since the effect of the movement of GEO satellite on Sagnac correction calculation is on the level of 10^{-2} ns [9], it needs not to be considered during a sub-nanosecond time comparison.

Since the uplink and downlink signals of TW(C) differ in carrier frequency, they experience a different ionospheric delay. The total electron content (TEC) maps provided by IGS were used in ionospheric error correction in this paper [10]. TEC maps are at fixed time and geographic grid. The TEC of pierce point at requisite time is calculated by spatial four grids interpolation algorithms and proper two linear interpolation algorithms [11]. Slant TEC (STEC) can be calculated with proper mapping function, and then ionospheric delay Δ_{ion} can be calculated through (15).

$$\Delta_{ion}=(40.3\cdot STEC)/(c\cdot f^2) \quad (15)$$

Where f is carrier frequency. Since the carrier frequency of uplink and downlink are different, ionospheric delay cannot be offset. The ionosphere effect on C-band is about (0~0.5) ns range, it must be considered for time comparison at sub-nanosecond level [12].

III. TEST METHODS AND TEST RESULTS

The data used in this paper is from June 10th to June 19th, 2005. (DOY: 161-170), the reading of the time counter was recorded every second. The GEO satellite used in the experiment was Sinosat-1 telecommunication satellite (110.5°E). The ground stations were NTSC and Shanghai Astronomical Observatory (SHAO). The code rate was 20 MChips. The carrier frequency of uplink was 6.3 GHz, which of downlink was 4.1 GHz. The clock of NTSC was a HP5071A Cs atomic clock, and a SONH H atomic clock was equipped in SHAO.

Fig. 2 and Fig. 3 show the Sagnac correction and the ionospheric delay respectively during experiment.

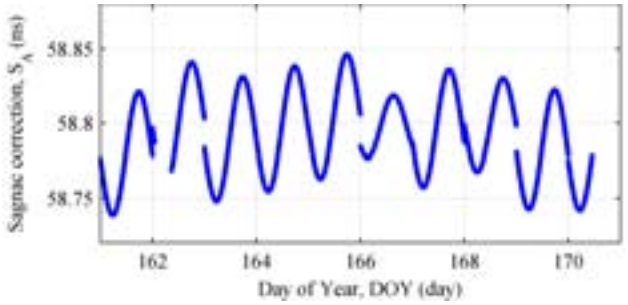

Figure. 2 Sagnac correction of TW(C).

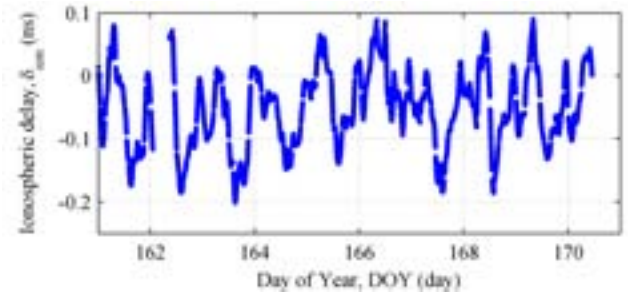

Figure. 3 The affect of ionosphere on TW(C).

The data is collected every other 0.5,1, 1.5, …… 8.5, 9 days. Each observation lasts for 1 hour and sampled 3600 data points. After interpolation processing, non-continuous TWSTFT was compared with continuous TWSTFT to find out the effect of interval on TWSTFT. Fig. 4 shows the result of continuous TWSTFT, Fig. 5 shows residuals δ of linear fit.

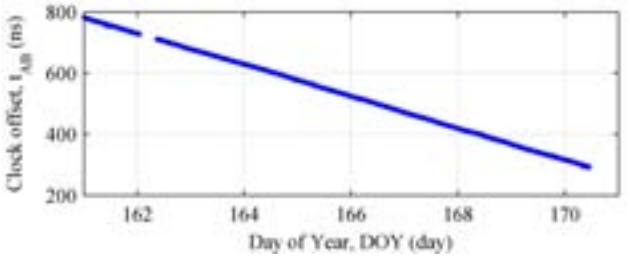

Figure. 4 Clock offset between Station A and B.

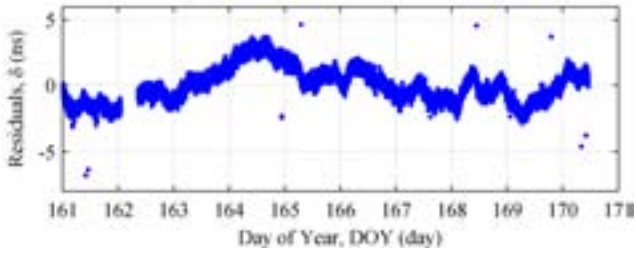

Figure. 5 Linear fit residuals of the clock offset between Station A and B.

In TAI generation, linear interpolation is used for TWSTFT. Jiang [4, 13] compared 9 kinds of smoothing-interpolation techniques by comparing to the GPS PPP as a reference. It concludes that a high-order interpolation method is better for the simple linear interpolation and the Vondrak smoothing interpolation with a filtering power of 10^5 gives the best result in most cases. In this paper, the difference between Vondrak smoothing interpolation with a filtering power of 10^5 recommended in [13] and linear interpolation was less than 0.01ns, and can both achieve the best performance when adopting different observation intervals. The improvement of Vondrak smoothing interpolation was not clear. Therefore, the traditional linear interpolation method was used in this paper. Evaluation of non-continuous TWSTFT with continuous TWSTFT is calculated as (16):

$$t^{diff}_{AB}=t^{nc}_{AB}-t^{c}_{AB} \quad (16)$$

Where t^{nc}_{AB} is the interpolation result of non-continuous TWSTFT, t^{c}_{AB} is the result of continuous TWSTFT, t^{diff}_{AB} is the difference between the 2 kinds of method.

T is the interval (*T=0.5, 1, 1.5, …… 8.5, 9 day(s)*), with every measurement lasting 1 hour (about 3600 sample points). The difference between continuous TWSTFT and non-continuous TWSTFT with different intervals is shown in Fig. 6.

Dark colored points are the measured data of non-continuous TWSTFT without interpolation. t^{diff}_{AB} of this part is 0. With the increase of the observation interval, the extent of t^{diff}_{AB} deviation from the 0 also increases. Table 1 and Fig. 7

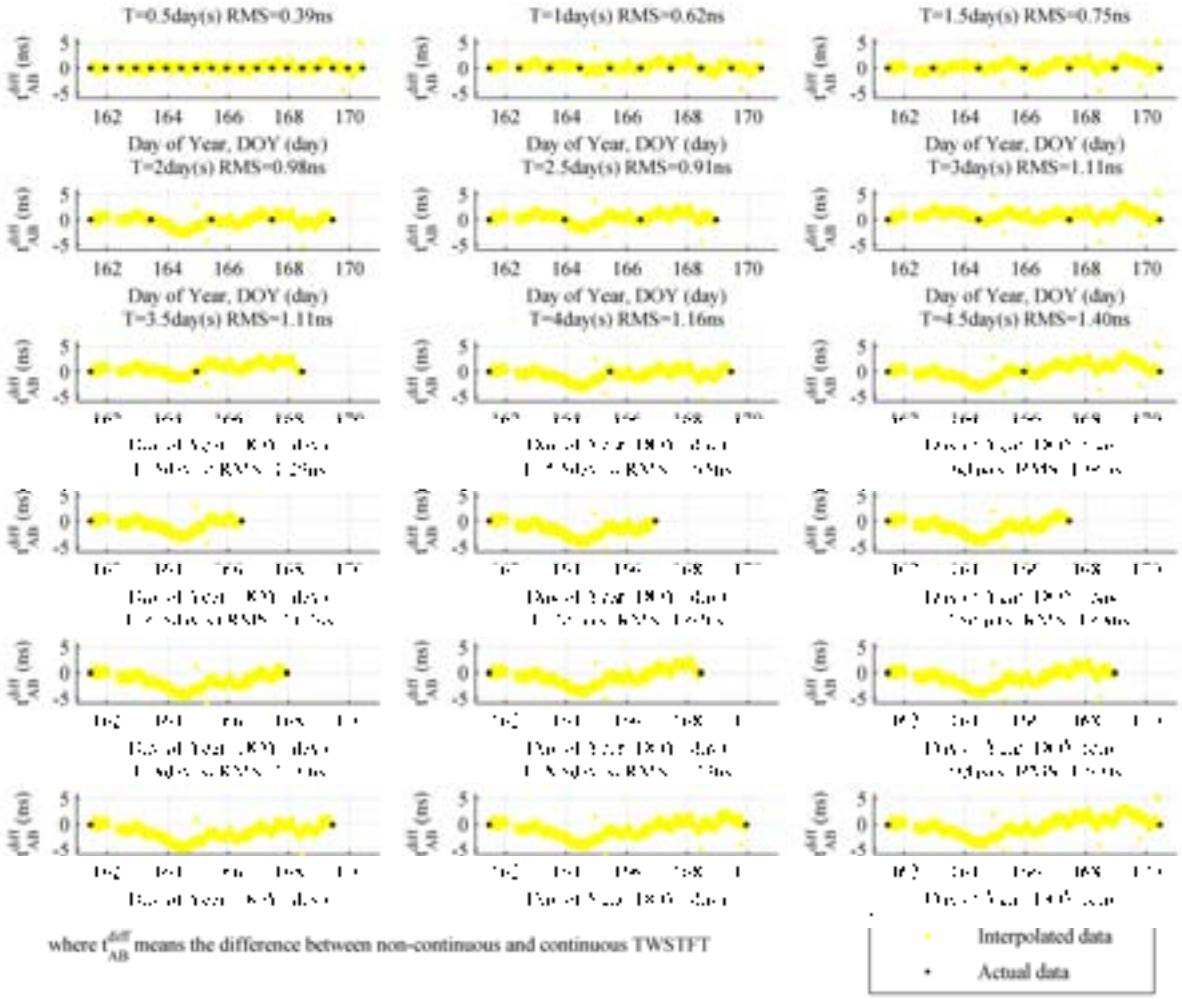

Figure. 6 The difference between continuous TWSTFT and non-continuous TWSTFT with different intervals.

depict the relationship between t^{diff}_{RMS} and the interval. where t^{diff}_{RMS} is the RMS of t^{diff}_{AB}.

Table 1 Statistically analysis for t^{diff}_{AB}.

Interval (day(s))	Max	Min	Mean	RMS
0.5	5.34	-4.22	0.04	0.39
1	5.36	-4.17	0.22	0.63
1.5	5.49	-4.56	0.30	0.75
2	2.93	-5.32	-0.26	0.98
2.5	3.71	-4.36	0.35	0.92
3	5.55	-4.32	0.87	1.12
3.5	3.31	-2.57	0.60	1.11

9	5.55	-5.19	-0.38	1.60

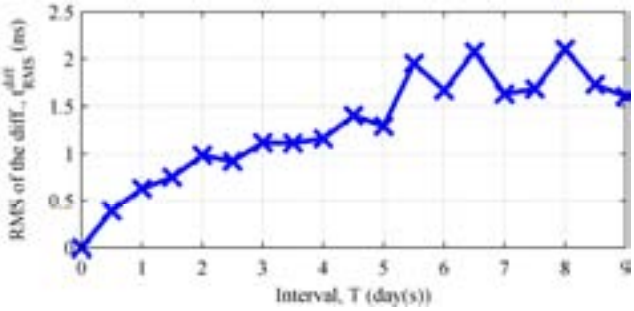

Figure. 7 The affect of interval T on t^{diff}_{RMS}.

IV. CONCLUSION

The RMS of the difference between non-continuous and continuous TWSTFT is positive correlative with the observation interval (cf. Fig. 7). When the interval is less than 2.5 days, the RMS of the difference between non-continuous and continuous TWSTFT is better than 1 ns; when the interval is 0.5 day, the RMS is better than 0.5 ns. In this paper, the accuracy will decline less than 1 ns with the interval being less than 2.5 days; In order to guarantee the reduction of accuracy being better than 0.5 ns, the observation interval should be no more than 0.5 days.

***Abstract*—The building algorithm of system time is one of the research focus of auto-navigation. This paper bases on centralized processing mode of auto-timekeeping, gives a kind of building algorithm of system time. On-board clock's weight are determined by the clock quantity which referring to the computation, change of clock velocity can reflect change of clock frequency, so it uses clock velocity instead of clock frequency for determining weight; this algorithm uses two kinds of method of predicting initial velocity: a. with the former two epochs each satellite of each day predict initial velocity, b. with the former two epochs each satellite of first day predict initial velocity. Choosing one clock as the main clock, according to defined sample interval, getting all the available clock error relative to the main clock. This paper gives the computation model of system time, testing the algorithm with IGS precise clock error(system time is IGST). The result shows: comparing to the equal weighted algorithm, the weighted algorithm has better stability. Adding prediction has a significant improvement on the system time's stability, method a: the difference between TA(weight) and TA(IGST) (International GNSS Service Time) is about 45ns, method b: the difference be-tween TA(weight) and TA(igst) (International GNSS Service Time) is about 65ns. The algorithm is in reason, it can be used for the building algorithm of system time of auto-navigation.**

Keywords-autonomous running; system time; navigation constellation; weight algorithm

I. INTRODUCTION

The basis of determining orbit and positioning of satellite is building and sustaining of system time. The basic observation of inter-satellite is distance. The trans-mitting distance of signal is velocity multiply time. Due to light velocity is 10^8, so the microsecond error can cause hundred meters error. The inter-satellite ranging of two way of radio is relatively observation, only to determine relatively clock error of inter-satellite, the absolute clock error is got by comparing to the system time. So we should build system time in order to determine the change of satellite clock relative to system time.

This paper places emphasis on the research of system time which bases on the in-ter-satellite links.

II. THE GENERATION PRINCIPLE OF SYSTEM TIME UNDER THE AUTONOMOUS RUNNING MODE

There are two kinds working mode of autonomous timekeeping of navigation satellite: centralized processing mode and distributed processing mode. The working principles of centralized processing mode: selected one satellite as the main star, inter-satellite ranging and communicating by the way of TDMA, other satellites send the observations to the main star, the relative clock error of satellite regard as the known input which is measured by inter-satellite link[1]. The time scale is established by the algorithm of atomic time. Comparing distributed processing mode, centralized processing mode can get system time easily. Based on the centralized processing mode, this paper advances the building algorithm of system time[2]. With the deviation of each satellite clock relative to the atomic time, then sends the parameter results of clock error to each satellite by communication links so that it can update the navigation information.

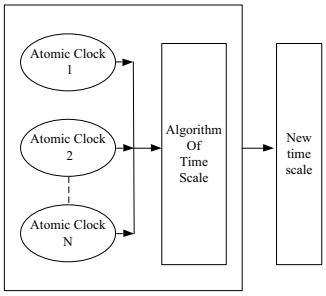

Figure 1. combinated timescale of on-board clocks

III. THE CALCULATION MODEL OF SYSTEM TIME OF CENTRALIZED PROCESSING MODE

The calculation model of system time of centralized processing mode is expressed as[3-5]:

$$TA(t) = \sum_{i=1}^{N} w_i(t) \sum_{i=1}^{N} w_i(t) h_i(t) \qquad (1)$$

$h_i(t)$ is the reading of each atomic clock, i = 1,2, • • • N, when the weight of clock i changes or the atomic clock's number of involved in the calculation changes, adding prediction in order to ensure the continuity of time scale. $h_i^{'}(t)$ is a corrective prediction, so the formula (1) can be rewritten as formula(2):

$$TA^{'}(t) = \sum_{i=1}^{N} w_i(t) \sum_{i=1}^{N} w_i(t)(h_i(t) - h_i^{'}(t)) \qquad (2)$$

The formula of corrective prediction is expressed as:

$$x_i(t_0) = TA(t_0) - h_i(t_0) \qquad (3)$$

$$h_i^{'}(t) = x_i(t_0) + y_i^{'}(t)(t - t_0) \qquad (4)$$

t_0 is the calculated moment, $y_i^{'}(t)$ is the deviation which clock i relative to the calculated time scale, or the velocity of clock i relative to the calculated time scale. Solving $x_i(t_0)$ and $y_i^{'}(t)$ is the course of epoch-wise conducting.

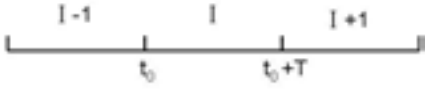

Figure 2. Epoch simple figure

choose $h_m(t_j)$ as the main clock, i=1,2,m…n, we obtain the difference between each clock and reference clock in t_j.

$$x_{im}(t_j) = h_i(t_j) - h_m(t_j) \qquad (5)$$

So we can get the calculation formula of system time of centralized processing mode:

$$x_m(t_j) = \sum_{i=1}^{N} w_i(t) \sum_{i=1}^{N} w_i(t)\{h_i^{'}(t_j) - x_{im}(t_j)\} \qquad (6)$$

$x_m(t_j)$ is the clock error which is obtained by new time scale.

3.1 The clock velocity determination

Clock velocity is obtained by linear fitting, or computed by two points:

$$y_i^{'} = \frac{x_i(t_n) - x_i(t_1)}{t_n - t_1} \qquad (7)$$

3.2 The weight determination

We use the algos weighted principle of BIPM (International rights bureau). The change of clock velocity can reflect the change of clock frequency.

This paper uses the velocity instead of frequency for determining weight. So the improved weight formula is expressed as:

$$p_i = 1 / std(y_i^{'})^2 \qquad (8)$$

In the calculation course, if we give the better clock too much weight, the time scale has too much dependence on better clock. We should restrict the weight in order to avoid the problem happening,. So we advences the maximum weight principle. Becasuse the choosing principle of maximum weight of on-board clock is not ripe, we all use the choosing principle of ground-clock:

$$w_{max}(t) = A / N \qquad (9)$$

A is an experience constant, BIPM uses 2.5, N is the clock number of involved in the calculation. When the weight exceeds the maximum, we should normalize the weight. The solution of $w_i(t)$ and $y_i^{'}(t)$ is not fixed, method changes with the da-ta changes.

IV. EXAMPLE ANALYSIS

In order to validate the rationality of algorithm, this paper downloads the data of on-board clock from IGS website, the sampling interval is 5 minutes, then carry out the simulation. Data arces from 2011.1.1 to 2011.3.1, there are 19 satellites which covering all the sampling points in the 60 days, the same sampling number assures the continuity and integrality of data and rationality of determining weight. The figure of inter-satellite as follows:

Figure 3. the figure of building inter-satellite link

All the running state of satellite involving calculating don't change in sixty days.

TABLE I. THE TYPE OF GPS ON-BOARD CLOCK(2011.1.1-3.1)

The work support by the National Natural Science Foundation Of China: the research of time transfer of GPS precise common view(No:11173026)

In order to reduce calculative burden, resampling the time interval of five minutes to the time interval of one hour. Due to the effect of measuring noise、multiple-path effect and device time-delay, the precision of relative clock error of inter-satellite link don't reach the precision of IGS clock error. So adding 1ns random noise to simulation data.

This paper chooses the PRN 05 as the reference clock, validating the algorithm from following strategy:

TABLE II. PROCESSING STRATEGY

scheme	Determine initial value of clock velocity	Determine weight	
No prediction	no	equal	weight
prediction	with the former two epochs each satellite of each day predict initial value	equal	weight
	with the former two epochs each satellite of first day predict initial value	equal	weight

4.1 The system time's algorithm without satellite prediction

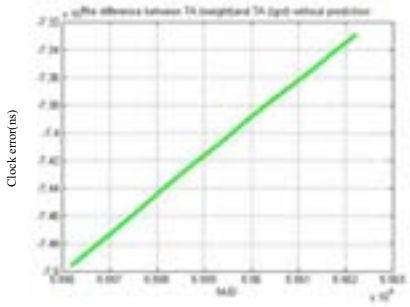

Figure 4. the difference between TA(weight) and TA(igst) without prediction

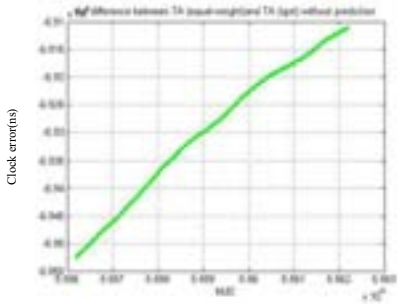

Figure 5. the difference between TA(equal-weight) and TA(igst) without prediction

Figure 4 and 5 shows distinct linear excursion without prediction, the difference between TA(weight) and TA(igst) is 1800ns, the difference between TA(equal-weight) and TA(igst) is 450ns.

4.2 The system time's algorithm with satellite prediction

This paper uses two methods for predicting initial clock velocity:

A: with the former two epochs each satellite of each day,

B: with the former two epochs each satellite of first day.

4.2.1 With the former two epochs each satellite of each day predict initial velocity

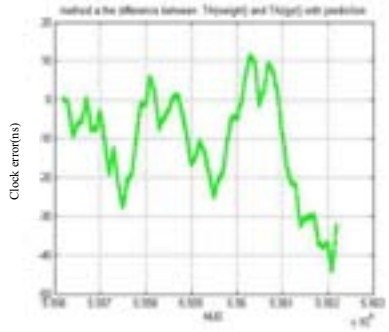

Figure 6. method a:the difference between TA(weight) and TA(igst) with prediction

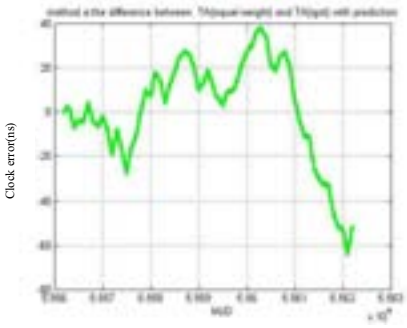

Figure 7. method a:the difference between TA(equal-weight) and TA(igst) with prediction

4.2.2 With the former two epochs each satellite of first day predict initial velocity

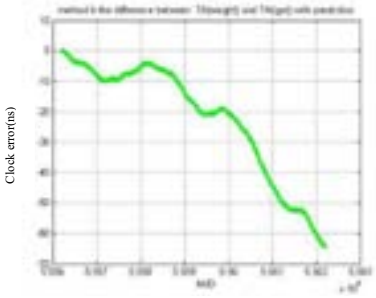

Figure 8. method b:the difference between TA(weight) and TA(igst) with prediction

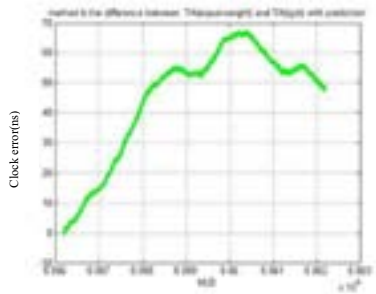

Figure 9. method b:the difference between TA(equal-weight) and TA(igst) with prediction

Figure 6-9 shows: the four figures remove linear excursion with the prediction. Method a: the difference between TA(weight) and TA(igst) is 42ns, equal is 65ns. Method b: the difference between TA(equal-weight) and TA(igst) is 65ns, equal is 68ns. The results show: the prediction method of former two epochs of each satel-lite of each day is better than the former two epochs of each satellite of first day.

4.3 Stability analysis

The designing principle of system time is obtaining the best stability[6-8]. Compare stability of system time with Hadamard deviation. Using former two epochs of each satellite of each day predicting initial velocity, it validate stability of system time from equal weight and weight[9-10].

Figure10 shows the figure of Hadamard variance of PRN05, other satellites are similar to the PRN05. It is not list for limited space. It can know: weight algorithm is more stable.

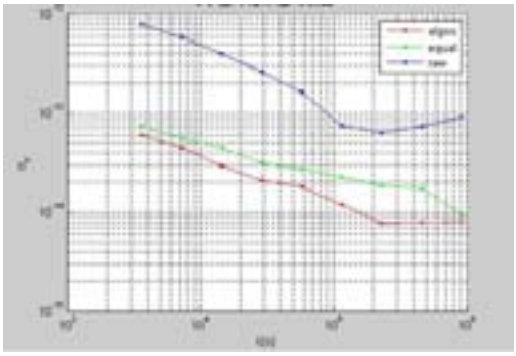

Figure 10. the Hadamard variance of three kinds of system time

V. CONCLUSION

This paper advances the building algorithm of system time of autonomous running mode.

The conclusions as follows:

(1) Prediction considers prior information of epoch-wise satellite clock, it ensures continuity and rationality of built time scale;

(2) This algorithm gives two kinds of method for predicting initial velocity:

A: former two epochs of each satellite of each day;

B: former two epochs of each satellite of first day.

The system time of Method a is more stable than method b. The reason is that: the first method considers long running condition, which is a continuous course, the second considers short running condition, which is a non-continuous course.

(3) The equal algorithm ignores the advantage and disadvantage of satellite clock so that the built system time is not ideal. The weight algorithm con-siders the advantage and disadvantage of satellite clock. Relatively, the built system time is stable and reliable. From equal algorithm and weight algorithm we know: Do not exist best algorithm of system time. We should design proper algorithm according to the intention.

***Abstract*—According to the frame structure of CMMB, A method of pseudo-range measurement with the aid of disciplined sequences for CMMB is proposed on the basis of simulating frame synchronization, carrier synchronization and sampling clock synchronization. The method adopts the pseudo-random code tracking technique and implements pseudo-range measurement on CMMB system. The simulation results show that carrier frequency offset error is less than 1e-13 and the pseudo-range measurement error is less than 6 meters when the sampling rate is 60 MHz.**

Keywords—CMMB, carrier synchronization, pseudo-range measuerment

I. INTRODUCTION

The technology of China Mobile Multimedia Broadcasting (CMMB), which has been the multimedia broadcasting standard of small-size portable electronic equipments, is winning favor of more and more users. With the development of CMMB, many research institutes and their staffs are focusing on mobile location technique by CMMB signal. CMMB, which has the advantage of a fewer station amounts and a less period of building stations because of the structure of Single Frequency Network (SFN) adopted in the ground supplementary stations, is especially suitable for navigation enhancing application to enhance and supplement the demand of GNSS navigation and orientation in China. CMMB, which adopts Orthogonal Frequency Division Multiplexing (OFDM) modulation technique, can improve largely location precision because of its favorable anti-multipath performance in the frequency selective fading channels and multi-path fading channels [1].

In signal framing structure of CMMB， both identical synchronization sequences in every beach and the continual pilots in all OFDM symbols can be used to capture and track the received signal. In the process of Pseudo-range measurement, coarse symbol timing in the time domain is carried out, and then the fraction part (F_D) and the integer part (F_I) of frequency offset are separately estimated and corrected. F_D is less than half of the sub-carrier spacing, and F_I is a multiple of the sub-carrier spacing. At last, with tracking and correcting of the sampling frequency offset in real time, the frequency offset from Doppler effects is decreased effectively.

After symbol timing and frequency synchronization, we can achieve the cross correlation between the Pseudo-random sequence of received signals and local corresponding Pseudo-random sequence in a receiver. At the same time, we track the Pseudo-random sequence by code tracking loop and achieve the time difference and pseudo-range between the base station and the receiver by the correlation peak value.

II. METHOD OF PSEUDO-RANGE MEASUREMENT

To measure Pseudo-range between a base station and a receiver in CMMB system, frequency offset must be captured , tracked and corrected in the first place, and then the sampling clock is synchronized to correct the remainder frequency offset, in the mean time, symbol timing is carried out and tracked by delay-locked loop (DLL) to measure precisely the pseudo-range.

A. frequency offset capture

Frequency offset capture includes F_D estimation which is written as $\hat{F}_D$ and F_I estimation whose value is written as $\hat{F}_I$. F_D can destroy the orthogonality among the sub-carriers and result in Inter Carrier Interference(ICI), and it can be calculated by maximum-likelihood (ML) method[2,3]. By means of the correlation of both identical OFDM disciplined

Project supported by "Western Light Talents training program of CAS" (Y305YZ1301 and "Scientific Research Equipment Development Project of CAS" (YZ201218 (Y307YR1301))

sequences with 2048 sampled values, a correlator is used to calculate the correlation of the 2048 sampled values between the selected current window and the anterior window, when the window moves continually, the coarse symbol timing is found once the correlation peak value exceeds the specified limit. The correlator can be written as:

$$Corr(n)=\sum_{k=0}^{2047} r_n(k)\cdot conj(r_n(k+2048)) \quad n=-l.....l \tag{1}$$

Where r_n is the received signal sequence, $Corr(\theta)$ is the maximum value among all the correlation values which are larger than the specified limit, and the corresponding r_θ is the synchronization sequence in the beacon, and its first sampling value is the starting position of the window. As a result, we can achieve $\hat{F}_D$ which can be written as:

$$\hat{F}_D=\frac{1}{2\pi}\arctan\frac{\mathrm{Im}\left[\sum_{k=\theta}^{\theta+2047} r_\theta(k)\cdot r_\theta^*(k+2048)\right]}{\mathrm{Re}\left[\sum_{k=\theta}^{\theta+2047} r_\theta(k)\cdot r_\theta^*(k+2048)\right]} \tag{2}$$

In a general way, after finishing the symbol timing and F_D estimation and correction, F_I is estimated [4,5]. According to the perfect characteristic of self-correlation and cross-correlation of Pseudo Random Noise (PRN) code which is demodulated by OFDM (IFFT), a correlator is used to calculate the correlation between the local sequence which is corrected by m times sub-carrier spacing and the received sequence which is corrected by $\hat{F}_D$. The integer m is adjusted continually till the correlating peak is found. The correlator can be written as:

$$sync(n)=s_l(n)\cdot\exp(\frac{-j2\pi m}{2048}) \tag{3}$$
$$k=0,1,...,2047, m=-\max,...,\max$$

Where max is specified frequency scan ranges. It is supposed that the correlating peak occurs when local signal is corrected by N times sub-carrier spacing, $\hat{F}_I$ is the algebraic product of the N and the sub-carrier spacing. Finally, both $\hat{F}_D$ and $\hat{F}_I$ are sent to the carrier numerical controlled oscillator (NCO) to finish coarse frequency synchronization.

B. frequency offset tracking

Because of Doppler effects and the instability of the oscillator, the frequency offset must be tracked in the frequency domain to finish estimating and correcting the remainder frequency offset F_d in time after finishing estimating and correcting the coarse frequency offset. In this paper, to estimate the remainder frequency offset, an effective method is used as follows [6,7]:

$$\hat{F}_d=\frac{1}{2\pi}\arctan\frac{Im\left(\sum_{k=0}^{N_b-1} Y_k'\cdot Y_k^*\right)}{Re\left(\sum_{k=0}^{N_b-1} Y_k'\cdot Y_k^*\right)} \tag{4}$$

Where Y_k is received sequence, $\hat{F}_d$ is the fraction part of frequency offset fine estimation.

All the factors such as the multi-path channel, noises, estimation errors, time delay in circuits result in large fluctuation of F_D [9]. So F_d must be corrected to make the frequency offset error which is the difference of F_d and $\hat{F}_d$ vary slowly near zero, F_d can be corrected by the F_d fine correcting model which can be given in Fig.1.

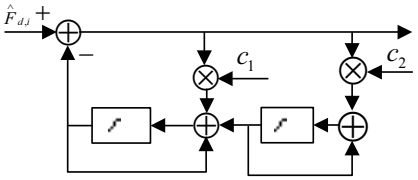

Figure 1. F_d fine correcting model

The filter coefficient c_1 and c_2 can be expressed by the freedom frequency $W_n=2\pi f_n/f_s$ and the attenuation factor η, where f_s is the sampling frequency in a disperse time system. $c_1=4\pi f_n/f_s$, $c_2=4\pi^2(f_n/f_s)$. When the model works stably, W_n and η should be satisfied with $2\eta\geq W_n$, that is $\eta\geq\pi f_n/f_s$. The bigger the value of η is, the shorter the oscillating time, but the smaller the noise attenuation extent, and the bigger the noise. So generally let η equal to the numerical value near 0.5. The value of f_n should be selected properly.

C. sampling clock synchronization

In synchronous sampling system, the joint estimation for the carrier frequency offset and sampling clock frequency offset by pilot symbols are used mostly in the frequency domain to achieve the sampling clock frequency offset estimation.[9,10] Therefore, the symbol timing error contains information about the sampling clock frequency offset. It is supposed that the sampling period is T_s, and the integer part of symbol timing offset is T_d, the fraction part is Δt, the length of the symbol is T_u, the phase deflection of K^{th} sub-carrier is ϕ_k, initial phase difference is ϕ_0, the algebraic addition of the sampling clock offset and the fraction part of frequency offset is τ, then the phase offset of k_1^{th} and k_2^{th} sub-carrier in j^{th} symbol is as follows:

$$\Delta\phi_{k21}(j)=\Delta k/T_u\times 2\pi\times\left[T_d+\Delta t(j)\right] \tag{5}$$

The phase offset between two pilots in one symbol is the function of frequency difference Δk between two pilots and

the normalized symbol timing error $[T_d + \Delta t(j)]/T_s$, where T_u is equal to NT_s.

The total timing error within the same symbol is expressed as follows:

$$\hat{\tau}_{k2,1}(j) = \frac{T_d + \Delta t(j)}{T_s} = \frac{N}{2\pi} \times \frac{\Delta\phi_{k2,1}(j)}{\Delta k} \tag{6}$$

Because of using amounts of pilots, its average is expressed as follows:

$$\hat{\tau}(j) = \frac{1}{L-1} \cdot \frac{N}{2\pi \cdot \Delta k} \sum_{n=1}^{L-1} \Delta\phi_{kn+1,n}(j) \tag{7}$$

The integer part of this average corresponds to the integer part of symbol timing errors, and the fractional part corresponds to the sampling clock frequency offset.

D. Pseudo-range Measurement Principle

The destination of pseudo-range measurement for CMMB system is to seek signal propagation time from the base station to the receiver, consequently to calculate the distance. The signal synchronization determines the pseudo-range measurement precision. Because of the noise interference, not only the top of correlation peak of synchronization sequence has a section of flat segment, but the rising and falling edges of the related triangle are not monotone, so large errors exist in the symbol timing. However, these errors can be tracked by code phase with the help of digital Delay-locked loop (DLL) technique. Fig.2 describes the block diagram of DLL module.

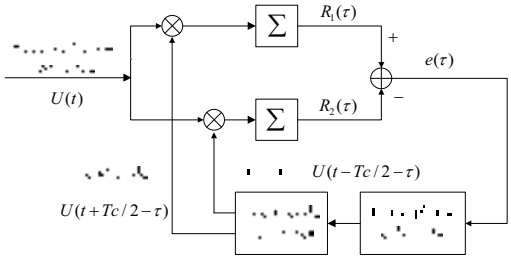

Figure 2. Block diagram of DLL module

During the measurement process, a correlator is used to find the correlation peak between the local and the received synchronization sequence bearing pseudo-random binary sequence demodulated by OFDM, and to finish coarse symbol timing. In the DLL of a receiver, the error control signal which is the difference of lead code and lag code produced by the receiver performs the code tracking by controlling code phase. Because this error control signal increases or decreases monotonously near zero, it is easy to achieve accurate symbol timing and pseudo-range measurement accuracy.

III. SIMULATION RESULT AND ANALYSIS

A. Fraction part of frequency offset Estimation simulation

The F_D estimation algorithm is simulated to assess its performance. In simulation, according to the GY/T 220.1-2006, the channel coding and modulation of synchronization sequence is generated. Fig.3 is the curves of limited representative F_D estimation errors. In the curves whose scope of the carrier frequency offset is in $(-\Delta f_b/2, \Delta f_b/2)$, the abscissa is the specified carrier frequency offset, and the ordinate is the F_D estimation error.

As can be seen from the curves that the residual frequency offset estimated by this algorithm is less than one percent of total fraction part of frequency offset.

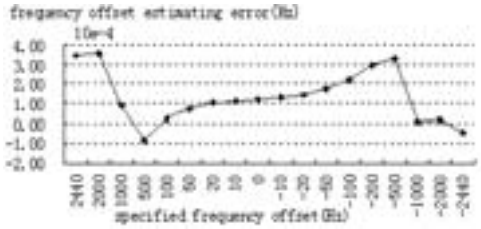

Figure 3. Curves of the fraction part of frequency offset estimation errors

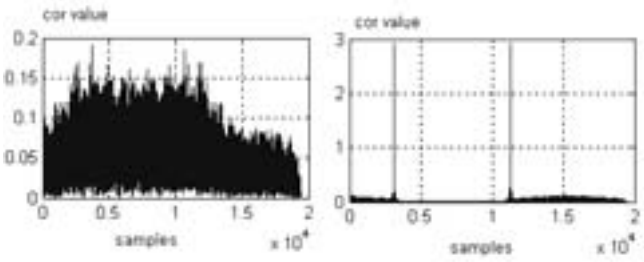
B. Interpart of frequency offset Estimation simulation

Fig.4 is the effect diagram of the F_I estimation in simulation system whose local signal frequency is deviated from the actual frequency for one time of sub-carrier spacing. In Fig.4, (a) shows the correlated effect between the actual signal and local signal not corrected, and (b) shows that of actual signal and local signal corrected by one time of sub-carrier spacing. As can be seen from the diagram that actual signal is not correlated with the local signal before corrected by the integer part of frequency offset. Actually, after only finishing frequency offset correction, local signal and actual signal have maximum correlation peak.



（a）not corrected by the integer part of frequency offset （b）corrected by the integer part of frequency offset

Figure 4. Eeffect diagram of the integer part of frequency offset estimation

C. frequency offset tracking simulation

In simulation, we let $f_n = 1.0e-6$, $f_s = 6e7$, $\eta = 0.5$, and track frequency offset after corrected by $\hat{F}_D$ and $\hat{F}_I$ to estimate and analyze the estimation error. Fig.5 is $\hat{F}_d$ error tracking curves. As can be seen from the curves that frequency offset estimation error after corrected by $\hat{F}_d$ converges quickly. And the estimation error changes slowly near zero.

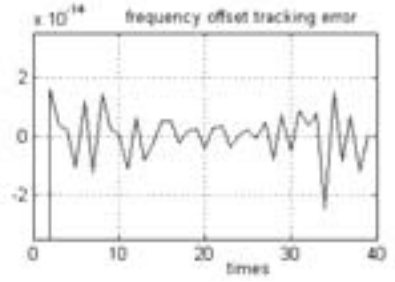


Figure 5. Tracking curves of the fraction part of frequency offset fine estimation

D. pseudo-code tracking and pseudo- range measurement

After coarse symbol synchronization and frequency offset correction, residual frequency offset is vary small, DLL is used to perform code tracking and achieve accurate symbol timing and pseudo-range measurement. In simulation, lag code gets behind lead code for 6 sampling value which is the length of one code chip, and the sampling rate is 60MHz。The simulation result shows in Fig.6, where "*" stands for the simulation wave diagram of lead code, "--" stands for that of instant code, "+" stands for that of lag code, and "o" stands for that of the difference between lead and lag code.

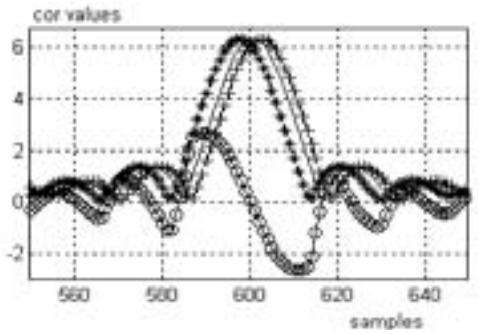

Fig.6 Diagram of DLL tracking

As can be seen from the diagram that the difference between lead and lag code has the largest change rate and a minimum of noise near zero when the instant code is correlated with the local code. It is very sensitive to control the phase of tracking code by the difference signal, so we can track precisely the phase of received code and the symbol starting position to measure precisely the pseudo-range.

IV. CONCLUSION

The traditional single carrier pseudo-range measurement tech- nique cannot be used directly in CMMB system because OFDM technique is applied. In this paper, according to the characteristic of CMMB signal, we capture and track the carrier frequency offset, estimate and correct the fraction part, the integer part of frequency offset and sampling clock frequency offset by virtue of the disciplined sequence in CMMB signal, and then further track and correct the remain frequency offset. On the basis of frequency offset correction, we use a DLL to track the pseudo-range measurement errors. Simulation results show that frequency offset tracking error is smaller than 10^{-13} Hz and pseudo-range measuring accuracy is smaller than 6 meters when the sampling rate is 60 MHz. The pseudo-range measuring method is satisfied with the measuring requirement for CMMB system.

V. ACKNOWLEDGMENT

The authors thank Yuanyuan Gao for many stimulating discussions and part simulation work during the early stages of the project leading to this paper. Thanks everyone of Project 'digital television positioning' of Timing Method and Technology Department, NTSC, CAS for their hard work. Finally thanks Professor Yu Hua for his persevering and meticulous guidance.

***Abstract*—Based on GNSS time and frequency transfer receiver of NIMTFGNSS-1 type, real-time remote calibration has been studied, and one new type of real-time remote calibration system named RTRC has been designed and implemented. The users who should be authorized can use RTRC(including one local NIMTFGNSS-1 receiver) to check and get real-time (16-minute latency) and historical data of remote calibration for their time scales and frequency standards on the web throughout the internet. Calibration uncertainties of the system for time and frequency have been evaluated as 6 ns and 2e-14 averaging one week respectively. For the user who has no time scale or frequency standard and needs either or both of them which time or frequency should be traced to UTC(NIM), National Time and Frequency Primary Standard of China, NIM can provide one low-cost rubidium clock as the accessory of NIMTFGNSS-1 receiver to make up one time scale disciplined by UTC(NIM) in real-time, its time and frequency stability averaging one day could be better than 5 ns and 3e-14 separately.**

Keywords-time and frequency; remote calibration; GNSS; atomic clock

I. INTRODUCTION

GNSS(Global Navigation Satellite System), especially GPS is one of the most useful tools for time and frequency transfer. With the quick development of GLONASS(GLObal Navigation System), BDS(Beidou Navigation Satellite System) and Galileo, GNSS time and frequency transfer becomes the more and more significant research direction. GNSS takes us the convenience of remote calibration for time and frequency. With the techniques of modern network communication, remote calibration base on GNSS time and frequency transfer in real-time is feasible.

At NIM (National Institute of Metrology, Beijing, China), real-time remote calibration(RTRC) system has been developed, and it is able to provide the timing users remote time and frequency measurement and calibration service in real-time for local time and frequency reference, and helps the metrology and timing laboratory to keep the local reference highly accurate and precise for the purposes of scientific research and metrology by remotely measuring the tiem difference between local reference and UTC(NIM)(at Changping campus) in real-time. It is easy for users to log on the website and check the real-time and historical time and frequency difference and some of their statistics.

II. DESIGN AND IMPLEMENTATION

The scheme of RTRC is illustrated as follows in Fig. 1. Each user who uses RTRC will receive one GNSS time and frequency transfer receiver of NIMTFGNSS-1[1] type(NIMGNSS-1 for short) and client software that performs the measurements and sends the instant results to RTRC central server for data storage and processing via internet. RTRC uses GNSS system as the common-view reference. NIMTFGNSS-1 and the central server are two main parts of RTRC. For user, the interface is shown in Fig. 2.

In processing, the system uses the data that are the same to CGGTTS REFSYS data of two stations every 16 min. Two stations may be the reference station NIM with UTC(NIM) and one user, or the two users. The time difference between two stations is calculated by processing of RTRC central server in real-time and the real-time or historical difference can be displayed on the webpage whenever the user logs on the RTRC web site.

If the user has no time and frequency standard, one UTC(NIM) disciplined rubidium clock with one NIMTFGNSS-1 by RTRC link can be combined as one UTC(NIM) disciplined oscillator, named NIMDO, which is provided to the user as his or her local time and frequency standard and has the advantage in the performance over GPSDO(GPS Disciplined Oscillator)[2,3]. The similar former research is NISTDO, and some detailed information can be found in [2] and [3]. NIMDO has the legal and direct traceability to UTC(NIM); its time and frequency accuracy and stability has been improved thanks to the high level reference time scale and time scale algorithm.

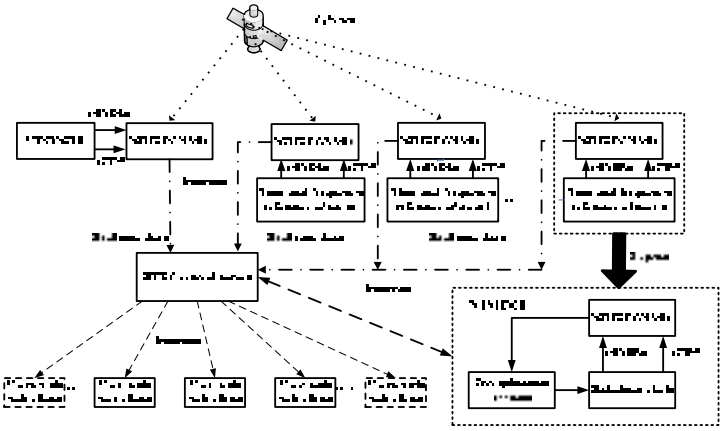

Figure 1. System scheme of RTRC

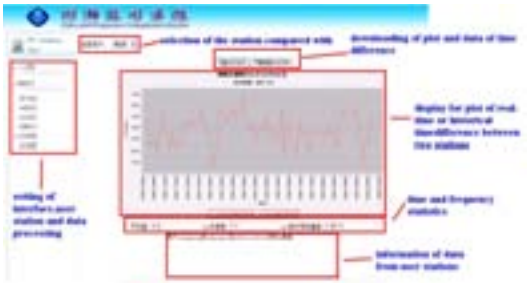

Figure 2. User interface of RTRC

III. Experiment Setup and Numric Results

Four kinds of experiments have been done for performance verification and evaluation of RTRC and NIMDO.

A. CCD(Common Clock Difference) Experiment

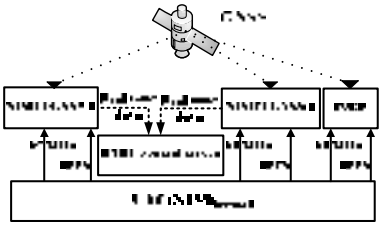

Figure 3. Schematic diagram 1

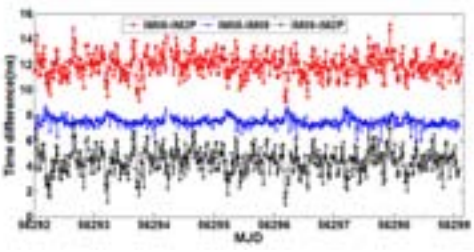

Figure 4. Results in the CCD experiment

To verify the noise level of RTRC system, the CCD experiment should be implemented. Three receivers IM08 and IM09(NIMTFGNSS-1), and IM2P(Septentrio PolaRx2eTR receiver) with the same time and frequency reference $UTC(NIM)_{hepingli}$(one cesium clock with one micro-stepper steered by UTC) at Hepingli campus of NIM, were involved in the experiment described in Fig. 3.

From Fig. 4, the standard deviations of CCD results for one week using the links of IM08-IM2P, IM08-IM09 and IM09-IM2P are 0.9 ns, 0.4 ns and 1.0 ns respectively. IM08 and IM09 have the excellent coherence with each other. Another reason for much smaller standard deviation for IM08-IM09 is that IM2P located very near to $UTC(NIM)_{hepingli}$ in the second floor is at least 20 meters far away from IM08 and IM09 located in the fourth floor, and we use more than 20 meters length radio cable for connection of two location. RTRC system uses the CGGTTS(CCTF Group on GNSS Time Transfer Standards) data indeed, so we use P3 code CGGTTS data of each link for demonstration of RTRC link noise level by post-processing.

B. Zero Baseline Experiment with the Different References

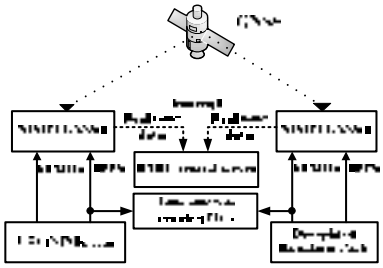

Figure 5. Schematic diagram 2

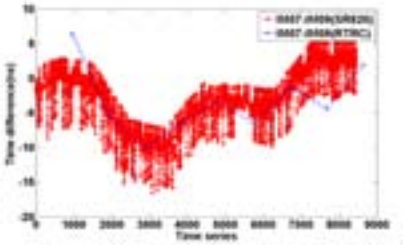

Figure 6. Comparison between RTRC and direct measurement

In Fig. 5, IM07(NIMTFGNSS-1) and IM08 at Hepingli campus with the reference to UTC(NIM)$_{hepingli}$ and the disciplined rubidium clock respectively were used to verify the calibration performance of RTRC, and in the meantime, for comparison, one local TIC(time interval counter, SRS SR620 type) was operated to measure the time difference between UTC(NIM)$_{hepingli}$ and NIMDO every second. The P3 code measurement every 16 min by RTRC is acquired from data downloading function of the system.

From Fig. 6, the trend of RTRC link agrees with that of direct measurement by TIC.

C. Long Baseline Experiment

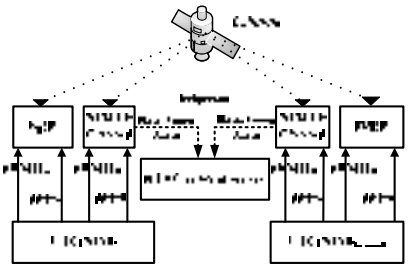

Figure 7. Schematic diagram 3

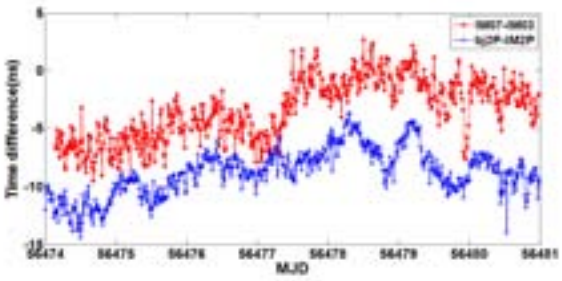

Figure 8. Comparison of two links in long baseline

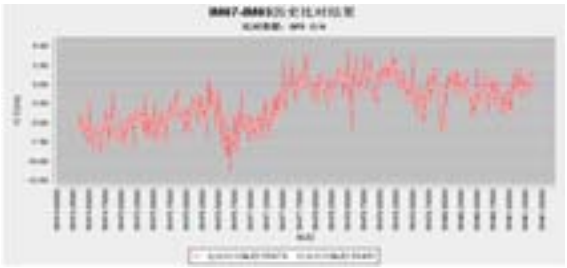

Figure 9. Real-time results by RTRC in long baseline

To show the calibration effect of RTRC directly, long baseline experiment has been implemented as shown in Fig. 6. The baseline between Hepingli campus and Changping campus is about 40 km. IM07 and IM2P referenced to UTC(NIM)$_{hepingli}$ are at Hepingli campus; IM03 and bj2P(Septentrio PolaRx3eTR receiver) referenced to UTC(NIM) are at Changping campus. The scheme of the experiment is described in Fig. 7.

Fig. 8 and 9 show the time difference between UTC(NIM)$_{hepingli}$ and UTC(NIM) with the links of IM07-IM03 by P3 code CGGTTS files, IM2P-bj2P by P3 code CGGTTS files and IM07-IM03 by C/A code measurements of RTRC in real-time from MJD 56474 to 56480. We see the quite similar results and correspondence with one another of three links. The standard deviations of time difference for three links are 1.5 ns, 1.0 ns and 1.4 ns separately. IM07 is located in the fourth floor that makes UTC(NIM)$_{hepingli}$ used for the reference of IM07 more noisy, and corresponds to the plots in Fig. 8 and 9.

D. NIMDO Performance Verification

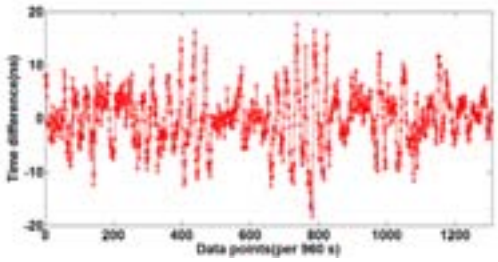

Figure 10. Time difference of NIMDO from UTC(NIM)

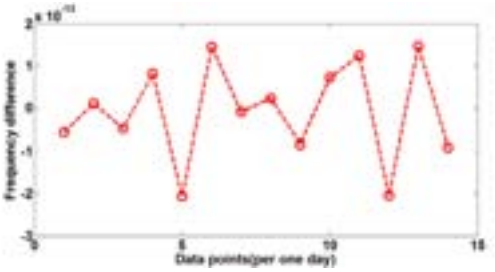

Figure 11. Frequency difference of NIMDO from UTC(NIM)

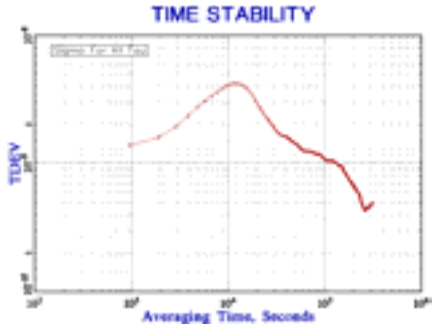

Figure 12. TDEV of NIMDO referenced to UTC(NIM)

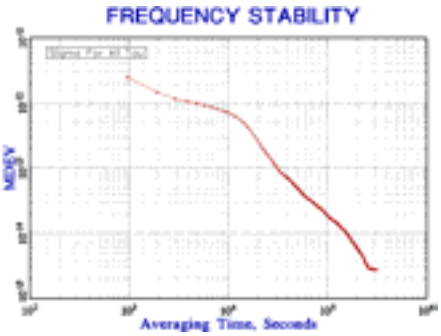

Figure 13. MDEV of NIMDO referenced to UTC(NIM)

The phase of the undisciplined rubidium clock is arbitrary and hasn't the good frequency stability because the big frequency drift. As well, the frequency accuracy would be worse and worse. For example, the direct measurement of one rubidium clock by one phase comparator for several days, its frequency stability (modified Allan deviation(MDEV)) for averaging time one hour and one day are 1.4×10^{-12} and 3.5×10^{-12} respectively, and the frequency accuracy is 1.1×10^{-10}.

Referenced to UTC(NIM), using the time difference data of about 15 days for the sampling interval 960 s by RTRC, frequency differences averaging one day were calculated, and we can reach preliminarily that in most situations the time and frequency accuracy of NIMDO could separately be within 10 ns and 1e-13 averaging one day as shown in Fig. 10 and 11; the time and frequency stability(time deviation(TDEV) and MDEV) averaging one day could be better than 5 ns and 3e-14 respectively illustrated in Fig. 12 and 13. The long frequency stability of the rubidium clock has been ameliorated due to the real-time and short latency steering to UTC(NIM).

IV. Uncertainty Analysis

Estimating the calibration uncertainty of RTRC involves evaluating the uncertainties using both Type A and Type B methods. In Type A method, we use statistical analysis by directly calculating the jitter (standard deviation) of measurement results for the link between two NIMTFGNSS-1 in the CCD experiment, and we can use the standard deviation of CCD results(0.4 ns for P3 code) shown in section 2, however, for GNSS C/A and P3 code measurements, 1.5 ns and 0.7 ns would be used usually by BIPM, and we choose the bigger one. Uncertainty evaluated by type B method, such as some theoretical analysis based on the experience, theory or authorized specification and manual, mainly includes several items as follows.

A. Calibration Uncertainty of GNSS Time and Frequency Transfer Receiver

Calibration uncertainty of GNSS time and frequency receiver using the differential method by BIPM is 5 ns, in generally. If two GNSS time and frequency transfer receivers have been calibrated, and the calibration uncertainty should be cancelled by most part of 5 ns, so the compound standard uncertainty of the time transfer link between two GNSS time and frequency transfer receivers should be less than 5.5 ns.

B. Propagation Errors

The standard uncertainty components due to ionospheric and tropospheric errors are 0.3 ns and 0.7 ns respectively which are valid for baselines up to 5000 km[4]

C. Delay Error of Cables and Converters

Evaluated by type B method, the standard uncertainty component due to the cables and the converters calibrated by VNA could be less than 0.1 ns.

D. Combined Uncertainty and Its Expension

The combined uncertainty u_c and its expension U_c can be obtained by (1) and (2) in table I.

$$u_c = \sqrt{{u_A}^2 + {u_B}^2} \tag{1}$$

$$U_c = k \cdot u_c \tag{2}$$

TABLE I. Uncertainty Budget

Source	Type	Uncertainty (ns)	
		C/A code	*P3 code*
Measurement jitter of GNSS time transfer link between two receivers	A	1.5	0.7
Uncertainty for calibration of GNSS time transfer link	B	5.5	5.5
Propagation errors(including ionospheric and tropospheric error for GNSS time transfer link)	B	0.8	0.8
Delay error of cables and converters for one GNSS time and frequency transfer receiver	B	0.1	0.1
Delay error of cables and converters for the other GNSS time and frequency transfer receiver	B	0.1	0.1
Combined uncertainty		5.8	5.7
Expanded uncertainty (k=2)		11.6	11.4

V. Conclusion and Prospect

The combined uncertainty of about 6 ns for time calibration and the corresponding uncertainty of about 2e-14 averaging one week for frequency calibration could be obtained. Preliminarily the time and frequency accuracy of better than 10 ns and 1e-13 separately averaging one day for NIMDO could be realized, and the time and frequency stability averaging one day could be better than 5 ns and 3e-14 respectively. Soon we would improve the steering algorithm and lay up five NIMTFGNSS-1 receivers at four different cities (Urumchi, Guiyang, Haerbin, and Beijing) in China to verify the effects more deeply in the longer baseline. In the near future, using GNSS real-time or near real-time precise ephemeris products, GNSS carrier phase time and frequency transfer will be studied and applied in RTRC and NIMDO to improve their performances.

Abstract— **The concept of Common-View based One-way Timing Method (CV-OWTM) is proposed by the author in the IFCS conference last year. This method provides users a way to acquire the standard time with the accuracy of about 5ns. However, the CV-OWTM performs the same deficiency as the common view time transfer, that is, its timing accuracy decrease with the increase of distance between users and the reference stations. In order to solve this problem, the Virtual Reference Station (VRS) technique that used in RTK is improved and applied to CV-OWTM. Based on a potential reference stations network in China, this paper will discuss the optimal virtual correction generation algorithm for users. The number of reference stations that users adopted and the weights of involved stations both are key factors for the generation of VRS correction. For different kinds of user, combinations of different number of stations and two methods of determining weights are experimented. The optimal number of reference stations for users' application is one or three. And the distance between the user and reference station decide the weight of timing observation of this station. All in all, the application of VRS can guarantee CV-OWTM provides the timing accuracy of 5ns.**

Keywords-CV-OWTM; VRS; VRS correction; standard time; timing accuracy

I. INTRODUCTION

CV-OWTM is a new timing method proposed by the author. This method operates on network consists of several reference stations. The local time of each reference station is already synchronized with the standard time. Each station sets up receivers and monitors satellites timing signals. The observables derived from each reference stations are sent to a data processing center where generates the timing biases of each satellites in view at each reference station. The information of these biases is broadcast to users. Users who desire an accurate time use the information can get a 5ns timing accuracy.

It is not difficult to figure out that CV-OWTM has the same principle as common view time transfer. Therefore, the accuracy of this method degrades with the increasing of distance between users and the reference stations [1][2].

To guarantee the 5ns timing accuracy of CV-OWTM (Common-View based One-way Timing Method), the Virtual Reference Station technique (VRS) is adopted. VRS is initially applied in RTK to provide service in larger area. With the same purpose, the VRS is adopted to solve the fatal weakness of CV-OWTM.

II. VRS IN HERE

A. *Some Differences*

The VRS discussed herein is different from that in RTK in several aspects. The timing biases are computed according to the code observations not those of carrier phase of the reference stations. Therefore, the VRS here isn't sensitive to the movement of users and still works when users and the network are in long base line. Moreover, using the timing biases of reference stations, it is the users that calculate the VRS correction. This reduces the burden of data processing center and simplifies the communication between them. Finally, the timing biases that the data processing center broadcast contain all the errors from satellites to receiver which is different from that in RTK.

B. *Key Points*

When the VRS is applied to CV-OWTM, there are several problems should be considered. Given a fixed network, there

This work is supported by the National Science Foundation of China (11033004).

are mainly two problems need to be considered. Above all, how many timing biases of reference stations is optimal to calculate the VRS correction. The other is how to determine the weight of the selected stations. These are the two important aspect of VRS virtual observation generation algorithm.

According to a promised network consists of six reference stations, these issues are studied. Some significant conclusions are given for future research.

III. VRS VIRTUAL OBSERVATION GENERATION ALGORITHM

For CV-OWTM, clock error has no effect on its timing accuracy. The uncompensated ionospheric delay and the ephemeris error become the contributor of timing error under long base line. These two errors are both related with the distance from the user to the reference stations in CV-OWTM network. The further users away from the reference station the less relativity of timing errors in the path from satellites to users and reference stations. This characteristic of timing errors are the theory basis of the VRS [3][4].

A. VRS Algorithm

The VRS virtual correction can be expressed with the following formula (1):

$$\delta t_{vrs} = \left(\sum_{i=1}^{n} w_i \cdot \delta t_i\right) \Big/ \left(\sum_{i=1}^{n} w_i\right) \quad (1)$$

δt_i is the timing bias observed at the reference station I and w_i is its weight. n is the number of reference stations and δt_{vrs} is the VRS correction at the user position. Given the positions of the reference stations and their approximate position, users select n optimal reference stations and then compute the VRS correction themselves.

The VRS correction is virtually the result of interpolation of n timing biases of n reference stations. The user should lie in the polygon area consisted by n reference stations.

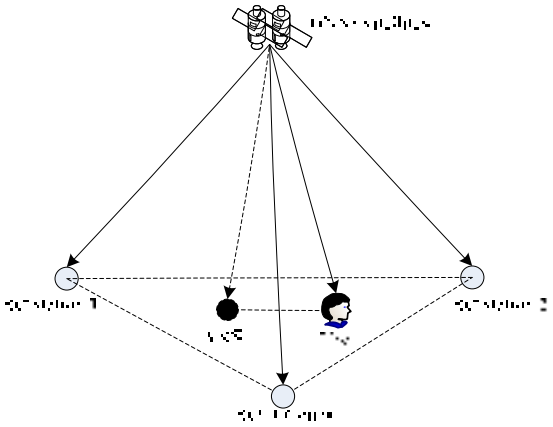

Figure 1. The principle of VRS

According to (1), the number of reference stations and their weights together determine the VRS correction. Take a promised China network for example, these two aspects are studied.

B. The Number of Reference Stations

Fig. 2 shows the distribution of the China network. Six sites are selected as the reference stations where Xi'an will also be the data processing center. If the network operates normally, it can obtain at most six sets of observations of a same satellite. Are these observations all necessary for users to compute the VRS correction?

In order to answer this question, two kinds of different locations are selected as the user positions. The first kind of users lies in the central part of the triangle with one vertex being Xi'an. The second lies in the effective range of the reference stations with the distances relative to the closest station being less than 800km.

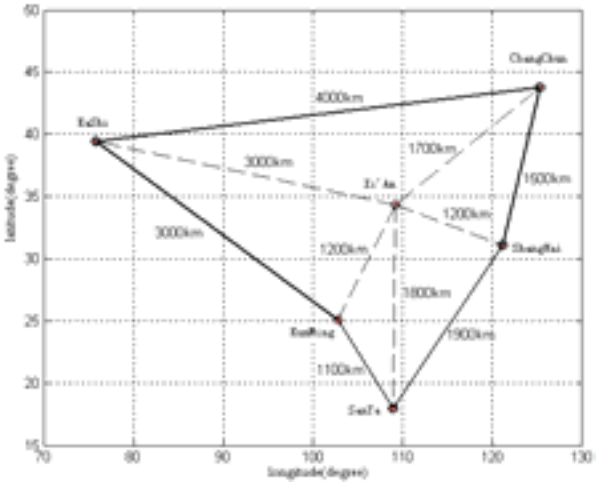

Figure 2. The network of CV-OWTM

In this paper, the correction effect of different combinations of one, three, four, five and six reference stations are compared for each kind of users. Take the user of located at Ji'nan for an example, the ephemeris and ionospheric errors together can be reduced to 2ns after applying the correction. Based on the correction results of all the first kind of users, the combination of three stations has the equivalent effect as the best result.

The distance between Shanghai and Ji'nan is about 725km which is the closest station in the network. According to the results in Table I, the user in Ji'nan can reduce the errors of ephemeris ionospheric errors to 1.23ns only with the correction provided by Shanghai station.

TABLE I. THE EFFECT OF DIFFERENT COMBINATIONS TO JI'NAN

Different combinations	User lies in Ji'nan	Correction result (ns)	
		Before	*After*
Single station	ShangHai	5.21	1.23
Three stations	Xi'an, ChangChun and ShangHai	5.04	**0.40**
Four stations	Exclude KaShi and KunMing	5.04	0.73

	Exclude SanYa and KunMing	5.21	**0.35**
	Exclude Xi'an and KunMing	5.21	0.98
	Exclude Xi'an and SanYa	5.21	0.75
	Exclude ShangHai and ChangChun	5.21	0.98
Five stations	Exclude Xi'an	5.21	1.17
	Exclude KaShi	5.06	0.91
	Exclude ShangHai	5.38	0.96
	Exclude SanYa	5.21	0.59
	Exclude KunMing	5.21	0.71
	Exclude ChangChun	5.40	1.28
Six stations	All stations	5.21	1.37

The reason why we chose the second kind of users is to test the correct effect of a single station. When users are close enough to any one of the reference stations, it may become an easy thing for the user to choose stations. In order to answer this question, we compute the correction effect of the second kind users. The results of using the correction of the nearest single station are lists in Table II. The correction results of three stations for these users are given in Table III. Comparing the results of these two tables, it is easy to answer the former question. As each station covers a specific area, users only need the correction of this station when they lie in the range of this area. The radius of the area is normally less than 1000km.

C. *The Weights of Reference Stations*

As the timing biases are highly related with the distance between the users and the reference stations, two methods of determining the weights are tested.

- $w_i = 1/r_i$, $r_i = \sqrt{(x_u - x_i)^2 + (y_u - y_i)^2 + (z_u - z_i)^2}$ where (x_u, y_u, z_u) is the user position and (x_i, y_i, z_i) is the position of the ith reference station.
- $w_i = \cos(E_i - E_u)/d_i$, where E_i is the elevation of the ith reference station observe the satellite. E_u is the elevation of user observes the same satellite [5].

Thirty points are selected to compare the effects of these two weighting methods. Table IV shows the results of these two methods under the combination of three reference stations. According to the results, these two weighting methods have almost the same effect. The second weighting method not only considers the distance between user and station, but also takes the observation elevation into account. Considering the computational complexity, the first weighting method is adopted here.

IV. APPLICATION GUIDE AND CONCLUSIONS

Based on the research results derived from part III, we can summary some application guides for users. These guides virtually determine the VRS virtual correction algorithm. The implementation procedure for users is:

- Receiving the positions and timing biases of six reference stations.
- Calculating the distances respect to each station.
- If the shortest distance is less than the effective radius of the station, users only need the timing bias of this station to correct their observations.
- If the shortest distance is more than the effective radius of each station, users select three stations that are more closely. The weights of these three stations are inverse proportion to the corresponding distances.

For the stations in low latitude areas, as Sanya and Kunming displayed in Figure 3, the effective radius is smaller than those stations in middle and high areas. This is because the amplitude of ionospheric delay is large in these areas. So the residual after the ionospheric compensation is still large and change quickly.

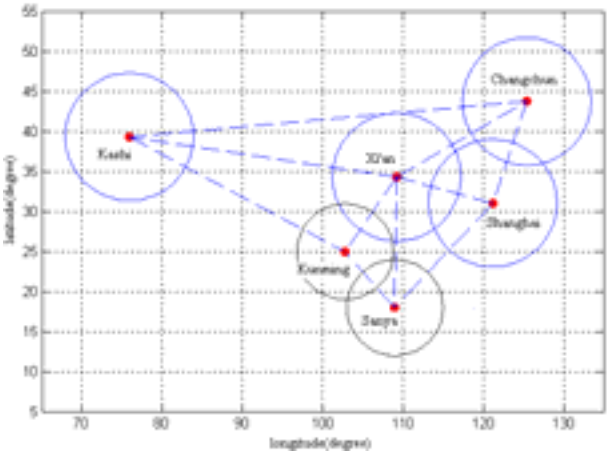

Figure 3. The effective range of each station

Finally, the VRS algorithm can eliminate the ephemeris and ionospheric delay errors and keep these errors in 2ns which guarantees the accuracy of the CV-OWTM.

The VTEC Data used in this paper are from website "http://www.dccdnc.ac.cn/dataservice/gps_tec.jsp" and the broadcast navigation message and precise ephemeris data are used to compute the ephemeris error.

***Abstract*—As the frequency and time reference of space satellites, satellite clock has a direct influence on GNSS service performance. Any anomaly of the atomic clock behavior on board the satellites causes errors for user position. Therefore, it is necessary to detect clock anomaly. Frequency jumps are one of the most common anomalies in atomic clocks of on-board satellites, which appear due to space radiation, temperature change and other factors. In this paper, a detection algorithm of frequency jumps based on the batch least squares residues is proposed. Performance of the new algorithm is analyzed and verified by numerical simulation. The detection algorithm of frequency jumps for satellite clocks proposed in this paper is helpful to GNSS satellite clock autonomous integrity monitoring.**

Keywords-frequency jump; least square estimation; sum test statistic

I. INTRODUCTION

As the frequency and time reference of space satellites, satellite clock has a direct influence on GNSS service performance. Therefore, it is necessary to monitor its integrity [1]. Several methods are proposed to detect anomaly of atomic clocks on board [2-5]. An extended version of the Allan variance, the dynamic Allan variance (DAVAR) [2, 3], has been used to detect anomalies in clocks, which is inapplicable to autonomous integrity monitoring of atomic clock on board due to its computational complexity and detection delay. A useful method to detect clock anomaly on board using the one-step predicted residue of Kalman filter is proposed in [4, 5]. It is effective to detect obvious anomaly bias, but ineffective for weak anomaly. Clearly, it is appreciable to provide a solution to weak frequency anomaly detection for atomic clocks on board with tolerable computational complexity and detection delay.

In this paper, clock parameters are achieved by least squares estimation. Real-time frequency residues are obtained by wiping off the trend item, and a novel sum test statistic based on residues is constructed. Performance of the new algorithm is analyzed and verified by simulation. The results show that the new algorithm has a perfect performance of detecting frequency jump.

II. THE NEW ALGORITHM

The average frequency deviation of an atomic clock, commonly modeled as a sum of white frequency noise (WFM), random-walk frequency noise (RWFN), and a slowly varying deterministic drift [5], can be written as

$$y(k) = y_{\mathrm{W}}(k) + y_{\mathrm{RW}}(k) + d(k) \tag{1}$$

Where $y_{\mathrm{W}}(k)$ is WFN, $y_{\mathrm{RW}}(k)$ is RWFN, and $d(k)$ is the time-varying drift, which can be defined as

$$d(k) = d(k-1) + d \cdot T \tag{2}$$

Where $d(0)$ equals to the standard frequency f_0, and d is the linear frequency drift, which is regarded as a constant value.

According to [5], $y_{\mathrm{W}}(k)$ has zero mean and variance given by

$$\sigma_1^2 = E[y_{\mathrm{W}}^2(k)] \tag{3}$$

The RWFN component is the solution to the random differential equation as following

$$y_{\mathrm{RW}}(k) = y_{\mathrm{RW}}(k-1) + \Delta y_{\mathrm{RW}}(k-1) \tag{4}$$

Where $y_{\mathrm{RW}}(k) = 0$, and increments $\Delta y_{\mathrm{RW}}(k)$ are statistically independent Gaussian random variables, with zero mean and variance given by

$$\sigma_2^2 = E[\Delta y_{\mathrm{RW}}^2(k)] \tag{5}$$

The frequency deviation measurements given in (1) is rewritten using matrix notation

$$\boldsymbol{y} = \boldsymbol{HA} + \boldsymbol{\varepsilon} \tag{6}$$

Where $\boldsymbol{H}=\begin{bmatrix}1 & t_1\\ \vdots & \vdots\\ 1 & t_n\end{bmatrix}, \boldsymbol{A}=\begin{bmatrix}f_0\\ d\end{bmatrix}, \mathbf{y}=\begin{bmatrix}y_1\\ \vdots\\ y_n\end{bmatrix}, \boldsymbol{\varepsilon}=\begin{bmatrix}\varepsilon_1\\ \vdots\\ \varepsilon_n\end{bmatrix}$.

It is supposed that the elements of ε have zero expectation and, for the moment, a known covariance matrix $\boldsymbol{V}(\boldsymbol{\varepsilon})$. The elements ε_i are taken as a linear combination of (independent) samples of known noise types, including WFM, RWFM.

$\boldsymbol{V}(\boldsymbol{\varepsilon})$ is expressed in terms of known covariance matrices that relate to each noise type and parameters describing the 'magnitude' of each noise type are present [6]. Each noise type is characterized by a transformation of a white noise process. The covariance matrices $\boldsymbol{V}$ for standardized WFM and RWFM, for which the transformed white noise process has unit standard deviation, are given, respectively, by confirmed by false alarm as following [7]

$$\boldsymbol{V}_{\mathrm{WFM}}=\boldsymbol{I}, \quad \boldsymbol{V}_{\mathrm{RWFM}}=\boldsymbol{W}\boldsymbol{W}^{T} \tag{7}$$

$$W=\begin{bmatrix}1 & 0 & \cdots & 0\\ 1 & 1 & \ddots & \vdots\\ \vdots & \ddots & \ddots & 0\\ 1 & \cdots & 1 & 1\end{bmatrix} \tag{8}$$

The covariance matrix $\boldsymbol{V}(\boldsymbol{\varepsilon})$ for noise arising as a linear combination of (independent) WFM and RWFM is then expressed as confirmed by false alarm as following [7]

$$\boldsymbol{V}(\boldsymbol{\varepsilon})=\boldsymbol{\sigma}^2_{\mathrm{WFM}}\boldsymbol{V}_{\mathrm{WFM}}+\boldsymbol{\sigma}^2_{\mathrm{RWFM}}\boldsymbol{V}_{\mathrm{RWFM}} \tag{9}$$

As some parameters of the measurements are unknown, it is necessary to estimate the unknown parameters. A GLS analysis is applied to obtain estimates of the normalized frequency offset f_0 and the frequency drift d together with their associated uncertainties. The estimates determined can be expressed as following

$$\hat{\boldsymbol{A}}=\begin{bmatrix}\hat{f}_0\\ \hat{d}\end{bmatrix}=(\boldsymbol{H}^T\boldsymbol{V}\boldsymbol{H})^{-1}\boldsymbol{H}^T\mathbb{V}\mathbf{y} \tag{10}$$

In order to achieve real-time detection of frequency jumps, two windows are adopted. The first window with past measurements is used to estimate the unknown parameters, while the second window with current measurements is used to construct the proposed detector.

Similar to the snapshot residual-based detection approach, a batch residual vector is obtained by taking difference between the measured and predicted frequency offsets within the second window. And a sum test statistic is built based on the batch residual vector, which is used to construct the frequency jump detector.

The batch residual vector is given as

$$\Delta\boldsymbol{y}=\tilde{\mathbf{y}}-\tilde{\boldsymbol{H}}\hat{\boldsymbol{A}} \tag{11}$$

Where $\Delta\boldsymbol{y}=\begin{bmatrix}\Delta y_1\\ \vdots\\ \Delta y_n\end{bmatrix}$, $\tilde{\mathbf{y}}=\begin{bmatrix}y_{n+1}\\ \vdots\\ y_{n+\mathrm{n}}\end{bmatrix}$, $\tilde{\boldsymbol{H}}=\begin{bmatrix}1 & t_{n+1}\\ \vdots & \vdots\\ 1 & t_{n+n}\end{bmatrix}$.

The batch residual vector follows generalized Gaussian distribution, which can be expressed as $\Delta\boldsymbol{y}$~N($\mathbf{0}$,$\mathbf{C}$). The covariance matrix of batch residual vector is expressed as (12) consequently.

$$\boldsymbol{C}=\begin{bmatrix}c_{1,1} & \cdots & c_{1,n}\\ \vdots & \ddots & \vdots\\ c_{n,1} & \cdots & c_{n,n}\end{bmatrix} \tag{12}$$

Where

$$c_{i,j}=E[(\boldsymbol{y}_{N+i}-\tilde{\boldsymbol{H}}_i\hat{\boldsymbol{A}})\cdot(\boldsymbol{y}_{N+j}-\tilde{\boldsymbol{H}}_j\hat{\boldsymbol{A}})^T] \tag{13}$$

As the residues are correlated, it is a good choice to prewhitening the residues. For any $\boldsymbol{C}$ that is positive definite, it can be shown that $\boldsymbol{C}^{-1}$ exists and is also positive definite. Consequently, it may be factored as $\boldsymbol{C}^{-1}=\boldsymbol{D}^{\mathrm{T}}\boldsymbol{D}$, where $\boldsymbol{D}$ is called the prewhitening matrix, which produces WGN. The residues prewhitened can be expressed as $\boldsymbol{Z}=\boldsymbol{D}\cdot\Delta\boldsymbol{y}$.

A frequency jump is a sudden variation in the frequency trend, which can be modeled as

$$y'(k)=y(k)+\Delta f\cdot u(k-n) \tag{14}$$

Where n is the time instant at which the frequency jump occurs, and Δf is its size, which is often a constant value. Therefore, the frequency jump detection problem can be modeled as

$$\begin{aligned} &H_0: z(n)=z'(n) && n=0,1,...,N-1\\ &H_1: z(n)=\Delta f_n'+z'(n) && n=0,1,...,N-1 \end{aligned} \tag{15}$$

Where $z'(n)$ is the nth element of the residues without frequency abnormal values, $\Delta f_n'$ is the nth element of $\Delta\boldsymbol{f}'$, which can be expressed as following

$$\Delta\boldsymbol{f}'=\boldsymbol{D}\cdot\begin{bmatrix}\Delta f\\ \vdots\\ \Delta f\end{bmatrix} \tag{16}$$

In order to improve detection performance, residues are accumulated. The new test statistic proposed for weak anomaly detection can be expressed as following

$$z = \sum_{i=1}^{n} (z_i')^2 \tag{17}$$

As prediction residues prewhitened are uncorrelated, which follow a Gaussian distribution, test statistic z follows a chi-square cumulative distribution.

Assume the probability of false alarm is P_f, and the probability of detection is P_d, the detection threshold can be confirmed by false alarm as following [7].

$$P_f = \int_{T(P_f)}^{\infty} (2^{\frac{N}{2}} \Gamma(\frac{N}{2}))^{-1} z^{\frac{N}{2}-1} e^{-\frac{z}{2}} dz \tag{18}$$

The probability of detection is given as following

$$P_d = \int_{T(P_f)}^{\infty} \frac{1}{2} (z/\lambda)^{\frac{N}{4}-\frac{1}{2}} e^{-\frac{z+\lambda}{2}} I_{\frac{N}{2}-1}(\sqrt{z\lambda}) dz \tag{19}$$

Where the noncentral parameter λ equals to $\sum_{i=1}^{N} (\Delta f_i')^2$. Performance of the test statistic can be obtained for a given probability of false alarm detection according to (18) and (19). The detection performance is decided by noncentral parameter λ, which is square sum of abnormal residues. It is obvious that parameter λ increase with large length of measurement window, which indicates better detection performance.

A frequency jumps detection method based on the new test statistic is proposed, whose implementation is shown in Fig. 1. A GLS analysis is applied to 1st window to obtain estimates of the normalized frequency offset f_0 and the frequency drift d, which are used to wipe off the trend item. A batch residual vector is obtained by taking difference between the measured and predicted frequency offsets within the second window. The residues are prewhitened by a prewhitener, and the new test statistic is acquired by accumulating the residues prewhitened. Each value of the test statistic is compared with the detection threshold, which can be confirmed by (18) with a given probability of false alarm. If value of the test statistic is bigger than the threshold, clock anomaly is decided.

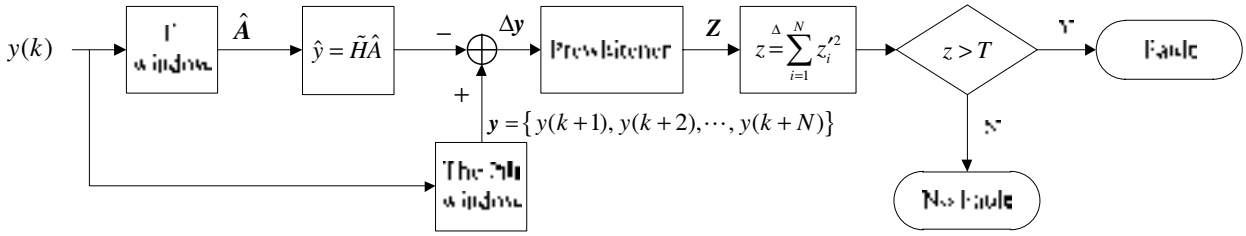

Fig. 1 Block diagram of implementation structure for frequency jumps detection

III. NUMERICAL SIMULATION

To evaluate the new detection method, numerical simulations of frequency jump detection for atomic clock is performed. The case of a rubidium clock is considered, whose variance values for a sampling time T_s=1s are given by

$$\sigma_1^2 = (5\times10^{-12})^2 \tag{20}$$

and

$$\sigma_2^2 = (5.2\times10^{-16})^2 \tag{21}$$

These values are examples of the stability reached by a space-based rubidium frequency standard following the first Galileo space clock specifications [8]. The frequency drift is given as a constant linear drift represented by

$$d = 1\times10^{-16}/s \tag{22}$$

The detection performance of the proposed detector can be confirmed by (19). In order to verify detection performance of the new detector, numerical and Mont-Carlo (M-C) simulation are verified. Numerical calculation results of fault detection probability according to formula (19) are compared with simulation results of repeat 10000 M-C simulations.

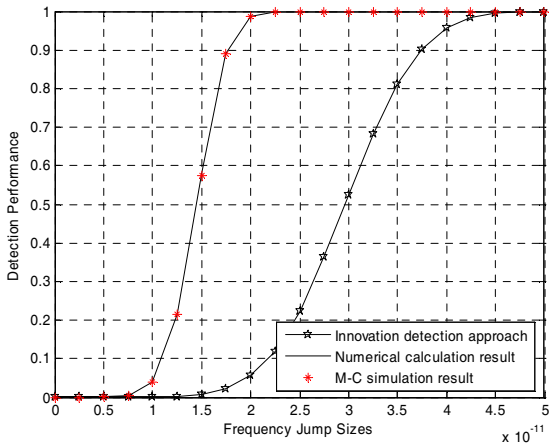

Fig. 2 Detection performances of the proposed detector

The accumulation number is 10, and the probability of false alarm is 10^{-6}. Values of P_d as a function of values of frequency jump with a constant P_{fa} are shown in Fig. 2.

It can be seen from simulation results that Mont-Carlo (MC) simulation results are highly consistent with results of the calculation formula, which illustrates the correctness of the calculation formula of detection probability. It is also obvious that detection performance of the proposed detector is better than that of innovation detection approach provided in [4, 5].

IV. CONCLUSION

A method of weak frequency detection is proposed. A GLS analysis is applied to obtain estimates of the normalized frequency offset f_0 and the frequency drift d, which are used to wipe off the trend item. A batch residual vector is obtained by taking difference between the measured and predicted frequency offsets, and a novel test statistic based on the batch residual vector is constructed. Simulation is adopted to verify detection performance of the proposed method. Such a method is simple to implement with tolerable computational complexity and detection delay. Several improvements to our method are currently been working on, such as the detection of weak frequency jumps.

Plateau de Calern, France

Abstract—**The Time Transfer by Laser Link (T2L2) experiment, developed by both OCA and CNES, performs ground to ground time transfer over intercontinental distances. The principle is derived from laser telemetry technology with dedicated space equipment designed to record arrival time of laser pulses at the satellite. Using laser pulses instead of radio frequency signals, T2L2 allows realizing some links between distant clocks with expected time stability of a few picoseconds and accuracy better than 100 ps.**

On the one hand, several experiments demonstrated the capability of the T2L2 system to perform time transfer with a residual accuracy in the 100 ps range [1]. Nevertheless laser operations are weather dependent and do not allow continuous comparison of remote clocks. On the other hand GPS time transfer is a worldwide, all weather and fully operational system. GPS data processing has been widely improved since the first common view / single satellite time transfer and GPS Carrier Phase techniques now allow continuous comparison with accuracy in the nanosecond range. However, carrier phase data are ambiguous and several method were developed in order to reduce them. Performances of these methods are widely demonstrated for frequency transfer and with continuous data. But some ambiguities remain as soon as there are gaps in the data and for accurate time transfer.

This work investigates the possibility to combine GPS-CP time transfer using single-difference integer ambiguity resolution [2] and T2L2 data in order to improve the resolution of the remaining GPS-CP ambiguities, in case of interruption in the data, and the accuracy of the time transfer. First we introduce the method and then we present some first results for common view time transfer in between European stations.

Keywords- Time Transfert; Space; T2L2; GPS-CP

I. INTRODUCTION

Optical time transfer is an evolution of RF techniques that takes advantage from optical signals such as higher modulation bandwidth, insensitivity to ionosphere and mono carrier schemes to improve the performances of remote clocks comparisons [3]. T2L2 is a time transfer technique based on laser ranging network at ground and on a dedicated space segment, the T2L2 instrument. Developed by CNES (Centre National d'Etudes Spatiales) and OCA (Observatoire de la Côte d'Azur), this instrument has been launched in 2008 with the Jason-2 satellite for a 3 year mission. It celebrated its fifth in orbit anniversary in June 2013 and its mission is now extended until the end of 2014.

T2L2 relies on the propagation of laser pulses between the clocks to be synchronized. It provides the capability to compare today's most stable frequency standards with unprecedented stability and accuracy. Expected T2L2 performances are in the 100 ps range for accuracy, with ultimate time stability about 1 ps over 1,000 s and 10 ps over one day. The objectives of the T2L2 experiment on Jason-2 are threefold:

- Technological validation of optical time transfer, including the validation of the experiment, its time stability and accuracy and of one way laser ranging.
- Characterization of the onboard Doris oscillator for Jason-2 purposes and a contribution to the Jason-2 laser ranging core mission.
- Scientific applications such as time and frequency metrology (comparison of distant clocks, calibration of RF links), fundamental physics (such as anisotropy of the speed of light), earth observation or very long baseline interferometry (VLBI).

Among these objectives, a special attention was paid on the assessment of the accuracy of the time transfer. This assessment had been done both in zero baseline / common clock configuration and in common view, comparing T2L2 with other technique such as GPS Carrier Phase (GPS-CP) and Two Way Satellite Time and Frequency Transfer (TWSTFT).

II. BACKGROUND

A first comparison between T2L2, GPS-CP and TWSTFT was performed between June and October 2010 during the 2nd T2L2 international campaign. Among the laser stations involved in this campaign, two sites were of a particular interest: The SYRTE / Observatoire de Paris (OP) and the Plateau de Calern / Observatoire de la Côte d'Azur (OCA). Those 2 sites were equipped with GPS receivers, TWSTFT stations, cold atoms clocks and Satellite Laser Ranging Stations. Comparison of the different T/F transfer techniques on the link between OP and OCA, regardless of absolute aspects (the links were not calibrated), showed that the noise between T2L2 and GPS or TWSTFT remained within 2 ns

during the 60 days of the campaign, with no relative drift, at least at the nanosecond level [4].

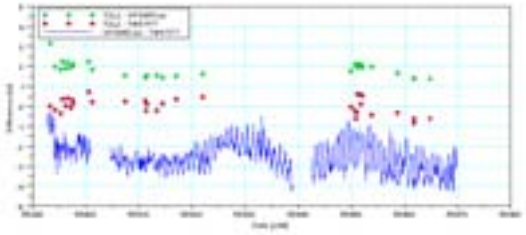

Figure 1. Comparison between T2L2, GPS and TWTFT on the link OP-OCA : T2L2-GPS (green), T2L2-TWSTFT (red) and TWSTFT-GPS (blue) (The offset between each curve was adjusted to facilitate the graph reading)

For this first comparison GPS time transfer was computed using a Carrier Phase Time Transfer / Precise Point Positioning method with ambiguity resolution on single-difference measurements developed by CNES [2]. Typical performances of the method are given in Figure 2, with frequency stability of a few 10^{-15} for integration times around 10^5 s.

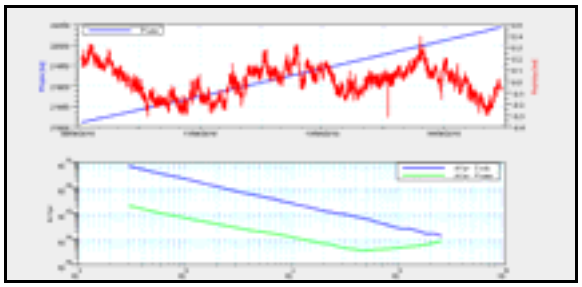

Figure 2. Typical performances of GPS Carrier Phase Time Transfer / Precise Point Positioning method with ambiguity resolution on single-difference measurements (OP/Z12-T vs OCA/GTR50 link, H-Masers)

One of the main benefits of this method is to combine phase measurements on L_1 and L_2 GPS carriers so that the phase ambiguity becomes a round number of what one calls the "Narrow Lane". The Narrow Lane is defined as

$$\lambda_c = \lambda_1\lambda_2 / (\lambda_1 + \lambda_2),$$

Where λ_1 and λ_2 are the wavelengths of the two GPS carriers. Its wavelength is 10.7 cm or 0.356758 ns. Thus, it is possible to identify, and then correct, Narrow Lane's ambiguities inside a given data set. But this correction is only relative, not absolute: An uncertainty remains and the results could be shifted by an integral number of λ_c. As far as the data set is continuous, the uncertainties are the same. Nevertheless, any gap in the data, or the necessity to process data by discontinuous batches (Figure 6), could lead to a change in this uncertainty from one data set to the next one and to induce some jumps.

Somehow, the first T2L2/GPS comparison confirms this phenomenon. The differences between T2L2 time transfer and GPS solutions extrapolated at T2L2 dates exhibit some jumps between the mean values of each period. And amplitudes of jumps are exactly an integral number of Narrow Lane wavelengths λ_c (Figure 3). We can take benefit from expected T2L2 long term stability and accuracy to identify and fix theses jumps. Since there is no other "100 ps" accurate time transfer available today (except T2L2), these jumps clearly introduce some limitation in our capability to validate this absolute and accurate comparison between T2L2 and GPS-CP time transfer.

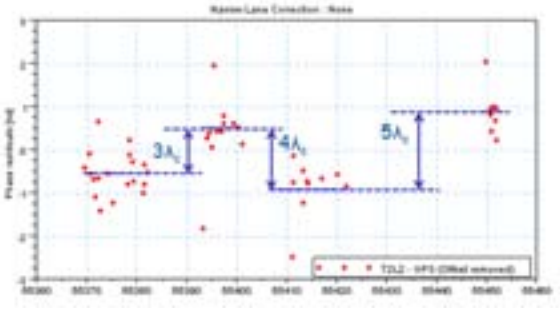

Figure 3. Difference between T2L2 and GPS ground to ground time transfer (115 ns offset removed)

III. ATTEMP TO FIX RESIDUAL NARROW LANE AMBIGUTIES

The idea there is to see if GPS data are self-sufficient to allow identification and correction of residual Narrow Lane ambiguities. Two main assumptions are done:

- First, the code time transfer is supposed to be unambiguous (with respect to Narrow Lane ambiguity) and accurate,
- Second, the Narrow Lane ambiguity introduces simple and constant "jumps" of an integral number of λ_c between code and phase solutions for the time transfer.

Two methods will be evaluated here:

- One based on a least square approach and called hereafter the 'Quadratic Fit' method,
- One based on an averaging process and called here after 'Average Differences' method.

Their aim is to identify the Narrow Lane offset NL_{Ofs} between the phase and the code, and then to remove this offset from phase data.

A. *'Quadratic Fit' method*

The method relies on the adjustment of a 2nd order polynomial within code and phase data using the least square method. But whereas all the coefficients of the polynomial are adjusted within phase data, only the zero-order coefficient (time offset) is adjusted within code data, other coefficients being the same as the ones identified using phase data. The Narrow Lane offset between code and phase is then simply the difference between the two zero-order coefficients, modulo the Narrow Lane wavelength:

- Step 1 : Phase ⇨ $P = \mathbf{a_{0p}} + a_{1p} \times t + a_{2p} \times t^2$
- Step 2 : Code ⇨ $C = \mathbf{a_{0c}} + a_{1p} \times t + a_{2p} \times t^2$
- Step 3 : $NL_{Ofs} = \text{round}((\mathbf{a_{0c}} - \mathbf{a_{0p}}) \text{ modulo } \lambda_c)$
- Step 4 : $P = P + NL_{Ofs} \times \lambda_c$

Note: In order to reduce influence of outliers during code processing (step 2), it is possible to improve the process by rejecting them (k-sigma filtering).

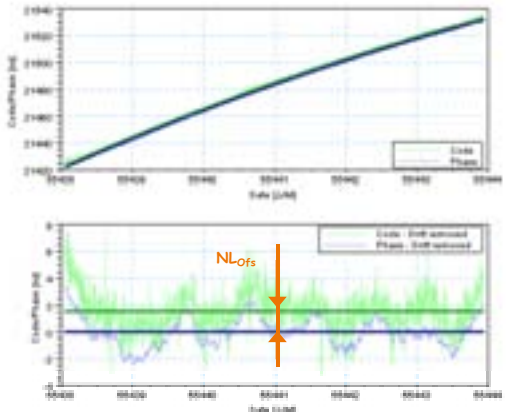

Figure 4. 'Quadratic Fit' method : Least square polynomial is performed within the full data setadjustement

B. *'Average Differences' method*

The method aims at taking advantage of the τ^{-1} behavior of the stability of the time transfer (Figure 2): For long integration periods, one can 'average' the noise on both code and phase measurement (up to reach the stability of the clocks), and it could be possible to compute the difference between code and phase time transfer with an uncertainty lower than the Narrow Lane wavelength.

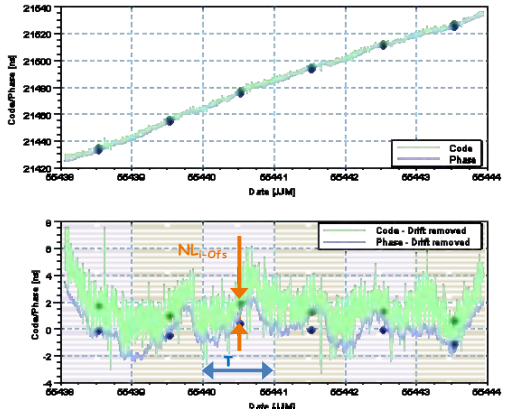

Figure 5. 'Average differences' method : Averaging on code and phase is computed for each period τ

Thus, for each adjacent window of length τ, we compute first the average code and phase values and then the offset, modulo the Narrow Lane wavelength, between these two values. At the end, the overall Narrow Lane offset between code and phase will be the median of individual offsets:

- Step 1 : Compute $\langle P_i \rangle$ and $\langle C_i \rangle$ for each period i,
- Step 2 : $NL_{i\text{-}Ofs} = \text{round}((\langle C_i \rangle - \langle P_i \rangle) \text{ modulo } \lambda_c)$
- Step 3 : $NL_{Ofs} = \text{median}(NL_{i\text{-}Ofs})$
- Step 4 : $P = P + NL_{Ofs} \times \lambda_c$

With respect to clocks and GPS-CP performances, typical length τ of the averaging window will be of some 10.000 seconds.

C. *Preliminary validation*

The validation has been performed on a 'continuous' data set, using WTZA (Wettzell, Germany) and OPMT (Paris, France) receivers between JJM 55328 and JJM 55456. We processed data by batches of 5 + 1 (overlapping) days. Such a configuration allows a simple identification and a 'manual' correction of the Narrow Lane offset, by simple difference between the 2 solutions during overlapping periods (Figure 6). Thus, resulting from this 'manual' processing, we will have our 'reference' solution (The solution is still not absolutely accurate, the Narrow Lane of the first batch being arbitrary fixed).

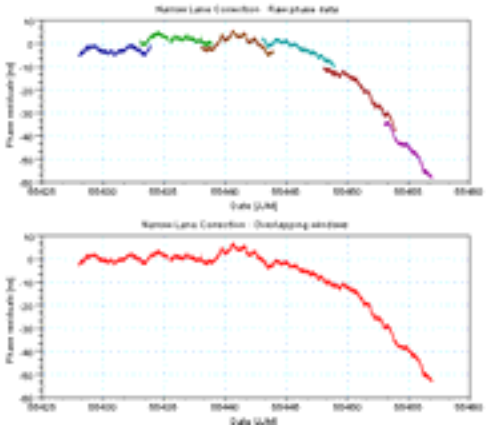

Figure 6. Data set and 'reference' solution: Phase residuals before (top, offset has been emphasized for the plot) and after (bottom) manual identification and correction of the narrow lane jumps

First results are questionable:

- Table 1 shows that each method gives a different result. Figure 7 confirms that, if the phase solution is perfectly continuous with manual corrections, some jumps remain whether we use 'Average differences' or 'Quadratic fit' methods.
- Table 1 also shows that, if the 'Quadratic fit' method seems to be rather insensitive to the filtering level, the 'Average differences' method is more sensitive to the integration time. And it is not really possible to define an optimal integration time with respect to the 'reference' solution.
- However, the standard deviation of the (code – phase) residuals (last row of Table 1) is slightly better when using our 'automated' methods than with the reference solution. Indeed, it seems to have a small differential slope between code and our phase 'reference' solution (Figure 7, top).

Batch	Ref	Quadratic fit			Average Differences		
		K=3	K=6	K=9	$\tau=10^4$	$\tau=10^5$	$\tau=10^6$
1	**0**	0	0	0	0	0	0
2	**0**	2	2	2	2	1	2
3	**3**	4	4	4	4	4	5
4	**-3**	-1	-1	-1	-1	-2	3
5	**-4**	1	1	1	1	0	0
6	**-1**	3	3	3	3	3	3
StdDev	***1.99***	***1.35***	***1.35***	***1.35***	***1.35***	***1.35***	***1.35***

Table 1. Results of the Narrow Lane identification : Each method produces each one solution (Relative comparison, the first offset is enforced to 0). The StdDev row gives the standard deviation, in ns, of the (code – phase) residuals

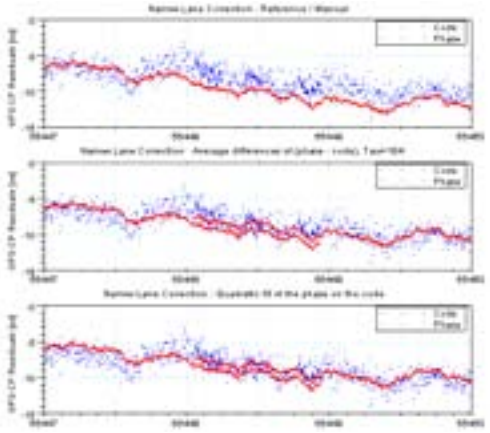

Figure 7. Zoom on an overlapping period : Whereas the 'manual' correction allows to align phase solutions, some jumps remain wthever we use 'Average difference' or 'Quadratic fit' methods

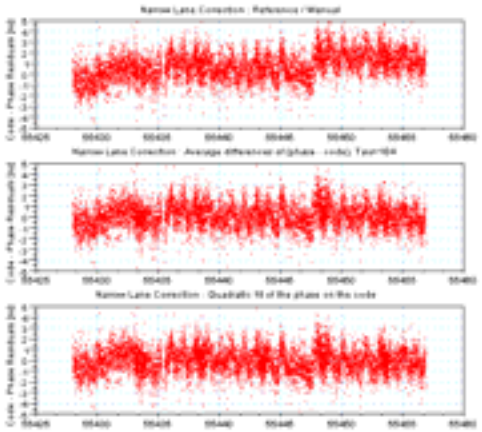

Figure 8. (Code – Phase) residuals : 'Reference' solution seems to exhibit a smal drift (top) which is not present with 'Average difference' or 'Quadratic fit' methods

This last point is confirmed by the analysis of the (Code – Phase) residuals (Figure 8): A slope appears in the reference solution (top), whereas the residuals are almost flat with 'Average difference' or 'Quadratic fit' methods. It suggests that the assumption of the consistency of code and phase solutions have to be more deeply investigated.

IV. CONCLUSION

Comparison of T2L2 and GPS-CP has demonstrated the necessity to improve the identification of Narrow Lane ambiguities to allow absolute and accurate comparison of the two systems. Different identification methods were evaluated in this paper, nevertheless the results are not reliable enough and some points need to be investigated around the consistency between code and phase solutions in GPS-CP time transfer.

This study of Code / Phase consistency can take place on two levels:

- Extending the comparison of T2L2 and GPS-CP for long batches with continuous GPS and T2L2 data set, to confirm that T2L2 can provide an independent method to identify Narrow Lane residual ambiguity. The fact that a large amount of data is now available should facilitate this analysis;
- Trying to understand the root cause of this inconsistency: does it come from the GPS measurements or from the receivers or is it introduced by the data processing?

However, it is still possible to identify Narrow Lane jumps using T2L2 as a reference, at least in a relative way. Moreover, with an accuracy better than 100 ps, T2L2 should allow an absolute identification of Narrow Lane's jumps and thus an absolute / accurate (but not really independent) comparison with GPS-CP. As soon as these will be achieved, T2L2 comparisons could permit to calibrate GPS-CP links at the 100 ps level and to improve the understanding of both the physics and the metrology involved in such CP technology.

ACKNOWLEDGMENT

The authors wish to thank the FTLRS and MeO teams from the OCA for operating the SLR stations, SYRTE staff for their welcome and support at the Observatoire de Paris, IGS, SYRTE and Wettzell teams for their GPS data and F. Mercier (CNES, GPS PPP software) for its software and support.

***Abstract*—We present first results on the spectroscopy of the $^1S_0 \rightarrow {}^3P_0$ transition at 578 nm in a transportable ^{171}Yb optical lattice clock. With the Yb atoms confined in a one-dimensional optical lattice, we have observed linewidths below 200 Hz, limited by saturation broadening. Currently the system is being upgraded towards full clock operation and use of more compact and robust subsystems.**

I. Introduction

Optical lattice clocks based on elements with two valence electrons are strong competitors in the quest for next generation time and frequency standards. Promising results have already been obtained in several stationary setups using Sr [1]–[4], Hg [5], Mg [6] and Yb [7], [8]. In particular, a record instability in the 10^{-18} range has recently been demonstrated for Yb lattice clocks [9]. However, in addition to stationary setups, transportable clocks are desirable for a variety of reasons. The ability to transport them and compare them with other frequency standards allows for a performance evaluation beyond what is possible with standards at a single institute. Furthermore, many applications, e.g. geodesy and ground stations for space missions, will benefit from transportable optical clocks. Last but not least, sending optical clocks into space will allow greatly improved tests of fundamental physics [10].

In the framework of the ESA candidate mission "Space Optical Clock", an optical lattice clock is foreseen to be operated on the ISS around the year 2018. As part of technology development towards that goal, breadboard and transportable lattice optical clock demonstrators using Sr and Yb are being developed in a EU FP7 project [11].

Our transportable Yb clock system is based on compact diode lasers (399 nm, 1156 nm frequency doubled in a PPLN waveguide, 759 nm) and a fiber laser (1111 nm frequency doubled in a PPLN waveguide), and features an intra-vacuum enhancement resonator to allow the formation of a large-volume one-dimensional optical lattice using moderate laser power. Our current experimental setup for the atom source is shown in figure 1a and comprises an optical table of $2\,\mathrm{m} \times 1\,\mathrm{m}$ for the optical and vacuum setup and approximately two standard 19" rack shelves of non-optimized electronics.

This does not include the clock laser setup shown in figure 1b, which takes up another 90 cm × 120 cm breadboard and is currently located in another laboratory. Here a commercial ECDL is frequency doubled and stabilized to sub-Hertz linewidths using a highly stable ULE cavity [12]. A phase-stabilized 300 m intra-building fiber link connects this setup to the atom apparatus, where after frequency doubling 1.5 mW are available for spectroscopy.

(a) Atom apparatus (b) Clock laser

Fig. 1: Photographs of the experimental setup, showing (a) the atom source including the lattice and cooling lasers and (b) the clock laser setup.

A. Atom source

The ytterbium atoms are loaded into the first-stage MOT on the $^1S_0 \rightarrow {}^1P_1$ transition at 399 nm with a typical time constant of 500 ms, resulting in 10^7 atoms after 2 s loading time. The second-stage MOT operating on the $^1S_0 \rightarrow {}^3P_1$ transition at 556 nm, optimized for temperature, contains several times 10^5 atoms at a temperature of around 25 µK.

From this second-stage MOT the atoms can be efficiently transferred to the optical lattice. By using an intra-vacuum enhancement resonator, we achieve a circulating laser power of 10 W, corresponding to a trap depth of 40 µK in a large volume trap (155 µm trap radius) using a moderate laser power of a few hundred mW. Due to good matching of the lattice to the volume of the postcooling MOT, we routinely achieve transfer efficiencies in excess of 20 % for atom temperatures of $\sim$ 25 µK. The addition of optical pumping on the $^1S_0 \rightarrow {}^3P_1$ transition will allow us to spin polarize the atoms. After the clock probe pulse is applied, the atoms remaining in the ground state are detected by fluorescence on the $^1S_0 \rightarrow {}^1P_1$ transition.

When operating at an appropriate oven temperature, the

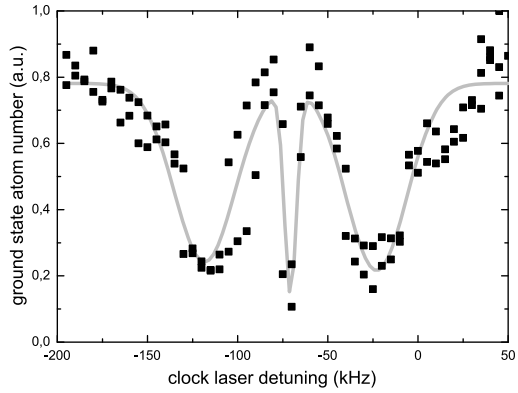

Fig. 2: Spectrum of the clock transition using the chopped lattice technique. The number of atoms remaining in the ground state after the chopped lattice sequence is plotted as function of the detuning of the clock laser.

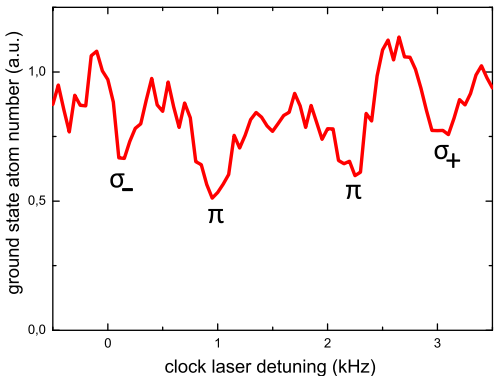

Fig. 3: Spectrum of the clock transition with the atoms held in a one-dimensional optical lattice in the presence of a magnetic bias field. The number of atoms remaining in the ground state after the clock pulse is plotted as function of the detuning of the clock laser. The four Zeeman components of the transition can be resolved.

total cycle time can be reduced to below 1 s while retaining sufficient signal from the atoms captured in the lattice.

B. Spectroscopy on the clock transition

In order to rapidly locate the clock transition, we use a *chopped lattice* technique, similar to that applied during the first frequency measurement of this transition [13]. Alternating short pulses of 578 nm light to excite the clock transition and of 556 nm light to retrap and cool the atoms allows us to achieve high contrast signals, with observed linewidths adjustable between a few kHz and hundreds of kHz. The retrapping pulses allow us to interrogate the atoms for several trap lifetimes, thus yielding a high contrast even for incoherent excitation due to loss of excited atoms. Figure 2 shows a spectrum obtained in this manner. The sharp carrier transition is clearly visible, surrounded by sidebands corresponding to motional excitations in the lattice. The sideband spacing corresponds to a trap depth of 40 µK.

Probing the transition on atoms trapped in the lattice we have successfully resolved the Zeeman components and achieved linewidths of less than 200 Hz, consistent with saturation broadening. A typical spectrum is shown in figure 3. The observed Zeeman splitting is due to a magnetic background field of ~ 2.5 G, which for clock operation will be partially compensated using the magnetic coils.

C. Next generation laser systems

Having demonstrated the capabilities required to operate our experimental apparatus as an optical clock, we are currently improving several aspects of the experimental setup, with a focus on more compact and robust subsystems. In particular, we are replacing most laser systems by more compact modules promising better performance. While several hours of hands off operation have been achieved with the previous setup, we are striving for improved reliability as well as a more compact and modular overall system.

For the first-stage cooling and detection at 399 nm we have developed a new laser system shown in figure 4, comprising two injection-locked diode lasers. For the generation of

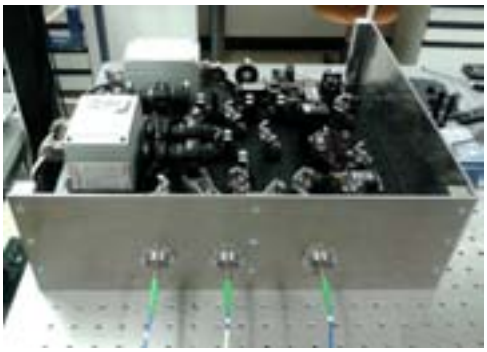

Fig. 4: New 399 nm laser system module during testing. The grey boxes contain the master ECDL and two slaves respectively. The whole system fits into a 19" rack shelf and all outputs are fiber coupled.

seed light, we are investigating several setups, among them AR coated laser diodes in an interference-filter-based ECDL design [14], developed in collaboration with the University of Hannover (LUH). The master as well as the two slave lasers and all frequency generation steps for frequency stabilization, slower and precooling MOT are contained on a $45\,\mathrm{cm} \times 45\,\mathrm{cm}$ breadboard with fiber outputs.

An interference filter based design from LUH is also currently being evaluated for the generation of the lattice light at 759 nm. Together with a new enhancement resonator providing higher finesse and tighter focusing, this self-injecting tapered amplifier will present a considerable simplification with respect to the current MOPA system consisting of a commercial ECDL and a tapered amplifier.

Our home-built 556 nm laser has already been replaced with an integrated module by Menlo Systems, which directly provides output at 556 nm employing frequency-doubling of a fiber laser, with the actual laser system requiring a volume of only 3 l. Using this system, we have successfully operated the experiment and demonstrated improved atom numbers and

stability in the postcooling MOT.

Additionally, we are currently integrating a DFB laser at $1388\,\mathrm{nm}$ into the experiment, which will be used as a repumper for the upper clock state and allow direct detection of the excited atoms. Together with further efforts to improve detection, this will lead to improved signal quality.

II. Conclusion

We have demonstrated spectroscopy of the clock transition in ^{171}Yb in a one-dimensional optical lattice. We have already observed linewidths of below $200\,\mathrm{Hz}$ and estimate an uncertainty of less than 10^{-14} to be readily achievable with minor modifications to our setup.

The current setup provides a solid foundation for a transportable ^{171}Yb lattice clock. Several ongoing modifications of the experimental apparatus will improve transportability, reliability and performance of the system and will allow rapid characterization of the system for competitive clock operation.

***Abstract*— We present an upgraded setup for cooling and trapping of ytterbium atoms in a optical clock experiment. The experiment aims to cool and trap ytterbium atoms in a two stage magneto-optical trap (MOT) (at 399 nm and 556 nm for the first and second stage, respectively) and to probe the narrow-line clock transition at 578 nm in an optical lattice at the magic wavelength (759 nm). We describe here the generation of all the laser sources and the design of a new physic package, including the vacuum chamber and the atomic source.**

I. Introduction

Optical lattice clock based on ytterbium are being studied and developed worldwide, for example at National Institute of Standards and Technology (NIST) [1], at the National Metrology Institute of Japan (NMIJ) [2] and at the Korea Research Institute of Standards and Science (KRISS) [3]. We present here an upgraded setup for cooling and trapping ytterbium atoms for an optical clock experiment. For the experiment ytterbium atoms have to be cooled and trapped first in a 399 nm magneto-optical trap (MOT) then in a 556 nm MOT. Finally the narrow-line clock transition at 578 nm is probed with the atoms trapped in an optical lattice at the magic wavelength (759 nm). The laser ensemble at Istituto Nazionale di Ricerca Metrologica (INRIM) is now completed and a new physic package is build, including the vacuum chamber and the atomic source.

II. Laser systems

A. Blue laser at 399 nm

In our experiment the blue 399 nm radiation is obtained by second harmonic generation (SHG) from a 798 nm titanium-sapphire (Ti:sapphire) laser using a lithium triborate (LBO) crystal, chosen to achieve high power, stability and tunability [4].

The 798 nm source is a Ti:sapphire laser pumped by a 8 W solid state pump laser at 532 nm that can be tuned from 700 nm to 970 nm and has an output power at 798 nm of 1.3 W with a linewidth < 20 kHz.

Our LBO crystal is $l = 15$ mm long, has a section of 1.5 mm $\times$ 1.5 mm, and is cut for normal incidence with antireflection coating on the faces. To increase the output power at 399 nm the crystal is placed in a bow-tie enhancement cavity, resonant at 798 nm. The cavity has been designed with two concave mirrors (radius of curvature $r = 100$ mm) around the LBO crystal leading to a beam waist inside the crystal of 35 µm [5] close to the optimum value [6]. Total length of the cavity is 715 mm, for a free spectral range of 210 MHz and the distance between the curved mirrors is 114 mm. For maximum stability and simplicity in the alignment we mounted the mirrors on top-actuated mirror mounts placed on a monolithic block of aluminum. One flat mirror is mounted on a small piezo actuator for locking of the cavity on the Ti:sapphire laser with the Hänsch-Couillaud technique. The LBO crystal is mounted on a rotational stage.

The power circulating in the enhancing cavity P_{1c} is related to the power injected in the cavity P_1 by [7]

$$P_{1c} = \frac{P_1 T_1}{\left[1 - \sqrt{(1-T_1)(1-l_{cav})(1-E_{nl}P_{1c})}\right]^2}, \quad (1)$$

where T_1 is the transmission of the input coupler of the cavity and l_{cav} represents the linear losses in the cavity, by the crystal and mirrors other than the input coupler and $E_{nl} = 7.5 \times 10^{-5}\,\mathrm{W}^{-1}$ is the effective nonlinear coefficient for LBO [6]. The optimal input coupler transmission depends on the linear losses and the input power

$$T_1 = \frac{l_{cav}}{2} + \sqrt{\frac{l_{cav}^2}{4} + E_{nl}P_1}. \quad (2)$$

We estimated a linear loss in the cavity coming from the mirrors and the coating on the faces of the crystal $l_{cav} \sim 4 \times 10^{-3}$. For a well matched input power of 1.1 W the transmission of the input coupler was chosen $T_1 = 0.012$

Figure 2 shows experimental data for the SHG power at 399 nm as a function of the input power. The output has a maximum at 0.65 W with 1.2 W of input power; the SHG efficiency is 54 %. The same figure shows also a theoretical prediction. Theory and experimental data are well matched; they slightly diverge at high power because each data point was taken without re-alignment of the optics. This system replaced a similar one that used a periodically-poled potassium titanyl phosphate (PPKTP) crystal that was found to be too absorptive at 399 nm and was delivering a maximum output power of 60 mW.

To cope for the long term frequency drift, the laser is locked to the atomic resonance by transverse spectroscopy on an auxiliary ytterbium beam. This source at 399 nm will be used for the blue MOT, for a slower beam, and for a resonant probe beam for detection since it has enough power.

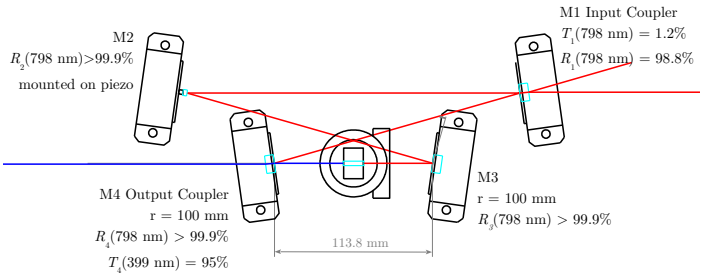

Fig. 1. Draw of the cavity for the SHG of 399 nm with the LBO crystal.

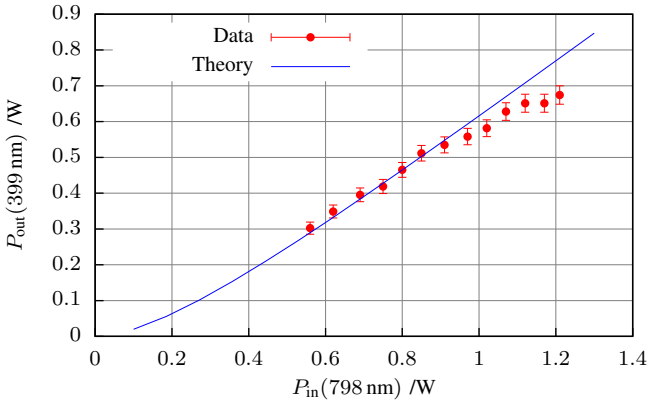

Fig. 2. SHG power as a function of input power. The continuous line is theoretically calculated for $T_1 = 0.012$ and $l_{cav} = 3.8 \times 10^{-3}$.

B. Green laser at 556 nm

The green 556 nm radiation is obtained by SHG from a 1112 nm fiber laser using a PPKTP crystal.

The 1112 nm laser source is a ytterbium doped fiber laser. It has a maximum output power of 10 mW at this wavelength and a linewidth $<$ 20 kHz. The output of the fiber laser is amplified by a fiber amplifier up to 2 W.

The amplified laser is send on the non-linear crystal using free-air optics. The PPKTP crystal is 20 mm long and used in single pass. It is held in a copper oven for temperature stabilization. The laser is focused on the crystal with a waist close to the optimum value of 35 µm [6]. Two mirrors for the visible wavelengths are used to filter the infrared light before the green is sent to the acousto-optic modulators (AOMs) and the fiber couplings needed for the experiment.

Up to 22 mW of 556 nm light has been obtained starting from 1.3 W of 1112 nm measured at the crystal. The frequency of the green laser is locked to the resonance of an ultrastable cavity.

C. Lattice laser

The Ti:sapphire laser that will be used as optical lattice is a M Squared SolsTiS pumped by a solid state pump laser at 10 W. It has a maximum output power of 3.2 W at the magic wavelength 759 nm. We have estimated its linewidth to be less than 20 kHz by comparison with another Ti:sapphire laser.

This source is able to provide large trap depths both for 1D and multidimensional lattice configurations. For example about 1 W of power in the lattice focused to a 35 µm waist gives a trap depth of $500E_r$, where E_r is the recoil energy.

D. Clock laser at 578 nm

The yellow laser at 578 nm is obtained by sum frequency generation (SFG) in a periodically-poled lithium niobate (PPLN), $LiNbO_3$, crystal, using two infrared laser sources (1030 nm and 1319 nm).

The 1319 nm source is a monolithic neodymium-doped yttrium aluminium garnet (Nd:YAG) laser with an output power of 90 mW. The 1030 nm source is an erbium fiber laser with 80 mW output power. The linewidth of both lasers is less than 10 kHz

The crystal is a waveguide, magnesium-doped, PPLN device. Infrared light of both lasers is delivered to the crystal through a polarization-maintaining fiber coupler (Y-shaped). The output of the coupler is a bare fiber, and it is simply put near to the input face of the crystal to couple the light with the non-linear waveguide (the distance is of the order of 1 µm). Being a waveguide crystal, the infrared lasers are coupled to one of 32 working channels where are tightly confined over the length of the crystal (20 mm). This design avoids problems arising from the focusing of the beam, diffraction, or walk-off angles. The output power is maximized by tuning the temperature of the crystal. We have obtained up to $P_{out} = 12$ mW of laser at 578 nm which represents the damage threshold of the crystal.

The frequency of the yellow laser is stabilized using the Pound-Drever-Hall technique on a ultra-stable cavity entirely made of Corning Ultra Low Expansion glass (ULE) and a length of 10 cm. Once locked, it has a stability of 3×10^{-15} at 1 s of integration time or a linewidth $<$ 2 Hz [8]. An improved setup using a cavity with fused-silica mirrors is planned for the near future [9].

III. Physics Package

A. Description of the chamber

Figure 3 shows a scheme of the vacuum chamber and of some of its features. The atomic source is an effusion oven at 400 °C that produces a collimated atomic beam.

The core of the design is a custom aluminum chamber for the trapping region with 6 lateral viewports (diameter 40 mm) and two larger horizontal viewports (diameter 70 mm). The other components are standard stainless steel fittings. Indium sealing is used for the viewports on the aluminum chamber (a similar solution has been adopted in the strontium optical clock at LNE-Syrte in Paris). Indium is used also between a flat-flat mating achieved using a K flange transition for sealing together aluminum and stainless steel. This solution allows for a wide area of the viewports to be available for optical access but requires only a small retaining force reducing the induced birefringence in the glass. For this reason it is preferred to Kasevich-style sealing.

Using indium-sealing, all the surface of the viewports can be coated because no flange shadows the deposition of the coating. The anti-reflection coating of the viewports is especially made by ATFilms for all the wavelengths of interest.

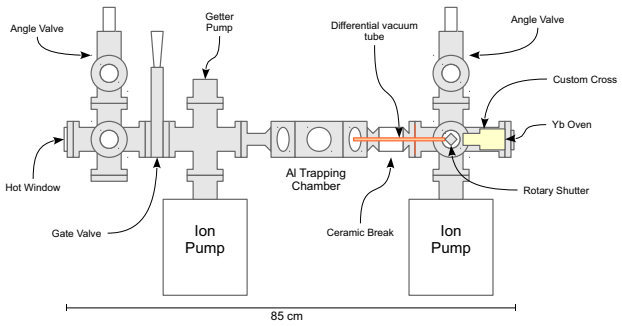

Fig. 3. Scheme of the improved vacuum chamber.

The reflectivity for the blue 399 nm is $R = 0.08\,\%$, for the green 556 nm $R = 0.1\,\%$, and for the clock laser at 578 nm is $R = 0.03\,\%$. The anti-reflection coating is especially important at the magic wavelength 759 nm ($R = 0.05\,\%$), anticipating an external enhanced cavity for the lattice.

The chamber is designed without a Zeeman slower. Instead the distance between the trapping region and the atomic source is made as short as possible to maximize the atomic flux. The distance between the oven nozzle and the MOT region is 21 cm. Considering the atomic beam divergence from the oven the flux of atoms is 5 times larger than for an hypothetical setup with the oven at 60 cm [10].

A differential-vacuum tube divides the oven side of the structure from the clean trapping region. The differential-vacuum tube has internal radius 2.5 mm and length 120 mm. It is designed to maintain a pressure ratio between the two sides of 100 both for nitrogen and hydrogen. This means that a vacuum pressure of 10^{-10} mbar in the clean side of the chamber is compatible with a pressure of 10^{-8} mbar on the oven side.

The oven is made by a stainless steel reservoir and it is heated under vacuum [11]. At the exit of the reservoir ~ 37 stainless steel capillaries are used to collimate the atomic beam. Between the oven nozzle and the differential-vacuum tube is placed a shutter that can turn off the atomic beam. The shutter is based on a rotary feedthrough, whose shaft can rotate at high speed. During clock operations the shutter will prevent scattering of the trapped atoms with the thermal beam. It will also shield the blackbody radiation from the oven and thus simplify the evaluation of the blackbody radiation shift on the clock transition.

Facing the oven nozzle, on the clean side, a window is used for a slower laser beam, counterpropagating the atomic beam. The windows is heated at 230 °C to prevent deposition of ytterbium.

Two angle valves are used for connection to turbo-molecular pumps. On both sides there is an ion pump of nominally 40 L/s speed. On the clean side there is also a non-evaporable getter pump. The getter pump is a passive pump for hydrogen (H_2) but also pumps water and carbon oxide. The getter pumping speed for hydrogen is 50 L/s.

B. Preliminary results

All the indium seals and the other flanges has been helium-checked at a level of 1×10^{-12} mbar L/s. The pressure in the trapping region is 1×10^{-9} mbar with the oven temperature 400 °C, limited by the pressure in the oven side 6×10^{-8} mbar. The atom lifetime in the lattice is expected to be ~ 3 s at this pressure, that is more than enough for clock operations. At room temperature the pressure on the trapping chamber is $< 5 \times 10^{-10}$ mbar.

With the oven at 380 °C the atomic beam flux in the trapping chamber, after the differential vacuum tube, has been measured 5×10^{10} atoms/s (for all Yb isotopes). The flux raises to 1.2×10^{11} atoms/s with the oven at 400 °C. The beam divergence in the chamber is 29 mrad, given by the capillaries in the oven nozzle and not limited by the differential vacuum tube.

C. Capture numbers and simulations

The trapping efficiency can be enhanced increasing the number of atoms with velocity lower than the capture velocity. The atomic beam from the oven can be slowed using a counter-propagating, detuned to the red, laser beam .For this purpose a Zeeman slower is usually used; a space dependent magnetic field is engineered so that the atoms are always kept on resonance while decelerated. Without the magnetic field the effect of the beam is limited because, once slowed down, atoms go out of resonance and are decelerated only for a short portion of their path.

In our setup a Zeeman slower is not used for simplicity. The simply addition of a slower beam usually improves a factor of ten the number of trapped atoms [12], [13]. Moreover a Zeeman slower is usually 50 cm long while without it is possible to keep the setup shorter.

We performed numerical simulations to investigate the possibility of exploiting the magnetic field of the MOT coils in the slowing process [10]. In our configuration the magnetic field gradient in the plane is $A_r = 0.23$ T/m. Considering the mean radius of the coils 5.5 cm we expect a maximum magnetic field of 13 mT in the plane between the coils.

We assumed a capture velocity of 30 m/s and a thermal beam at 400 °C. Considering ^{171}Yb (isotopic abundance 14.3 %), the fraction of atoms below thermal velocity (4×10^{-4}) and the measured atomic flux we obtain a capture rate in the MOT $R = 7 \times 10^6$ atoms/s without any slower beam. For a linera loss rate in the MOT $\alpha \simeq 2$ s this corresponds to a number of atoms in the MOT of $N_{\max} \sim 3 \times 10^6$.

Two example of the effects of a slower beam are simulated in fig. 4. The plots shows the trajectories in the phase space for atoms with different initial velocities 20 cm far away from the MOT center, with a fixed detuning and polarization of the slower beam. The gray thick line shows the space-dependant velocity at which the atoms are resonant with the light because of the magnetic field, given the slower detuning. The top figure shows the simpler approach. This is a simulation with detuning $\delta = -150$ MHz and polarization σ^-. With this polarization the magnetic field from the coils pushes slower atoms out of resonance and the slower is effective only far away from the MOT center. There is not enough space to slow down faster

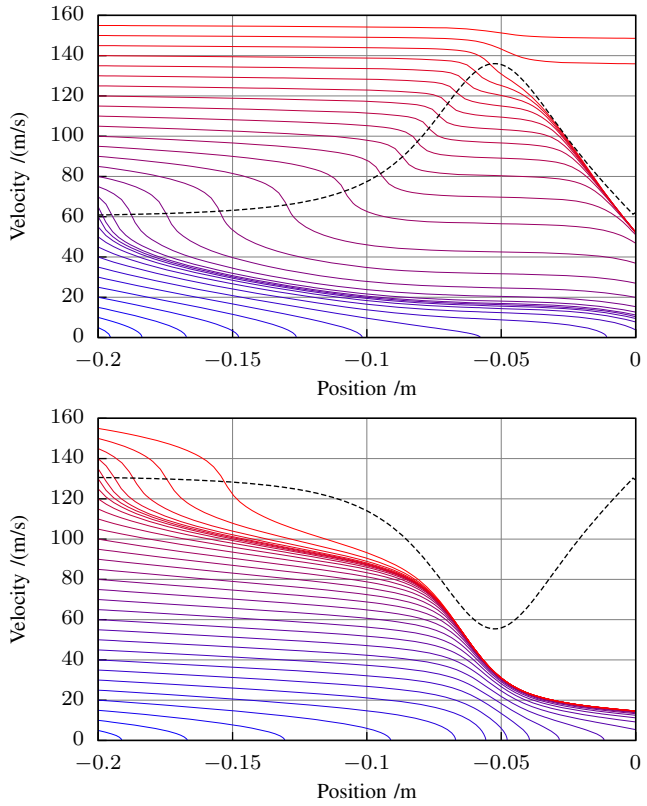

Fig. 4. Numerical simulation of the trajectories in the phase space for atoms slowed by a beam with: top, power $P = 8\,\mathrm{mW}$, waist radius $w = 4\,\mathrm{mm}$, detuning $\delta = -150\,\mathrm{MHz}$, polarization σ^-; bottom, $P = 20\,\mathrm{mW}$, $w = 4\,\mathrm{mm}$, $\delta = -330\,\mathrm{MHz}$, polarization σ^+. The thick broken line shows the velocity at which the atoms are resonant with the light, modulated by the total magnetic field of the MOT coils. The MOT is at position 0 cm with the atoms moving from left to right.

atoms brought in resonance by the magnetic field gradient of the MOT. In this configuration atoms with initial velocity $v_\mathrm{i} = 60\,\mathrm{m/s}$, usually not captured by the MOT, are brought to a velocity of $v_\mathrm{f} = 20\,\mathrm{m/s}$ that is below the capture velocity. Simulations predicts an increase of 50 for the number in the MOT respect at the case withouth the slower beam, or a fraction of atoms below the capture velocity of 2.0 % for a capture rate of $R = 3.4 \times 10^8$ atoms/s and a maximum number of atoms in the MOT $N_\mathrm{max} \sim 1.7 \times 10^8$.

The bottom figure shows a different approach, with the beam further detuned to $\delta = -330\,\mathrm{MHz}$ and polarization σ^+. With this polarization the leaking magnetic field can be used to keep atoms in resonance, achieving a makeshift Zeeman slower. This configuration is predicted to be more efficient than the previous one, with a gain in the atom number of 200, a fraction of atoms below the capture velocity of 7.6 % for a capture rate of $R = 1.3 \times 10^9$ atoms/s and a maximum number of atoms in the MOT $N_\mathrm{max} \sim 7 \times 10^8$.

***Abstract*— An Al^{+} ion optical clock is under development at Huazhong University of Science and Technology in China. We have successfully crystallized Magnesium ions. Through micro-motion compensation and trapping parameters optimization, temperature of a trapped single ion is lowered to be around 19 mK.**

Keywords- optical clock; Al ion; laser cooling; ion trap

I. INTRODUCTION

The $^{1}S_0$ - $^{3}P_0$ transition of $^{27}Al^{+}$ at 267.4 nm has long been recognized as an excellent optical clock transition candidate. Here we give a progress report on an $^{27}Al^{+}$ ion optical clock developed at Huazhong university of Science and Technology in China. The first stage design goals for the $^{27}Al^{+}$ ion optical clock are an inaccuracy level of 10^{-17} and a stability of $10^{-16}/\sqrt{\tau}$. The implementation of the $^{27}Al^{+}$ ion optical clock will be through quantum logic spectroscopy (QLS), as first proposed by NIST [1]. A single $^{25}Mg^{+}$ ion will be trapped together with a single $^{27}Al^{+}$ ion. The $^{25}Mg^{+}$ ion acts as the logic ion and is used for sympathetic cooling and internal state detection of the $^{27}Al^{+}$ ion.

II. EXPERIMENT SETUP

In our experiment, we use a 285 nm fourth harmonic generation (FHG) laser and a 394 nm laser to photo-ionize Mg and Al atoms respectively, and we use a single 280 nm FHG laser system to cool and detect Mg ions. A 267.4 nm FHG laser is served as clock laser of Al ion, and a 267.0 nm laser as a shelving laser for the purpose of quantum logic.

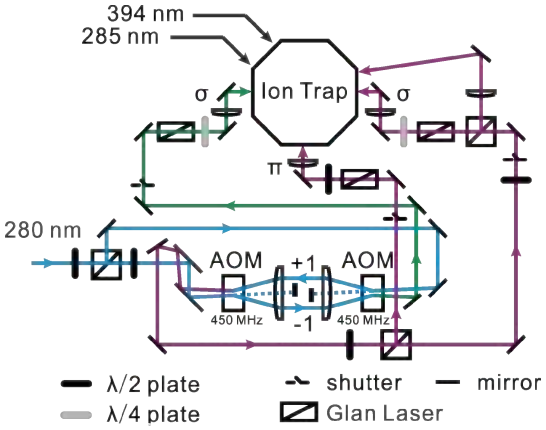

Figure 1. Experimental setup of Mg ion trapping

The 280 nm and 285 nm laser is frequency quadrupled from a 1120 nm and a 1140 nm laser respectively, and each of them can be digitally locked to a high precision wavemeter. The 560 nm second harmonic generation (SHG) of 1120 nm is locked to the transition of molecular I_2 or the wavemeter for long term stability. An electro-optic modulator (EOM) is placed between the SHG and FHG cavity of the 280 nm laser, which is used for generating 9.2 GHz sidebands [2]. The blue sideband of the laser will be used for Doppler cooling and state detection of $^{25}Mg^{+}$, while the carrier of the laser is used for Raman sideband cooling of $^{25}Mg^{+}$.

Experimental setup of Mg ion trapping is shown in Fig.1. The 280 nm laser used for laser cooling of Mg ions has been separated into two lights. Each light passes through two acoustic-optic modulators (AOMs) with a 447.5 MHz drive frequency to generate two lights with a 1.79 GHz frequency difference. The higher frequency one is further separated into three light beams. One is a σ light for Doppler cooling of $^{25}Mg^{+}$, one is a π light for Raman sideband cooling, and the third is used for micro-motion compensation of the vertical direction.

Figure 2 shows the ultrahigh vacuum system in our experimental setup. A linear ion trap, made of titanium, is placed in the center of the vacuum chamber, which is also made of titanium to reduce magnetic field influence. Two CF63 inverted viewports and two sets of custom-made image lens system are used for maximizing the fluorescence Rate. One of lens system with a 3 times of magnification is used for a photon counting PMT and the other with a 10 times of magnification is for an EMCCD.

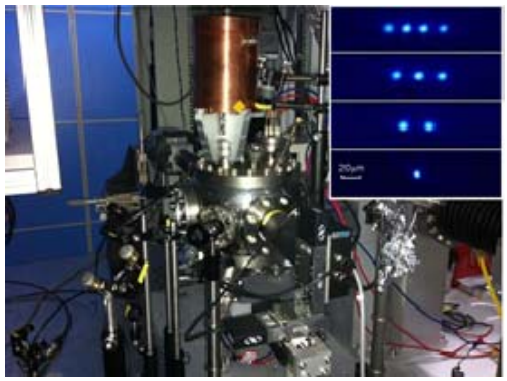

Figure 2. Vacuum system for ion trapping experiments. Inset shows pictures of crystallized Mg ions.

III. Experiment Results

Photo-ionization processing of Mg enables us to observe a strong fluorescence signal of Mg $^1S_0$ - $^1P_1$ transition during loading Mg ions. This signal ensures that the 285 nm laser is tuned to the frequency with high ionization efficiency and is also traveling through the trap center. When suitable parameters of the ion trap are set, we can successfully trap Mg ions and detect fluorescence signals with the help of the 280 nm cooling laser. Crystallized Mg ions are shown in the inset of Fig. 2. One single $^{25}Mg^+$ ion can be stably trapped.

As we know, electric potential experienced by trapped ions is not exactly the same as the ideal linear Paul trap model prediction. In fact, there exist three geometric-depended shielding factors κ_x, κ_y and κ_z for an ion trap. These shielding factors can be evaluated by finite element simulation, and also can be derived by measuring secular motion frequencies of Mg ions which are directly correlated with trap potentials.

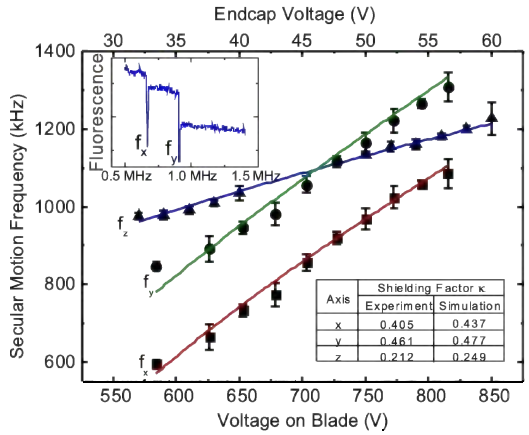

Figure 3. Shielding factors of the ion trap. Experiment results agree with finite element simulation results.

To measure secular motion frequency, we applied an alternating voltage on compensation electrodes, ions will be forced to oscillate with external oscillate electrical field. Resonance appears when the frequency of the electrical field is the same with ions' secular motion frequency. At this moment, fluorescence rate will drop greatly, as shown in the inset of Fig. 3. Shielding factors in three directions are shown in Fig. 3. Experimental results agreed with the finite element simulation results.

Single Mg ion can be trapped by reducing loading time of Mg ions. For a single Mg ion, the collected maximum fluorescence rate depends on the intensity of light and the collection efficiency of the detection system. Our collection efficiency is measured to be 0.27% which is close to the designed efficiency of 0.2%.

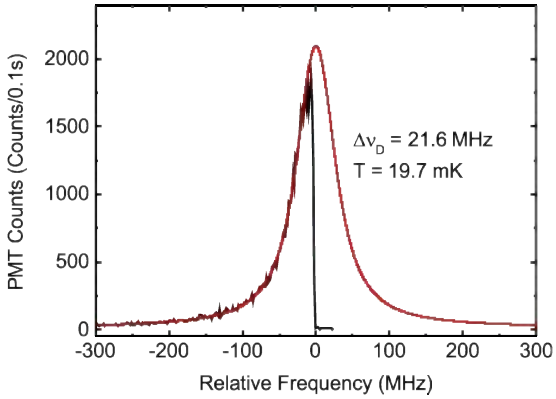

Figure 4. Spectrum of a single $^{25}Mg^+$ and its temperature estimation.

$^{25}Mg^+$ have a nuclear spin of 5/2 with hyperfine structures. Its ground state split into two levels due which is chose as a qubit for Al^+ clock transition detection. Existence of the hyperfine structure can be easily observed with the optical pumping effect, the most distinguish property between $^{25}Mg^+$ and $^{24}Mg^+$/$^{26}Mg^+$. Figure 4 shows the temperature of a trapped single $^{25}Mg^+$ ion can reach about 19 mK through micro-motion compensation and trapping parameters optimization, approaching to Doppler cooling limit.

IV. Conclusion and Outlook

We have successfully trapped single Mg ion and cooled the $^{25}Mg^+$ down to a low temperature to apply Raman sideband cooling for proposed Al^+ optical clock experiment.

***Abstract*—The recent progress of ultra-stable lasers used for $^{27}Al^{+}$ optical frequency standards is presented. Two diode lasers are phase stabilized to ultra-stable ULE cavities, which will be frequency quadrupled to UV as the 267.4 nm $^{27}Al^{+}$ clock laser with sub-Hz level linewidth and the 267.0 nm shelving laser with 100 Hz level linewidth for fast detection respectively. In this report, less than 3 Hz linewidth of IR lasers at 1068 nm are achieved via Pound-Drever-Hall (PDH) stabilization for the 100 Hz shelving laser application. Dynamic analysis of cavity sensitivity to vibration is also presented.**

Keywords—optical clock; ultrastable laser; dynamic analysis

I. Introduction

Optical frequency standards play important roles in high precision metrology, such as high-resolution spectroscopy and test of fundamental physics, etc. [1] [2]. Among all of them, $^{27}Al^{+}$ is one of the most promising candidates for next generation optical clock. The $^{1}S_0 - ^{3}P_0$ transition of Al^{+} ion has a natural linewidth of 8 mHz in 267.4 nm and will offer great stability in both long term and short term range. Because of this ultra-narrow transition, the clock laser is required to have a comparably narrow linewidth, and also an excellent long term stability. Moreover, for a narrow transition, its lifetime is too long to be detected, thus a shelving transition from $^{1}S_0$ to $^{3}P_1$ is needed for fast detection, as shown in Fig. 1. In this case, a shelving laser with sub-100 Hz level linewidth at 267.0 nm is also required. This report is about the recent progress on the development of ultra-stable lasers used for $^{27}Al^{+}$ optical clock.

II. Experimental Setup

To develop a shelving laser with 100 Hz linewidth, a diode laser at 1068 nm is phase locked to an ultra-stable ULE cavity (Cav1 in Fig. 2) via Pound-Drever-Hall (PDH) stabilization [3]. It is frequency quadrupled to 267.0 nm UV light for the de-shelving applications. For the clock transition, another diode laser at 1070 nm is locked to the same cavity as pre-stabilization, then to another independent cavity (Cav2 in Fig. 2) for a second stage locking. Its frequency will be quadrupled to 267.4 nm as the clock laser for $^{27}Al^{+}$.

The experimental setup is shown in Fig. 2. Two identical notched cavities are mounted inside two vacuum chambers with pressure at 10^{-8} mbar level on their optimal supporting position, where both the vibration-induced length variation and mirror tilting of the cavity are eliminated. Cavities are

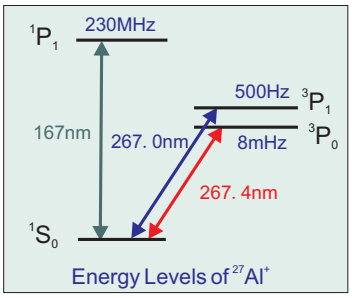

Fig. 1. Energy levels of $^{27}Al^{+}$ involved in optical clock application.

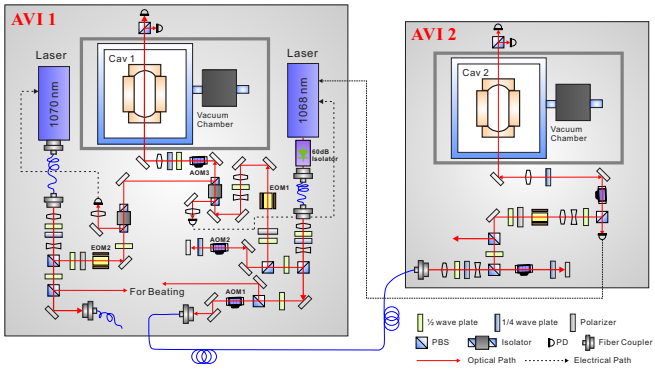

Fig. 2. Experimental setup of ultra-stable lasers for $^{27}Al^{+}$ frequency standard.

made of ultra low expansion (ULE) materials with a zero-crossing temperature of coefficient of thermal expansion (CTE) [4] around 25 °C. Both vacuum chambers are placed inside temperature controlled and acoustic-shielded boxes, with a thermal fluctuation of mK. Two active vibration isolation (AVI) platforms are applied for vibration isolation of the cavities and optics, and a vertical vibration at 10^{-7} g/$\sqrt{\text{Hz}}$ level is achieved with the AVI on. Figure 3 shows photos of the experimental setup and the cavities used in this system.

III. Experimental Results

Recently, two IR diode lasers have been stabilized to the two independent cavities respectively and beat notes of less than 3 Hz are obtained between these two lasers, indicating the shelving laser for $^{27}Al^{+}$ is ready for use. The second stage stabilization of clock laser is in progress, and a third ultrastable cavity system for beat note analysis will also be built soon.

Fig. 3. Photos of experimental setup.

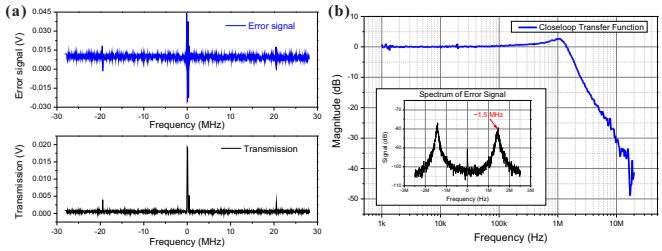

Fig. 4. (a) PDH error signal and cavity transition; (b) closed-loop transfer function of the feedback loop. The inset in (b) is the spectrum of in-loop error signal.

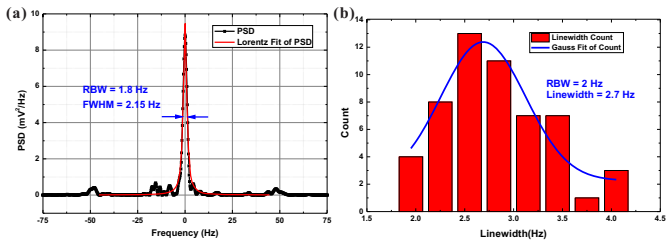

Fig. 5. (a) Laser beat note between two independent cavities; (b) histogram of linewidth distribution of beat notes from more than 50 measurements.

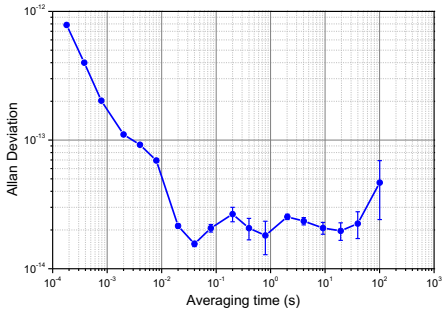

Fig. 6. Allan deviation of the beat note between two cavities.

Figure 4(a) shows PDH error signals and cavity transmission when laser frequency is scanned near resonance. In order to achieve higher signal-to-noise ratio, the modulation depth of EOM has been increased to near optimal value of about 1.08. The laser frequency is locked to the cavity with a feedback control bandwidth of about 1.5 MHz. Figure 4(b) shows the closed-loop transfer function of the system, including the cavity, detector and actuator of lasers etc., illustrating a $\sim$1.5 MHz bandwidth, with the roll-off slope of -20 dB/decade. The inset is the spectrum of in-loop error signal, where the shoulders represent the control bandwidth.

In order to study the stability of the stabled laser, we have locked the two lasers to two cavities on independent AVIs for beat note analysis, and an average linewidth of less than 3 Hz is obtained. Figure 5(a) is one of the laser beat notes, showing a linewidth of 2.15 Hz at FWHM. Figure 5(b) shows a histogram of linewidth statistical distribution of more than 50 measurements. An averaged linewidth of 2.7 Hz is obtained, indicating a linewidth of $\sim$1.9 Hz assuming two identical laser stabilization systems.

Beat note frequency is also measured with a frequency counter (Agilent, 53230A) and Allan deviations are analyzed. Stability of 2×10^{-14} at 1 s with a 0.49 Hz/s linear drift subtracted is obtained, as shown in Fig. 6. The long term stability will be further improved by searching the zero-crossing temperature of CTE of the cavities. Moreover, the residual amplitude modulation (RAM) suppression and EOM temperature stabilization will also be performed.

IV. Dynamic Analysis of Cavity Vibration Isolation

To reduce the vibration sensitivity of the ULE cavity, the cavity supporting positions are optimized according to quasi-static finite element analysis (FEA) [5]. The result is shown in Fig. 7. When mounted on this optimal position, the length variation and mirror tilting induced by vibration can be eliminated simultaneously, and the sensitivity to mounting inaccuracy is as low as 5×10^{-12} g^{-1}mm^{-1}. Cavities used in our experiments are both mounted on this optimal position for vibration insensitivity purpose. To further reveal the response of the cavity under higher frequency excitation, such as acoustic noise, we also simulated FEA dynamic analysis of the cavities' steady state response under dynamically changing loads, considering inertia and damping effects.

The ultrastable cavity has a 10 cm cylindrical ULE spacer, with a 0.5 inch bore hole along its central axis. Two 1-inch-diameter ULE mirror substrates are optically contacted to both sides of the spacer. For the FEA, spacer, mirrors and four symmetric supporting cubes are considered as a rigid body. The lower face of the support cubes are constrained in the vertical direction and free in the other two directions. The cavity is meshed with 149,000 prim elements. FEA simulations have been done using mechanical properties of ULE including mass density (2210 kg/m^3), Young's modulus (67.6 Gpa), Poisson's ratio (0.17) and Loss factor (1.64×10^{-5}). With optimized supporting positions calculated by quasi-static FEA, we performed dynamic analysis from 1 Hz to 20 kHz. Two largest resonant peaks in the vertical direction are shown in Fig. 8, which are consistent with the cavity's eigen-frequencies calculated by model analysis. The inset (a) of Fig. 8 shows that the relative deformation of the cavity length between 1 Hz to 100 Hz is in a level of 10^{-16} /g, which confirms with the quasi-static method. Vibration sensitivity of the cavity length reaches 10^{-8} /g at eigen-frequencies, as shown in the inset (b) and (c) of Fig. 8. Vibration modulation experiments are under way to examine the influence of resonant frequencies on the cavity stability.

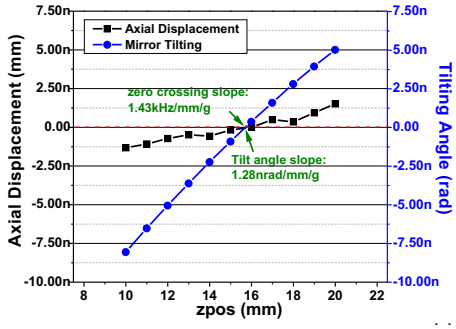

Fig. 7. Optimal mounting position of the cavity with smallest vibration sensitivity by quasi-static FEA analysis.

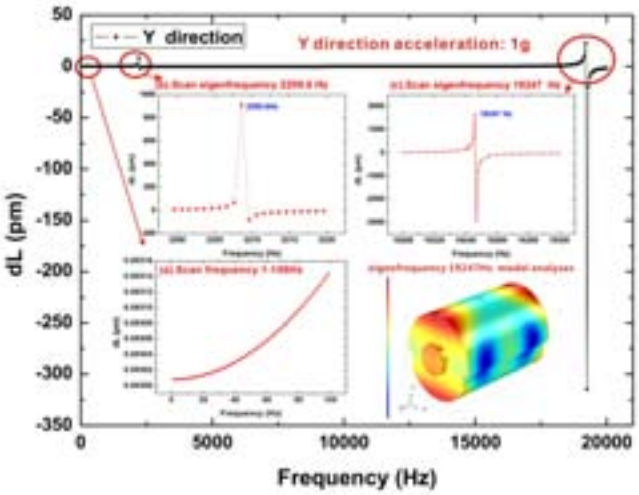

Fig. 8. Dynamic analysis of vertical vibration under optimal mounting position from 1 Hz to 20 kHz.

V. Conclusion and Outlook

In conclusion, two ultra-stable lasers for the application of $^{27}Al^{+}$ optical clock have been established and beat note of less than 3 Hz linewidth between them is obtained, one of which will be frequency quadrupled to 267.0 nm as the shelving laser. Experimental setup and the results are presented, and dynamic analysis of cavity via FEA simulations are also discussed in this report.

The second stage stabilization of the clock laser to sub-Hz level linewidth is on the way, and a third ultrastable cavity system for beat note analysis will also be built soon. Moreover, a 30 cm-long cavity with FS mirrors and a thermal compensation design [6] will be built to pursue a stability of 1×10^{-16} at 1 s for the clock laser.

***Abstract*—We demonstrated two femtosecond Ti:sapphire comb laser pumped by a continuous-wave 532 nm light which is generated from a frequency doubling 1064 nm ytterbium fiber laser. To make the system small, we develop HS-CTSDL being the frequency standard.**

Keywords-frequency comb; fiber laser; Ti:sapphire; Cesium

I. INTRODUCTION

Mode locked lasers are delicate to the pumping process in terms of mode frequency stability and pulse chirping. We showed that a 1064 nm fiber laser, via a single-pass second harmonic generation, could simultaneously pump two Ti:sapphire lasers and keep them in a stable mode-locking. The SHG photorefractive effect that might cause unstable pulses was not found. Our compact dual comb lasers are significant for interdisciplinary collaborations, especially for the applications of dual comb laser spectroscopy.

Femtosecond Ti:sapphire laser was commented by J. L. Hall and T. W. Hansch as the "intelligent and beautiful princess" [1]. Indeed, Ti:sapphire oscillator plays an important role in many experiments for strengthening light properties to the extreme edge, such as ultra-low phase noise [2], ultra-short pulse duration [3], ultra-high-field [4], and broadest laser output spectrum [5], at the wavelength ranged from infrared to visible.

Optical frequency combs which had a significant impact recently in spectroscopy and metrology [6, 7] are especially sensitive to power instability, because pump power fluctuations directly affect the repetition rate and the carrier-envelope phase. Improvements in IR fiber laser technology made possible to have sufficient optical pump power in the visible region [8] using second-harmonic generation in quasi-phase-matched ferroelectric materials such as MgO-doped periodically poled stoichiometric lithium tantalate (PP-MgO:SLT) [9]. Compared to the conventional diode pump solid-state laser pump sources, fiber laser based pumps have the advantages of being more compact, lower cost, and low power consumption.

In this paper, we successfully demonstrated that two fiber-pumped ultrafast Ti:sapphire lasers could be realized. We showed the pulse quality and directly monitored the mode frequency for the comparison with conventional pumping scheme.

II. EXPERIMENTAL SETUP

The pumping source, Yb fiber laser, provided 30 W, CW, single mode 1064 nm light, which was frequency doubled by an external single pass 30 mm PP-MgO:SLT crystal [10], generating about 10 W, CW, 532 nm light in TEM00 mode. The pump beam was optimized with a pair of collimating and mode-matching lenses.

Two Ti:sapphire oscillators were assembled together on the same one cooling base, measured as 55×110 cm^2 area, allowing for using the same one temperature-regulated cooling water to keep both being in similar drift rate of lasers' mode frequencies. Several chirped mirrors and folding mirrors were installed into laser cavities to reduce the area occupation of two Ti:sapphire oscillators, which resulted in the overall size of 9.5 cm high, 31 cm length and 36 cm width.

Repetition rates of Ti:sapphire oscillators were set to be 1 GHz, and the average power of the pulse is about 700 mW [11]. Absolute mode frequency of laser was locked to one hand size cesium two-photon stabilized diode laser (HS-CTSDL) [12], and monitored its beat frequency with respect to another HS-CTSDL.

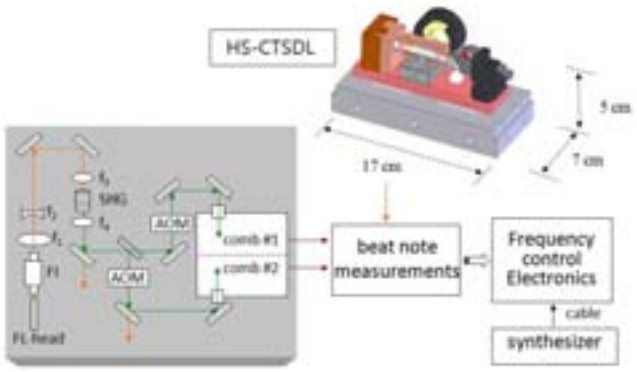

Figure 1. The experiment setup of the dual Ti:sapphire comb system pumped by a fiber laser.

III. The Effect of Pumping Source Noise

Not every fiber laser can be a good pumping source for frequency comb lasers. We compare two 1064 nm fiber lasers from different company. The first fiber laser yield 30 W maximum output power at 1064 nm wavelength, and with 2% power ripple within 100 kHz bandwidth. The second one support 20 W maximum output power at 1064 nm wavelength, and with 2% relative rms intensity noise at nominal power within 0.1 nm bandwidth.

We measured the behavior of the comb laser output pulse pumped by this two fiber lasers. The pulse output spectrums were measured by an optical spectrum analyzer, and time domain properties were measured by an autocorrelator. Both of them have about 30 nm pulse bandwidth and 26 fs pulse length. However, the mode locking of the second one is not as stable as the first one. The repetition rate of the comb laser which pumped by the second fiber laser has a messy background comparing to the other. We get beat notes from beating HS-CTSDL with these two mode locked lasers. It is about 1 MHz line width of the first one, which is about 5 times smaller than the second one, and the small line width is helpful for locking absolute frequency.

To figure out the reason of noisier output, we measured the noise spectrum of the pump light intensity by a photo detector as shown in figure 3. The standard deviation of first fiber laser's power noise is 15.2 mV while the dc output is around 1.8 V, and in the same situation, the second fiber laser's standard deviation is 49.9 mV. The second fiber laser had 35 dB higher intensity noise below 500 kHz for equivalent pump power.

This power instability would explain the less stable repetition rate and does have a direct impact on precision metrology measurements. We conclude that the second fiber laser could serve as a pump for Ti:sapphire mode-locked lasers, but to be an attractive pump source for optical frequency combs, the power stability needs to be improved.

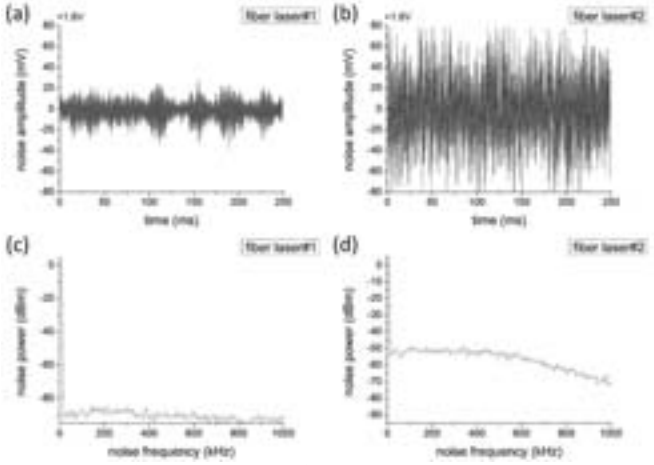

Figure 3. The intensity noise of the pump light. (a) & (b) In time domain. (c) & (d) In frequency domain.

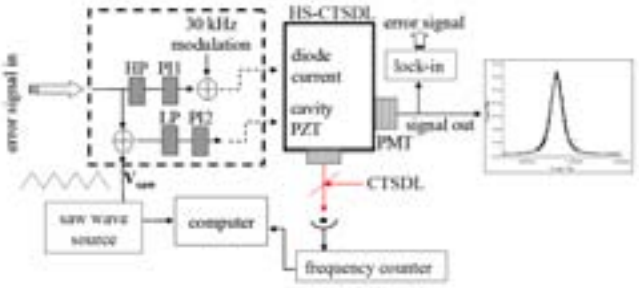

Figure 4. The experiment setup for testing mode pushing/pulling effect of HS-CTSDL

IV. Hand Size Optical Frequency References

In order to make the system small, we develop HS-CTSDL, and the biggest difference between HS-CTSDL and the other frequency stabilized laser is that the absorption cell of HS-CTSDL is put in the laser cavity.

Mode pushing/pulling effect is a big problem for intracavity One-photon spectroscopy [13, 14], and it creates lead-lag of the laser frequency. Laser frequency lead-lag, caused by the dispersion of the gain/absorption medium [14], is nonlinearly dependent on the physical length of the laser resonator. To make sure that HS-CTSDL has mode pushing/pulling effect or not, we have to record the cavity optical length synchronously with physical length.

HS-CTSDL, which has a current modulation, was locked on the cesium 6S-8S transition at the beginning. Then we add a slow saw wave to change the offset point of the PZT feedback loop while the laser kept locked (but the frequency changed). The beat frequency of HS-CTSDL and another cesium two-photon stabilized diode laser (CTSDL) is related to the cavity optical length, and the offset voltage of the PZT is related to the physical length. The result of test shows the liner relationship of offset voltage and the beat frequency, so we claim that the mode pushing/pulling effect is not obvious within our measurement precision.

Using this scheme we can also get the transition spectrum by recording beat frequency and PMT signal synchronously. Pressure shift and modulation shift of the HS-CTSDL are -2.9 kHz/0.01Pa and 3 kHz/MHz. The estimated Allan deviation [15] was deduced from a beat note measurement with two independent HS-CTSDLs stabilized to the same two-photon transition (note that figure 6(a) is just an estimated value because our lambda-type counter could not really provide appropriate sequences of frequency counting for directly deducing the Allan variance [15]) . Frequency offset of the laser is about 100 Hz/364.5 THz at 400 s sampling time, and maximum frequency discrepancy of 3.5 kHz/364.5 THz during 16 days shows the high reproducibility of the HS-CTSDL.

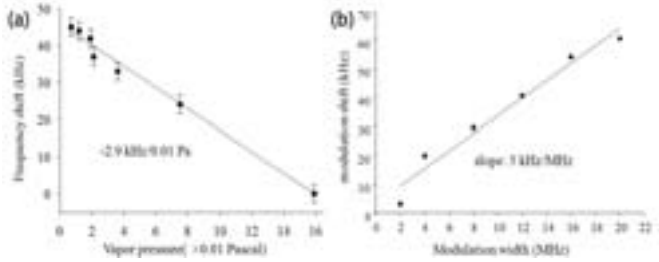

Figure 5. (a) Pressure shift and (b) modulation shift of the HS-CTSDL

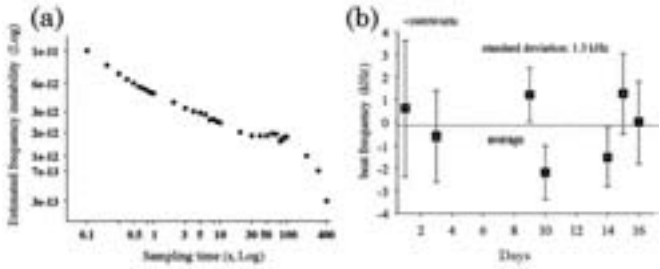

Figure 6. (a) Stability and (b) reproducibility of two HS-CSTDLs

V. RESULT

By feedback controlling the PZT (which is on the Ti:sapphire cavity mirror) and the AOM to change the cavity length and the pumping power, we can lock the repetition rate and the absolute frequency with reference to the synthesizer and HS-CTDSL. The line width of the repetition rate reduces to about 2 Hz after lock. The Allan deviation of the beat frequency was about 5×10^{-12} at 10 s sampling time.

***Abstract*—An Er-fiber laser comb with repetition frequency of 250 MHz made by the Center for Measurement Standards (CMS), Taiwan was shipped to the National Metrology Institute of Japan (NMIJ) to compare with the NMIJ fiber laser comb by simultaneously measuring the frequency of an optical cavity-stabilized Nd:YAG laser at 1064 nm. The measured average frequency difference is 32 mHz and corresponds to a relative difference of 1.1×10^{-16}, which is limited by the measurement time. Furthermore, method for determining the comb mode number using two combs with large difference of repetition rate is proposed.**

Keywords-optical frequency measurement; optical frequency comb; mode-locked laser; frequency standard; fiber laser

I. INTRODUCTION

Mode-locked (ML) femtosecond laser functioning as an optical frequency comb has revolutionized optical frequency metrology over a decade [1]. Due to this revolutionary technique, the practical realization of SI-meter has also been modified. Traditionally, various frequency-stabilized lasers have been recommended by the Bureau International des Poids et Mesures (BIPM) for the practical realization of meter [2]. National Metrology Institutes (NMIs) bring their frequency-stabilized lasers to join a key comparison initiated by the meeting of the Comité Consulative des Longeurs (CCL) to demonstrate the equivalence of national realization of the SI-meter. Nowadays, many NMIs use the laser comb to measure the frequency of the recommended lasers in their own labs to realize the SI-meter traceable to the SI-second. Validating the measurement capability of the laser comb in different NMIs is an important issue in the mutual recognition. Two independent laser combs phase-locked to a common microwave frequency standard and measuring a common optical frequency is the most direct way to validate the measurement capability of the frequency comb.

Among the different ML laser combs, ML fiber laser comb is popular in many labs due to its compactness and free-of-alignment and is suitable for transportation to perform the comb comparison. Comb comparison using fiber laser combs to measure the frequency of a an iodine-stabilized He-Ne laser at 633 nm has been demonstrated by the National Metrology Institute of Japan (NMIJ) and the National Metrology Institute of Australia (NMIA) [3]. The Center for Measurement Standards (CMS), which is the NMI of Taiwan, has also made self-referenced fiber laser combs for the optical frequency measurement [4, 5]. Recently, one of the fiber laser combs developed by CMS was shipped to NMIJ to validate the measurement capability of the fiber laser combs of CMS and NMIJ at 1064 nm. In this paper, the results of the comb comparison are reported. Furthermore, method for determining the mode number of the beating comb line using two combs with large difference of repetition rate is proposed.

II. FIBER LASER COMB DEVELOPED BY CMS

The CMS comb is similar to the previous construction [5]. Here, we simply describe the main difference from that system.

The fiber laser oscillator has a ring cavity mode-locked by nonlinear polarization rotation (NPR) with a polarization beam splitter (PBS) before an isolator to couple out the laser pulse from the rejection port [6]. A 38-cm-long highly doped Er-fiber is used as the gain medium. The Er-fiber is pumped by a 980 nm diode laser through a wavelength-division-multiplexing coupler. The diode laser has a maximum output power of 660 mW. The mode locked laser has a repetition rate of 250 MHz and delivers a maximum output power of 94 mW from the PBS rejection port. A piezoelectric transducer (PZT) is mounted on the fiber to control the cavity length. The PZT can tune the repetition frequency up to about 8 kHz with a maximal driving voltage of 150 V.

The output from the laser oscillator is further coupled into an optical fiber and divided to three ports by a 1×3 coupler after passing a polarization independent isolator. One port is used to detect the repetition rate and to monitor the laser oscillator. Each of the other two ports is amplified to 200 mW with an Er-fiber amplifier backwards pumped by a 980 nm diode laser with output power of 660 mW. The amplified laser pulses are then compressed by standard single mode fibers and sent to highly nonlinear fibers (HNLF) to generate two branches of octave-spanning supercontinua ranging from 1050 nm to 2200 nm. Each supercontinuum has an average power of

170 mW. One branch of the supercontinua is adopted to detect the carrier-envelope-offset (CEO) frequency using collinear self-referenced f-2f interferometer [7]. The comb lines near 2200 nm are frequency-doubled with a 0.5-cm-long periodically poled magnesium-oxide-doped lithium niobate (MgO:PPLN) and mixed with the comb lines near 1100 nm. The mixed comb lines at 1100 nm are filtered with a 10-nm-wide bandpass filter and the CEO beat signals are detected by an InGaAs photodiode. The group velocity mismatch between the 2200 nm and 1100 nm combs are compensated by splicing an 8-mm-long single mode fiber after the HNLF to optimize the beat signal. The detected CEO beat signal has a signal-to-noise ratio of 40 dB at 100 kHz resolution bandwidth. The other branch of supercontinuum is adopted for optical frequency measurement.

The fiber laser oscillator, amplifiers and the HNLF are mounted on an aluminum plated with temperature controlled by a thermal-electric cooler to maintain long term stability of the mode-locking. All the above mentioned constructions of the fiber laser comb are inside an aluminum box of A3 paper size with 6.5 cm thick. To the best of our knowledge, this is the most compact fiber laser comb with an f-2f interferometer inside and is convenient for transportation to perform the comb comparison.

III. Experimental Setup and Results of the Comb Comparison

The fiber laser comb with repetition rate of 250 MHz developed by CMS was brought to NMIJ for frequency measurement comparison. The NMIJ fiber laser comb is also based on a NPR mode-locked fiber ring laser with a repetition frequency of 87.6 MHz and is similar to the construction described in [8].

The setup for the CMS-NMIJ comb comparison is shown in Fig. 1. Both the repetition and CEO frequency of the CMS and NMIJ combs are phase-locked to the 10 MHz signal of a H_2-maser linked to the Coordinated Universal Time of NMIJ (UTC-NMIJ 10 MHz signal), which has a frequency uncertainty of 3×10^{-13} at 1 s. The 4th harmonic of the repetition frequency of the CMS comb is phase-locked to a 1 GHz reference signal multiplied from the UTC-NMIJ 10 MHz signal. The 10th harmonic of the repetition frequency of the NMIJ comb is mixed with a 900 MHz source multiplied from the UTC-NMIJ 10 MHz signal to generate a difference frequency of 24 MHz. This difference frequency is then phase-locked to a synthesizer (Stanford Research Systems DS345). The CEO frequencies of the two combs are stabilized to two other synthesizers (Agilent Technologies E4400B) and are monitored by two frequency counters (Pendulum CNT-90). All the synthesizers are referenced to the UTC-NMIJ 10 MHz signal.

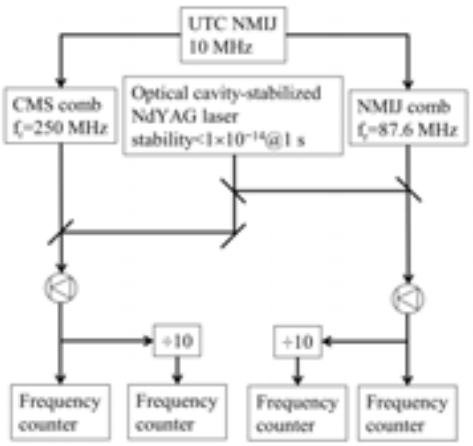

Figure 1. Experimental setup for the comb comparison.

To measure a common optical frequency, the two combs are mixed with an optical cavity-stabilized Nd:YAG laser operating at 1064 nm. The frequency stability at 1 s of the Nd:YAG laser is less than 1×10^{-14}. The two beat signals are then counted by two frequency counters (Pendulum CNT-90) simultaneously. The two beat signals are also divided by 10 and measured with another two frequency counters (Pendulum CNT-90) to check cycle-slip from the counters. If the counting of the beat signal does not match with that from the 1/10 of the beat signal, cycle-slip has happened and that data point is deleted. All the counters are referenced to the UTC-NMIJ 10 MHz signal and have a measurement time setting of 1 s.

The optical frequency of the Nd:YAG laser is calculated from the measured beat frequencies, CEO frequencies and the settings of the repetition frequencies. The mode numbers of the two combs are determined by slightly changing the repetition frequency of the NMIJ comb as demonstrated in [3]. Fig. 2 shows the measured frequency differences of the two combs. The average of the difference frequencies is 32 mHz, which corresponds to a relative difference of 1.1×10^{-16}. This is much lower than the uncertainty of the microwave frequency standard. Therefore, the absolute frequency measurement capability of the fiber laser combs is limited by the accuracy of the local reference. An NMIJ fiber comb had also been shipped to NMIA to compare the frequency measurement of an iodine-stabilized He-Ne laser at 633 nm in 2006. The NMIA comb is a commercial fiber laser comb with 100 MHz repetition rate and also has a ring cavity mode-locked with

Figure 2. Measured frequency difference between the two combs.

NPR. The measured frequency difference was 38 mHz [3], which corresponds to a relative difference of 8×10^{-17}. These comparison results validate that the NPR-based fiber laser comb can perform optical frequency measurement with a much smaller uncertainty than that of the current microwave frequency standards.

IV. Determination of the Mode Number Using Two Combs with Large Difference in Repetition Rate

To measure the frequency of a laser under measurement (LUM) using a mode-locked laser comb, the mode number of the beating comb line must be determined. Besides using a wavelength meter to offer a precise *a priori* knowledge of the frequency of the LUM, mode number can be determined by measuring the beat frequencies at various repetition rates [9, 10]. Peng et al. developed methods based on two combs with repetition rate difference of kHz to measure the mode number, which can be independent of the frequency fluctuations of the LUM [11-13]. Inaba et al. demonstrated the comb mode determination using two combs with large difference in repetition rate [3], which is also used in previous section to determine the mode number for measuring the frequency of the Nd:YAG laser. But, they need long measurement time of 1000 s to average down the uncertainty of the beat frequency difference. In this section, we propose another method that can determine the mode number in short time for two combs with large difference in repetition rate.

This method relies on measuring the beat frequencies at three different repetition rates f_{r11}, f_{r12} and f_{r13} of comb1, where two repetition rates f_{r11} and f_{r12} are close enough to have the same beating comb mode, while keeping the repetition rate of comb2 unchanged. For simplicity, assume that the offset frequencies are zero and the signs of the beat frequencies are determined to be positive. Thus, the frequency of the LUM can be expressed as:

$$f_L = n\cdot f_{r11} + f_{b11} = k\cdot f_{r21} + f_{b21}, \quad (1)$$

$$f_L = n\cdot f_{r12} + f_{b12} = k\cdot f_{r21} + f_{b22}, \quad (2)$$

$$f_L = (n+m)\cdot f_{r13} + f_{b13} = k\cdot f_{r21} + f_{b23}, \quad (3)$$

where f_{b1x} and f_{b2x} are the beat frequencies measured at repetition rate f_{r1x} of comb1 with $x=1$, 2, and 3, and at single repetition rate f_{r21} of comb2; n and k are the mode number of the beating comb line of comb1 and comb2, respectively; m is the mode number shift of comb1 when the repetition rate is changed from f_{r11} to f_{r13}. From (1), (2) and (3), the mode number shift m and the mode number n can be derived as

$$m = \frac{\frac{(f_{b21}-f_{b11})-(f_{b22}-f_{b12})}{f_{r11}-f_{r12}}(f_{r11}-f_{r13})+(f_{b11}-f_{b21})-(f_{b13}-f_{b23})}{f_{r13}}, \quad (4)$$

$$n = \frac{m\cdot f_{r13}+(f_{b21}-f_{b11})-(f_{b23}-f_{b13})}{f_{r11}-f_{r13}}. \quad (5)$$

The mode number difference m is calculated with (4) first and then substituted into (5) to get n. Both n and m are independent of the frequency fluctuations of the LUM since the two beat frequencies in all parentheses of (4) and (5) are measured simultaneously. They depend only on the relative fluctuation between the two comb lines beating with the LUM. Equations (4) and (5) is similar to (6) and (5) in [12], which are derived for two combs with about kHz difference in repetition rate. Since the two combs are phase-locked to a common highly stable microwave frequency standard, therefore, the mode number can be determined using short average time of 1 s similar to that demonstrated in [12].

Actually, the term $[(f_{b21}-f_{b11})-(f_{b22}-f_{b12})]/(f_{r11}-f_{r12})$ in (4) is equal to the mode number n, and (4) and (5) has the same form in such kind of substitution. But, this term is not used to calculate the real n in this proposal, because $f_{r11}-f_{r12}$ is small and it needs long measurement time to average down the uncertainty of the beat frequency difference to be much less than f_{r11}-f_{r12}, which was as demonstrated in [3]. This term is only used as an approximate mode number for the calculation of m in (4).

Since only the beat frequency between comb2 and the LUM appears in (4) and (5), the repetition frequency of comb2 can be any other values different from comb1 as long as the beat frequency can be effectively separated for measurement. This idea was not available during the comb comparison. The demonstration is realized with two other fiber laser combs with repetition rates of 500 MHz and 400 MHz and is published elsewhere [14].

V. Conclusions

We have shown that mode-locked Er-fiber laser combs phase-locked to a common microwave frequency standard have the capability to compare an optical frequency at 1064 nm with an uncertainty of 1.1×10^{-16}, which is smaller than the uncertainty of the best microwave frequency standard. Therefore, the absolute frequency measurement capability of the laser comb is limited by the microwave reference. In addition, we have proposed a method to determine the mode number of the beating comb line with short average time of 1 s when two laser combs with large difference in repetition rate are used for measuring the optical frequency.

***Abstract*—We are setting up an experiment to investigate an active optical clock scheme in four-level configuration with Cesium atoms. The 1469 nm Cesium active optical clock output in a bad cavity laser regime is generated and the wavelength is measured to be 1469.500 nm by using spectrometer. The 1469 nm lasing threshold and output power is measured when changing 455 nm pumping laser power and frequency. The 1469 nm Cesium active optical clock output multi-threshold is observed when changing bad-cavity length. We also sweep the bad-cavity length and measure the 1469 nm Cesium active optical clock output frequency using a wavelength meter, proving the cavity-pulling reduction due to the bad-cavity effect.**

Keywords—active optical clock; four-level configuration; bad-cavity

I. INTRODUCTION

To push the linewidth of optical clock from Hz to mHz is a main topic for current clock development [1]. Active optical clocks [2-5] theoretically have the potential of mHz linewidth, thus expected will provide much better stability than that of passive optical clocks. In a three-level configuration [2, 6], the pumping laser directly affects the frequency of clock transition. In order to greatly reduce the light shift of clock transition caused by pumping laser, an optical clock scheme in four-level configuration with Cesium atoms is proposed [7-12].

In this paper, we are setting up an experiment to investigate active optical clock in 4-level configuration with Cesium atoms. The Cesium active optical clock output at the wavelength of 1469 nm is observed. As the power and frequency of the 455 nm pumping laser is changed, the 1469 nm lasing threshold and output power is measured. The 1469 nm Cesium active optical clock output multi-threshold is observed when changing bad-cavity length and the 1469 nm Cesium active optical clock output frequency is measured using a wavelength meter to prove the cavity-pulling reduction due to the bad-cavity effect.

II. EXPERIMENTAL SETUP

The melting temperatures of alkali atoms, like Cs and Rb, are very low, and the laser diode for related wavelength of atomic transitions are commercially available, thus to set up 4-level Cs or Rb active optical clock experiment with thermal cell or magneto-optical trap is economic.

A homemade external-cavity diode laser at 455 nm is employed as the pumping laser. The related energy levels of

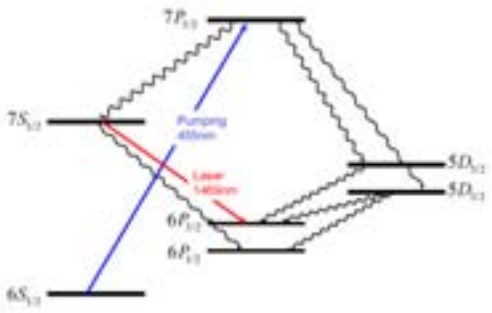

Fig. 1. The related energy levels of cesium.

cesium is shown in Fig. 1. The 455 nm external-cavity produces ~12 mW of optical power; 10 mW reaches the Cesium cell and 0.8 mW is used for saturated absorption spectrum of cesium between $6S_{1/2}$ (F=4) and $7P_{3/2}$ (F'=3,4,5) [13]. The population inversion between $7S_{1/2}$ state and $6P_{3/2}$ state in a thermal cesium cell has been experimentally established with the 455 nm pumping laser [10].

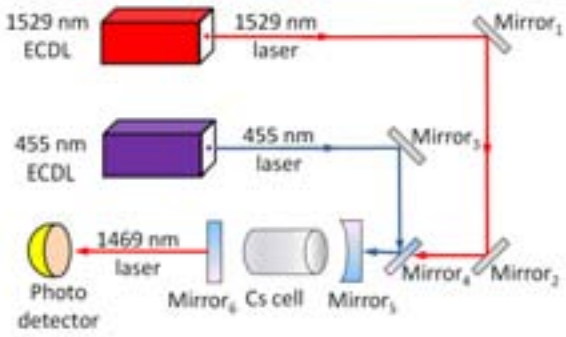

Fig. 2. Experimental setup of cesium active optical clock in four-level configuration. $Mirror_1$, $Mirror_2$ and $Mirror_3$ are highly reflecting mirrors at 1529 nm. $Mirror_4$ is coated with 1529 nm anti-reflection and 455 nm high-reflection coating. $Mirror_5$ is coated with 455 nm anti-reflection and 1469 nm high-reflection coating. $Mirror_6$ is coated with 455.5 nm high-reflection and the reflectivity of 1469 nm is 80%.

The experimental setup of cesium active optical clock is shown in Fig. 2. The cavity is composed of a concave mirror ($Mirror_5$) and a planar mirror ($Mirror_6$). $Mirror_5$ is coated with 455 nm anti-reflection and 1469 nm high-reflection coating. The radius of curvature is chosen to be 500 mm. $Mirror_6$ is coated with 455 nm high-reflection and the reflectivity of 1469 nm is 80%. The Cesium cell is 5 cm long and the cavity is 8.5 cm long. The cavity length can be swept by the piezoelectric ceramic transducer (PZT) fixed behind $Mirror_6$. The temperature of the Cesium cell is controlled around 123 ℃ and the transmission of the cesium cell at 1529 nm is measured to be 60%. A 1529 nm external-cavity diode laser is used to calibrate the cavity. Due to the loss of the cesium cell in the cavity, the finesse of the cavity is calculated to be 2, which agrees well with the experiment result indicated in Fig. 3. The free spectral range (FSR) is 1.76 GHz and the corresponding sweep voltage of the bad-cavity PZT for a single free spectral range is approximately 125 V. The cavity bandwidth is then measured to be 880 MHz. The 455 nm pumping laser is introduced into the cavity to generate Cesium active optical clock output at 1469 nm and the pumping laser power is 10 mW.

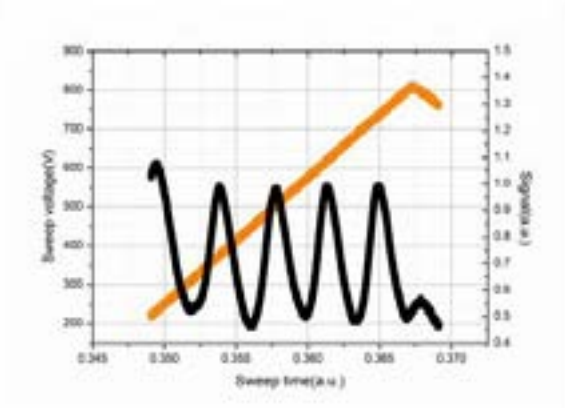

Fig. 3. Bad cavity calibration using 1529 nm laser. The sweep voltage of the bad-cavity PZT is represented by the orange line while the transmission signal of 1529 nm laser is represented by the black line. The finesse of the cavity is 2 and the free spectral range is 1.76 GHz..

III. RESULTS

Since the Cesium active optical clock output at the wavelength of 1469 nm is observed, we measured the lasing threshold and output power when changing the 455 nm pumping laser power (as shown in Fig.4) and frequency (as shown in Fig. 5).

Fig. 4 shows the measured lasing threshold and output power of Cesium active optical clock when the 455 nm pumping laser power is being changed. The frequency of 455 nm pumping laser is locked to the frequency between the saturated absorption spectrum of cesium $6S_{1/2}$ (F=4) - $7P_{3/2}$ (F'=5) and the crossover resonance corresponding to the cesium $6S_{1/2}$ (F=4) - $7P_{3/2}$ (F'=4,5) transition. Therefore the pumping laser is kept resonant with the cesium 455 nm transition and a maximum 1469 nm Cesium active optical clock output is observed (as shown in Fig. 5). The bad-cavity length is also kept in resonance with the 1469 nm Cesium active optical clock output wavelength (as shown in Fig. 6). Then the 455 nm pumping laser power is changed and the lasing threshold and output power of the Cesium active optical clock is measured. As indicated in Fig. 4, the 1469 nm Cesium active optical clock output has a threshold when the 455 nm pumping laser power equals to about 1.4 mW. When the pumping laser power is less than 1.4 mW, only weak

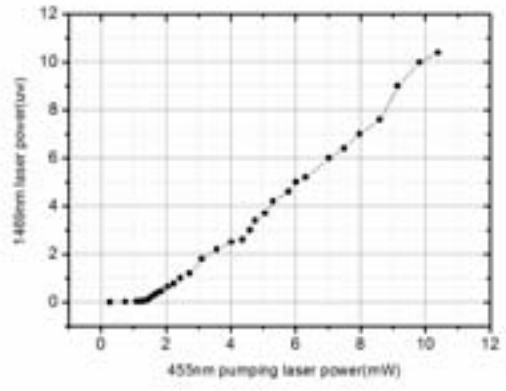

Fig. 4. 1469nm lasing threshold and output power of Cesium active optical clock when changing 455 nm pumping laser power. The frequency of pumping laser is locked to the cesium 455 nm transition and the bad-cavity length is kept in resonance with the 1469 nm Cesium active optical clock output.

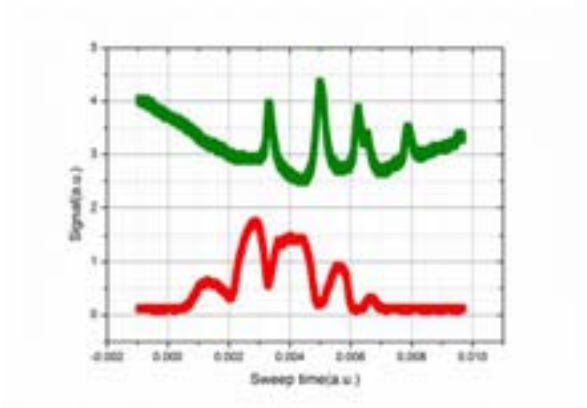

Fig. 5. 1469nm lasing threshold and output power of Cesium active optical clock when changing 455 nm pumping laser frequency. The power of 455 nm pumping laser is 10 mW and the bad-cavity length is kept in resonance with the 1469 nm Cesium active optical clock output. The green curve shows the saturated absorption spectrum and the red curve represents the corresponding 1469 nm output power of Cesium active optical clock.

fluorescence can be observed. As the 455 nm pumping laser power is increased to more than 1.4 mW, 1469 nm Cesium active optical clock output is then observed and the increase of 1469 nm Cesium active optical clock output power is proportional to the increased 455 nm pumping laser power.

Fig. 5 shows the measured lasing threshold and output power of Cesium active optical clock when the 455 nm pumping laser frequency is being changed. The power of 455 nm pumping laser equals to 10 mW and the length of the bad-cavity is kept in resonance with the 1469 nm Cesium active optical clock output wavelength.

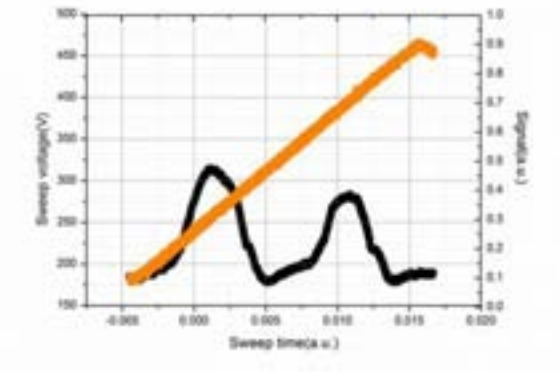

Fig. 6. 1469 nm Cesium active optical clock output multi-threshold when changing bad-cavity length. The frequency of pumping laser is locked to the cesium 455 nm transition and the incident pumping laser power is 10 mW. The sweep voltage of the bad-cavity PZT is represented by the orange line while the 1469 nm output signal of Cesium active optical clock is represented by the black line.

In Fig. 5 the green curve shows the saturated absorption spectrum and the red curve represents the corresponding 1469 nm output power of Cesium active optical clock. The 1469 nm output power indicated by the red curve has its dip where the saturated absorption spectrum shown by green curve has its peak. This can be attributed to the saturation effect of 455 nm pumping laser in the cesium cell of the bad-cavity. As shown in Fig. 2, the planar mirror of the bad-cavity ($Mirror_6$) is coated with 455 nm high-reflection. The 455 nm pumping laser will be reflected back and overlap the incident pumping laser beam in the cesium cell. When the peak of the 455 nm saturated absorption spectrum appears, the number of cesium atoms excited by the 455 nm pumping laser will decrease due to the saturation absorption in the cesium cell of the bad-cavity, resulting in the reduction of 1469 nm Cesium active optical clock output power.

Fig. 6 shows the measured lasing multi-threshold and output power of Cesium active optical clock when the length of the bad-cavity is being changed. The frequency of pumping laser is locked to the cesium 455 nm transition and the incident pumping laser power is 10 mW. The sweep voltage of the bad-cavity PZT is represented by the orange line while the 1469 nm output signal of Cesium active optical clock is represented by the black line. The measured sweep voltage of the bad-cavity PZT for a single free spectral range at 1469 nm is approximately 125 V, in accordance with the result of 1529 nm laser shown in Fig. 3. We also measured the wavelength of Cesium active optical clock output using a spectrometer. The central wavelength is measured to be 1469.500 nm as indicated in Fig.7.

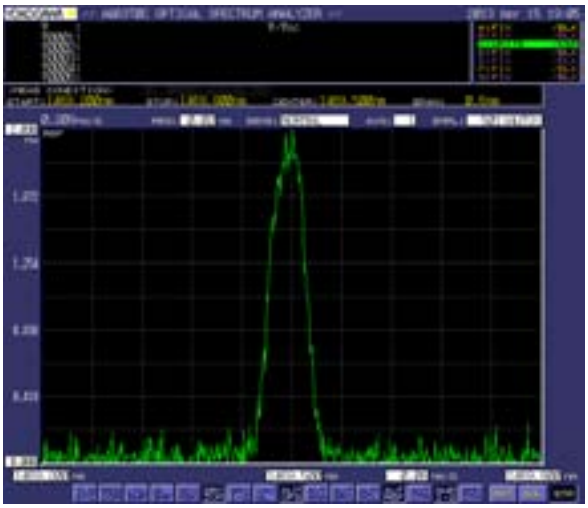

Fig. 7. 1469 nm Cesium active optical clock output wavelength measurement using spectrometer.

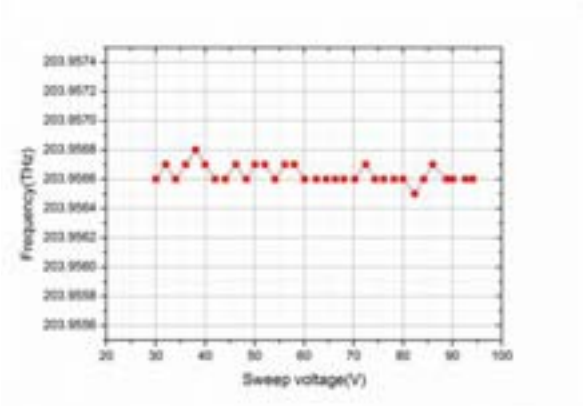

Fig. 8. 1469 nm Cesium active optical clock output frequency when changing bad-cavity length

Fig. 8 shows measured 1469 nm Cesium active optical clock output frequency when changing bad-cavity length. The sweep voltage of the bad-cavity PZT is gradually increased from 30 V to 96 V, more than half a free spectral range of the bad-cavity (the sweep voltage of the bad-cavity PZT for a single free spectral range is measured to be 125 V). In this progress the 1469 nm Cesium active optical clock output frequency is measured using the Advantest TQ8325 Digital Optical Wavelength Meter (with the resolution of 100 MHz). The measured linewidth of 455 nm transition can be as narrow as 1.4 MHz, approaching the natural linewith 1.2 MHz [13]. So right now, the linewidth of the gain is limited by saturation

broadening. The saturation intensity of Cesium 455 nm transition is I_s=1.66 mW/cm^2, while the power of 455 nm pumping laser is 10m W and the beam size is about 0.84 mm^2. The intensity of 455 nm pumping laser in the Cesium cell is then calculated to be 1.19 W/cm^2 and the saturation parameter is 717. Therefore, the gain linewidth, which is limited by saturation broadening, is 32.4 MHz, nearly 1/30 of the cavity linewdith (880 MHz). The 1469 nm Cesium active optical clock output is hence in the bad-cavity laser region. As indicated in Fig. 8, the sweep range of the bad-cavity is 900 MHz while the fluctuation range of 1469 nm Cesium active optical clock output frequency is only about 300~400 MHz, which proves the cavity-pulling reduction of the 1469 nm Cesium active optical clock output due to the bad-cavity effect.

IV. CONCLUSION

In summary, we are setting up an experiment to investigate active optical clock in 4-level configuration with Cesium atoms. We observed the 1469 nm Cesium active optical clock output and measured the wavelength to be 1469.500 nm using a spectrometer. The 1469 nm lasing threshold and output power is measured when changing the power and frequency of the 455 nm pumping laser. The 1469 nm Cesium active optical clock output multi-threshold is also observed when sweeping the bad-cavity length. The 1469 nm Cesium active optical clock output frequency is measured using a wavelength meter when sweeping the bad-cavity length and the cavity-pulling reduction due to the bad-cavity effect is observed. ***Abstract*—In order to develop small optical clock for various transportable applications with better stability and accuracy than that of commercial small Cs clock and H-maser clock, our group has proposed a small Ca atomic beam clock scheme with electron-shelving detection. Its potential stability was experimentally demonstrated recently. Here, we first demonstrated the dispersive detection of 657 nm transition via the Faraday rotation effect of 423 nm transition based on a thermal Ca atomic beam, this alternative detection method can effectively detect the clock signal by the ground state atoms after the clock laser interrogation. The Faraday anomalous dispersion optical filter of 423 nm transition can reach a maximum transmission of 10%. With a magnetic field of 84 G, the observed 3.3% of the ground state atoms has been excited to the $\sigma^{\pm}$ level of metastable $^3P_1(m=\pm1)$ state, which are separated 176.6 MHz to m=0 level.**

Keywords—electron-shelving detection; dispersive detection; the Faraday anomalous dispersion optical filter.

I. INTRODUCTION

In the past several years, many research groups have improved the performance of the optical atomic clock, especially based on laser cooled ions and neutral atoms. During the processing of the improvement, the compactness of the optical atomic clock also plays a key role. In order to develop small optical clock for various transportable applications with better stability and accuracy than that of commercial small Cs clock and H-maser clock, our group has proposed a small Ca atomic beam clock scheme with electron-shelving detection[1-3]. Its potential stability was experimentally demonstrated recently.

Optical filter, especially the narrow bandwidth optical filter has a great advantage on optical communication and sensing system. Additionally, the Faraday anomalous dispersion optical filter (FADOF), which has high transmission with narrow bandwidth, has been used on many areas.

In this paper, based on electron-shelving detection[4-5] and FADOF technology, we first demonstrated the dispersive detection of 657 nm transition via the Faraday rotation effect of 423 nm transition. This alternative detection method via FADOF[6] can effectively detect the clock signal by the ground state atoms after the 657 nm clock laser interrogation. The experimental system based on a thermal Ca atomic system is more convenient and transportable.

II. EXPERIMENTAL SCHEMATIC

The schematic diagram of the experimental setup is showed in Fig.1. And Fig. 2 shows the relevant Ca energy levels. The system detects the 657 nm clock signal of Ca atoms by the 423 nm transition signal after the clock laser interrogation. Because 1S0-1P1 transition and $^1S_0$-$^3P_1$ transition use the same ground state atoms, the detection technology can effectively detect the clock signal and improve the detection efficiency massively. The energy level will be split into three magnetic levels due to the additional external magnetic field. In this system, Ca atoms are loaded in a reservoir which is in vacuum. The whole vacuum system are pumped off to 10^{-6} Pa and heated to 850 ˚C. The temperature of the vacuum system is monitored using the thermocouple. When the vacuum system is heated to 807 ˚C, Ca atoms would be evaporated and becomes atomic beam. Then, the 657 nm clock signal laser is reflected to interact with Ca atomic beam. The 657 nm laser is Littrow's external cavity diode laser. Before the interaction, a λ/4 plate can change the polarization of the 657 nm laser and change the transition levels. With this interaction, the ground state of Ca atoms will be pumped to the $^3P_1$ state. Then, we detect the clock signal by 423 nm laser. The 423 nm laser is also Littrow's external cavity diode laser. Here, we detect the 423 nm signal by the Faraday rotation effect in a FADOF configuration. A folded seven-beam traveling wave configuration is employed to improve transmission efficiency. As showed in Fig.2, two high reflection mirrors are applied to realize the seven-beam configuration. The 423 nm laser beams are nearly perpendicular to the atomic beam. Two crossed Glan-Taylor prisms are set on both sides of the atomic beam. A λ/4 plate is placed between two Glan-Taylor prism. In this way, the stress-induced birefringence of vacuum windows can be compensated. Besides, a magnetic field of up to maximum 100 G is induced into the system. The magnetic field is perpendicular to the atomic beam and aligned to parallel to the resonant laser beam.

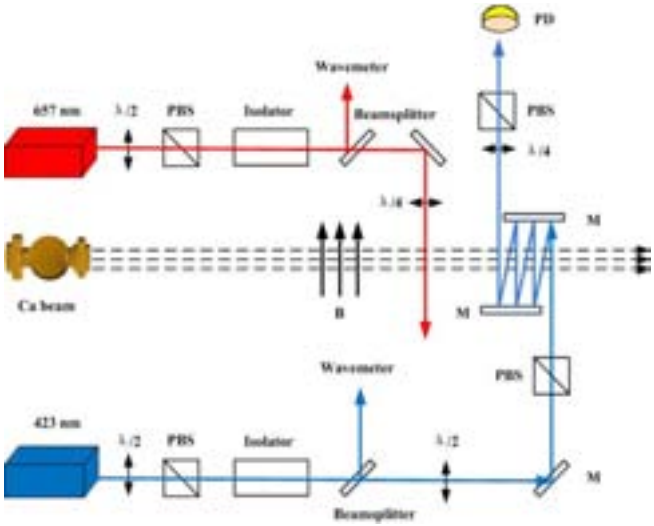

Fig. 1. The diagram of experimental setup. Lasers of 657 nm and 423 nm are the external cavity diode lasers at structure configuration of Littrow. Ca metals atoms are loaded in a reservoir which is in vacuum. The vacuum system are pumped off to 10^{-6} Pa and heated to 850 ˚C. Fig. 2. Relevant Ca energy levels.

III. Experimental Results

As illustrated in Fig.3, the Faraday effect transmission spectrum of 423 nm in red line has a signal peak at the center of the resonance transition. The blue line is the fluorescence detection in another vacuum system for a reference. The laser of the fluorescence detection is strictly perpendicular to the atomic beam. The Faraday effect transmission spectrum of 423 nm has Doppler broadening. The magnetic field is set to 84 G, which is produced by passing 2.5 A of dc current through the a pairs of magnetic coils. The 423 nm laser power is 0.73 mW. The linewidth of the red line is 248 MHz and the intensity is 3.2 V. The maximum transmission efficiency [6] of the Faraday effect is 10%. In this case, the transmission efficiency is 3.9%. In order to interrogate atoms with the 657 nm clock signal, we lock the 423 nm laser to the atomic resonance transition by another vacuum system. The locking time can be more than 1 hour. Then we scan the 657 nm laser by introducing a triangular wave to the PZT of the ECDL laser. The transmission spectrum of the 657 nm clock signal is showed in Fig. 4. The upper blue line in Fig. 4 is the fluorescence detection signal in another vacuum signal as a reference. The π transition of 657 nm is chosen by aligning the polarization of the laser to parallel to the direction of the magnetic field. The lower red line in Fig. 4 is the dispersion detection. Because the polarization of laser beam is always perpendicular to the direction of the magnetic field in this vacuum system, the $\sigma^{\pm}$ transition is chosen to demonstrate this detection method in principle. In Fig. 4, the left spectrum is the σ^- transition and the right one is the σ^+ transition. The $\sigma^{\pm}$ transitions are separated 176.6 MHz to m=0 level. The 657 nm laser's power is set to 8.1 mW. The signal intensity of each is 0.054 V and the linewidth is 86.7 MHz. Fig. 5 shows us the single σ^- transition by rotating the λ/4 plate, where is before the incidence of 657 nm laser. The signal intensity becomes 0.108 V, which is doubled, but the linewidth is the same to the $\sigma^{\pm}$ transition. Comparing the 657 nm signal to the 423 nm signal, we can see that 3.3% of the ground state atoms has been excited to the metastable 3P1(m=±1) state by $\sigma^{\pm}$ level and detected here.

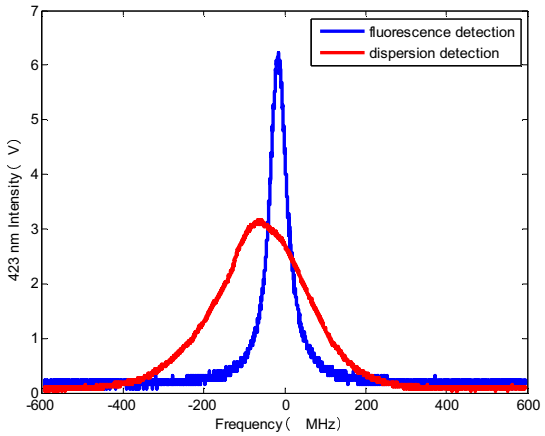

Fig. 3. Dispersion detection of 423 nm. Red (Wider): the transmission of the Faraday effect of 423 nm; Blue (Narrower): the fluorescence detection of 423 nm in another vacuum system for a reference.

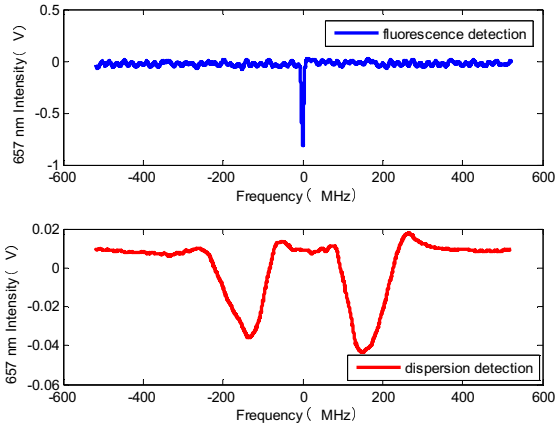

Fig. 4. Dispersion detection of 657 nm clock signal. The 423 nm laser was locked to the atomic transition center. Scanning the 657 nm laser, the upper blue line is the fluorescence detection signal of 657 nm, which is the π transition of Ca atoms. The lower red line is the dispersion detection signal of 657 nm, which is the $\sigma^{\pm}$ transition.

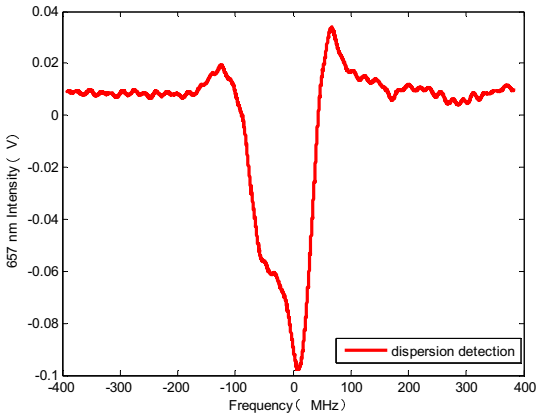

Fig. 5 The single 657 nm σ^- transition signal of the dispersion detection.

IV. CONCLUSION

In conclusion, we first demonstrated the dispersive detection of 657 nm transition via the Faraday rotation effect of 423 nm transition in a thermal Ca atomic beam. The Faraday anomalous dispersion optical filter[6] of 423 nm transition can reach a maximum transmission of 10%. With a magnetic field of 84 G, the observed 3.3% of the ground state atoms has been excited to the $\sigma^{\pm}$ level of metastable 3P1(m=±1) state, which are separated 176.6 MHz to m=0 level. In comparison with traditional atomic clocks, this new detection method provides great advantages to both integration and miniaturization.

***Abstract*—We report the absolute frequency measurements of rubidium 5S-7S two-photon transitions with an optical frequency comb. The digital lock to the transition, the procedures of evaluating the accuracy budget and measurements of the frequency with the optical frequency comb are tested with a simple setup for the sake of comparison of two optical lattice strontium clocks. The narrow, two-photon transition, 5S-7S (760 nm) is insensitive to a magnetic field and promising candidate for frequency standard. The preformed tests yield the transition frequency with accuracy better than reported previously.**

I. Introduction

The International Committee for Weights and Measures recommended several radiations for applications including the practical realization of the metre. At the border of the visible and near-infrared ranges the BIPM recommends the $5S_{1/2}$(F=3) - $5D_{5/2}$(F=5) two-photon transition in ^{85}Rb with a standard uncertainty of 5 kHz (the relative standard uncertainty of 1.3×10^{-11}) [1]. Recent development in phase-stabilized optical frequency combs based on mode-locked femtosecond lasers allowed determination of the absolute frequency of a similar transition in Rb, $5S_{1/2}$-$7S_{1/2}$, which is 100 times weaker than 5S-5D, yet less sensitive to the stray magnetic fields. At the 5S-5D transition the rubidium atoms must be carefully shielded against the magnetic field to avoid any linear Zeeman shifts. On the other hand, the 5S and 7S levels have the same Landé g factors which cancels the linear Zeeman shifts in the 5S-7S transition. The ac-Stark effect in the 5S-7S transition is also smaller than in the 5S-5D case. All previous measurements of the 5S-7S transition [2]–[5] gave worse estimations of the absolute frequency than the measurements of the 5S-5D transition [6]–[9]. In this work we report the measurement of the absolute frequency measurements of the $5S_{1/2}$(F=2)-$7S_{1/2}$(F=2) transition in ^{87}Rb with relative standard uncertainty of 5.8×10^{-12} which is better than measured previously.

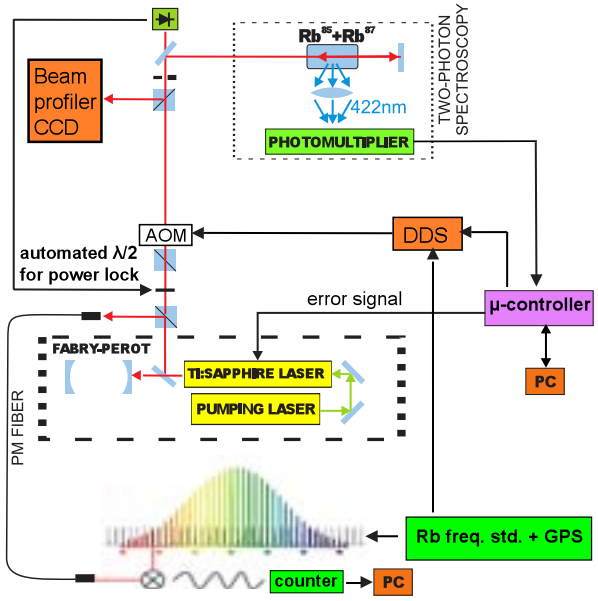

Fig. 1. Experimental setup.

II. Experimental arrangement

The experimental setup is shown in Fig.1. We have used a commercial ring-cavity titanium sapphire (TiSa) laser to study the two-photon $5S_{1/2}$-$7S_{1/2}$ transitions at 760 nm in a hot rubidium vapour cell at temperatures up to 140 Centigrades. The TiSa laser is pre-stabilised by a Fabry-Pérot cavity which narrows the laser linewidth to 300 kHz. The two-photon

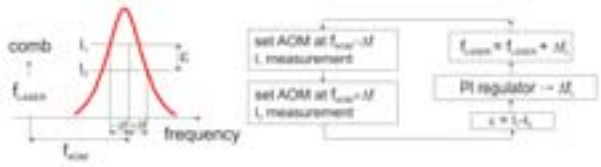

Fig. 2. The scheme of the digital lock.

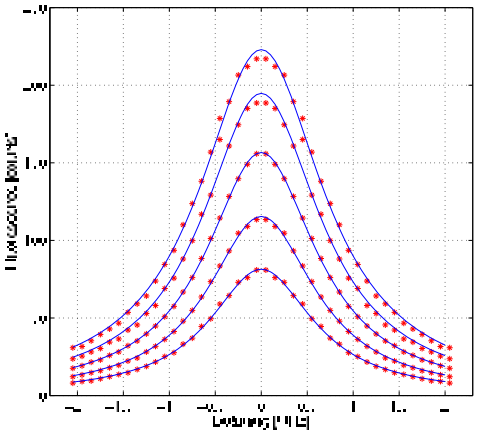

Fig. 3. The line profile for different intensities of the probing light. The Lorentz profile is fitted to the measured data.

spectroscopy signal is observed by a photomultiplier tube in the 7S-6P-5S radiative cascade, with the 6P-5S decay blue fluorescence around 421 nm.

The idea of the digital lock is depicted in Fig.2. An acousto-optic modulator (AOM) driven by a direct digital synthesizer (DDS) square-wave modulates the light frequency with the step 2Δf equal to the half-width of the line. The AOM carrier frequency f_{AOM} is chosen such that the AOM efficiency with $f_+ = f_{AOM} + \Delta f$ and $f_- = f_{AOM} - \Delta f$ is the same. The microcontroller (Atmel AT91SAM7S), which controls the DDS, counts the photomultiplier pulses. The error signal for the laser lock is calculated from the difference of the counts for f_+ and f_-. The software PI regulator in the microcontroller calculates the correction Δf_L and applies it to the TiSa laser. The power of the light sent to the rubidium cell is stabilised by the software PI regulator on the embedded PC (FOX Board G20) with a half-wave plate mounted on a piezo-driven mount and a polariser. To exclude the residual Doppler shift, the counter-propagating beams in the two-photon spectroscopy are not focused and their relative position is controlled by a CCD beam profiler camera. By changing Δf in the digital lock we can measure the line profile. Since the counter-propagating beams are not focused we can measure the line-shape of the transition broadened only by the 300 kHz laser linewidth and the light power (Fig. 3).

Part of the TiSa light is sent directly to the Er-dopped fiber optical frequency comb (Menlo FC1500-250-WG). The comb, the DDS synthesizers and counters in the experiment are locked to a microwave Rb frequency standard (SRS FS725), disciplined by the GPS (Connor Winfield FTS 375). The

fractional Allan variance of the beat frequency between the locked TiSa laser and the optical frequency comb is presented in Fig. 4. After 1000 s our Rb frequency standard reaches its final stability, and our system is further disciplined by the GPS which improves the stability, as seen in the plot, after 10^4 s integration time.

III. RESULTS

Several systematic effects should be taken into account to deduce the transition frequency. The measurements are dominated by a systematic pressure shift. By measuring the absolute frequencies at different temperatures (accuracy of 0.2K), we determined the pressures [10], estimated the pressure shift coefficient in our cell as -17.82(81) kHz/mTorr (Fig. 5) and extrapolated it to zero pressure. In the same way we measured and calibrated the ac-Stark and quadratic Zeeman shifts. By measuring the absolute frequency while misaligning the probe beams we estimated the uncertainty due to the residual Doppler shift. Varying the Δf value in the DDS lock and the AOM diffraction order ($+f_{AOM}$ or $-f_{AOM}$) to cancel any residual efficiency imbalance between f_+ and f_-, we also estimated the shift of the digital lock. The black body radiation and second order Doppler shifts were calculated for a given stabilised cell temperature in the cell.

The accuracy budget for typical experimental conditions, i.e. laser intensity of 8 W/cm^2 and temperature of 128.5°C, is presented in Table I.

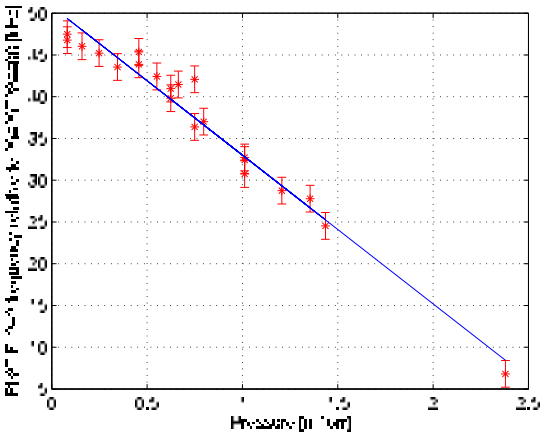

Fig. 5. Pressure shift. Frequency is relative to the best previously known value.

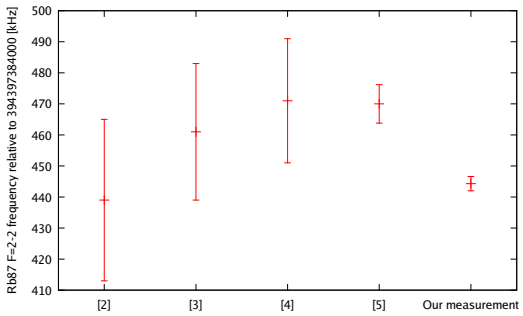

Fig. 6. Comparison with previously known values.

The absolute optical frequency for the ^{87}Rb F=2-F'=2 two-photon transition is determined to be 394397384444.3(2.3) kHz Its comparison with previously measured values is depicted in Fig. 6.

IV. Conclusion

We performed a series of measurements of the absolute frequency of the 5S-7S two-photon transitions in rubidium vapour with an optical frequency comb. The digital lock to the transition, the procedures of evaluation the accuracy budget and measurements of the frequency with the optical frequency comb, prepared for a future system of two optical lattice clocks with strontium atoms, were tested with a simple setup. Thanks to a very good long-term stability of our experimental system, we obtained higher accuracy of the 5S-7S transition frequency than any previously reported [2]–[5].

***Abstract*— We report on the frequency stabilization of an infrared (IR) laser emitting at 1.5 µm onto molecular iodine hyperfine transitions at 514 nm. Third harmonic generation process based on Periodically Poled Lithium Niobate non linear crystals (PPLN) is used to link the IR emission to the green region. We have developed and tested a compact experimental setup using a multi-pass iodine cell in order to meet transportable/spatial requirements. Narrow hyperfine iodine lines (FWHM ~ 300 kHz) corresponding to a quality factor Q > 10^9 are already detected and used for the IR sources stabilization purpose.**

Keywords - laser frequency stabilization, frequency tripling, second harmonic generation, molecular spectroscopy, iodine, metrology.

I. INTRODUCTION

Ultra stable optical frequency standards are of great interest for various fields such as optical communications, long distance optical links, transportable frequency standard, high resolution atomic or molecular spectroscopy, etc... Infrared lasers (IR) operating in the range 1 µm to 2 µm offer attractive possibilities for these applications regarding to their very low intrinsic phase noise, high output power, compactness and reliability in fiber mode configuration. To enhance the long term frequency stability of those lasers and to confer them a given accuracy, we must combine their use with an external frequency reference which exhibits high signal to noise ratio and linewidth as narrow as possible in same time.

Nowadays, the best performances in terms of short term frequency stability are achieved using rigid optical cavities (OC) which deliver excellent frequency discriminator and yield to impressive results in a wide range of the optical domain [1]. However, these couple laser/OC require an operative mode in a severe thermal and seismic environment, confining them to metrological laboratory activities.

Atomic and/or molecular transitions used in simple way with the saturated absorption technique constitute an elegant alternative to achieve compact experimental devices usable outside the laboratory even if the short term stability is more modest compared to the laser/OC systems. Many atomic or molecular species in coincidence with the IR sources gain curves allow already conferring levels of stability in the 10^{-11} 10^{-12} range (for example C2H2 for 1.5 µm lasers) [2]. The lines of some alkaline can also be used to stabilize these same lasers after frequency doubling [3, 4].

Molecular iodine has an absorption spectrum which extends from approximately 750 nm to 500 nm (limit of dissociation of the molecule) (Fig. 1). The atlas of iodine [5] lists some 100000 rovibrational transitions between the fundamental level (X) and the excited level (B), each of them being split in 15 or 21 hyperfine components. These molecular lines have been widely used for frequency stabilization of frequency doubled IR sources, such as Nd: YAG based systems [6, 7].

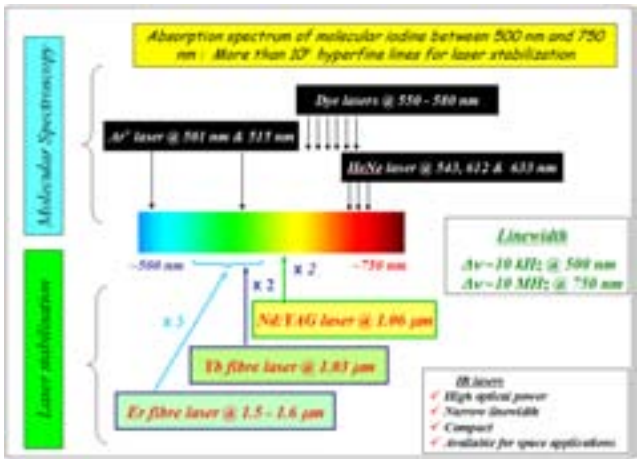

Figure 1. Laser stabilization possibilities onto molecular iodine transitions.

In this work, we report, for the first time to our knowledge, the frequency stabilization of a laser emitting in the C-band of optical telecommunications (around 1545 nm) onto an iodine line near 514 nm. The link between IR and visible regions is realized by means of a frequency tripling process. Previous attempts are reported in literature to realize the frequency tripling of an IR radiation to reach the green spectral region either by direct third harmonic generation (THG) [8] or by second harmonic generation (SHG) and sum frequency generation (SHG) within a single crystal [9]. In both cases, the tripling process was not efficient enough to give the possibility

to detect iodine transitions. The harmonic powers thus achieved in the nanowatts range, were not sufficient to realize iodine vapor saturation for the frequency stabilization purpose. Our scheme for THG is based on two cascaded non linear crystals, one for the SHG and one for the SFG from radiations emerging from the first one. We obtain by this way 1.5 mW of green radiation, a sufficient power for detecting iodine lines in a 20 cm long cell.

II. Frequency Tripling at 1545 nm

The experimental setup is depicted in Fig. 2. The IR source is an extended cavity laser diode (ECLD) operating over 100 nm from 1500 to 1600 nm emitting an output power of 20 mW. An Er doped fibre amplifier (EDFA) permits to reach an IR power more than 600 mW, incident onto the first non linear crystal involved in this experiment. The THG is operated in two steps by cascading two temperature controlled MgO: PPLN crystals (Fig. 2). The first one realizes the SHG at 772.5 nm from the IR radiation at 1545 nm produced by the amplified ECLD laser. The second one realizes the SFG between both radiations obtained at the output of the first crystal, i.e. the red beam at 772.5 nm and the residual IR beam at 1545 nm.

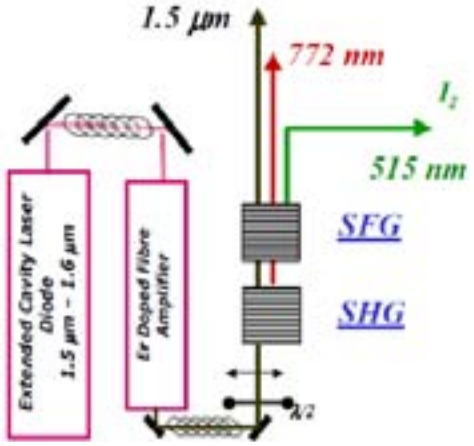

Figure 2. Experimental setup for third harmonic generation.

The dimensions of the fist crystal for SHG are 50 mm length, 1 mm width and 0.5 mm height. Its poling period is 18.2 µm. The quasi phase matching (QPM) is obtained around 50°C. The dimensions of the second crystal for SFG are 50 mm length, 2 mm width and 0.5 mm height. Its poling period is 6.92 µm. The quasi phase matching (QPM) is obtained around 19°C. The SH power measured at the output of the first crystal versus the IR power injected is plotted in Fig. 3. The conversion efficiency is found to be 0.9 %.W^{-1}.cm^{-1} and a maximum power of 12 mW of red radiation is obtained at 772.5 nm for 630 mW of IR power. Fig. 3 also shows the third harmonic (TH) power measured at the output of the second crystal producing the SFG between both radiations emerging from the output of the first crystal. A maximum output power of 1.5 mW at 514 nm is obtained (the conversion efficiency is estimated as 4.5 %.W^{-1}.cm^{-1}). This power is sufficient to detect hyperfine components of molecular iodine in a cell in saturation spectroscopy by means of the setup described in next section.

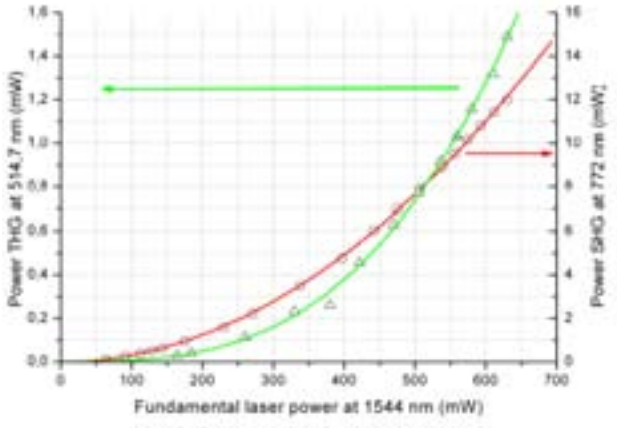

Figure 3. SHG and THG power versus the input IR power.

III. Spectroscopy of Molecular Iodine

A. *Iodine cell in multipass configuration*

We have developed a compact system for molecular iodine spectroscopy based on a multipass iodine cell (Fig. 4). The detail of this setup is in Fig. 5.

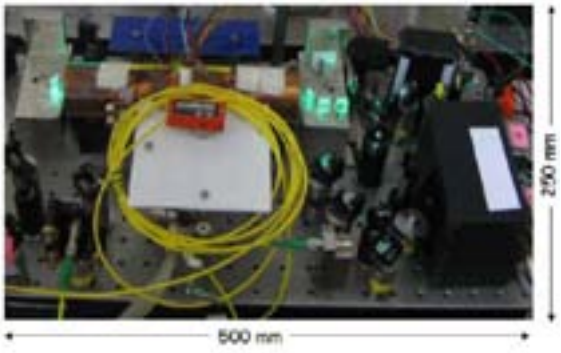

Figure 4. Photography of the experimental setup for saturation spectroscopy of iodine near 514 nm.

Hyperfine components at 514 nm are detected by saturation spectroscopy in a sealed cell (length 10 cm, diameter 2 cm) located in a thermal shield. The iodine pressure in the cell of about 0.8 Pa (6 mTorr) is controlled by thermo stabilization of a cold finger (-15°C). Probe and pump beams are counter propagating and pass four times through the cell. Input pump power of about 500 µW is sufficient to detect narrow hyperfine lines with excellent signal to noise ratio.

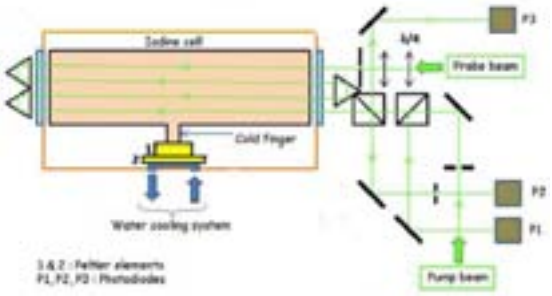

Figure 5. Experimental setup for saturation spectroscopy of iodine near 514 nm based on a multipass cell configuration.

B. Detected lineshapes

A typical spectrum showing the hyperfine splitting of a rovibrational transition near 514 nm detected with this setup is shown in Fig. 6, corresponding to the P46 (44-0) transition at 514.581 nm. The selection rules of hyperfine interaction in iodine lead to find 15 hyperfine components for an even rotational quantum number in the ground state ($J = 46$).

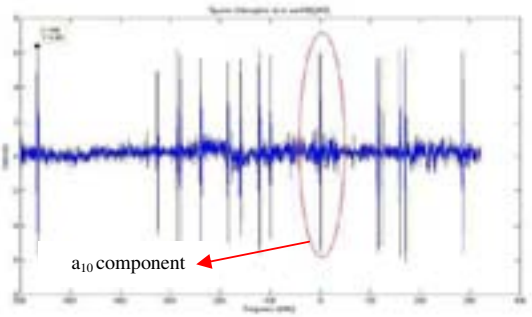

Figure 6. The complete spectrum of trasition P46(44-0) at 514.743 nm.

Fig. 7(a) shows the a_{10} component of this transition detected with the third harmonic and with a time constant of 300 µs. One can note the high signal to noise ratio of this signal and the good symmetry of the line shape. The peak-to-peak linewidth is close to 300 kHz.

We have identified a large number of rovibrational transitions with intense and narrow hyperfine components in the spectral region near 514 nm. Fig. 7(b) shows for instance the doublet a_3-a_4 belonging to transition R48 (44-0) at 514.585 nm.

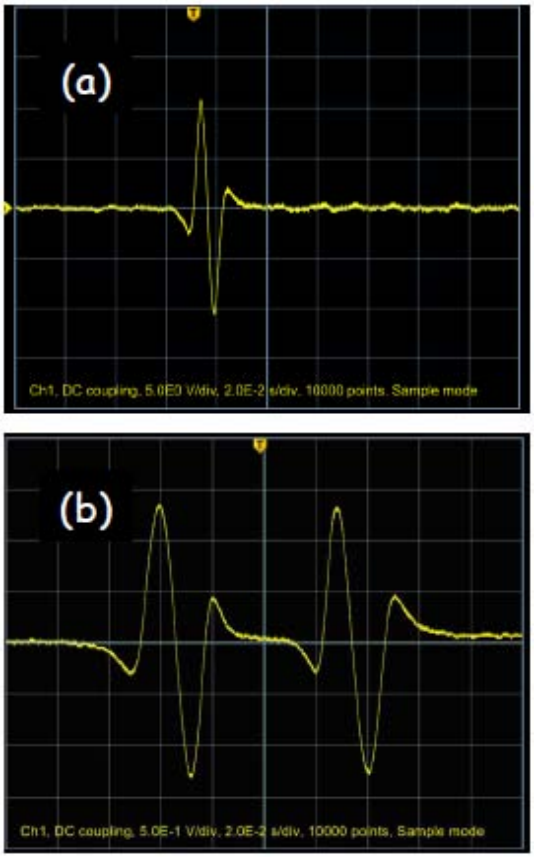

Figure 7. Third harmonic detection of hyperfine components near 514 nm.
(a) a_{10} component of the P46(44-0) line at 514.581 nm;
time constant is 300 µs;

(b) a_3-a_4 doublet of the R48(44-0) line at 514.585 nm;
time constant is 300 µs.

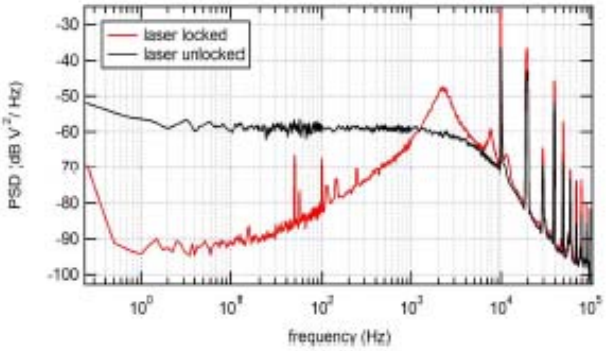

Figure 8. Noise spectrum of the error signal of the frequency stabilized IR source (inloop signal).

C. *Frequency stabilization of the source*

Such narrow lines are of first interest for the frequency stabilization of the IR source. We have locked the IR laser to the center of a_{10} component of transition P46 (44-0). Fig. 8 shows the noise spectrum of the error signal. A rejection of frequency noise more than 30 dB is reached up to 100 Hz. In this case, our laser can stay locked during several hours. The next step of this work consists on the metrological performances characterization by comparison with the cold atoms optical clocks of the SYRTE lab, located in an other building. This part is under development and the results will be reported subsequently.

IV. CONCLUSION

We have presented our first results concerning the frequency stabilization of an IR laser at 1.5 µm onto hyperfine components of molecular iodine near 514 nm. The IR emission is linked to the green region by means of a THG process achieved by cascading two PPLN crystals (SHG and SFG).

We have also developed a compact experimental setup based on a multi-pass iodine cell in which we have detected narrow hyperfine iodine lines (FWHM ~300 kHz) corresponding to a quality factor $Q > 10^9$.

Finally, we have locked the IR source onto those lines in order to stabilize the IR source frequency.

***Abstract*—In the frame of the REFIMEVE+ project, aiming at disseminating an optical frequency standard to more than 20 laboratories in France, we present the progress made towards a metrological fibre wide-area network.**

Keywords—Optical link; frequency transfert; ultrastable laser;

I. INTRODUCTION

Today, the transfer of ultrastable frequency is mainly provided through by GPS system. But its resolution is one order of magnitude too low for the best microwave clocks cold atoms. To anticipate the transfer of a reference signal from an optical clock whose performances are approaching at least an order of magnitude better than the microwave clocks, it is important to develop new and better transfer methods.

Since a decade, many institutes and laboratories around the world work on fibre optical links. Stabilities obtained for links of hundreds of kilometers are reaching some 10^{-15} at 1 s and 10^{-18} at 10 000 s [1-2-3].

So far the work has been to transfer the frequency between two points A and B. But it is not feasible to design a point-to-point distribution network which needs a lot of fibres. It is more efficient to have a single optical fibre, for the ultrastable signal with distribution along the fibre (see fig. 1). The first part of this work will present the issue of multiple user distribution and the second part will present the solution to build long-haul links using the internet academic network.

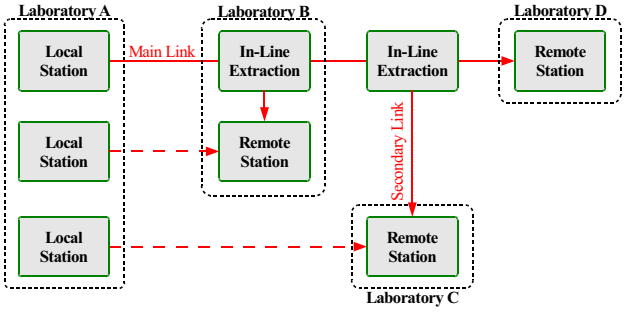

Fig. 1: Metropolitan network with a main link between Lab. A and Lab. D to transfer an optical frequency ultrastable and an In-line Extraction either directly distributed to Lab B or fed to another secondary link.

II. IN-LINE EXTRACTION

In-line extraction, as first proposed 3 years ago by G. Grosche [4], enables a very flexible distribution for several labs spread in the same metropolitan, area: the signal is extracted from the main link and either directly distributed to a lab or fed to another secondary link (see fig. 1).

A. Principle

A main link consists of copying the ultrastable signal from one end (Local Station) to the other end of the link (Remote Station). On the path of the optical fibre, the signal phase is disturbed by temperature fluctuation of the fibre and mechanical vibrations. The challenge is therefore to compensate these disturbances.

The principle of the phase correction is shown in Fig. 2. After a round trip in optical link, the signal has accumulated a phase noise $\varphi_A + \varphi_B$ and it is compared to the reference signal of the local station. Heterodyne detection allows discriminating the round-trip signal from stray reflections. The phase noise is corrected with a phase-locked loop (PLL) via an acousto-optic modulator (AOM).

The objective of the in-line extraction is to extract the reference signal along the optical fibre, at any distance from the ends of the link, and to compensate the phase noise accumulated between the starting end of the link and the extraction point. This setup must be inserted on the main link with the minimum of induced loss. Both forward and backward signals are extracted with a simple coupler and combined to detect the beatnote, which contains the fibre noise after the extraction. This provides a new phase correction applied to an

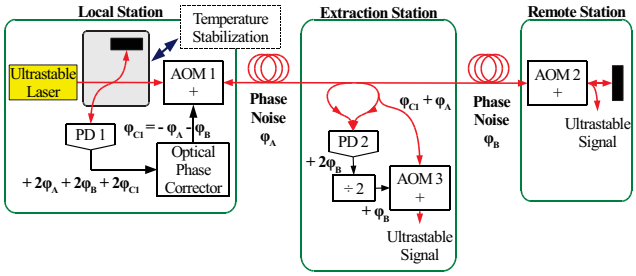

Fig. 2: The principle of a main link with phase noise correction at Local Station and the in-line extraction inserted on the link.

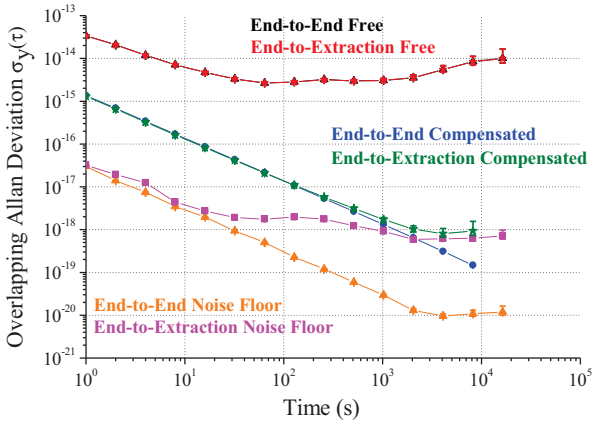

Fig. 3: Frequency Allan deviation for the end-to-end and extracted-to-end signals, in open and closed loop, and associated noise floors.

AOM. We can thus compensate for the over-correction of the phase noise at to the extraction point

B. Results

We tested this setup with an installed fibre link of 92 km in Paris area. The in-line extraction was inserted in this main link after 86th km. The relative frequency stability of σ_y (t) obtained with the main link is 1.5×10^{-15} at 1 s and some 10^{-19} after 10000 s, in accordance with the state of art. Concerning the in-line extraction signal, the results are consistent with those of the main link up to 1000 seconds of integration. Disturbances observed for longer integration time are due to thermal effect on the fibres used in the extraction setup.

III. LONG-HAUL LINKS

A link of 540 km of length has already been demonstrated from Laboratoire de Physique des Lasers (LPL) to Reims and back to LPL. An extension to Strasbourg is under progress which will leads to a link Paris-Strasbourg-Paris of around 1500 km.

This link is operated in parallel with data traffic and uses the academic internet network of RENATER (French Network for Technologies, Education and Research). For the data transmission, the telecom fibre is operated in one direction and mono-directional amplifiers are regularly placed in shelters. For the ultrastable signal transfer, the signal must flow in both directions. The fig. 4 presents the equipment to drop and add

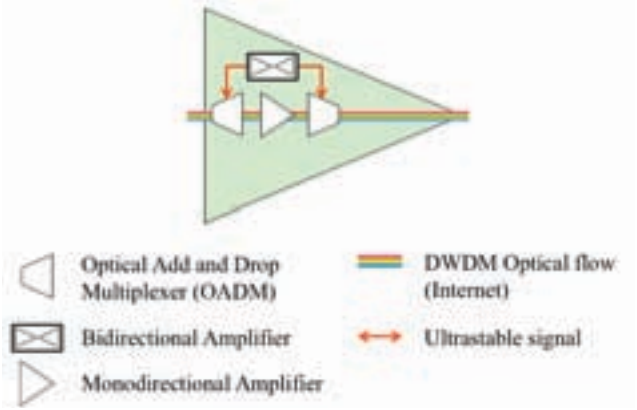

Fig. 4: Shelter with telecommunication mono-directional amplifier by-passed by two OADM and one bi-directional amplifier.

the ultrastable signal from the internet flow respectively before and after the mono-directional amplifier. For that purpose, we use two Optical Add and Drop Multiplexer (OADM) and the equipment includes also a bi-directional amplifier.

The Paris-Strasbourg-Paris optical link will be split in three cascaded link, which enables for a higher correction bandwidth and a better noise correction. Repeater stations will connect each segments, as already demonstrated in [5], and will achieve three functions, to send back part of the received signal to the previous station, to amplify and filter the received signal and to compensate the phase noise induced by the following segment. The amplification gain can reach more than 60 dB.

ACKNOWLEDGMENT

This work would not have been possible without the support of the GIP RENATER. The authors are deeply grateful to L. Gydé, T. Bono and E. Camisard from GIP RENATER for technical support. We also acknowledge S. Guellati-Khelifa and F. Biraben from LKB-Jussieu for encouraging part of this work and using the dedicated link between LKB and LNE-SYRTE. We acknowledge funding support from the Agence Nationale de la Recherche (ANR BLANC 2011-BS04-009-01), Université Paris 13 and IFRAF-Conseil Régional Ile-de-France.

I. INTRODUCTION

MEMS-based oscillators were first produced commercially six years ago. Now MEMS is making significant incursions into what was once the exclusive territory of quartz. At the time of this paper's publication, over 200M MEMS oscillators have been shipped, with over 100M units expected to ship in 2013, at a growth rate of about 70% per year [1].

There are five fundamental drivers for the transition from quartz to MEMS: (1) Basic MEMS oscillators are maturing with decreasing phase-noise and decreasing power consumption in smaller packages, and with these improvements they are reaching further into common quartz applications. (2) Specialized MEMS oscillators are transitioning new markets, for example in applications requiring ultra-low power, sub-ppm precision, high frequency differential signaling, sub-picosecond integrated jitter, voltage control, digital control, spread, and output edge-rate control. (3) MEMS oscillators have shown higher reliability and lower failure rates than quartz oscillators. (4) MEMS oscillators have demonstrated lower electromagnetic, vibration, and acceleration sensitivity than quartz oscillators. (5) MEMS oscillators sell at lower price points than the quartz parts they replace.

Why is this transition happening now, rather than ten years ago or ten years from now? One answer is that the transition has been paced by the MEMS community developing the necessary high stability, high frequency, high Q, and high output resonators. A second answer is that MEMS oscillators rely on advanced circuit architectures, particularly leveraging fractional-PLLs (fractional Phase Lock Loops, or frac-N) and precision temperature sensors. And these specialized circuits have only recently become sufficiently small, low noise, power efficient, and accurate.

Looking forward, the depth and breadth of the applications served by MEMS oscillators will continue to expand, while the drivers favoring MEMS oscillators will further accelerate their adoption.

This paper focuses on the present technical status of the MEMS oscillators built by the author's company. The second section presents the resonators and encapsulation, the third section the oscillator circuitry, the fourth section a look ahead at MEMS OCXOs.

II. MEMS RESONATORS AND ENCAPSULATION

Development of MEMS resonators dates to the mid-1960, with the first published results by Nathanson 1967 [2]. These early resonators were intended to be audio filters, and were not suitable for references. Their stability was limited by the metallic resonator material and the packaging cleanliness.

Work at Berkeley in the 1990's developed polysilicon [3] as a resonator material, and further work at Stanford and elsewhere [4] in the 1990's and early 2000's extended this to single crystal silicon. Presently both single crystal and polycrystalline silicon are used in commercial MEMS resonators. Other silicon-centric materials, including Aluminum Nitride are in development and early deployment [5]. Research on more exotic materials such as polycrystalline diamond is in progress [6].

The resonators described here are based on electrostatically transduced lateral motion in single crystal silicon.

Figure 1 shows an isometric view of a 48MHz resonator. The arrows indicate the in-phase resonant mechanical motion of each ring. There are drive and sense electrodes inside and outside of each ring. The rings are anchored beside the midpoint crosses of the support beams. The resonator Q is nominally 147k at room temperature. Further detail may be found in [7].

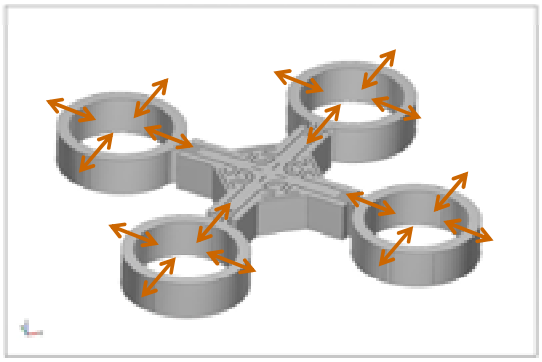

Figure 1. Low phase noise 48MHz resonator isometric diagram.

Figure 2 shows a 524kHz resonator that operates at very low power for sub-microamp timekeeping oscillators in applications now served by 32kHz quartz tuning fork crystals. In this application the output frequency is divided to 32kHz or drives a Real Time Clock (RTC) counter.

Figure 2. Low power 524kHz resonator isometric view.

As resonators are reduced in size their volume to surface ratio decreases, and consequentially their sensitivity to surface contamination increases. To maintain stabilities in the ppm (parts per million) to ppb (parts per billion) range expected of frequency references, it is necessary to minimize contamination mass-loading the resonators. Even a monolayer of surface contamination can shift a resonator's frequency out of specification. This drives a requirement for very clean packaging. Bonded covers have shown sufficiently clean vacuums to support commercial resonators with XO-type accuracy, while epitaxially encapsulation used for the parts in this paper enables tighter TCXO to OCXO-level stability.

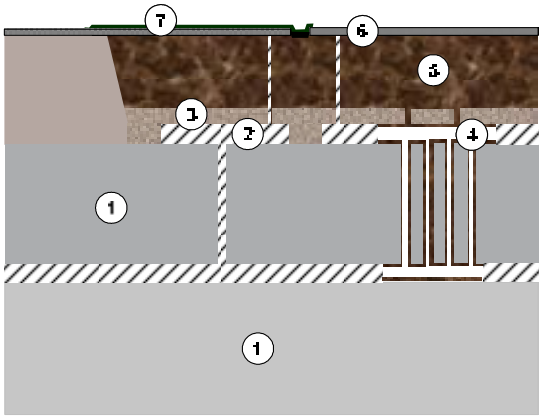

Figure 3. MEMS encapsulation process cross section.

Figure 3 shows a cross-section of the resonator and encapsulation fabrication. The resonators and encapsulation are built as follows: (1) an SOI wafer is trenched to define the resonator, (2) protective oxide is deposited and patterned, (3) silicon is deposited and patterned with vents, (4) the resonator is released, (5) the vents are closed and thick encapsulation is deposited, (6) contact isolation trenches are etched and oxide filled, and (7) metal traces are fabricated and passivated in the usual way.

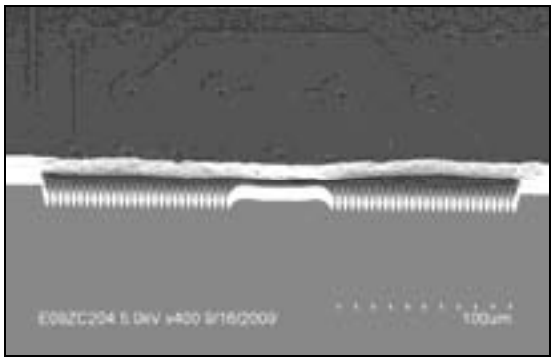

Figure 4. Cross section SEM of cleaved 524kHz resonator.

Figure 4 shows a cleaved wafer bisecting a 524kHz resonator. Aluminum interconnects are visible on the top surface, while the encapsulation is visible on the edge. The protruding serrated structure is one edge of a resonator.

MEMS thermistors for temperature sensing and frequency compensation can be built into the encapsulation beside the resonators. Like the resonators, they are fully vacuum encapsulated and released. Because they are encapsulated with the resonator, they are protected from environmental contamination and therefore highly stable [7].

The fully encapsulated resonators are singulated, paired with CMOS oscillators ICs, and molded into plastic QFN (Quad Flat No-lead) packages. These packages provide standard oscillator footprints for easy substitution into legacy quartz applications. Figure 5 shows a diagram of this package.

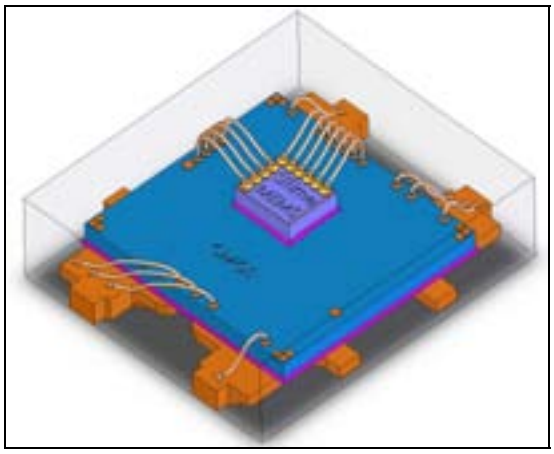

Figure 5. Package diagram showing leadframe, CMOS, and MEMS die.

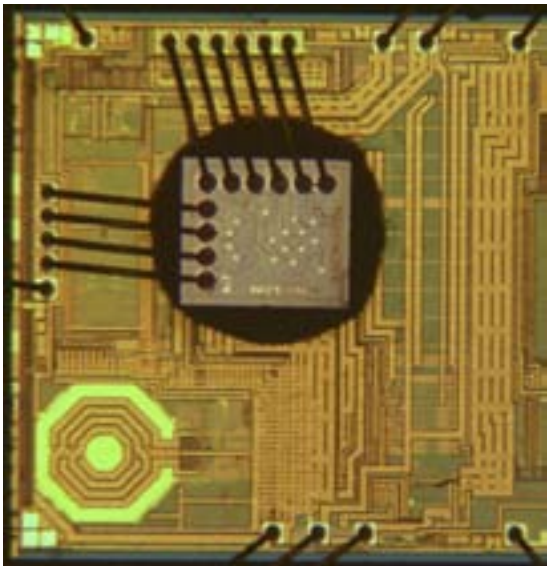

Figure 6. Die photo. The CMOS die size is 2.0x1.9mm^2, and the MEMS (bonded on top) die size is 0.55x0.48mm^2.

Figure 6 shows a photo of a MEMS die mounted on a CMOS die in a de-lidded package in which the plastic has been removed to expose the die and bondwires.

III. Circuit Architecture

There are two application drivers that quartz addresses with mechanical processes that MEMS addresses electronically: providing a wide range of application frequencies, and trimming the resonator frequency over production tolerances. In TCXOs, electronics also compensates the resonator frequency over temperature.

For MHz oscillators, applications require hundreds of different frequencies. For quartz, the resonators must normally be manufactured precisely to these frequencies, necessitating that the crystals be cut and ground to hundreds of different thicknesses. Second order effects often require the lateral dimensions of the crystals to be optimized for each frequency.

Building MEMS resonators across wide frequencies would be time consuming and expensive. Commercial MEMS resonators require years of individual development. For resonators with lateral modes, the dimensions or shapes are specific for each frequency, which implies dedicated mask sets for each frequency. For resonators with vertical modes, multiple material thicknesses must usually be optimized for each frequency, which implies process variants for each frequency. For MEMS oscillators, supplying dozens or even hundreds of frequencies could be commercially unviable.

Quartz crystals are individually trimmed to their specified frequencies, or in the case of TCXOs are trimmed to within the pull range of their specified frequencies. This mechanical trimming is usually done by ion milling or laser ablating the quartz or metallization. MEMS resonators can also be trimmed this way; however mechanical trimming can complicate the already difficult MEMS design and fabrication.

For most MEMS XO's and all TCXO's, the resonator temperature is measured and the resonator frequency is compensated across temperature. Unlike quartz TCXOs, MEMS oscillators are generally not compensated by resonator pulling, but instead with finely controlled multiplication in frac-N PLL's.

Frac-N PLL technology was not available for early quartz oscillators. The designers therefore had no alternative than to develop resonators that could be built in a range of frequencies, could be trimmed, and in some cases adjusted or pulled over temperature. On the other hand, we now have the circuit technology to translate MEMS resonator frequencies to their oscillator application requirements, trim them over production, and compensate them over temperature.

Using a circuit-centric approach also provides commercial benefits. For instance, inventories of oscillators with various pre-defined frequencies are not needed because the completed product can be quickly programmed. Further, custom frequencies can be readily supplied in large quantities.

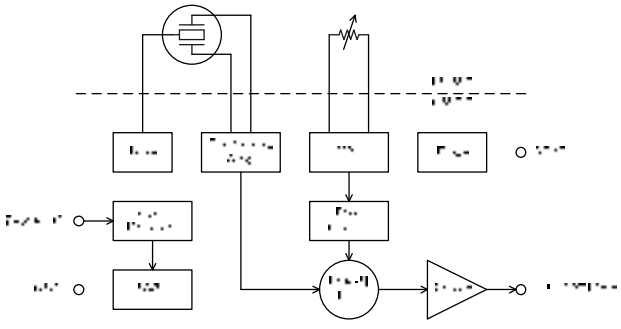

Figure 7. Oscillator topology.

Figure 7 shows the circuit-centric MEMS oscillator topology. The architecture includes a PLL to translate the resonator frequency to the application requirements. The PLL is fractional in order to trim the resonator across production tolerances, and its multiplication value is often variable in order to compensate for temperature. A state machine controls the PLL, drawing its parameters from non-volatile memory.

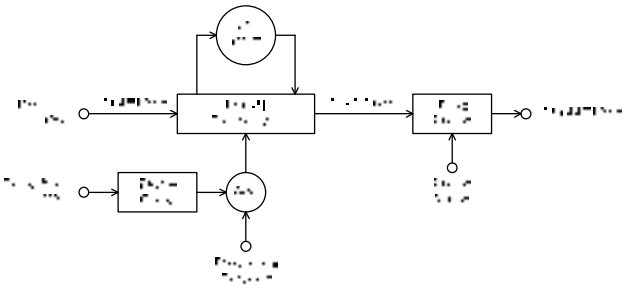

Figure 8. Frac-N PLL.

Figure 8 shows a block diagram of a frac-N PLL used in low-jitter oscillators. To provide low phase noise, and hence low integrated jitter, the PLLs use on-chip LC (inductor-capacitor) VCOs (Voltage Controlled Oscillators).

The frac-N PLL described here provides an output frequency programmable from 1MHz to 220MHz (after a final divide by 2) in sub-ppb increments. Details of the PLL have been published by F. Lee [8].

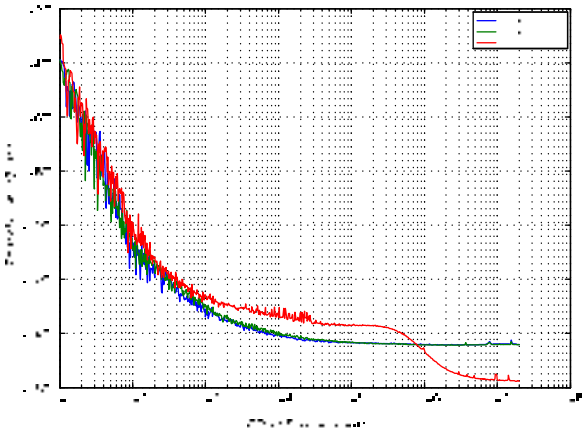

Figure 9. MEMS and PLL phase noise, reference frequency is 48MHz.

A PLL normally is thought of as a frequency translation circuit, and for that function it consumes power. It is sometimes thought that this is a "waste" of power because if the resonator had been at the output frequency then the PLL would not have been needed. However, a well-designed PLL like this one provides lower phase noise than its reference outside its filter bandwidth, and this is a significant advantage.

In Figure 9 one can see that outside of 1MHz offset the phase noise after the PLL (in red) is lower than the phase noise from of the MEMS sustaining amp (in blue and green). Phase noise is plotted on a log-log scale. In this case the phase noise outside of 1MHz dominates the integrated jitter because that integration is done on a linear scale. For that reason the decreased phase noise out of the oscillator is highly significant.

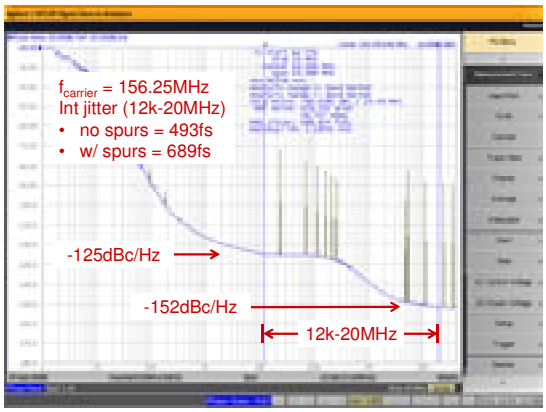

Figure 10. Output phase noise at 156.25MHz. Measured on Agilent 5052B.

Figure 10 shows the phase noise at 156.25MHz, a common reference frequency for high speed serial links. The integrated jitter from 12KHz to 20MHz in this case is 493fs not including spurs, and 689fs including spurs. Generally the telecom applications at this frequency account for spurs elsewhere and specify the integrated jitter without spurs to be under 1000fs.

The TDC (Temperature to Digital Converter) is need when resonator frequency is compensated over temperature. The TDC in the oscillator detailed here is optimized for low readout noise because noise in the temperature data becomes near phase noise in the output frequency.

One has many options when designing temperature sensors. Delta-VBE circuits using bipolar transistors in the CMOS die are ideal for consumer applications. These sensors have many favorable characteristics: they are linear, easy to calibrate, well understood, highly evolved, use moderate die area, and are low power. In addition they are purely circuit-based.

However, in these low jitter oscillators, we have chosen to use thermistors as the detection elements because they offer improved signal to noise.

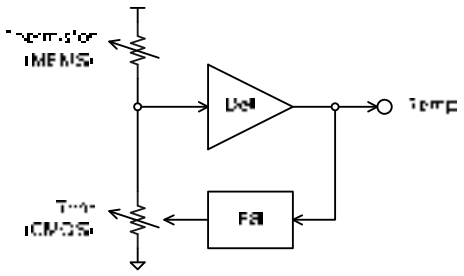

Figure 11. Balanced Bridge TDC.

Figure 11 shows a balanced bridge topology for digitizing thermistor resistance. A feedback loop keeps the node between the Thermistor and the Trim reference resistor at mid value. The variable resistance is implemented with switched capacitors and the feedback with a sigma-delta topology. The output of the feedback circuit is a high resolution digitized temperature value. A detailed description of the TDC is given in [9].

Note that there is never a voltage or current from the Thermistor to an ADC (Analog to Digital Converter). The Thermistor and TDC work in a feedback system to derive the temperature data, there is never an analog temperature value that is digitized.

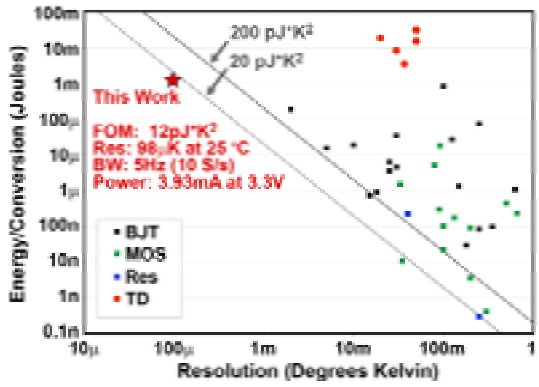

Figure 12. Figure of merit comparing conversion energy and resolution. Comparison data compiled by K. Makinwa [10].

The TDC delivers a resolution of 98uK at 5Hz bandwidth while consuming 3.9mA at 1.5V. Figure 12 compares its energy efficiency and resolution against other integrated TDCs. This TDC provides over an order of magnitude lower noise than others in the comparison population and does so at under 20pJK^2. The comparison data in this plot is compiled by K. Makinwa [10].

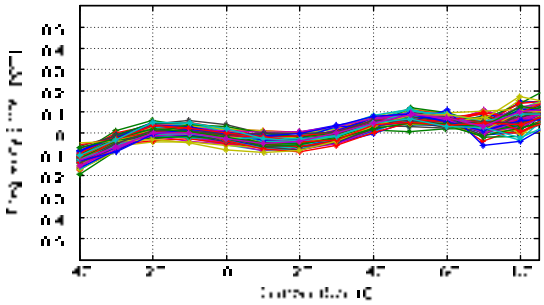

Figure 13. MEMS TCXO Compensated output frequency v. temperature.

Figure 13 shows the frequency over temperature of 68 MEMS TCXO's compensated to approximately 0.2ppm of their specified frequency from -40C to +85C.

IV. A MEMS OCXO

When an oscillator is maintained at an elevated temperature it delivers better frequency stability than when its temperature is allowed to vary with the ambient. This principle works as well in MEMS as it does in quartz.

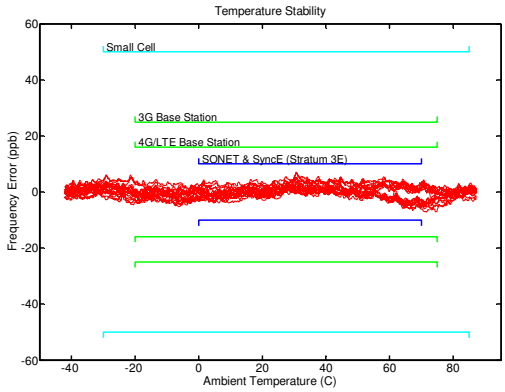

Figure 14. Oven controlled output frequency vs. ambient temperature.

Figure 14 shows the frequency vs. temperature of a MEMS oscillator built into an oven module. This is a single unit ramped over -45C to +90C at 0.5C/min bidirectionally for five days. The brackets in Figure 14 show the primary application temperature and accuracy requirements, including cell base stations and Stratum-3E oscillators for telecom networking. Accuracies better than 100ppb are normally provided by quartz OCXOs today.

Note that the results shown in this paper are from production material, except for the data in Figure 14 which is from a single part on a bench. Nonetheless, it is important to understand that MEMS oscillators will likely support OCXO applications.

V. CONCLUSIONS

Looking forward we believe that MEMS oscillators will replace quartz oscillators in consumer, telecommunication, and industrial applications.

Not discussed in this paper but still quite relevant are the higher quality levels and greater mechanical durability of MEMS oscillators. These features, combined with the performance described above, are driving MEMS oscillators into high reliability applications such as automotive and aerospace.

Presently over 200 million MEMS oscillators have been produced. The growth rate of this segment is strong, at about 70% per year. SiTime has been listed by Deloitte LLP in their Fast 500™ rankings as the fastest growing semiconductor company in North America [11]. This contrasts to modest or negative growth for the consumer quartz suppliers that are not adopting MEMS products.

ACKNOWLEDGMENTS

The authors would like to thank Mike Perrott, Jim Salvia and Renata Melamud for their contributions to the technology and data presented in this paper, and to Kofi Makinwa for guidance in temperature sensor development.

***Abstract*— This paper presents a new Laterally Vibrating Resonator (LVR) based on Y-cut ion-sliced Lithium Niobate (LN) thin films on silicon dioxide (SiO_2). In this work, the LN LVR is built on top of a SiO_2 layer and released from the underlying silicon wafer by dry etching in XeF_2. For a given sample having a LN layer thickness of 420 nm and SiO_2 thickness of 1600 nm, this first demonstration yielded resonators with temperature coefficient of frequency (TCF) of + 17 ppm/°C, and + 18 ppm/°C for devices vibrating at 500 MHz, respectively oriented at 10° and 30° to the x-axis, and TCF of +24.1 ppm/°C, and +27.7 ppm/°C for devices vibrating at 750 MHz, respectively oriented at 40° and 50° to the x-axis. The positive TCF clearly indicates the effect of the SiO_2, matches with finite element method simulations and non-linear analysis, and offers evidence that TCF engineering is possible. Most importantly, these LN LVRs still exhibited high values of electromechanical coupling, k_t^2, around 9% at 723.7 MHz , and Q in excess of 1,320 in air at 419.3 MHz. By optimizing the relative values of the LN and SiO_2 thickness it is ultimately possible to attain devices with zero first order TCF.**

Keywords*— Temperature coefficient of frequency (TCF), Lithium niobate ($LiNbO_3$) high coupling resonator, RF MEMS resonator, passive temperature compensation.

I. INTRODUCTION

Frequency references with low phase noise and drift, and temperature stable are key components of commercial and military wireless communication devices. Most of these communication systems also use many filters having relative bandwidths > 3%. Acoustic resonators and filters, such as surface acoustic wave (SAW) devices and thin film bulk acoustic resonators (FBARs), are primarily used in these systems. Nonetheless, these components are static and do not yet permit the synthesis of reconfigurable receivers capable of adapting their frequencies and bandwidths to variations in the spectrum. The development of high Q and temperature stable mechanical resonators having a high electromechanical coupling coefficient and capable of operating over a broad range of frequencies on a single chip would enable a new generation of reconfigurable communication systems.

The AlN Contour-Mode Resonators (CMRs) [1] previously demonstrated by our group have shown applicability up to 10 GHz and have introduced a paradigm shift over prior resonator technology because of the ability to devise multi-frequency filters on the same substrate. However, they are limited by the moderate material k_t^2 (~ 2% in AlN) to operate in systems that require BWs < 3 %. These devices also exhibit an uncompensated first order TCF of about - 25 ppm/°C, which is not adequate for accurate timing or frequency reference applications. The use of SiO_2 in the AlN CMR stack [2] [3] has achieved a low first-order TCF, but the moderate k_t^2 limits the applicability of these devices to wideband reconfigurable systems. Recently, LN laterally vibrating resonators (LVRs) have been demonstrated with both high k_t^2 and Q. The MEMS LN LVRs[4][5] have attained coupling larger than 20% and Q of about 1,000, but exhibited a rather large and negative TCF of about - 80ppm/°C. Furthermore, they were built on a LN substrate with either BCB or SiO_2 as sacrificial layers, which required a wet etch step for the release of the resonator.

In this paper, we present a new LVR technology based on Y-cut ion-sliced LN thin films on SiO_2 to intrinsically compensate the large negative TCF of LN films (see Fig.1). Additionally, dry etching in XeF_2 has been adopted to release the LN built on top of a SiO_2 layer from the underlying silicon wafer

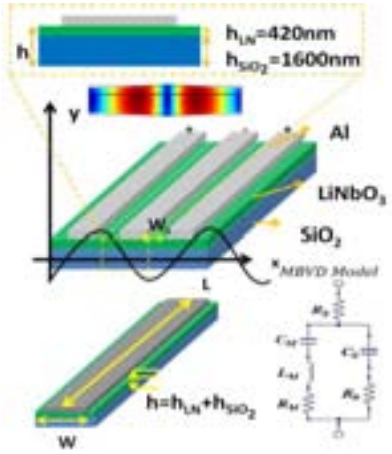

Fig. 1. Mock-up view of the LN on SiO_2 LVR. At the top, a zoomed in view of the cross section of one finger and the S0 mode of vibration of a full wavelenght (2 fingers) are shown. At the bottom, a 3D representation of a single finger with its characteristic geometrical parameters is also shown. The equivalent MBVD model of the resonator is displayed in the lower right corner.

II. ION-SLICE Y-CUT LN RESONATORS

A. Device Operation and Modeling

The LN LVR of this work consists of metal interdigital fingers (IDT) on top of a mechanically suspended LN/SiO_2 thin film. The electric field induced by the IDTs, which are alternatively connected to ground and signal, excites lateral expansion and compression in adjacent fingers (mode known as S0 lamb wave). The mechanical resonance is a function of the lateral dimension of the excitation electrode and is given by:

The author would like to thank NSF for funding.

$$f = \frac{1}{\lambda}\sqrt{\frac{E_p}{\rho}} = \frac{1}{2w}\sqrt{\frac{E_p}{\rho}} \quad (1)$$

Where w *is* the pitch of the IDTs, E_p the equivalent Young's modulus, and ρ the equivalent density of the resonator stack.

The resonator equivalent electrical circuit is described by the Modified Butterworth-Van Dyke (MBVD) model (Fig.1). The values of the motional parameters of the MBVD model are given by the following expressions [1]:

$$R_m = \frac{\pi^2}{8}\frac{1}{\omega_s C_0}\frac{1}{k_t^2 Q} \quad (2)$$

$$L_m = \frac{\pi^2}{8}\frac{1}{\omega_s^2 C_0}\frac{1}{k_t^2} \quad (3)$$

$$C_m = \frac{8}{\pi^2} C_0 k_t^2 \quad (4)$$

Where C_0 (static capacitance) is a function of finger pitch (w), length (L), and spacing between electrodes (w_s). k_t^2 refers to the effective electromechanical coupling, and Q is the quality factor of the series resonance frequency.

In this very first demonstration of LN/SiO_2 LVRs, the LN and SiO_2 thicknesses were set to 420 nm and 1600 nm because of sample availability from a third party vendor (Partow Technologies LLC). Nonetheless, as it will be shown in the next section, their relative values were appropriate to prove the concept of TCF engineering. The pitch of the electrode was set to 4 μm to ensure operation around 750 MHz for the fundamental S0 mode.

B. TCF Modeling of $LiNbO_3$ based Lamb Wave Resonator

The frequency shift of resonators under temperature variations is mainly caused by material softening. The resonator TCF is primarily related to the change of the stiffness coefficients with respect to temperature. Additionally, thermal expansion, which affects the resonator dimensions and material density, plays a secondary role.

In general, the TCF of a resonator is expressed in ppm/˚C and is defined as:

$$TCF = \frac{1}{f}\frac{\partial f}{\partial T} \quad (5)$$

$$TCF = -\frac{1}{w}\frac{\partial w}{\partial T} + \frac{1}{2}\frac{1}{E}\frac{\partial E}{\partial T} - \frac{1}{2}\frac{1}{\rho}\frac{\partial \rho}{\partial T} \quad (6)$$

Eq. (6) can be applied to the specific characteristics of the LN LVRs and results in [1]:

$$TCF = \frac{1}{2}(TC_{ij} + (\alpha_{11} + \alpha_{22} + \alpha_{33})] - \alpha_z \quad (7)$$

Where TC_{ij} refers to the relative temperature dependence of the stiffness constant C_{ij}; α_{11}, α_{22} and α_{33} are the thermal expansion coefficients along the x, y and z direction, respectively.

Given that LN becomes mechanically soft with an increasing temperature due to its negative TC_{ij}, uncompensated resonators based purely on Y-cut LN theoretically display a rather large and negative TCF of about - 80 ppm/°C. As SiO_2 exhibits positive TC_{ij}, it can be used in the device stack to enable temperature compensation of the LN LVR piezoelectric resonator.

In this work, the TCF characteristic of the S0 mode in a LN/SiO_2 composite plate has been modeled by COMSOL multiphysics finite element analysis (FEA). Both piezoelectric and thermal expansion moduli were used to describe the behavior of the device. The rotated stiffness and piezoelectric coupling matrix for each orientation in the Y-cut plane are derived from the Z-cut LN matrix [6] using the transformation matrix and bond matrix [7]. The obtained matrices are then input into the device model and used to predict the resonator frequency dependence on temperature. The simulated TCF for the S0 mode at various orientations are listed in Table I. Additionally, TCF FEA revealed that, for example, for 420 nm thick LN film, the ideal SiO_2 thickness for 0 TCF at 500MHz is 1.14μm. This value is definitely compatible with the manufacturing process of the sample and will be explored in future implementations.

C. Modeling of the electromechanical coupling of $LiNbO_3$ LVRs

Finite element method (FEM) was used to derive the electromechanical coupling factor for specific modes of vibrations as a function of the LN/SiO_2 composite plate thickness over acoustic wavelength ratio (h/λ) and in plane orientation. The coupling coefficient of the laterally vibrating devices is derived by comparing the phase velocity, v_m, of the thin film stack having electrodes patterned on the top surface with the phase velocity, v_0, of an unmetalized surface. The 2D FEA of the film stack is performed by imposing periodic boundary conditions at the two ends of the cross section having a width equal to the wavelength [8]. The k_t^2 can then be expressed as:

$$k^2 \approx \frac{v_0^2 - v_m^2}{v_0^2} \quad (8)$$

$$k_t^2 = \frac{k^2}{1 + k^2} \quad (9)$$

Where k^2 is the intrinsic electromechanical coupling. This technique permits us to rapidly evaluate different material orientations.

The FEM data suggested that, as expected, the introduction of a layer of SiO_2 in the resonator stack decreases the k_t^2 of the resonator. Nonetheless, for our sample, a maximum coupling for the S0 mode that exceeds 10 % is found for an in-plane rotation of 70° with respect to the x axis (see Fig.3). Additionally, the k_t^2 exhibits a slight dependence on wavelength (different h/λ ratio). The theoretically 0 TCF LN/SiO_2 device at 500MHz would yield a k_t^2 of 9.7%.

III. FABRICATION METHOD

As shown in Fig.2, a two mask fabrication process was adopted for the making of LN thin film on SiO_2 LVRs. In this work, a LN RIE recipe based on Cl_2/BCl_3 chemistry was developed for etching the Y-cut LN. SiO_2 is chosen to be the RIE mask for LN etching.

Devices having orientations varying from 0˚ to 90˚ in increments of 10˚ were fabricated on the same die to verify the k_t^2 and TCF dependency on orientation. The designed devices had pitch of 4 μm formed by 2 μm electrode and 2 μm spacing. The number of fingers was set to 10. Finger lengths of 40 and 80 μm were fabricated.

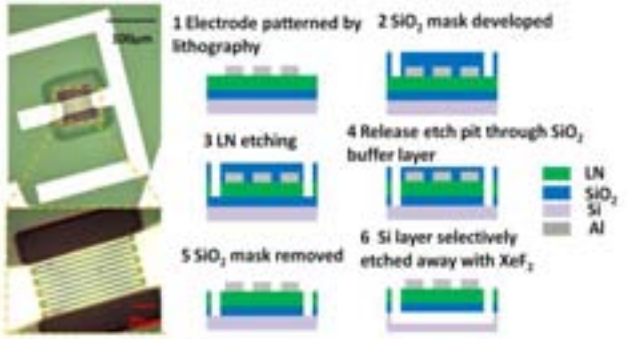

Fig. 2. Optical image of a fabricated LN LVR. The period of the interdigitated finger is 4 μm with each metal line having a width of 2μm , the length of each finger is 80 μm.On the right, a flow chart for the fabrication process of Y-cut ion-sliced LN thin film on SiO_2 MEMS resonators is shown.

IV. Experimental Results and Analysis

The first prototypes of LN on SiO_2 devices were tested in a Cascade RF probe station via an Agilent (N5230A) Network Analyzer. Q was extracted from the admittance plot by measuring the 3dB bandwidth of the resonance peak. The six equivalent circuit parameters were determined by fitting the measured results with the MBVD equivalent circuit model. A feedback controlled heating unit was employed to provide a control of the sample temperature during the measurements.

A. Characterization of k_t^2 and Q

The designed S0 mode is present in the admittance response of devices placed at all orientations, and is dominant (highest Q from 160 to 420) when the devices are placed at 40˚, 60˚, and 80˚ to x axis. As shown in Fig. 4(a), a maximum k_t^2 of 9.1% was measured for a resonator with center frequency of 730MHz and placed 60˚ to the x axis. The average value of the measured k_t^2 (Fig.4) displayed the same trend of the simulated results, but showed a value that is approximately 3/5 of the predicted one. The reason of this discrepancy is still under investigation.

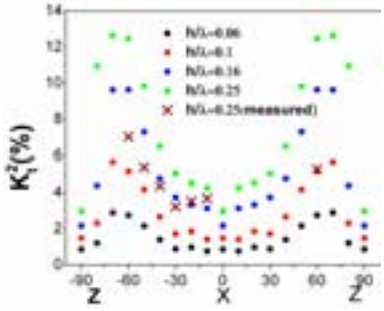

Fig. 3. The comparison of the averaged measured and simulated k_t^2 for LN on SiO_2 LVRs for various orientations.

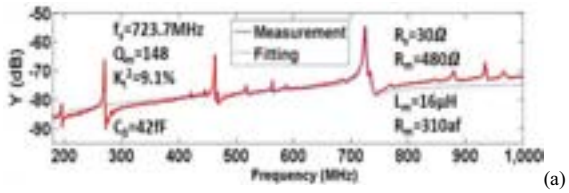
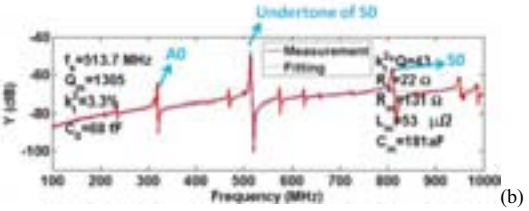


(a)



(b)

Fig. 4. (a) The measured and fitted admittance response of a LN on SiO_2 LVR with k_t^2 in excess of 9%. (b) The measured and fitted admittance response of LN on SiO_2 LVR with FOM(Figure of Merit = $k_t^2 \bullet Q$) of 43.

Devices oriented from 10˚ to 60˚ to the x axis also exhibited a resonance around 500 MHz. This resonance can be classified as an undertone of the main S0 mode. In particular, resonators oriented from 10˚ to 30˚ with respect to x axis displayed S0 undertone vibrations with high Q, and k_t^2. A Q higher than 1320 was observed on a LVR with a center frequency of 419.3MHz. A maximum k_t^2 of 6.2% was measured for a resonator with center frequency of 511.8MHz placed at 20˚ to the x axis. Hence, a FOM as high as 43 was obtained for a LVR having a 20˚ orientation to x axis (Fig.4 (b)). A0 mode vibrations were also seen in the spectrum of all resonators. The A0 mode has a lower phase velocity and lower coupling strength than the S0 mode and appears as a low frequency spurious mode (Fig.4 (b)).

B. Measurement of TCF

Resonators were measured in the temperature range of 25 to 115 °C in 10 °C increments. The TCF of devices exhibiting the main S0 mode at 750 MHz and an undertone of the S0 mode around 500 MHz were measured for various angles of orientation with respect to the x-axis (see Table I).

TABLE I. Comparison of TCF (ppm/°C) of LN LVRs at various orientations. TCF of the main S0 mode and undertone are shown. TCF is directly measured and extracted from non-linear analysis. For the main S0 mode the TCF was also calculated by FEM in COMSOL.

(a) Undertone of S0 mode, pitch of 4 μm formed by 2 μm electrode and 2 μm spacing

Orientation to X axis	TCF Direct Measurement	TCF Extracted from Non-Linear Analysis
20˚	20.4	18.8
-10˚	17	-
-20˚	15.3	17.1
-30˚	18	17.9
-40˚	15.4	15.5

(b) Main S0 mode, pitch of 4 μm formed by 2 μm electrode and 2 μm spacing

Orientation to X axis	TCF Direct Measurement	TCF Extracted from Non-Linear Analysis	TCF from COMSOL FEM
-20˚		32.2	27.7
-30˚		35	27.6
-40˚	24.1	-	27
-50˚	27.7	31.8	28
-60˚	32.5	-	28.4

C. TCF Extraction from Non-Linear Analysis

The nonlinear behavior and power handling capability of the LN on SiO_2 LVRs were experimentally investigated by measuring the admittance response at various power input

levels. As previously demonstrated for AlN CMRs [9], we hypothesize that self-heating is the main source of non-linearity in this kind of laterally vibrating micromechanical resonators. Self-heating can be used to extract the device TCF by monitoring the shift of the resonance peak as a function of the applied input power.

Self heating experiments were conducted on the LN LVRs reported in this paper. The input power was swept from -10 to +10 dBm in increments of 2 dBm. A characteristic Amplitude-frequency (*A-f*) response evolution for a resonator oriented at 50° to +x axis is shown in Fig. 3. The nature of the nonlinearities, which shows bending of the resonator admittance peak towards higher frequencies (stiffening of the resonator), is a clear evidence of a positive TCF. This supports our hypothesis that self-heating is the source of non-linearity.

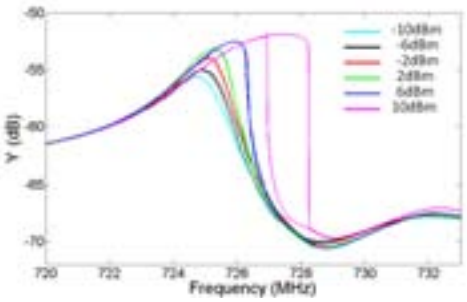


Fig. 5. A–f curves of a 724.1MHz resonator (VNA forward and backward frequency sweep, 1601 points, IF BW = 1 kHz) for P_{rf} from −10 to +10 dBm.

Applying the same analysis developed in [10] for AlN CMRs to LN LVRs, it is possible to model the thermal non-linearity in the resonator and use it to extract the resonator TCF.

Based on this model, the resonator temperature is described by the following equation:

$$T = \frac{(R_m + R_s)\omega_0^2 {q_{RMS}}^2 L_t}{2\sum \kappa_i T_{Ri} W_t} + T_{out} \tag{10}$$

Where κ_i is the material stack thermal conductivity, and L_t, W_t, and $T_{R,i}$ represent the geometrical dimensions of the structure through which the heat escapes (the anchors of the resonator). T_{out} refers to the reference temperature of the ambient environment and T, the effective temperature of the resonator undergoing vibration. q, is the charge flowing through the resonator, and ω is the input frequency. The effective TCF can then be derived as:

$$TCF = \frac{\Delta f}{T - T_{out}} = \frac{2\Delta f \sum \kappa_i T_{Ri} W_t}{(R_m + R_s)\omega_0^2 {q_{RMS}}^2 L_t} \tag{11}$$

Where Δf is the relative frequency shift recorded experimentally.

Using the geometrical parameters of the resonators and material properties from [11], [12], and [13], the TCF of LN LVRs was extracted from the self-heating measurements. Table I lists the TCF values and compares them to the direct measurements and prediction from COMSOL FEA. The agreement between these data further confirms our hypothesis that self-heating is the source of non-linearity in these devices.

V. Conclusion

This paper presented the first demonstration of LVRs based on Y-cut ion-sliced LN thin films on SiO_2. With 1.6 µm SiO_2 added to 420 nm LN, the micromechanical resonators exhibited $k_t^2 > 9\%$, *Qs* in excess of 1,320 in air at 419.3 MHz and FOM up to 43 at 513.7MHz. Moreover, the positive TCF measured from the manufactured devices clearly indicates the effect of SiO_2 and agrees well with FEM simulations and non-linear analysis results. By selecting an appropriate thickness ratio of SiO_2 to LN, a zero first-order TCF could be achieved.

Future work will mainly focus on attaining devices with zero first order TCF and simultaneously improving the performance of the resonators.

antti.jaakkola@vtt.fi

***Abstract*— We study experimentally the temperature dependence of the elastic constants of degenerately doped silicon as a function of the doping level. First and second order thermal coefficients of the elastic constants are extracted from the temperature dependent resonance frequencies of a set of MEMS resonators fabricated on phosphorus, arsenic and boron doped wafers having maximum doping levels of 7.5 x 10^{19}cm $^{-3}$, 2.5 x 10^{19}cm $^{-3}$ and 3 x 10^{19}cm $^{-3}$, respectively. Trends in the behavior of the thermal coefficients as a function of doping are identified and discussed.**

I. Introduction

Single-crystal silicon MEMS resonators are challenging quartz devices in the timing and frequency control market. The main disadvantage of silicon is the high thermal drift of about -30 ppm/K, which needs to be compensated to make a stable reference. Heavy doping of silicon has recently been found as an attractive way to achieve passive temperature compensation.

First experiments showing reduced temperature drift were achieved with p-type doping [1], but n-type doping soon appeared as a viable alternative [2]. Our work with bulk mode resonators has shown that n-type doping is an effective and versatile way of tailoring the temperature behavior of silicon resonators; we have demonstrated resonators with their f vs. T turnover point near room temperature, overcompensated devices (+18 ppm/K) [3], and shown that n-type doping is applicable to virtually all resonance modes of practical importance [4]. Recently, piezoelectrically driven temperature compensated devices [5] and resonators made of strongly n-type doped epitaxially grown silicon [6] have been reported.

In order to minimize the thermal drift of a MEMS resonator, a designer needs to know the temperature behavior of the elastic parameters of silicon; in particular the first and second order thermal derivatives of the elastic constants are of interest. However, experimental data of the thermal dependency of the elastic parameters of heavily doped silicon is limited; most usable results of n-type doped silicon have been published by Hall [7] for carrier concentration of 2×10^{19}cm $^{-3}$. In this work we study experimentally the temperature dependence of silicon elastic constants when doping is varied. Test wafers were phosphorus doped (carrier concentration 4.1 , 4.7 and 7.5×10^{19}cm $^{-3}$), arsenic doped (1.7 and 2.5×10^{19}cm $^{-3}$), and boron doped (0.6 and 3×10^{19}cm $^{-3}$). Elastic parameters are extracted from the temperature dependent resonance frequencies of a set of MEMS resonators.

II. Theory and Methods

The frequency of an acoustic resonator is given by

$$f = 1/L \times \sqrt{c/\rho}, \tag{1}$$

where ρ, c and L are the resonator material density, characteristic stiffness and characteristic length, respectively. Characteristic stiffness depends on elastic constants c_{11}, c_{12} and c_{44} that can be solved from a set of measured resonance frequencies of different resonators when their functional dependence on constants c_{ij} varies among the modes, and when there are three or more modes within the set. In our case, the set of two Lamé mode resonators and five length extensional (LE) modes in different orientations fulfill these conditions. Resonators are illustrated Fig. 1. Our approach is similar to that of Bourgeois et al. [8], [9], but we use a larger number of modes (7) for solving the three unknowns, and hence we are also able to assess the reliability of the results.

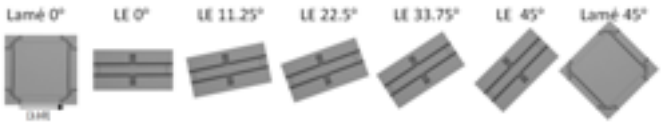

Figure 1. The set of resonators for determination of the elastic constants c_{11}, c_{12} and c_{44} consists of seven different resonators, each having different dependency on the c_{ij} parameters. Plate resonators operating in the Lamé resonance mode were fabricated in two different directions (either aligned with 100 or 110 directions). Beam resonators operating in the length extensional resonance were orientated at five different equispaced in-plane angles from 110 to 100.

The experimental data consists of measured resonance frequencies at different temperatures for all seven resonance modes $f_k^{\text{exp}}(T)$ ($k = 1, \ldots, 7$). Let us denote the corresponding theoretical estimates containing the c_{ij} dependencies – obtained through FEM modelling in our case – as $f_k^{\text{th}}(c_{11}, c_{12}, c_{44})$. We use an approach of first matching f_k^{exp} and f_k^{th} at $T_0 = 20$°C by numerical optimization to find elastic parameters $c_{ij}(T_0)$, and then linearize Eq. (1) to obtain the

relation

$$\frac{\delta f_k^{\text{exp}}(T)}{f_{k0}^{\text{exp}}} = \frac{1}{f_{k0}^{\text{th}}} \sum_{ij} \frac{\partial f_k^{\text{th}}}{\partial c_{ij}} \delta c_{ij}(T) + \frac{1}{2} \frac{\delta L}{L}(T). \quad (2)$$

Here $\delta c_{ij}(T)$ are the unknown changes in elastic parameters, $\delta f_k^{\text{exp}}(T)$ are the measured frequency differentials, while f_{k0}^{exp} and f_{k0}^{th} are shorthands for $f_k^{\text{exp}}(T_0)$ and $f_k^{\text{th}}(c_{ij}(T_0))$. Sensitivities $\partial f_k^{\text{th}}/\partial c_{ij}$ are calculated from the theoretical estimates. The last term accounts for thermal expansion $\beta(T)$. In matrix form Eq. (2) can be denoted as

$$\delta \mathbf{f}^{\text{exp}}(T) = A \cdot \delta \mathbf{c}(T) + \beta(T). \quad (3)$$

where $\delta \mathbf{f}^{\text{exp}}$ contains the relative frequency changes, and elements of the sensitivity matrix A are defined as

$$a_{kn} = \frac{1}{f_{k0}^{\text{th}}} \frac{\partial f_k^{\text{th}}}{\partial c_{ij}},\ n = 11, 12, 44;\ k = 1, ..., 7. \quad (4)$$

The changes in elastic parameters $\delta \mathbf{c}(T)$ can be solved as a least squares fit from Eq. (3):

$$\delta \mathbf{c}(T) = (A^T A)^{-1} A^T [\delta \mathbf{f}^{\text{exp}}(T) - \beta(T)]. \quad (5)$$

We assume that the thermal expansion has a form

$$\beta(T) = (\alpha_1 \Delta T + \alpha_2 \Delta T^2 + \alpha_3 \Delta T^3)/2, \quad (6)$$

and use the values reported for undoped silicon by Lyon et. al [10]; a similar choice was made in Ref. [9] by Bourgeois et al.

III. Experimental

Table I
DETAILS OF THE WAFERS. CARRIER CONCENTRATIONS ARE CALCULATED FROM THE RESISTIVITY SPECIFICATION USING REF. [11]. CARRIER CONCENTRATION RANGES ARE INCLUDED AS ERROR BARS IN FIG. 3A.

		specified resistivity [mOhm cm]		calculated carrier concentration n [10^{19} cm^{-3}]		
wafer id	dopant	min	max	min	max	avg
B3	B	3.48	3.66	2.88	3.04	2.96
B0.6	B	10	20	0.33	0.86	0.60
As1.7	As	3.98	4.36	1.55	1.77	1.66
As2.5	As	2.94	3.08	2.39	2.52	2.46
P4.1	P	1.67	1.76	3.98	4.22	4.10
P4.7	P	1.47	1.59	4.45	4.86	4.66
P7.5	P	0.95	1.05	7.05	7.89	7.47

Test resonators were fabricated on seven different Silicon-On-Insulator wafers with 15-μm-thick Czochralski grown device wafers. Dopants (B, P, and As) and their concentrations were varied according to Table I. Carrier concentration range for each wafer was calculated from the specified resistivity range using conversion method of Ref. [11]. Measured devices were located near the wafer center. As the wafers featured pre-etched cavities, it was possible to fabricate monolithic resonators without a grid of release etch holes within the devices, and thus the elastic properties of the resonators could be accurately modelled. Existence of release etch holes was a source of uncertainty in our previous studies [3]. The resonators (Fig. 1) were fabricated by a process including Al contact metallization and patterning followed by DRIE etching of vertical gaps (width $0.5\,\mu$m).

The resonators were measured in atmospheric pressure on wafer level with an impedance analyzer while applying a DC bias of 40 V over the gaps. Quality factors of $\sim 10,000$ were measured for all resonance modes, and thus the resonance frequencies could be detected with good accuracy. The wafer was held on a temperature controlled chuck, whose temperature was varied from -40°C to 85°C with seven steps. The accuracy of the chuck temperature was ± 0.5°C. Resonances of interest were identified and their frequencies were tracked over temperature.

IV. Results

Measured temperature dependent relative frequency changes are plotted and tabulated in Fig. 2(a)–(g) for each of the wafers. The elastic parameters $c_{ij}(T)$ were extracted from the frequency data using the least squares method described in Section II. We used Comsol Multiphysics for calculating numerical estimates for the modal frequencies f_k^{th}. Angular misalignment of the wafers was taken into account in the FEM simulations. Second-order polynomials centered at $T_0 = 25$°C were fitted to the elastic parameter data as

$$c_{ij}(T) = c_{ij}^0 [1 + a_{ij}(T - T_0) + b_{ij}(T - T_0)^2], \quad (7)$$

where a_{ij} and b_{ij} are the first-order and second-order temperature coefficients, respectively, and c_{ij}^0 is the constant term. A second-order expansion was found to be valid to within ± 20 ppm for all $c_{ij}(T, n)$. The results are summarized in Fig. 3(a)–(l). Fig. 2(e) shows an overlay of measured data and corresponding numerical estimates which use the solved parameters $c_{ij}(T)$ as an input.

V. Discussion

Following observations concerning the temperature coefficients of Fig. 3 can be made: i) Fig. 3(k) shows that the linear temperature coefficient a_{11-12} goes to zero at approximately $n = 2 \times 10^{19}$cm^{-3} , and it obtains values of more than $+40$ ppm/K with highest n-type doping. This is the key effect of n-type doping for MEMS applications [4]. The effect appears to saturate at highest carrier concentrations. ii) Fig. 3(l) reveals an attractive trend of the second order temperature coefficient b_{11-12}: it appears to approach zero with increasing carrier concentration. This suggests a possibility of a flat or positive second order response at high enough doping. iii) Arsenic and phosphorus as dopants do not stand out from the plots as separate groups. iv) Fig. 3(h) shows that the linear temperature coefficient a_{44} decreases in magnitude with increasing p-type dopant concentration.

Temperature coefficients measured in this work are compared to values found in literature in Fig. 3. Values for weakly n- or p-doped silicon, reported by Bourgeois et al. [9], appear to be in satisfactory agreement with our data; the data points near zero carrier concentration follow the trends observable from our data points. However, there is more

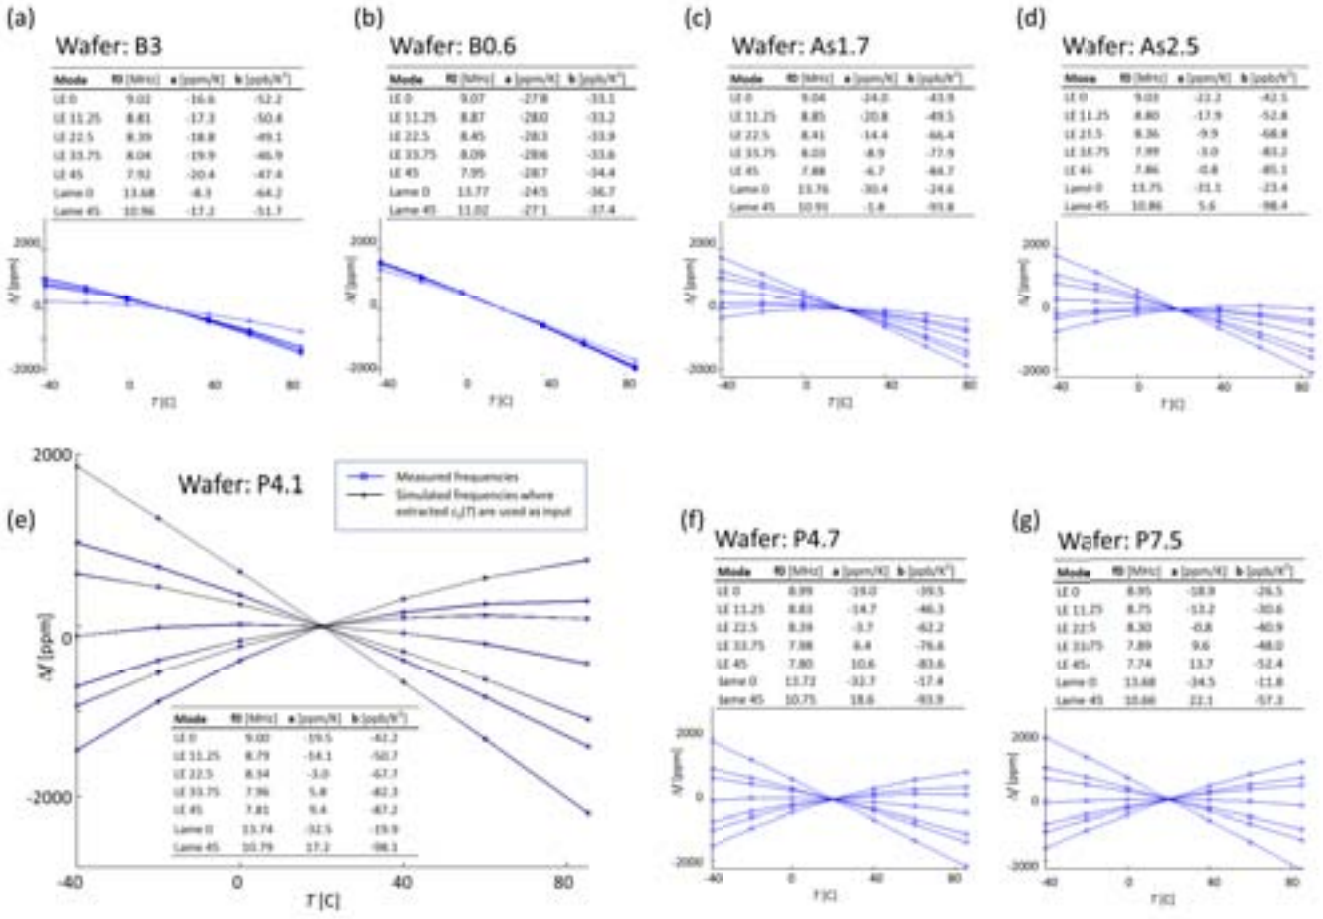

Figure 2. (a)–(g): temperature dependent relative frequency changes for each measured wafer. Temperature coefficients for resonance modes were calculated and they are shown in the tables. (e): measured data (blue line with hollow circles) from wafer P4.1 overlaid with corresponding numerical estimates $f_k^{\text{th}}(T)$ which use the solved parameters $c_{ij}(T)$ as an input (black lines with dots).

disagreement when our results are compared to data by Hall [7]. In particular, the second order temperature coefficients are not in line with the other data points. This could be explained by the fact that the values were extracted directly from the published plots of Ref. [7].

Quality of the least squares fit can be assessed by comparing the measured frequency data $f_k^{\text{exp}}(T)$ to the corresponding numerical estimates $f_k^{\text{th}}(T)$ obtained from FEM simulations which use the solved parameters $c_{ij}(T)$ as an input. Fig. 1(e) shows an example of the overlap between experimental and simulated data. Maximum deviation between the measured and simulated data points was below 30 ppm for all seven resonance modes under investigation for all of the wafers, which speaks for the reliability of the extraction method. We expect that the thermal drift of any resonance mode on a wafer with similar carrier concentration could be predicted with similar accuracy, when calculated using $c_{ij}(T)$ as an input.

VI. Conclusions

Elastic parameters of degenerately doped silicon were extracted from temperature drift measurements of a set of MEMS resonators fabricated on seven wafers with varied dopants (As, P, B) and doping concentrations. It was observed that the linear thermal coefficient of $c_{11} - c_{12}$ is zeroed at approximately $n = 2 \times 10^{19}\text{cm}^{-3}$, and that it appears to saturate to ~ 40 ppm/K with increasing n-type doping. The second order thermal coefficient of $c_{11} - c_{12}$ was found to decrease in magnitude when n-type doping was increased. Linear thermal coefficient of c_{44} was found to approach zero with increasing p-type doping.

VII. Acknowledgements

Authors would like to acknowledge the Finnish Funding Agency for Technology and Innovation (Tekes), Okmetic Oyj, Murata Electronics and Micro Analog Systems for funding. Okmetic Oyj is acknowledged for providing the silicon wafers.

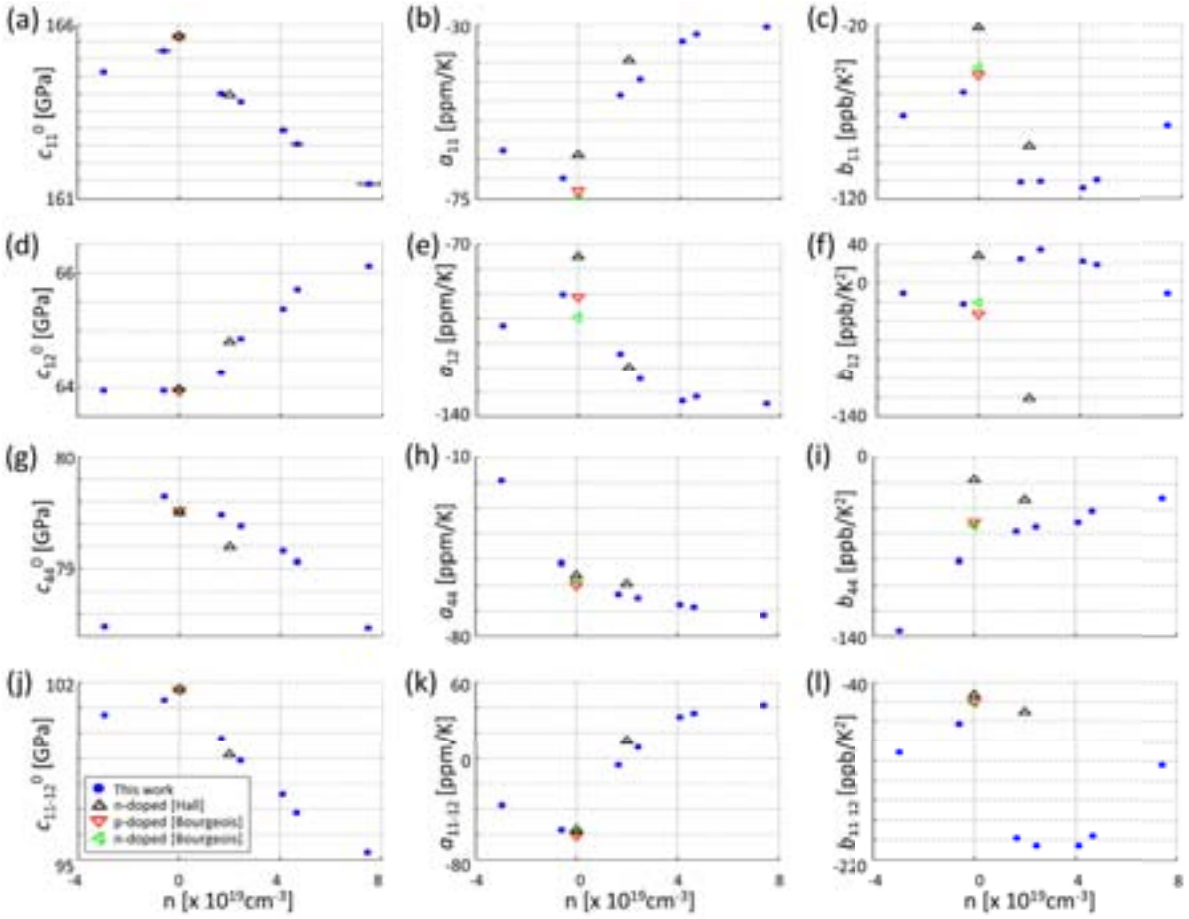

Figure 3. Temperature coefficients of the elastic parameters c_{ij} as a function of carrier concentration n. Data from p-type doped wafers is represented with negative carrier concentratios. First, second and third column represent the constant terms c_{ij}^0, linear coefficients (a_{ij}), and second-order coeffients (b_{ij}), respectively (see Eq. (7)). c_{11-12}^0, a_{11-12} and b_{11-12} are shorthands for the coefficients of $c_{11} - c_{12}$. Blue dots are the experimentally determined values of this work. Values reported in [9] are shown as red triangles pointing down (weak p-type doping) and as green triangles pointing left (weak n-type doping). Data reported by Hall in Ref. [7] was used for calculating data points shown as black triangles pointing up. The error bars of figure (a) indicate the carrier concentration ranges calculated from the resistivity specification for each wafer (see Table I).

A.J. acknowledges funding from the Academy of Finland, and wishes to thank Arto Nurmela for help in the measurements.

***Abstract*—A high-frequency CMOS-MEMS bulk-mode resonator via a differentially piezoresistive transduction was proposed in this work, demonstrating quality factor (Q) greater than 15,000, temperature coefficient of frequency (TC_f) around -12.5ppm/°C, and operating power lower than 400μW, all in a single device. To attain the highest Q among reported CMOS-MEMS resonators to date, a dog-bone design was adopted with its two oxide-rich longitudinally vibrating beams which consist of only low-loss materials (i.e., poly-Si and SiO_2) from a standard 0.35μm 2-poly-4-metal (2P4M) CMOS technology. To achieve such decent temperature stability, a constant-resistance control approach was implemented to enable an ovenized element where the poly-Si heater and thermometer are both embedded inside the resonator structure, hence providing excellent thermal isolation, localized heating capability, and on-site/real-time temperature measurement.**

I. Introduction

Ubiquitous electronics are widely used in our daily life and most of them necessitate the timing reference devices for the signal processing. Demanded by the portable and wearable purpose, the device volume must be miniaturized and integrated with circuits. Discrete components, such as quartz and SAW resonators, are against the trend of miniaturization and integration due to their bulky size and non-silicon-based substrate. In the past decade, MEMS technology played an important role to address this issue due to the small form factor and batch production of the mature micromachining processes. However the effective solutions to MEMS/IC integration are still under development.

To integrate the circuits and mechanical structures, the prior literature has reported on the MEMS-first and MEMS-last processes [1]. However, those processes are complicated and have limited thermal budget. In contrast, micro structures formed by the CMOS back-end-of-line (BEOL) materials are simple to be implemented as micromechanical devices. For example, the CMOS-MEMS resonators can be released by two major post-CMOS processes, including the dry release [2] and wet release [3] processes. To construct the device, the metal, oxide, and polysilicon layers are used to form the resonator structure. However, pure metal or polysilicon capacitive transducers have to be designed by a very thin layer in this case, which would significantly limit the capacitive transduction areas. Furthermore, their gap spacing is also constrained by the foundry process rules; therefore, the electromechanical coupling coefficient becomes quite low, leading to much-larger-than-50Ω motional impedance. In addition to the high motional impedance, the CMOS-MEMS resonators often suffer poor thermal stability due to their structural materials. To enhance their thermal stability, the metal/oxide composite structures can be designed to take advantage of the balance of the negative TC_f from the metal and positive TC_f from the SiO_2. However, the metal layer of the CMOS BEOL process is not a low-loss material [4]. The more metal used to construct the structure, the lower quality factor of the resonator.

To solve the abovementioned issues on both Q and thermal stability, a bulk-mode resonator with an oxide-rich structure was previously developed in our group, demonstrating Q > 10,000 [5] which is more than sufficient for high-performance oscillator implementation. However, its electromechanical coupling coefficient is still limited by purely capacitive transduction caused by its relatively large transducer's gap. To enhance the coupling coefficient, a piezoresistive sensing was

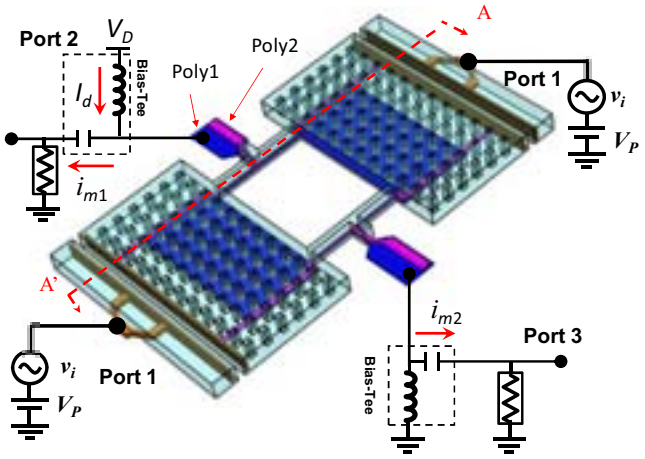

Fig. 1: Perspective-view schematic of a bulk-mode CMOS-MEMS resonator driven (common mode) by the electrostatic force and sensed (differential mode) by the piezoresistive transduction.

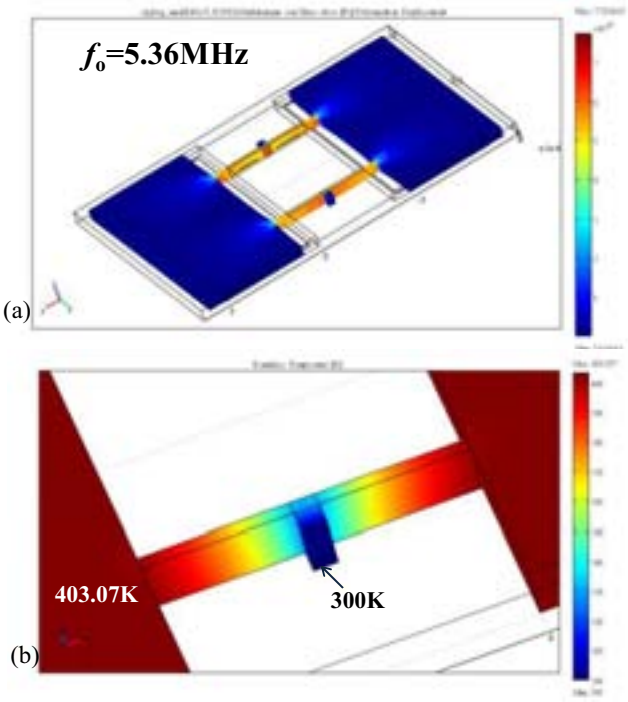

Fig. 2: (a) Finite-element simulated mode shape and stress distribution plot during vibration. (b) Simulated temperature distribution plot under resistive heating.

utilized by implementing the polysilicon layer of the CMOS process, previously showing the piezoresistive transduction is less sensitive to the gap spacing as compared to the purely capacitive transduction [6]. With that, the piezoresistive transduction has been proved as an alternative once the foundry process rules of the CMOS technology nodes are limited. Furthermore, the polysilicon layer not only serves as a piezoresistor, but a heater and a temperature sensor embedded inside the resonator. Therefore, a constant-resistance control [7] for the active temperature compensation can be easily applied into the CMOS-MEMS-based resonators.

In this work, the proposed CMOS-MEMS resonators were fabricated by a TSMC 0.35μm 2P4M CMOS process. The structure was designed as a dog-bone like resonator [8] which enables a large capacitive driving area from its wide proofmasses. Furthermore, the longitudinal beam structures of the resonator were designed using low-loss materials, such as silicon dioxide and polysilicon to attain high-Q performance. To enhance the overall transduction of the device, a differentially piezoresistive sensing was adopted, and at the same time alleviates the parasitic feedthrough effect. Due to the configuration of the CMOS process, two individual polysilicon layers can be used to serve as a piezoresistive sensor and a heater (i.e., ovenized element), separately. Unlike the silicon-based piezoresistive resonators, the piezoresistor and the heater of the proposed CMOS-MEMS resonator can be physically (or electrically) isolated by the oxide structure of the resonator. Therefore, the piezoresistive transduction can be decoupled from the power control of the ovenized functionality. The resonators finally exhibits high Q (>15,000) and enhanced thermal stability with the TC_f around -12.5ppm/°C, leading to an alternative single-chip solution for timing applications. It is worth mentioning that the demonstrated TC_f in this work shows the best temperature stability among any CMOS-MEMS resonators to date.

II. Device Design and Operation

The proposed resonator implemented two longitudinally vibrating beams consist of only low-loss materials, including poly-Si and SiO_2 from the standard CMOS BEOL process to attain high Q. Fig. 1 presents the drive and sense configurations of the CMOS-MEMS bulk-mode resonator. Both driving electrodes and embedded electrodes (yellow) of the resonator are stacked from poly-1 (original gate poly-Si) to metal-3 layer for the capacitive driving. The dog-bone like resonator is horizontally driven by the electrostatic force from the input electrodes. Then, the poly-1 and poly-2 (original resistor poly-Si) layers embedded in the beam serve as the piezoresistor (blue) and heater (pink), respectively. At the same time, poly-2 is also connected to the embedded electrode of the proofmasses to setup their bias voltage. To operate this device, an ac signal v_i (port-1) together with a dc-bias V_P generates an electrostatic force to drive the resonator into resonance with a mode shape shown in Fig. 2(a). The mechanical resonance frequency of the corresponding mode shape can be determined from the equivalent spring-mass-damper mechanical model with an effective spring constant k_{eff} and an effective mass m_{eff}.

When using the capacitive detection, the motional current becomes very weak due to the limited equivalent gap spacing g_o. To enhance the motional signal, the piezoresistor embedded inside the beam structure can be utilized to perform the piezoresistive transduction. As the resonator starts to vibrate, the displacement will be amplified by Q times. The displacement x is expressed as

$$x = \frac{Q \cdot F_e}{k_{eff}} = \frac{Q}{k_{eff}} \frac{\varepsilon W_e h_e}{g_o^2} \qquad (2)$$

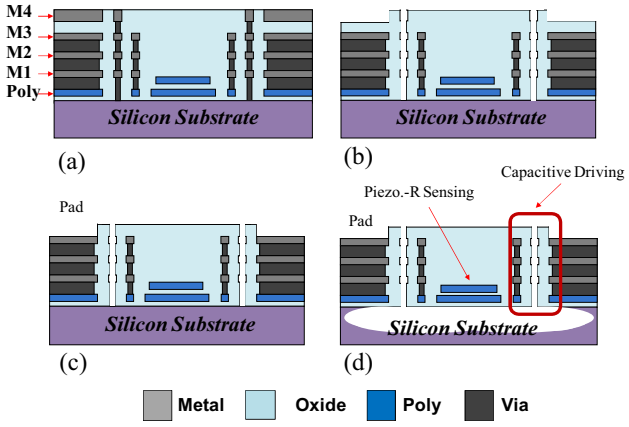

Fig. 3: Fabrication process flow, showing (a) the chip received from the CMOS foundry, (b) wet etching to remove the sacrificial metals, forming the air gaps and resonator geometry, (c) RIE to open bond pads, and (d) XeF_2 dry etching to finally release the resonator structures.

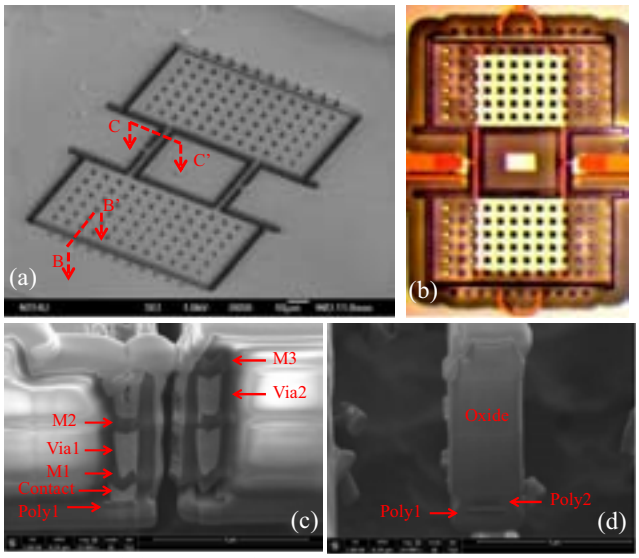

Fig. 4: (a) Global SEM view, (b) OM view, and (c) FIB cross-sectional view for a fabricated CMOS-MEMS resonator. (d) Close-up photo of the resonator beam structure consisting of two polysilicon layers from the CMOS BEOL configuration.

where F_e is the electrostatic force; W_e is the width of the capacitive driving electrode (about 99μm); h_e is the thickness of the driving electrode (about 4.865μm). When a dc current I_D is applied through the piezoresistor, variations of stress/strain caused by the beam vibration would induce a resistance change, resulting in output motional signals i_{m1} and $_{im2}$ which could be detected on port-2 or port-3, respectively, in Fig. 1 where both poly-1 and poly-2 resistors were measured in this work to evaluate their sensing capability. The feedthrough will be cancelled by the use of the differential readout, hence producing a symmetric frequency spectrum. As the dc current I_D is applied on the resistor, the resonator will also be heated. Fig. 2(b) presents the finite-element simulation of the temperature gradient. When the heating power is 0.895mW, the maximum temperature of 403.07K occurs on the proofmass.

III. Device Fabrication

To realize the high-Q structure, the composition of the metal materials should be as low as possible. In order to increase the ratio of the oxide inside the resonator, the metal wet release process was adopted [9]. In this work, the devices were manufactured using a TSMC 0.35μm 2P4M process. The bare chips were received from the foundry as shown in Fig. 3(a) which depicts the A-A' cross-sectional view of Fig. 1. Then a metal wet etching solution containing H_2SO_4 and H_2O_2 with very high selectivity between oxide and metal layers was utilized to remove both sacrificial metal and tungsten-via layers as shown in Fig. 3(b). The electrode-to-resonator gap spacing is defined by the width of the sacrificial metal stack while the transistor circuits were protected by the passivation layer. This maskless etching technique leaves the driving electrodes, piezoresistors, heaters, and oxide structures intact. Next, an RIE process was used to remove passivation and oxide layers to open the bond pads for later wire bonding as shown in Fig. 3(c). Finally, the underneath silicon substrate was isotropically etched away by XeF_2 to suspend the resonator structure as shown in Fig. 3(d).

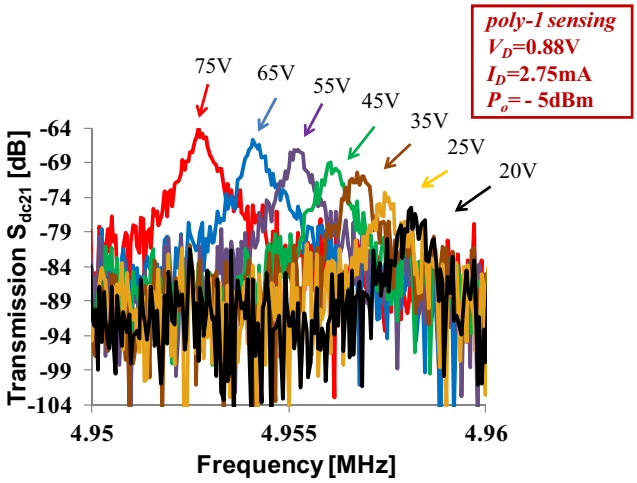

Fig. 5: Measured frequency transmission (Sds21) characteristics (in vacuum) under different bias voltages V_P using the piezoresistive detection (poly-1) for a fabricated CMOS-MEMS bulk-mode resonator.

Fig. 4(a) presents the global SEM view of a fabricated oxide-rich resonator. To clearly observe the inner of the fabricated resonator, Fig. 4(b) presents the optical photo view of the resonator structure since the high-Q structural material (SiO_2) is transparent to the visible light, showing the embedded electrodes and polysilicon layout. Fig. 4(c) presents an FIB-cut cross-sectional view of the embedded electrodes for the capacitive driving. The electrodes consist of the metal, tungsten via, and polysilicon layers stacked to form the capacitive transducer. Fig. 4(d) presents an FIB-cut cross-sectional view of the oxide-rich beam structure where two polysilicon layers are clearly seen.

IV. Measurement Results

The measurement scheme is shown in Fig. 1 where a three-port test setup was used to characterize the piezoresistive transduction of the CMOS-MEMS bulk-mode resonator. Since the resonator is driven by the electrostatic force, Fig. 5 presents

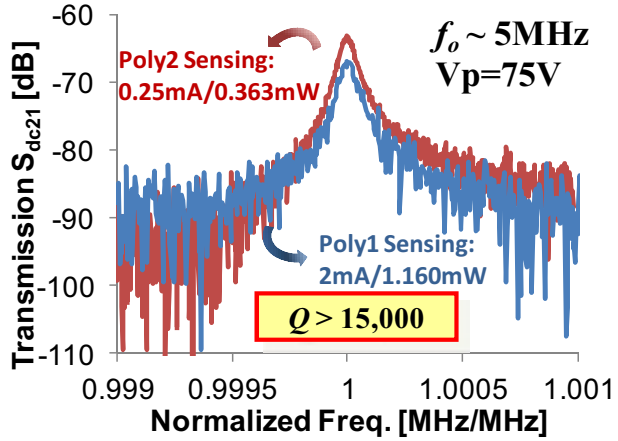

Fig. 6: Comparison of the measured frequency characteristics under poly-1 and poly-2 piezoresistive detections.

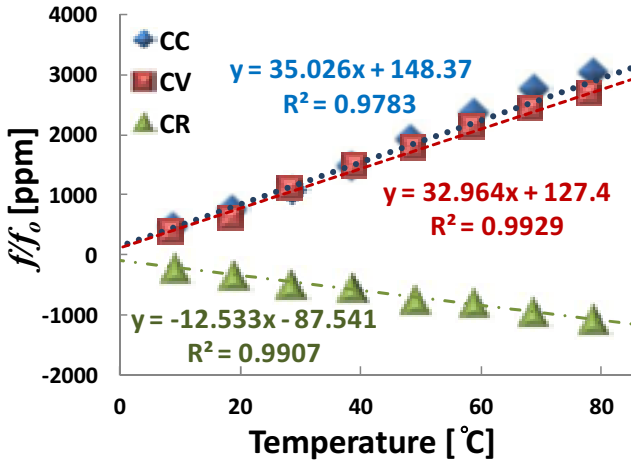

Fig. 7: Measured thermal stability of the CMOS-MEMS resonator under the constant-current (CC), constant-voltage (CV), and constant-resistance (CR) controls of the piezoresistor (poly-1).

the transmission amplitude, showing the resonance frequency can be tuned using the dc-bias voltage V_P through the electrical stiffness effect. Even the gap spacing is about 1μm, the piezoresistive output signal could still be measured under a low bias voltage of 20V. The frequency tuning range is around 1200ppm from 20V to 75V. Due to the large electrode-to-resonator gap spacing, we cannot find motional signal using the traditional capacitive sensing readout. As a result, the piezoresistive transduction not only brings signal enhancement but helps to ease the dc bias voltage which becomes more amenable to the CMOS charge pump designs.

Fig. 6 presents the measured frequency characteristics with clear resonance behavior under poly-1 and poly-2 piezoresistive detections, respectively. Both configurations were carried out by V_P of 75V, showing resonator Q > 15,000 and more than 20dB stopband rejection. It is worth noting that the poly-2 sensing scheme exhibits a low-power operation mode (only 363μW) and attains a high electromechanical coupling coefficient due to its larger gauge factor than that of the poly-1 scheme. The measured single-ended transconductance g_m from the poly-1 and poly-2 schemes are 3.144μS and 4.9μS, corresponding to the extracted gauge factors of 7.8 and 16, respectively.

Though the poly-1 resistor has a lower gauge factor, it allows a higher dc current to pass through (i.e., higher current density), making poly-1 a suitable heater candidate for the temperature compensation. TC_f of 76ppm/°C of the uncompensated resonator was simulated using COMSOL Multiphysics. As the power was applied on the poly-resistor, Fig. 7 presents the measured thermal stability of the resonator by using the constant-current (CC), constant-voltage (CV), and constant-resistance (CR) controls of the poly-resistor (poly-1), demonstrating the lowest TC_f (-12.53ppm/°C) to date in CMOS-MEMS resonators.

V. Conclusions

A CMOS-MEMS bulk-mode oxide-rich resonator was proposed in this work. These resonators were fabricated by a standard foundry CMOS technology together with maskless metal and silicon etching processes to accomplish high-Q oxide-rich structures. We utilized embedded metal electrodes and piezoresistor for capacitive driving and piezoresistive sensing configuration to enhance motional signals. To attain high Q, the longitudinally vibrating beams of the resonator consist of low-loss materials from the CMOS BEOL process. The measured Q of the proposed CMOS-MEMS resonator is greater than 15,000, a record-high value among CMOS-MEMS resonators, and also comparable to silicon-based resonators, thus benefiting phase noise of their oscillator implementation. To improve the thermal stability, the resonator takes advantage of the poly-resistor which serves as an ovenized element to perform active temperature compensation. A constant-resistance (CR) control was utilized, finally demonstrating the lowest TC_f feature among CMOS-MEMS resonators to date under a low-power operation mode. This work offers an alternative way for the future timing reference and time-keeping applications in a single-chip format.

Abstract—**Traditional phase measurement is limited by the identical nominal frequencies of two compared signals. In a lot of applications, there are higher requirements not only on measurement accuracy, but also on the frequency range of compared signals. After years of exploration and efforts, we have discovered some concepts and characteristics which can reflect mutual phase relationship among different frequency signals, such as Least Common Multiple Period, Phase Difference Quantization Step, Equivalent Phase Comparison Frequency, and the continuous phase group characteristics with the least common multiple period (as the time interval and the quantization step phenomenon that the phase difference of the two different frequency signals will change according to a specific value in one least common multiple period). In the process of experiments, we have discovered ambiguity zone edge effects and measurement method of periodic signal parameter quantization error elimination. We achieved precise frequency source synchronization and link, phase processing and measurement between completely different frequency signals with complex relationship. Through updating concepts, we move phase comparison and processing beyond identical frequency signals and extend to arbitrary frequency signals. Major applications include measurement of transient stability, phase noise measurement, edge effects for accurate frequency measurement method of Serial and Parallel. These breakthroughs promote rapid development in the area of measurement and instrument, and some difficult research problems have been solved.**

Keywords-frequency measurement; frequency link; edge effect

I. INTRODUCTION

Phase measurement and processing has the highest resolution in time-frequency measurement and processing area and even on generalized precision measurement area[1]. However, traditional phase measurement is limited by identical nominal frequencies of two compared signals [2]. Fig.1 shows phase detection between same nominal frequency signals.

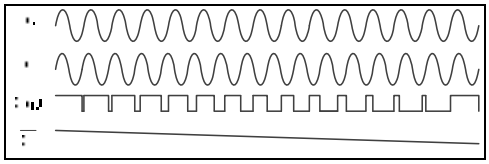

Figure 1. The work waveform of phase detector

In order to get wider frequency range in phase processing, assistive technologies such as frequency transformation and synthesis are applied [3]. These measuring methods increase the complexity of equipment and limit the further improvement of the measurement accuracy. Especially in recent years, in the industry and research applications, there are higher requirements on not only measurement accuracy, but also the frequency range of comparison signals [4]. In the area of precise frequency source synchronization and link, phase processing, comparing and measurement between completely different frequency signals are required in the accuracy and stability transmission of frequency signals with complex relationship [5]. Traditional limits must be broken from concepts and methods according to updating work.

II. THE BASIS OF GENERALIZED PHASE PROCESSING

From the basic consideration, an arbitrary periodic phenomenon has phase relation. Arbitrary periodic phenomenon should show their mutual phase difference changes, which means the research of phase relation does not depend on whether nominal frequencies of two signals are identical or not, but depend on whether they are stable periodic signals or not. What's more, a series of applications and purposes based on phase relation will be achieved, such as frequency measurement, phase noise measurement, frequency link, etc.

Generalized phase processing breaks the limit of traditional phase comparison method which can only compare identical frequency signals. This new technology can perform comparing and processing between any frequency signals. Through the research on phase variation of periodic signals, we analyzed characteristics of the greatest common factor frequency $f_{\max c}$ and the least common multiple period $T_{\min c}$ which exist between signals, and discovered the physics law of quantization step that is counted by equation (1), and equivalent phase detecting frequency that is counted by equation (2) of quantized phase difference of periodic signals [6].

The phase difference between different frequency signals is not necessarily continuous in $T_{\min c}$. It is often discrete. Fig.2 shows phase group synchronization phenomenon.

The work was supported by the National Natural Science Foundation of China (Grant Nos. 10978017 and 61201288)

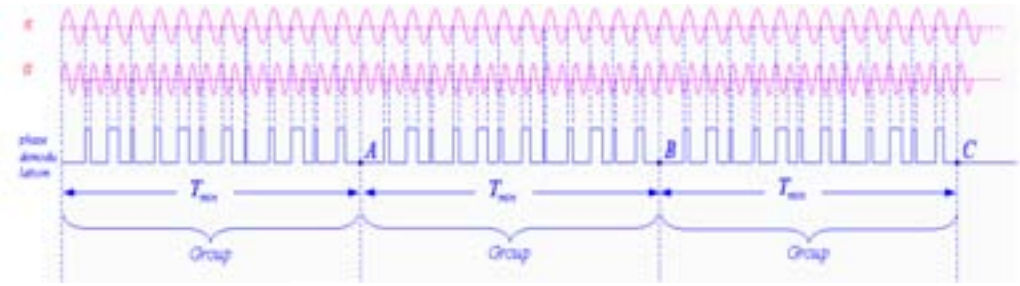

Figure 2. Phase group synchronization

$$\Delta T = \frac{f_{\max c}}{f_1 f_2} \tag{1}$$

$$f_{equ} = \frac{1}{\Delta T} = ABf_{\max c} \tag{2}$$

However, if we rearrange the phase differences according to the order or size, the quantum characteristics are displayed, which means the difference between two adjacent phase differences is constant[6]. The phase differences between $T_{\min c}$ present the continuity of group status. In addition to the inherent signal frequency relationship, if there are additional frequency differences, the changes in the phase difference between signals possess characteristics of synchronized increases and decreases. The follow fig.3 and fig.4 show the phase differences which have been converted into $V(t)$ between two frequency signals with simple or complex relationship. This phenomenon shows the quantization step feature of phase relationship.

Figure 3. Phase difference between two frequency signals with simple relationship

Figure 4. Phase difference between two frequency signals with complex relationship

Therefore, any periodic signal must have the phase comparability and a high processing resolution can be obtained in many situations. This result can produce a key foundation for the analysis and processing of comparison relationship in other periodic signals. Therefore, the research in this area has important significance.

Especially the variation characteristics of the regularity of phase differences shown by periodic signals are in response to the periodicity of mutual phase relationship between two signals[7]. It is not depending on the type of signal and the frequency value. So the periodicity phenomenon and variation regularity of phase difference is widespread applied [12].

III. Generalization Of Phase Processing

According to the research of basic signal characteristics, the limit of traditional phase processing method which can only process identical frequency signals is broken. Through updating concepts, we move phase comparison and processing beyond identical frequency signals and extend to arbitrary frequency signals. The repetition period of phase comparison is equal to the least common multiple period between frequency signals. The full period of phase comparison is equal to ΔT. Because ΔT is much smaller than the periods of two compared signals, so the processing resolution based on generalized phase processing is related to ΔT or equal to part of ΔT according to different situations. ΔT represents a time mark which reflects mutual periodic phase changes between completely different frequency signals. But ΔT absolutely is not the smallest in time.

Because frequency relationship between signals can be selected as adjusted, ΔT may be much smaller than period of radio frequency signed by equation (1). The signal processing accuracy is improved greatly, in which Picosecond, even Femtosecond resolution is reached[17].

In the application, there are significant differences among processing accuracy, ease of implementation, special performance of typical mutual frequency relationship in different phase processing methods [10]. Exploration about this aspect which makes phase processing in different applications has a significant advantage. The implementation of the phase processing problems becomes more flexible. The application will be broader and have more engineering application selection. The frequency range of the signal processing is overall expanded, the measurement accuracy is improved, and the equipment structure is simplified.

IV. The Improvement In Measurement Aspect Based On Generalized Phase Processing

Repeated capture and use of the special phase phenomenon between signals can be effectively used for eliminating the quantization error in the presence of the digital measurement [15], which can greatly improve measurement accuracy about 3-5 orders of magnitude, even higher.

TABLE I THE FREQUENCY MEASUREMENT RESULTS

f_x	Measured （Hz）	Frequency stability σ(/s)	Frequency stability σ(/10s)
10MHz Rubidium atomic frequency standard of X72	10 000 000.0001±1	7.3×10^{-12}	8.7×10^{-13}
5MHz signal of Austron 1250A	5 000 000.4731±1	6.2×10^{-12}	3.1×10^{-12}
12 800 000Hz signal of HP8662A	12 800 000.5379±1	6.7×10^{-12}	3.5×10^{-12}
16 384 000Hz signal of HP8662A	16 384 000.5584±1	6.6×10^{-12}	3.4×10^{-12}
20 971 523Hz signal of HP8662A	20 971 523.5796±1	6.3×10^{-12}	3.2×10^{-12}

We make captured "Phase coincidence" to be on signal and off signal of measurement gate[3], which can effectively eliminate a ± 1 count error. Fig.5 is the principle diagram of a frequency measurement instrument by means of phase coincidence capture and DDS-assisted measurement. This frequency measurement instrument can achieve broader frequency range, high-resolution, normal measurement gate time. Table Ⅰ shows the measurement results.

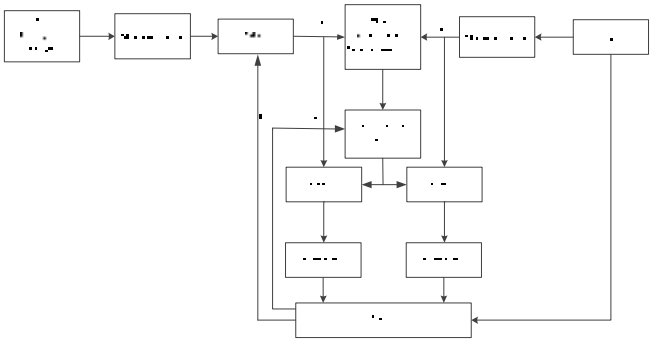

Figure 5. The principle diagram of frequency measurement

Usually the method of making phase coincidence detection to be measuring gate has low response time[17]. When the signals are in the phase "coincidence" detection edge, the phenomenon that coincidence detected signals appear in "0" or "1"(here"1" represents there is a signal pulse, "0" represents not), which results from signal phase noise, can reflect the fastest stability which is equivalent to the corresponding sampling time of the cycle of the compared signal[16] [8]. Using ΔT as small as possible makes the phase difference step values stable in the detected "phase coincidence cluster". The signal background noise, which makes the phase variation obvious, causes phase jitter and lose some "coincidences". So it has provided the basis for us to analyze the phase noise specification.

According to sampling interval of the coincidence information, the phase difference of the signals is increasing or decreasing by step ΔT. The "0" after coincidence detection "1" in different position represents amplitude change of the phase difference variation caused by noise. But when there appears some associate "0" in a certain position, the reflected amplitude changes need special treatment including the phase change value and duration time on the corresponding numbers of "0".

$$\sigma_y(\tau)=\frac{1}{\tau}\sqrt{\sum_{i=1}^{m}\frac{(\Delta\Phi_{i+1}-\Delta\Phi_i)^2}{2m}} \tag{3}$$

In equation(3), the parameters include the information of phase difference changes $\Delta\Phi$ and corresponding duration time τ[9]. This equation was used to calculate stability in the measurement results of the same nominal frequency by using phase comparison method. In fact, its inference and change has provided an important basis on frequency stability with the information processing of coincidence detection area. The duration detection of coincidence conditions can obtain whether $\Delta\Phi$ is changing or not. According these methods, the transient state stability measurement of an ordinary 10MHz crystal oscillator can be achieved by 10MHz higher stability. Table Ⅱ shows frequency stability calculation results by equation(3).

TABLE II FREQUENCY STABILITY MEASUREMENT RESULTS

group	**1**	**2**	**3**	**4**
Frequency stability（100ns）	7.23×10^{-4}	7.19×10^{-4}	7.19×10^{-4}	7.16×10^{-4}
group	**5**	**6**	**7**	**8**
Frequency stability（100ns）	7.02×10^{-4}	6.92×10^{-4}	6.67×10^{-4}	6.56×10^{-4}

V. FREQUENCY LINK AND ATOMIC CLOCK PERFORMANCE IMPROVEMENT BASED ON GENERALIZED PHASE PROCESSING

The frequency signals with large frequency difference can be linked through phase processing method, which performs the transfer of the accuracy and stability. The concept will bring new opportunities for the development of quantum frequency standard technology, such as the link between the signals with above 5 orders of magnitude frequency difference, and the phase group synchronization, different frequency optimization of phase-locked loop frequency standard of cesium and rubidium atomic clock circuits[16]. The detailed experiment about phase processing on

a large frequency ratio condition shows in reference [4]. On the basis of which the phase lock of large frequency ratio has been achieved.

At present, frequency link has played a significant role in atomic clock performance improvement [7]. Whether active atomic clock or passive atomic clock, the generalized phase processing frequency link method can modify the clock system structure and improve its performance. In the active atomic clock such as the hydrogen atomic clock, because of the directly high precision phase detection of different frequency signals, the hydrogen maser frequency from atomic energy level transition through simple transformation and the signal from the crystal oscillator will be able to realize different frequency detection and phase-locked [4]. In passive atomic clock, the crystal oscillator which is more easily to energize clock transition signal is been chosen to produce drive signal, thus, the output signal produced by phase-locked based on phase group synchronous between selected oscillator outputs and the 10 MHz oscillator not only has high accuracy and long-term stability, but also ensures a better short-term stability and phase noise specification. As in the corresponding cesium atomic clock, in order to simplify the system frequency transformation circuit, the 14,591,479Hz voltage-controlled crystal oscillator is used as source to produce drive signal of the physical package. Its 630 times can get the incentive signal of cesium atomic clock 9,192,631,770 Hz. The final output of the cesium atomic clock is 10MHz, we use more convenient and high quality 10MHz oscillator signal, by directly phase processing and control – using the method of the phase group synchronization of two signals, to achieve the link control of 14,591,479Hz signal to the oscillator signal 10MHz. Fig.6 shows the achievement process of phase group synchronization, the key is to use the equation $\frac{\Delta f}{f} = \frac{\Delta \Phi}{\tau}$. τ is effective comparing time, which should be the integer multiples of 1s; $\Delta\Phi$ is a selected fixed phase difference of the start signal - the corresponding change of the measuring interval time. The Comparison of the phase noise curve in Fig.7 and Fig.8 can fully show the advantage of frequency link based on generalized phase processing.

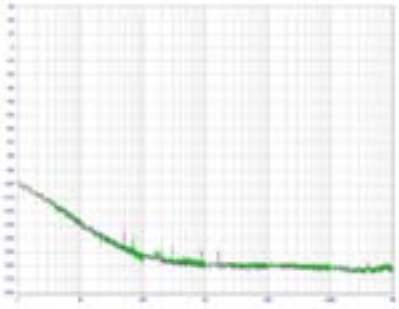

Figure 8. The phase noise of the10MHz output on the condition of group synchronization

VI. The Basis Performance Of Generalize Phase Processing In Broader Periodical Phenomenon And The Mutual Relationship

The basis application of generalize phase processing is mainly applied in the field of engineering. Fig.9 shows the various application of phase measurement based on generalized phase processing.

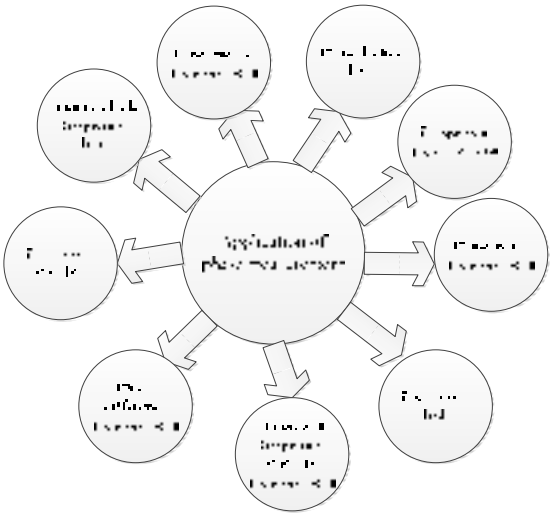

Figure 9. Various applications of phase measurement based on generalized phase processing

Furthermore, a periodic phenomenon is common one in nature [1]. The research of its change and mutual influence, especially the performance in high-accuracy has important significance[11].The technology can better explain the performance of different phase characteristics between the periodic movements, and the causes of the abnormal phenomenon. In the broader natural environment, this research can become the basis of exploring, analyzing, and predicting a variety of periodic relevant factors.

VII. CONCLUSION

Briefly, the exploring of the generalized phase relationship between the periodic signals and processing technology helps us to understand deeply the various relationships existing between the various cyclical movements. Now this thought and method have more application prospects on precise frequency and phase difference measurement and processing, high-precise frequency link, phase-locked loop devices, and system transformation of quantum frequency standard. We believe this method and corresponding technology can achieve extensive application in time-frequency measurement, control, process of periodic signals and periodic phenomenon which exist in a lot of corresponding subjects.

Source Impedance Influence on Cross-Correlation Phase Noise Measurements

Jason Breitbarth, Ph.D.
Holzworth Instrumentation Inc.
Boulder, CO, USA
jason@holzworth.com

***Abstract*—The phase noise floor of an oscillator has been shown both theoretically and experimentally to be the ratio of the source noise power divided by the delivered power. In a 50Ω system this is determined by –177dBm - P_{OUT} in dBc/Hz. Recent measurements have shown what appears to be better than theoretical noise floors in some oscillators, assuming a 50Ω environment. However, oscillators rarely exhibit an output impedance of exactly 50Ω and vary significantly farther from the carrier. While the input impedance of a modern cross correlation analyzer may be 50Ω, the assumption the analyzer introduces 50Ω common mode noise can be erroneous. This paper presents theory and measurements that demonstrate the extremely low phase noise measured on some oscillators is real and not in violation of theoretical limits by isolating the noise sources in a series of additive phase noise measurements.**

Keywords—phase noise; additive; residual; noise; noise-floor cross-correlation.

I. Introduction

Leeson's model of an oscillator includes a term for the impedance of the system, usually set to 50Ω, and based on the assumed architecture of the oscillator, is often very accurate for predicting the performance of an oscillator [1]. This model assumes the output power of an oscillator is delivered from the output of the amplifier in the system and includes the noise due to the amplifier and the loop impedance. An alternative to this architecture is the block diagram of an oscillator in Fig 1. The output power is pulled prior to the amplifier and after the resonator. In an inductively coupled parallel resonator, such as a cavity, the impedance of the resonator far from the -3dB bandwidth can be a very low impedance. Regardless of the input impedance of the amplifier, the output noise source impedance far from the arrier will dominated by the resonator impedance past the -3dB point.

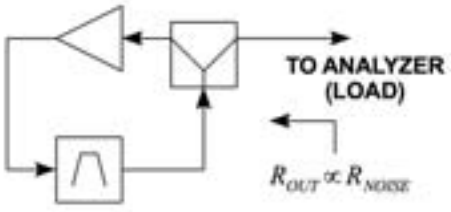

Fig. 1. Oscillator digram where output impedance and noise is dominated by the output impedance of the resonator, assuming the resonator has a low impedance.

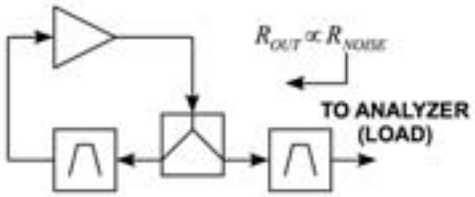

Fig. 2. Oscillator digram where output impedance and noise is dominated by a resonator clean-up loop.

A second architecture that Leeson's formula does not account for is shown in Fig. 2. This architecture adds a clean-up loop to a traditional oscillator. Again, the cleanup loop can be a resonator with a near short circuit far from the -3dB point. Since an oscillator is fundamentally just filtered noise from a positive feedback circuit, this additional loop will filter the noise induced by the amplifier in feedback. The source impedance of Fig. 2 is similar to Fig. 1 where far from the -3dB point it may be a very low impedance. In both of these systems, the measurement of delivered power is still in a 50Ω environment while far from the carrier the noise power is in an entirely different impedance. This discrepancy will result in phase noise levels, far from the carrier, that will be lower than what is possible in a theoretical 50Ω environment.

The fundamental question if the above is true is two-fold. First, can a cross correlation phase noise measurement truly differentiate between different sources of noise, itself and the source. Second, can a cross correlation system measure phase noise far from the carrier in which the noise source impedance is something other than 50Ω. Presented below are two measurement setups. First at baseband to demonstrate the ability of the baseband portion of measurement system to identify only noise that is common, regardless of impedance. Cross-correlation systems have shown to measure far below that of either individual channel [2-4]. Second, three additive phase noise measurements are shown in which the noise source is common to all three inputs at two different impedances and one where a 50Ω noise source is added to the common path as a verification. This verification is to provide a reference from [5] in which -177dBm has been determined to be thermal noise floor in a 50Ω environment.

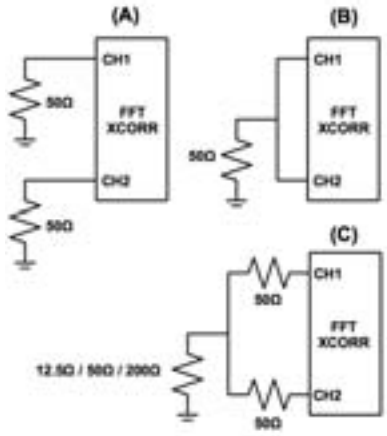

Fig. 3. Measurement setups for demonstrating the ability of a cross correlation system to identify only common noise, regardless of impedance.

II. Baseband Cross-Correlation

To demonstrate the cross correlation measurement and the ability to cancel noise that is common only between the two channels, regardless of the impedance of either channel, a simple test setup is shown in Fig 3.

The first test identifies the capability of the cross correlation system to show truly independent noise paths. In Fig. 4, the first (blue) and second trace (red) shows the measurement from Fig. 3c and Fig. 3b, respectively, as a single channel. The third trace (red) and fourth traces (black) are the cross correlation results from Fig 3c and Fig 3b, respectively. This measurement demonstrates that any noise introduced in either channel uniquely, but not common, will be correlated out of the measurement. The fourth trace (black) in Fig. 4 is from the setup in Fig 3a, demonstrating the isolation of the measurement. A setup similar to this was originally used to calibrate the cross correlation measurement system in [6].

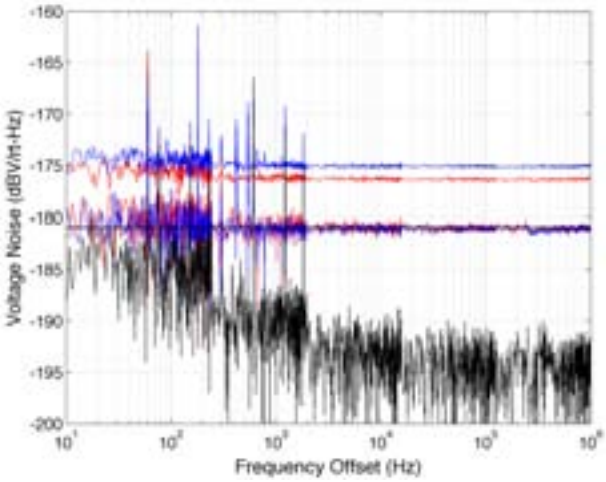

Fig. 4. Measurements from Fig. 3. The top trace (blue) is setup 3c with 50Ω in common to each port taken as a single channel measurement. The second trace down (red) is setup 3b with only 50Ω in common taken as a single channel measurement. The third and four traces down (nearly identical) are a cross correlation measurement of setups 3b and 3c, demonstrating the 50Ω in series adds no common noise. The fifth trace down is setup 3a where no noise is common. The measurement demonstrates the channels are independent. The rise in the noise at low frequencies is due to a different number of correlations per measurement band to optimize measurement speed. Low frequencies have fewer overall correlations.

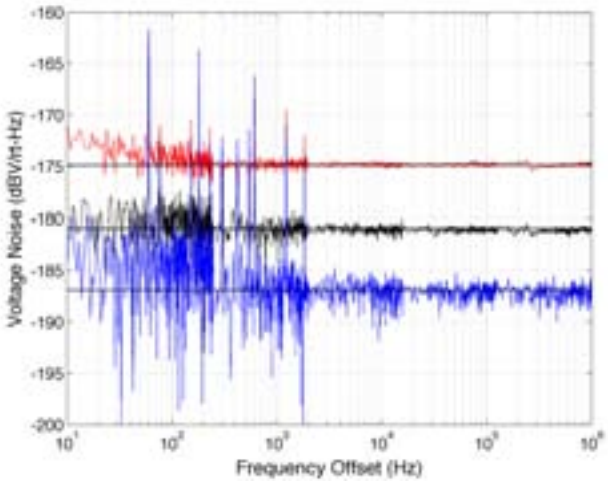

Fig. 5. Measurements from Fig. 3c. The top trace (red) is for a 200Ω impedance. The second trace (black) is for 50Ω. The bottom trace (blue) is for a 12.5Ω resistor. In all three cases, the measurements demonstrate results within ~0.1dB of theoretical noise for a resistor at 293K (temperature of measurement). The sold lines are the theoretical values.

The second test results are shown in Fig. 5 using the setup in Fig3c. The series 50Ω resistor into each path emulate a resistive splitter that can be used to split a signal without introducing common mode noise. The measurements in Fig. 5 demonstrate the near theoretical results for each resistor value inserted. In each case, the results are within 0.1dB of the theoretical noise values.

III. Cross-Correlation at RF Frequencies

A. Measurement Setup

Cross-correlation at RF frequencies accomplished two identical discriminators, each with their own unique noise source. A Holzworth HA7402B cross-correlation engine was used for these measurements. The input circuits were optimized for 0-5dBm levels to ease the measurement time. The important aspect of the HA7402B is the >100dB port-port isolation of each of the three ports at 100MHz. Port match is better than -30dB. A good cross-correlation measurement system is designed to not introduce any common mode noise into the DUT path while maintaining very high port to port isolation. In mixer only systems port isolation may only be 20-40dB, causing feedthrough and corrupting the measurements at these levels.

The source is a Wenzel Onyx series 100MHz OCXO with very good close to the carrier phase noise and a -175dBc/Hz floor. The output of the OCXO was buffered by attenuators and a Holzworth HX2400 amplifier. Careful attention was paid to isolate the OCXO from the measurements so as not to introduce any potential injection locking or pulling.

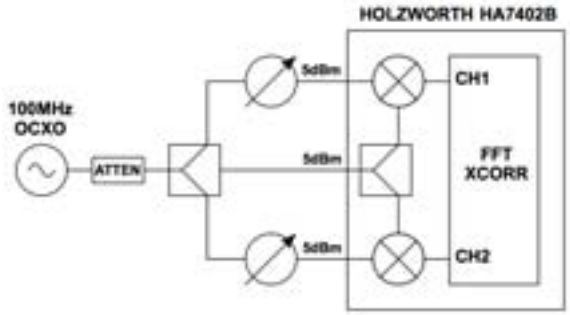

Fig. 6. Setup for measuring the floor of the cross-correlation system. Two different splitters were used, a resistive splitter with 12.5Ω resistance and a wilkinson three-way splitter with 50Ω port match and 20dB isolation. The splitters are shown in more detail in Fig. 10.

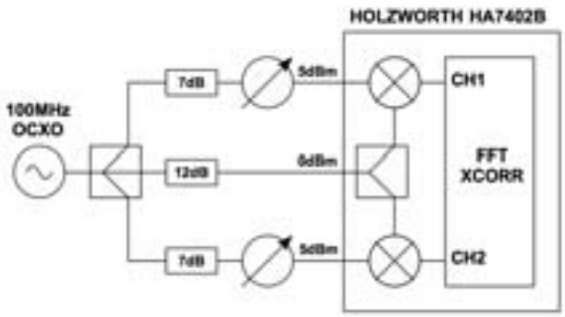

Fig. 8. Setup for proving the -177dBm/Hz floor in a 50Ω environment. The setup from Fig 6 was modified to introduce a 12dB attenuator in the common path, providing a 50Ω noise source that is unique only to the common path. The wilkinson power splitter from Fig. 7 was used.

To identify that the cross correlation system only measures noise unique to the common path, regardless of output impedance of the source, a setup was built shown in Fig. 6 using two different types of power dividers. One divider is resistive only at the input, providing a low impedance direct connection to all three paths while providing a 50Ω port match at the input. The output impedance is 12.5Ω. The second is a more traditional three-way wilkinson power divider. The schematic level of these dividers is shown in Fig. 10. This experiment identifies whether the cross-correlation engine with two discriminator paths can cancel noise due to the source, regardless of impedance. It adds a secondary result on whether a divider introduces a unique noise component to each path or is common to all and therefore cancelled.

B. Measurement Results

The measurement results of the two splitters are shown in Fig. 7. The measurements were stopped at 200 correlations for reasons of measurement time. After 200 correlations the measured floor was -186dBc/Hz for both power dividers and still relatively uncorrelated. At 5dBm input power and a 50Ω noise source system, the measurement noise floor would be -182dBc/Hz. What this measurement demonstrated was the noise was common between all three ports. This is easy to see for the resistive splitter but more difficult for the wilkinson, both shown schematically in Fig. 10. Two different source impedances were used to show that the source noise is cancelled out (similar to the noise around the carrier) regardless of impedance. The additive measurement will only measure noise added by the common path, regardless of impedance.

The verify that the correct floor is measured, assuming a 50Ω noise source environment unqiue to the DUT path, the setup in Fig. 8. was built to provide 0dBm into the HA7402B while maintaining 5dBm LO drive levels. To introduce 50Ω noise that is common only to the DUT path, a 12dB attenuator was used. The pi-attenuator topology introduces near 50Ω noise, incoherent with the other two channels. The measurement results are shown in Fig. 9. A level of -177dBc/Hz was measured, as predicted by theory.

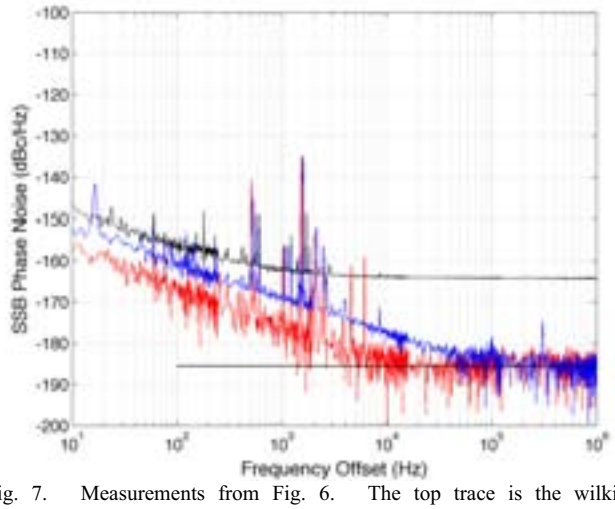

Fig. 7. Measurements from Fig. 6. The top trace is the wilkinson measurement from a single channel. The middle trace (blue) is from the resistive splitter and the bottom trace (red) is from the wilkinson using 200 cross-correlations. At that measurement level, there is no performance difference far from the carrier at -186dBc/Hz.

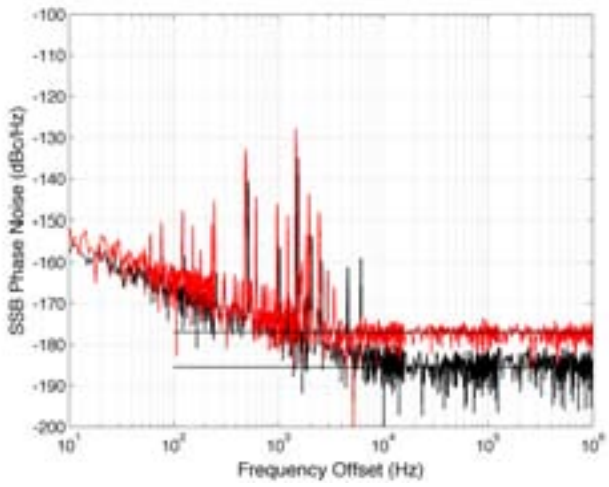

Fig. 9. Measurement of the setup from Fig. 8. demonstrates the -177dBc/Hz (or -177dBm/Hz at 0dBm) theoretical limit by introducing a 50Ω noise source common to both channels. This was taken using the wilkinson 50Ω power divider. The bottom plot is from Fig. 7 of the floor without the attenuator. The attenuator adds unique 50Ω noise to the system, matching theory.

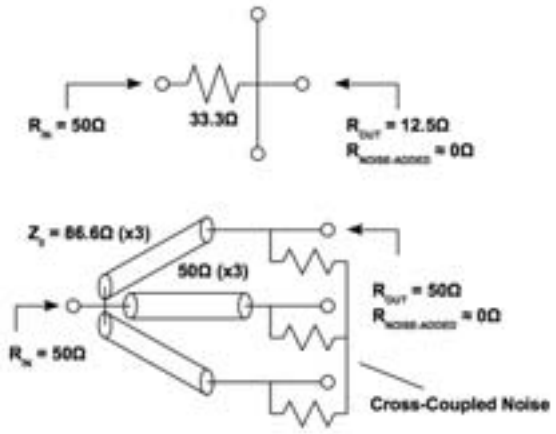

Fig. 10. Schematic representations of the two power dividers used in the cross-correlation measurements. Both split the signal equally with the resistive splitter port matched at the input with low output impedance. The wilkinson is band limited but provides additional isolation. The noise in both cases is entirely common to all three paths, being cancelled out in the discriminator. The resistors in the star-topology wilkinson add noise, but add it in common to all three channels.

C. Power Dividers as Noise Sources

Two drastically different power dividers were chosen. The first is resistive only. This changes the output impedance of the splitter to be 12.5Ω with the noise component being common by a direct connection. This was done deliberately to isolate the power divider from the noise source. The results are conclusive in that the cross-correlation engine, far from the carrier, is not adding 50Ω noise to the system.

The second splitter is the wilkinson. Given it's output impedance is 50Ω, it is not immediately clear that the noise source is common between all ports. Measurement results indicate that the noise component is transposed back to the input of the divider, becoming common mode. The cross-coupled nature of the resistors in the wilkinson also cross-couple the noise. This results in the noise becoming common and is input referred. This also demonstrates that a wilkinson divider, as the front end of a cross-correlation measurement setup, may actually introduce 50Ω noise, as it could input refer the resistor noise, which would be common in the DUT path

This is a significant result as potentially not all cross-correlation engines will have a similar front end as HA7402B and some may actually introduce noise in that path, limiting the dynamic range of the measurement. The HA7402B uses a broadband resistive splitter shown to not introduce common mode noise in the first series of baseband measurements.

IV. Conclusions

The impetus behind these series of measurements were to try to prove that source phase noise can be below that of the theoretical -177dBm/Hz - P_{OUT} levels of a 50Ω system, provided the output impedance is sufficiently low. The question is whether a cross correlation system could correctly measure a signal source noise that is below the 50Ω input impedance of the analyzer.

Based on the measurement results it can be concluded that the cross correlation measurement system has the ability to measure signals with a source noise impedance lower than 50Ω. A measurement can be taken (assuming enough correlations and time) that would show an oscillator could have better than the 50Ω assumed -177dBm/Hz - P_{OUT} provided the source impedance of the oscillator was sufficiently low and no other significant noise source was introduced after the oscillator. The power dividers at the input of the HA7402B analyzer do an effective job of isolating the noise channel to channel while not introducing 50Ω noise but maintaining a matched port impedance.

As a side note, modern simulators often include all noise sources in the system, including the noise due to a 50Ω termination. It may be unclear how this may affect the predicted noise floor. The cross-correlation engine is designed specifically to isolate only the oscillator and not include the presence of this noise. Therefore, simulator predicted noise floors may be different than actual measurements due to the uncertainty in the simulated noise sources.

The additive cross-correlation phase noise measurement technique was applied to test this theory to help isolate any form of injection locking or inadvertent non-linearity when using multiple oscillators. To add more proof to the basis of this work an additional measurement may be taken in which a very low noise oscillator is followed by a very high-Q cavity filter with an effective short circuit beyond the -3dB point. The author expects that a measurement floor below -177dBm - P_{OUT} will be observed based on the measurements provided in this paper.

Acknowledgment

I thank Wenzel Associates, Inc. for providing oscillators for testing and to Charles Wenzel for discussions regarding theoretical phase noise floors.

***Abstract*—This paper focuses on key phase noise measurement techniques for oscillators and reviews their advantages and disadvantages. Several test methods and test instruments are investigated. There's no "one size fits all" solution, for e.g., measuring a phase noise value of -130dBc/Hz at 1Hz offset from the carrier, and achieving a measurement noise floor better than -200dBm is challenge, using existing test equipment and methods.**

Keywords- Oscillator, AM, PM, Phase Noise, Cross-Correlation

I. INTRODUCTION

Noise is associated with all the components of the oscillator circuit; however the major contribution of the noise in an oscillator is from the active device, which introduces AM (amplitude modulation) noise and PM (phase modulation) noise [1]. The conventional wisdom is to ignore AM component of the noise because the gain limiting effects of the active device operating under saturation allow little variation in the amplitude noise in comparison to PM noise component, may directly affects the frequency stability of the oscillator and creates noise sidebands [2]. But in reality, many oscillator topologies create significant AM noise, therefore effective noise contribution is the combination of 1/f spectrum with the $1/f^2$ effect in all phase modulation, makes the low-frequency noise much greater, and that's where the information in most modulated signals resides [3]-[6].

In the order of increasing complexity, noise models are grouped into one of the three categories as: linear time invariant (LTIV), linear time variant (LTV), and nonlinear time variant (NLTV). Leeson's model [1] is based on LTIV (Linear-time-invariant) properties of the oscillator, such as resonator Q, feedback gain, output power, and noise figure; a second model is proposed by Lee and Hajimiri [7, 8], based on time-varying properties of the oscillator RF current waveform (LTV); and a third is proposed by Kaertner and Demir using a perturbation model based on numerical techniques (NLTV) [9]-[11]. Nallatamby et al. [2] revisited the Lesson's noise model, providing a detailed and enlightening analysis, demonstrating its applicability to several oscillator circuits. The theories proposed by Hajimiri and Lee, and from Kaertner and Demir are based on time-domain approaches for harmonic oscillator circuits (like LC resonator). The approach from Hajimiri and Lee can be seen as a particular case of the theory of Kaertner and Demir, as it can be shown in the analytical comparison between time and frequency-domain techniques for phase noise analysis, carried out by Suárez et al. [12]. The Impulse Sensitivity Function (ISF) proposed by Hajimiri and Lee can be employed to optimize the phase noise performances of a given oscillator and ISF can be obtained from Harmonic Balance (HB) as shown by Ver Hoeye et al. [13]. More insight about phase noise analysis can be found in the paper of Rizzoli [14], and Sancho et al, [15].

Table 1 shows the comparative analysis of 3-most cited phase noise models, their relative strength and weakness for the characterization of oscillator phase noise. All the three models discussed in Table 1 explain and predict the phase noise of autonomous circuits (oscillators), and one can argue the superiority of any of the three models based on accuracy, reliability, simulation time, and convergence for a given oscillator circuit topology. Comparing the noise models discussed above, it is up to the designers to choose noise models for predicting the phase noise because none of the 3-models allow closed form solution for both harmonic and non-harmonic oscillator circuits. Similarly, oscillator phase noise measurement is one of the most difficult measurements in all of electrical engineering. The biggest challenge is the huge dynamic range required in phase noise measurements. There are several methods to measure phase noise and the right one must be chosen to make the necessary measurements. To properly select among the various methods it is necessary to know and appreciate the weaknesses and strengths of each of the different measurement techniques, because none of these methods is perfect for every situation.

Table 1: Describes the strengths and weaknesses of the noise models

Model	Leeson	Lee and Hajimiri	Kaertner and Demir
Assumptions	LTIV	LTV	NLTV
Perturbing noise Source	Constant white noise (KTB)	Cyclostationary $1/f^k$ for any $k \in N$	Modulated $1/f^k$ for any $k \in N$
Accuracy	Reasonable	Good	Exact
Simplicity	Simple	Moderate	Involved
Computer dependence	Independent (Calculation by hand)	Computer to evaluate ISF	Computer dependent (no closed form solutions)
Predicts close-in phase noise	No	Yes	Yes
Retained circuit parameters	Loaded Q-factor (Q_L), output power (P_s)	Γ_{rms}	None

II. PHASE NOISE MEASUREMENT

In general, measuring phase noise is more difficult than measuring amplitude or frequency related properties. Different signal sources, whether it is an oscillator alone or within a synthesizer, have widely varying phase noise performances. Higher noise sources do not work well with phase noise measurement equipment optimized to measure very low noise

levels. An ability to measure the phase noise performance of ultra-low phase noise oscillators drives the specifications of the best performing phase noise analyzers.

Phase noise is usually expressed in units of dBc/Hz at some specific offset frequency f, from the carrier, the value of the noise level relative to the carrier level calculated in 1Hz bandwidth. Most often only single sideband (SSB) noise is considered. Some measurement set-ups measure both noise sidebands and a conversion factor is required to report SSB noise. The pioneer in Phase Noise measurement unquestionably was Hewlett Packard [17]. Once adequate for advanced designs, a noise floor dictated by SSB thermal noise (Johnson Noise at kT of -174 dBm) for zero dBm output power is not enough anymore for some special requirements and also marketing of these reference frequency sources. Any type of amplifier in the test signal chain will also serve as a source of noise. While the main purpose of the amplifier is to increase the power level of a weak carrier signal, it also adds its own noise to the signal and boosts any input noise. The net result is that the amplifier, thermal noise, and flicker noise continue to give any PN plot a characteristic shape and, more significantly, reduce the theoretical lower limit of sensitivity for any phase-noise measurement. The noise correlation technique allows us to look below kT level (< -174 dBm). But the usefulness of the noise contribution below kT is debatable in the perspective of overall system performance. To achieve a very low noise floor, modern phase noise measurement instruments use the cross-correlation principle [18]-[20].

A. Phase Noise Mesaurement Techniques

The usual goal for measuring phase noise in an R&D environment is to achieve the lowest measurement noise floor possible. As we shall see, this is not necessarily the best choice, depending on the signal source being measured. In a production environment, the objective is fast throughput for product phase noise performance testing. Again, this is best achieved by using a method that is appropriate for the source being measured. There are some very capable general purpose phase noise measurement instruments available on the market, including the Agilent-E5052B, Rhode & Schwarz-FSUP, Holzworth-HA7402A, Noise XT-DCNTS, Anapico-APPH6000-IS, and OE Wave-PHENOM™. With the growing demand for improved dynamic range and lower noise floor, equipment companies are introducing general purpose phase noise analysis software driven tools for extracting far out (offset frequency > 1MHz) noise below the kT floor even though claims of -200dBm or lower lack the practical utility. Modern phase noise test equipment addresses these issues, following primary phase noise measurement techniques, listed in the order of increasing precision [21]-[25] :

(a) Direct Spectrum Technique

(b) Frequency discriminator method

- Heterodyne (digital) discriminator method

(c) Phase detector techniques

- (Reference source/PLL method)

(d) Residual Method

(e) Two-channel cross-correlation technique

The Direct Spectrum Method, PLL method, delay line discriminator method, and cross-correlation method are frequently used to measure the oscillator phase noise. The first one is the simplest and has the biggest limitation. The last one requires the most complex measurement system but it is a most versatile, can measure phase noise performance better than that of its reference oscillator. Figure 1 shows the typical block diagram of the 2-channel cross-correlation technique [17]. As shown in Figure 1, there are two reference oscillators, one power splitter, two mixer/amplifier/PLL circuits and a cross-correlation FFT analyzer. The cross-correlation technique is used to minimize the noise contribution from mixer, filter and LNA from the measurement results. The noise from output of each mixer can be modeled using two noisy signals [18]-[27]:

$$x(t) = a(t) + c(t) \overleftrightarrow{FFT} X(f) = A(f) + C(f) \quad (1)$$

$$y(t) = b(t) + c(t) \overleftrightarrow{FFT} Y(f) = B(f) + C(f) \quad (2)$$

Where *a(t)* and *b(t)* are uncorrelated equipment noise present in each channel and *c(t)* represents the correlated DUT noise. The cross-spectrum of these two signals after averaging over *M* samples is described by

$$\overline{S_{XY}} = \frac{1}{M}\sum_{m=1}^{m=M}[X_m \times Y_M^*] \quad (3)$$

Where '*m*' represents the sample index and (*) implies the conjugate function. From (1)-(3),

$$\overline{S_{XY}} = \frac{1}{M}\sum_{m=1}^{m=M}[(A_m + C_m) \times (B_m + C_m)^*] \quad (4)$$

$$\overline{S_{XY}} = \frac{1}{M}\sum_{m=1}^{m=M}[(A_m B_m^*) + (A_m C_m^*) + (C_m B_m^*) + (C_m C_m^*)] \quad (5)$$

From (5) the DUT noise through each channel is coherent and is therefore not affected by the cross-correlation, whereas, the internal noises generated by each channel are incoherent and diminish through the cross-correlation operation at the rate of $\sqrt{M}$ (M=number of correlations):

$$[Noise]_{meas} = [Noise]_{DUT} + \left(\frac{[Noise]_{chanel\#1} + [Noise]_{chanel\#2}}{\sqrt{M}}\right) \quad (6)$$

Where $[Noise]_{meas}$ is the total measured noise at the display; $[Noise]_{DUT}$ the DUT noise; $[Noise]_{chanel\#1}$ and $[Noise]_{chanel\#2}$ are the internal noise from channels 1 and 2, respectively; and M the number of correlations. From (6), the 2-channel cross-correlation technique achieves superior phase noise measurement capability but the measurement speed suffers when increasing the number of correlations.

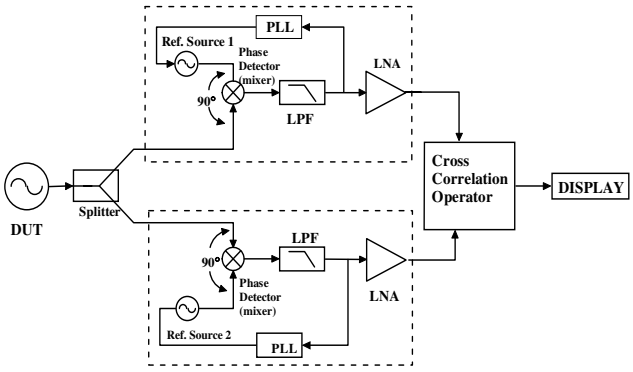

Fig.1: The block diagram of 2-channel cross-correlation technique

This method offers 15 to 20 dB improved phase noise measurement sensitivity when compared to the Reference source/PLL method, therefore, it is possible to measure oscillators with better noise performance than the reference oscillators, because phase noises from the reference oscillators are suppressed considerably [21]. The improved dynamic range and noise floor of the cross-correlation phase noise measurement technique comes at price; large samples are required for averaging out the uncorrelated noise. The practical value of the noise floor is given by [28]:

$$[L(f)_{SSB}] = -177 + N_a - P_i \quad (7)$$

Where N_a is the noise figure and P_i is the power available.

B. Phase Noise Measurement and Verification of 100 MHz Crystal Oscillator Using PN Measurement Equipments

Figures 2, 3, and 4 show the schematic and simulated plots of phase noise output power of 100 MHz oscillator circuit. For validation of the CAD simulated and theoretical phase noise plots shown in Figures (2) and (5), 100 MHz Crystal oscillator was built. The theoretical (Fig.5) and simulated (Fig.2) phase noise data agrees within 1-2dB of accuracy.

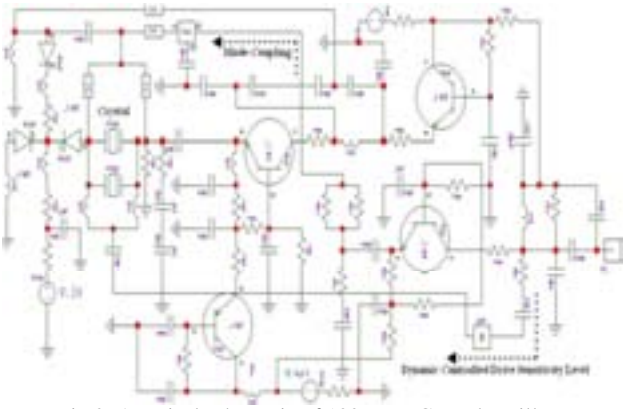

Fig.2: A typical schematic of 100 MHz Crystal oscillator

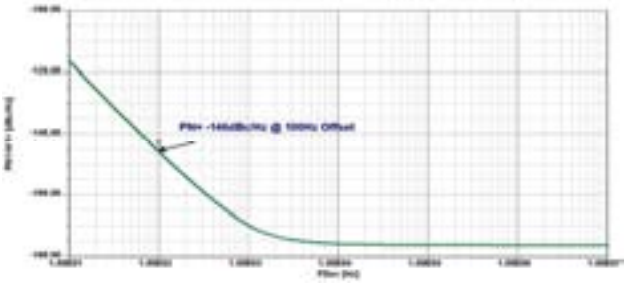

Fig.3: Simulated (Ansoft) PN plot of 100MHz Crystal oscillator

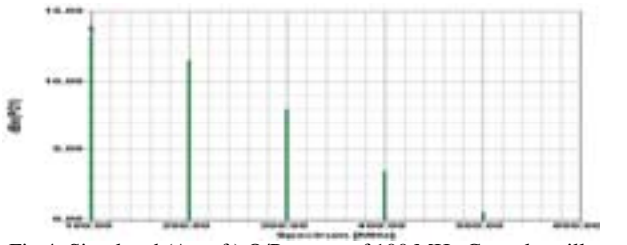

Fig.4: Simulated (Ansoft) O/P power of 100 MHz Crystal oscillator

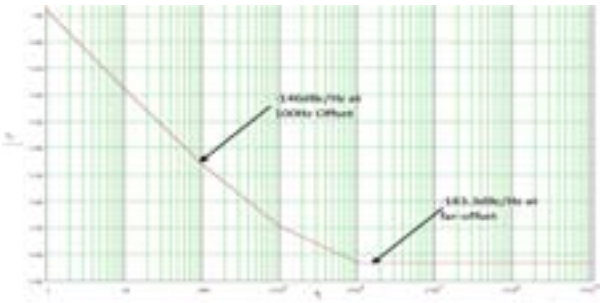

Fig.5: Theoretically calculated Phase noise plot of 100MHz OCXO

The rigorous measurements were conducted on 100 MHz Crystal oscillator using different Phase Noise Measurement Equipments (Agilent E5052B, R&S FSUP, Holzworth HA7402-A, Noise XT DCNTS, and Anapico APPH6000-IS) available on the market. The PHENOM™ (OEwaves) is high performance automated PN measurement system, this equipment was not made available for the validation in our Faraday Cage (Figure 6); nevertheless authors are keen to validate the PN measurement in future using PHENOM™ for broader acceptance of the fact and myth linked with variation in measurement phase noise data below the kT. Table 2 shows the measured phase noise of commercial available 100MHz OCXOs (Pascal, Synergy) on different test equipments for comparative analysis of the measured data under similar test conditions.

As shown in Table 2, it can be seen that there is a variation in PN measurement using identical DUT on different equipments. The consequences are the reliability and repeatability of the measured data below kT. If the equipment in use, after many correlations gives out a better number, it violates the laws of physics and if it gives a worse number, then either the correlations settings needs to corrected or the dynamic range of the equipment is insufficient.

Table 2: Comparative PN data measured on different Equipments

100 MHz OCXO O/P=14dBm, NF=7dB	Theoretical Model	Agilent E5052 B	R & S FSUP 26	Anapico APPH 6000-IS	Holzworth HA7402-A	Noise XT DCNTS
@ 100 Hz offset	-146 dBc/Hz	-143 dBc/Hz	-143 dBc/Hz	-141 dBc/Hz	-147 dBc/Hz	-140 dBc/Hz
@ 1 kHz offset	-170 dBc/Hz	-167 dBc/Hz	-163 dBc/Hz	-170 dBc/Hz	-170 dBc/Hz	-170 dBc/Hz
@ 10kHz offset	-182 dBc/Hz	-173 dBc/Hz	-174 dBc/Hz	-172 dBc/Hz	-178 dBc/Hz	-181 dBc/Hz
@ 100KHz offset	-183 dBc/Hz	-174 dBc/Hz	-183 dBc/Hz	-181 dBc/Hz	-179 dBc/Hz	-183 dBc/Hz
@ 1 MHz offset	-184 dBc/Hz	-174 dBc/Hz	-184 dBc/Hz	-182 dBc/Hz	-179 dBc/Hz	-186 dBc/Hz

C. Phase Noise Mesaurement Issues

There are important measurement issues that, if not well understood, can lead to erroneous results and interpretations [24]. They involve measurement bandwidth masking of, and accurate distinction between, true discrete spurious signals and narrowband noise peaks (typically encountered under vibration). Although the phase noise data displayed by phase noise equipment is usually normalized to 1Hz measurement bandwidth, most automated phase noise measurement equipment actually measures the phase noise in measurement bandwidths that increase with increasing carrier offset frequency. This is done for two reasons: (1) it results in shorter, overall measurement time, and (2) at high carrier offset frequency (i.e., > 100 kHz), many measurement systems employ analog spectrum analyzers that are not capable of 1Hz resolution. Noise measured in a 1kHz bandwidth, for example, is 30dB higher than that displayed in a 1Hz bandwidth. That means that low level discrete spurious signals (and narrowband noise peaks typically encountered under vibration as a result of high Q mechanical resonances) may not be detected. The second problem involves the software employed by the noise measurement system vendor used to discriminate between random noise and discrete spurious signals. Usually, when a reasonably sharp increase in noise level is detected, the system software assumes the increase marks the presence of a "zero bandwidth" discrete signal. It therefore (when displaying the phase noise on a 1Hz bandwidth basis) applies a bandwidth correction factor to the random noise, but does not make a correction to what was interpreted as a discrete signal. This results in an erroneous plot if/when the detected "discrete" is really a narrowband noise peak [24].

Another problem is the physical length of the crystal oscillator connection cable to the measurement system. If the length provides something like "quarter-wave-resonance", incorrect measurements are possible. The uncertainty in PN measurement due to output load mismatch, output phase mismatch, cable length, equipment dynamic range, etc creates certain ambiguity whether or not to trust these measurements or can they be repeated on different PN equipments for a given DUT and test & measurement conditions.

III. CONCLUSION

There are many areas in which design engineers can be tricked into false readings or frustrated with the process of trying to achieve a good measurement. Characterizing the phase noise of a system or component is not necessarily very easy. Many different approaches are possible, but the key is to find the best approach for the measurement requirements at hand based on (1) accuracy, (2) repeatability, (3) speed, (4) operating range, (5) cost, and (6) ease of data retrieval.

***Abstract*—The ULISS Cryogenic Sapphire Oscillator (CSO) offers unprecedented short-term frequency performances. It was specially designed to be transportable by car in order to test this new technology in different European sites. During the last 18 months, it was used to qualify with success several high stability frequency sources. In February 2013, a new measurement campaign was lead at CNES, Toulouse (France) to qualify the flight model of the frequency synthesis of the PHARAO clock. During the same period we built a second CSO unit based on the same design and conducted new characterisations of frequency stability and environmental sensitivity. Optimisation of the system has led to an improved frequency stability reaching currently better than 1×10^{-15} at 10,000 s integration times. Eventually we developed a new low phase noise and high-resolution frequency synthesis delivering 10 GHz, 100 MHz and 9.192 GHz ultra stable signals. In this paper we draw a progress report on the ULISS project, updating performances and describing the latest experiments conducted with our CSO in different sites in Europe.**

I. Introduction

The ULISS project aimes to promotte the Cryogenic Sapphire Oscillator (CSO) technology, which today has reach enough maturity to be used outside a well equiped metrological lab [1]. The CSO offers unprecedented short term frequency stability currently reaching better than 1×10^{-15} for integration times ranging from few seconds to 3 hours. Some units have demonstrated a relative frequency stability of 5×10^{-15} over 1 day without any clear drift identified [2]. A specialy designed CSO was build to be transportable by road, and during the last year ULISS was tested in different european sites. Experience feedback allowed to make the prototype progress. In this paper we present the last results obtained by comparing directly two identical CSOs operating at 9.99 GHz.

II. FEMTO-ST CSO Technology

The CSO is based on a microwave whispering gallery mode sapphire resonator made of a 54 mm diamter and 30 mm hight high purity sapphire cylinder. This resonator was designed to present a high-Q quasi-TM mode, i.e. $WGH_{15,0,0}$ at 9.99 GHz ± 5 MHz. The difference to the 10 GHz round frequency allows the use of a low noise Direct Digital Synthesizer (DDS) to compensate for the sapphire resonator machining tolerances [3], [4]. At the liquid helium temperature, the Q-factor approches 1 billion and the temperature-frequency senstivity presents a null near 6K. We developped in the frame of an ESA project a CSO (nicknamed ELISA) incorporating a cryocooler as cold source, which can be operated during two years without any maintenance. This first prototype was eventually installed in the ESA ground station in Malargua (Argentina) in May 2012. ULISS a mobile version of the same instrument was build at the end of 2011. Before the implentation of the fisrt prototype in Argentina, the two CSOs was comparated and the results were presented in [5] demonstrating a relative frequency stabilty better than 1×10^{-15} at short term with a flicker floor of 4×10^{-16}. At long term, the Allan standard deviation was limited by the CSO residual temperature sensitivity. ADEV reaches 1×10^{-14} at one day. The figure 1 shows the interior of the CSO cryostat. We can see the two stages of the cryocooler with the copper braids used to transfert the cooling power to the resonator whithout transmitting the Pulse-Tube mechanical vibrations. The figure 2 shows the cryostat and rack containing the electronic controls and the frequency synthesis.

Fig. 1: *ULISS cryostat interior.*

Fig. 2: *ULISS CSO with electronic controls rack.*

The sustaining loop is placed at room temperature in a thermaly stabilized aluminium box (see Fig. 2). ULISS incor-

porates a Pound and a power servo controls to correct phase and power fluctuations along the sustaining loop.

III. ULISS's Odyssey continues

The objectif of the ULISS project is to propose to european potential users to test directly in their applications an ultrastable cryocooled sapphire oscillator. During the past 18 months, Uliss visited several sites by making approximately 9000 km by the road in a van:

- LTF Neuchâtel, Switzerland, January 2012. ULISS was used to qualify an ultrastable laser source looked on an ULE cavity and to measure the frequency stability of quartz Xtal oscillator industrial prototypes.
- CNES Toulouse, France, March 2012. First validation of the PHARAO clock synthesis.
- Exhibition of the EFTF 2012, Göteborg, April 2012.
- CNES, Toulouse, France, February 2013. Second run in the validation of the PHARAO instruments.
- UTINAM Institute, Besançon, France, April, 2013. Validation of the composite clock.
- SYRTE Paris, France, june, 2013. First tests with SYRTE metrological equipments.
- Exhibition of IFCS-EFTF joint meeting 2013, Prague, July 2013.
- Wettzel VLBI station, Germany, measurements with the ring laser, August 2013.

Between these differents measurement compaigns, ULISS came back to Besançon and was continously improved/adapted to fulfil the users requirements and to solve some encountered issues. The Pound servo was optimized: one integrator was added to provide enough gain at low frequencies. Preliminary tests using digital electronic controls have been realized during the past year, but due to the lack of time have not been integrated in the systems that we describe here. After the stay in SYRTE last June, where preliminary tests have been conducted with the higest resolution, a wide effort was recently dedicated to solve some EMC issues: replacement of bad switching power supplies, improvement of the earth and ground loops...

Initally ULISS was equiped with the same frequency synthesis than ELISA developped by TimeTech [6]. This frequency synthesis has three frequency outputs: 5 MHz, 100 MHz and 10 GHz. As several users need other frequencies, we designed our own frequency synthesis to get 500 MHz, 1 GHz and 9.192 GHz outputs. The CSO frequency stability is totally transfered at the microwave outputs. For the VHF and RF outputs, we observe as expected a small degradation due to the intrinsic noise of electronic components operating these frequency bands.

IV. Building of a new unit

The building of a new CSO was finalised at the end of 2012. In its design this CSO is identical to ULISS. Nevertheless some differences exist:

- The mechanical tolerances of sapphire resonator geometry were relaxed to decrease the cost of this key component. It results a frequency difference between the two CSOs of about 7 MHz.
- As the ULISS Odyssey focus a large part of our efforts, the second CSO is not totally optimized. It suffers from some technical problems that can be solved in a next step: i.e. i) the compressor He pressure is not optimized for 50 Hz supply, ii) due to some still non well identified leaks, the residual pressure inside the cryostat is 1×10^{-6} mbar, one order of magnitude higher than those obtained in the first system , iii) we suspect a possibly bad thermal contact in the resonator set-up. It results the cryocooler is less efficient than those of ULISS. The lower temperature currently achievable is 5 K (instead of 3.8 K), not far from the resonator turnover temperature, which is 5.8 K . In these conditions, the temperature control was found difficult to get optimized.

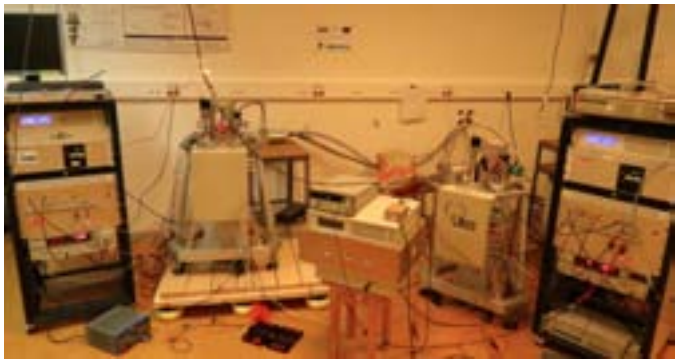

Fig. 3: The two CSOs during the last characterisation campaign (July 2013).

V. Improvements and comparison of the two CSOs

The ULISS travels requires a big effort of logistics and takes away our best reference for several weeks. Thus, since the first operation of the second CSO, we had only the possibility to make three short comparison campaigns in order to optimize its parameters. Nevertheless we made some progress in the electronic control loops (Pound and Power servos), improving the signal to noise ratio of the error signal detection and adding gain at low frequencies. We also modified the thermal filtering imrpoving the rejection of slow temperature variations of the Pulse-Tube.

The figure 4 shows multiple ADEV characterisations obtained by counting directly the 7 MHz beat-note during approximatly 15 hours. As usual we present the ADEV without any post-traitment. It clearly shows the reproductibity of the measurements and the exceptionnal flicker floor of 5×10^{-16}. At 1s the measurement is limited by the counter contribution due to the high value of the beat-nore frequency. The bump

at 20 s is due to a residual thermostat oscillation in the newly built CSO.

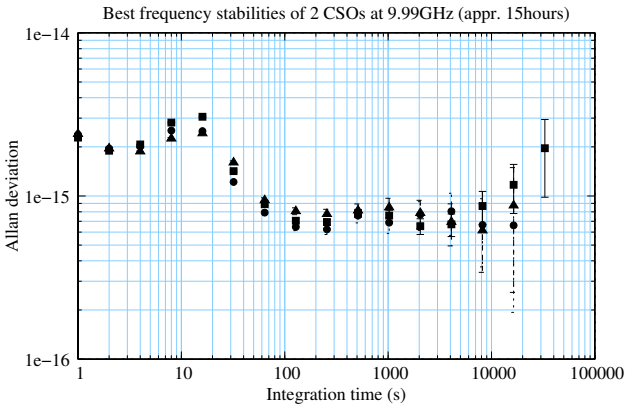

Fig. 4: 2 CSOs Short term frequency stability (July 2013).

The figure 5 shows the ADEV calculated after 5 days integration compared to the 2012 results [7]and to a state-of-the-art hydrogen Maser.

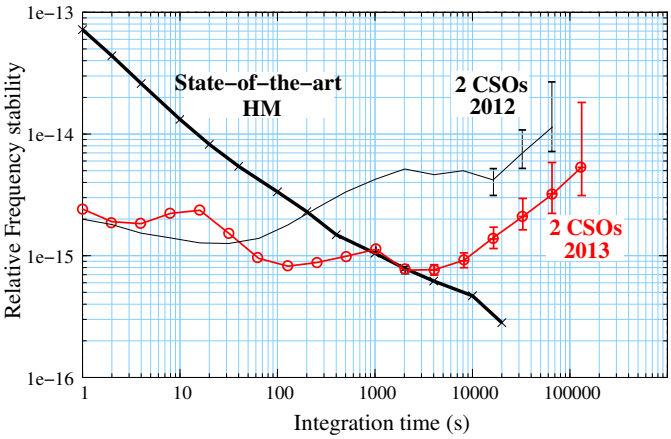

Fig. 5: CSO frequency stability.

ACKNOWLEDGMENT

The ULISS team wish to express acknowledgements to the *Fond Européen de développement Régional* (FEDER), *le Conseil Général de Franche-Comté* and OSEO for their support to the ULISS project.

The second CSO is founded by the ANR Oscillator IMP project and FIRST-TF network.

***Abstract*— A compact cold-atom clock based on coherent population trapping (CPT) is being developed. Long-term goals for the clock include achieving a fractional frequency accuracy of 1×10^{-13} in a package of less than 10 cm^3 in volume. Here we present an overview of a prototype clock design, and a systematic evaluation of the first-order Doppler shift. We also introduce our second-generation physics package.**

Keywords- Atomic Clocks; Coherent Population Trapping; Doppler Shift; Laser Cooling; Ramsey Spectroscopy.

I. INTRODUCTION

A compact, cold-atom clock is under development. The clock is interrogated with light by use of coherent population trapping (CPT) in a lin ∥ lin polarization configuration [1]. This technique allows for excellent control of the phase of the interrogation fields on size scales much smaller than that of a microwave cavity, which is desirable for a small system. The use of cold atoms allows the system to achieve relatively long interrogation periods without requiring buffer gases, which introduce large, temperature-dependent shifts in clocks based on vapor cells.

The use of laser-cooled atoms eliminates the buffer-gas shift present in vapor-cell CPT clocks but in general introduces a 1st-order Doppler shift, since the atom cloud expands and falls during interrogation and the atoms are therefore not in the Lamb-Dicke regime [2]. Atomic fountains also operate outside of the Lamb-Dicke regime, and the distributed-cavity phase shift is equivalent to the Doppler shift in fountain clocks. In fountains, this shift is made to be small by use of interrogation with a standing wave in a high-Q microwave cavity [3], but the shift can nevertheless contribute to the overall clock uncertainty at the 1×10^{-16} level [4].

The atoms are interrogated by use of a combination of CPT and Ramsey absorption spectroscopy in a scheme similar to the approach taken by Hemmer and colleagues [5], who used Ramsey CPT spectroscopy to interrogate Na atoms in an atomic beam. Our system differs from theirs in that it is based on laser-cooled ^{87}Rb atoms, so the Ramsey pulses are time-separated instead of spatially separated. The use of Ramsey spectroscopy reduces the light shift [6-8] and eliminates power broadening [9].

The CPT scheme used here is a double-Lambda lin ∥ lin configuration [1], in which a higher contrast is achieved over conventional CPT spectroscopy owing to the elimination of trap states (for a review, see [10]). The linear polarization of the CPT light can be represented as a sum of σ^+ and σ^- circularly polarized light components, which results in probing the atoms with a superposition of two Lambda systems. The energy-level diagram for ^{87}Rb with the two clock Lambda systems is shown in Fig. 1. The frequencies of both of the resonances are sensitive to magnetic fields in first order, but the size of the first-order shift is equal and opposite. As long as the two Lambda systems have the same signal strength, the linear Zeeman shift will cause no net shift on the clock's frequency.

With the goal of making an atomic clock with a size of less than the microwave wavelength (44 mm for ^{87}Rb), we chose to use CPT interrogation with balanced counterpropagating beams to maintain good control of the CPT phase versus position in volumes that are much smaller than a microwave cavity. Early CPT clock work by Ezekiel and colleagues also pointed out that the CPT phase could be made uniform by use of counterpropagating beams [11].

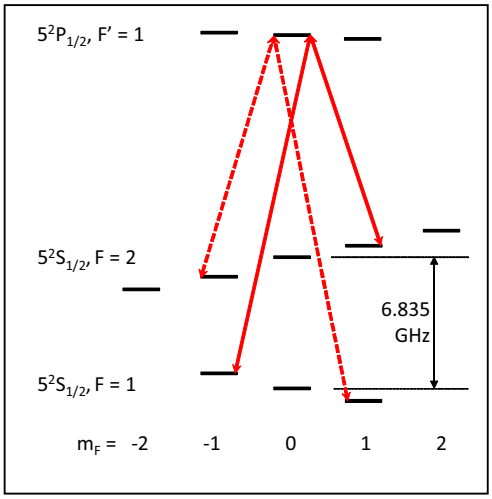

Figure 1. The energy-levels of ^{87}Rb probed with the double- Lambda lin ∥ lin technique. The two Lambda systems are shown. We use light resonant with the D1 transition at 795 nm.

II. EXPERIMENT

The apparatus has been described in detail previously [12], and will be briefly reviewed here. The system is based on a compact vacuum system that has a two-chambered design, with 2D and 3D magneto-optical traps (MOTs).

The CPT light is generated by use of an optical phase-lock loop built from two megahertz-broad DFB and DBR laser diodes, which produces a relatively clean, two-component spectrum that is free from zero- and higher-order modulation sidebands that cause light shifts without contributing to the CPT signal. The master laser is locked to the $F = 2 \rightarrow F' = 1$ transition on the D1 line at 795 nm via saturated absorption, and the slave laser is locked to a frequency near the $F = 1 \rightarrow F' = 1$ transition by locking the beat-note frequency between the master and slave lasers to an accurate reference, which enables accurate absolute frequency measurements for the evaluation of systematic shifts. So far, about 75 % of the power is in the coherent carrier. Work is in progress to increase this percentage.

The Ramsey spectroscopy performed here is different from traditional Ramsey spectroscopy in that the pulses are not $\pi/2$ pulses. Instead, the first pulse, which is typically 400 µs long and has an intensity of 20 µW/cm^2 for each frequency component, prepares the atoms in the dark quantum superposition state. Then the quantum superposition state evolves during the Ramsey period. The second pulse, which is typically 50 µs long, probes the relative phase of the quantum superposition state with respect to the light after the dark state has evolved during the Ramsey period. The clock signals are derived from the ratio of the transmission of the second Ramsey pulse to that of the first Ramsey pulse.

The Ramsey period, T_R, is typically less than 10 ms. The short interrogation periods allow for efficient recapture of atoms from cycle to cycle with 3 mm MOT beams, enabling a typical laser cooling-stage duration of 45 ms for loading about 10^6 atoms. For longer Ramsey periods, the fringes also begin to wash out because of magnetic-field gradients in the unshielded system combined with thermal expansion of the atomic cloud.

We observe Fourier-limited Ramsey resonances with a transmission contrast of 55 % and a typical absorption of 7 %. To lock the clock to the hyperfine ground-state splitting, we alternately probe the central fringe on opposite sides of the line and steer the clock to the central fringe. The short-term fractional frequency stability is currently limited to $4\times10^{-11}\tau^{-1/2}$. The atom shot noise contribution is $1\times10^{-12}\tau^{-1/2}$. The long-term fractional frequency stability is limited by magnetic field drift in our unshielded system to 2×10^{-12} for a 1000 second averaging period.

III. DOPPLER SHIFT MEASUREMENT

When the atoms are illuminated by a CPT light field from a single direction, a Doppler shift arises from motion of the atoms along the direction of the CPT beams during the Ramsey period. The phase of the CPT interrogation field varies linearly with position, and the moving atoms are pumped into the dark state and probed in different positions. The resulting frequency shift is given by

$$2\pi\Delta\nu_D = \Delta\phi/T_R = k_{HF}\cdot dz/T_R\,, \qquad (1)$$

where dz is the change in position of the atom along the propagation axis during the Ramsey period and $k_{HF} = k_2 - k_1 = 2\pi/\lambda_{HF}$, where $k_i = 2\pi/\lambda_i$ are the wavenumbers for the two CPT frequencies, and λ_{HF} is the microwave wavelength. When the atoms are probed with travelling-wave CPT beams along the direction of gravity, the fractional frequency Doppler shift from free fall from Eq. (1) is 1×10^{-10} for a 10 ms Ramsey period. To substantially reduce the shift, the atoms are probed with standing waves by applying CPT beams symmetrically from above and below.

When counterpropagating fields are applied to the atoms, the phase of the dark state created from the up and down CPT interrogation fields varies linearly with position as $\pm k_{HF}\cdot z$ [13, 14]. The slopes are opposite for the up and down beams. The dark-state phase versus position is visualized in Fig. 2. When the beams have equal intensity, the dark state phase is the average of the phases created by the up and down beams and is constant versus position and equal to the phase at the point where dark states created by the up and down beams have equal phase – the "equiphase point". The dark-state amplitude is modulated due to interference of the dark states created from the up and down beams, with maximum amplitude at the equiphase point.

Having balanced beams minimizes Doppler shifts when the signals from both the up and down beams are averaged during detection. In the experimental configuration described here, the absorption signals are detected independently and averaged. In a more elegant retroreflected configuration that we are currently using, the averaging is done automatically and only one signal is measured.

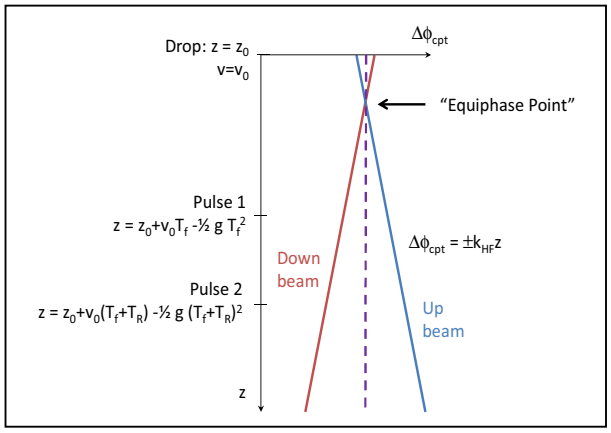

Figure 2. Phase versus height for dark states created by the up and down beams. The average phase for balanced up/down interrogation is shown as the dashed line. The atom position versus time after the drop is marked on the vertical axis. z_0 and v_0 are the atoms' mean initial position with respect to the "equiphase point" and the atoms' initial average velocity. The Doppler shift resulting from measuring the absorption signal on only one of the beams can be found from Eq. 1 and the position of the atoms during the second CPT pulse.

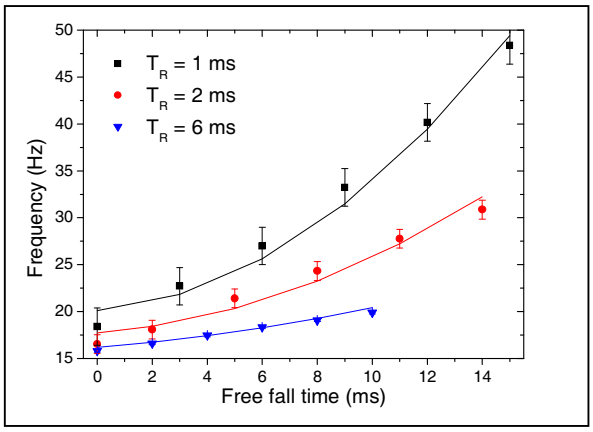

Figure 3. Clock frequency versus extra free-fall period for different Ramsey periods compared to the basic kinematic model for the Doppler shift. Only the signal from the downward beam was used to lock the clock, which maximizes the shift. The offset frequency is the only fit parameter. The three curves are slightly offset from each other because the Zeeman and light shifts were slightly different for the measurements with different Ramsey periods. The full scale (35 Hz) corresponds to a fractional frequency shift of 5×10^{-9}.

For our evaluation of the Doppler shift, independent up and down beams are simultaneously applied to the atoms, and absorption signals are measured for the up and down beams individually. The individual signals are then used to lock the clock to either the up beam signal only, the down beam signal only, or the average of the up and down signals. A variable extra period of free fall, T_f, is also inserted before the first Ramsey pulse to enlarge the shift so that it can be easily compared to a basic model.

Measurements of frequency shift versus free-fall period, Ramsey period, and probe direction show very good agreement with a simple kinematic model for the atoms' average position and velocity. Measurements of frequency shift versus free-fall period are shown in Fig. 3 for three different Ramsey periods when only the down beam signal was used to lock the clock. Detailed results from these studies are presented in a separate publication [15]. When the atoms are probed symmetrically along the direction of gravity, the total shift for the clock's typical Ramsey period of 6 ms is consistent with zero and has a current fractional frequency uncertainty of 1×10^{-11}. The shift magnitude should be more than an order of magnitude smaller when the probe direction is within 5° of a direction perpendicular to gravity.

***Abstract*— We present the realization of a highly compact absolute atomic gravimeter. The main purpose is to prove that atomic interferometers can overtake the current limitations of inertial sensors based on "classical" technologies for field and on-board applications. We show that the complexity and the volume of cold-atom experimental set-ups can be drastically reduced while keeping the performances close to the state-of-the-art, enabling such atomic sensors to perform precision measurements outside of the laboratory.**

Atomic interferometry, compact quantum sensor, atomic gravimeter, field gravimetry

I. THE MINIATOM PROJECT

The MiniAtom project is a feasibility study meant to improve concepts and technologies to support the operation of inertial sensors relying on atom interferometry outside of the laboratory. As a prototype we chose to realize an absolute gravimeter to measure the acceleration of the Earth's gravity. It is a collaboration that gathers two laboratories and four companies Iksea, Kloé, Thalès and III-V Lab. The work on the reduction of size concerns the gravimeter head, the laser and electronic system and the filtering of the ground vibrations.

II. SINGLE LASER BEAM ATOMIC GRAVIMETER

A. Atom interferometry to measure accelerations

The measurement of the acceleration of gravity (g) is performed with a Mach-Zender type $\pi/2$ - π - $\pi/2$ interferometer using stimulated Raman transitions to couple $|F=1, mf=0\rangle$ and $|F=2, mf=0\rangle$ hyperfine states of free-falling ^{87}Rb atoms [1]. After the loading of a 3D Magneto-Optical Trap (MOT) and an optical molasses stage, a micro-wave pulse is used to select the internal quantum state $|F=1, mf=0\rangle$. The interferometer is then performed during the free fall of the atoms. The maximum achievable duration is on the order of 100 ms. The readout of the output ports of the interferometer then simply consists in determining the population of the two states. This is carried out by fluorescence measurements and gives access to the interferometer phase shift [2].

In the free-fall referential frame of the atoms, the Raman laser frequencies are linearly Doppler shifted. We apply a frequency chirp to the laser in order to stay at resonance and exactly compensate for the Doppler effect. It is the measurement of the slope of this chirp that results in the determination of g.

B. Sensor head

The use of an innovative hollow pyramid as the usual retro-reflecting mirror of quantum inertial sensors enables to perform all the steps of the atomic measurement (trapping and cooling the atoms, performing the interferometer and reading out its outputs) with only one single laser beam instead of 6 or more usually [3]. We use a magnetically shielded two liter titanium vacuum chamber whose windows are indium sealed. The length of the interferometer (~ 10 cm) and the dimensions of the pyramid (2 cm) scale the size of the sensor head. This design allows for a loading of a few 10^7 atoms in 400 ms and a maximum interrogation time for the interferometer of 100 ms. The reduction of number of optical beams results in a drastic dicrease of the volume of the sensor head which fits in a cylinder 40 cm high and 20 cm in diameter. By comparison the transportable absolute gravimeter developed in SYRTE has a sensor head size of a 80 cm high 50 cm wide cylinder [4].

C. A highly compact laser system

The laser system is based on a single telecom laser diode, frequency doubled to achieve 780 nm for manipulation of the Rb atoms [5]. Low noise phase modulation with EOMs creates sidebands to perform Raman transitions. The laser is stabilized thanks to a saturated absorption set-up. The laser system provides about 180 mW of output optical power with a polarization quality of 4.10^{-3}. The use of off-the-shelf fiber coupled optical telecom components enables a tremendous reduction of the complexity and the size of the laser system down to a 70 cm^3 physics package. In the future even greater integration of this module is envisioned. Most of these components are Telcordia certified, which is of great interest for the reliability needed for a field operation of the apparatus.

Particular efforts have been made to push on the integration of the micro-wave frequency reference chain used to drive both the frequency reference at 6.835 GHz for the Raman transitions and to deliver microwave pulse for the quantum state selection. The Raman output has an agility of 500 MHz and delivers an output power of 25 dBm. The overall size is 14x14x23 cm and with a 30 W electrical power. Our chain features a phase noise that will only limit our relative sensitivity to gravity at the level

of 10^{-7} m.s^{-2}, as seen in Fig 1. We thus reach a trade-off between the integration in a two-litter package and the required phase noise level.

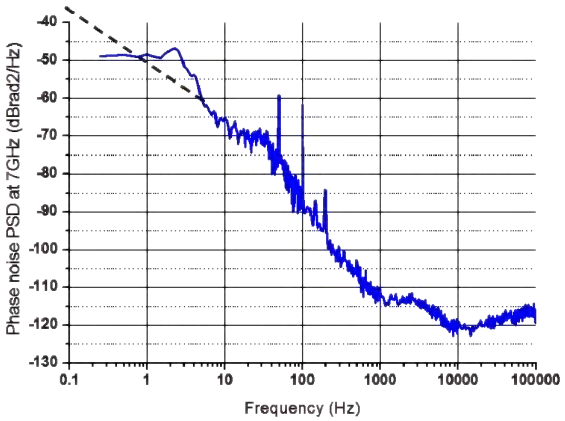

Figure 1. (Blue) Phase noise PSD of the compact frequency chain. (doted black line) Low frequency behaviour of the phase noise PSD measured separetly. The computation of the sensitivity function with this spectrum results in an atomic phase noise of 6 mrad, which corresponds to a limitation of the sensitivity in the 10^{-7} m/s2 level [6].

III. COMPACT QUANTUM SENSOR AND VIBRATIONS

An atomic accelerometer is sensitive to the motion of the referential frame of the laboratory with respect to the referential frame of the atoms. The phase shift at the output of the interferometer is a measurement of the relative acceleration between the atoms and the equiphase planes of the Raman lasers, which are referenced to the retro-reflecting mirror. As a result, any spurious motion of the mirror happening during the interferometer is recorded with the useful signal. In particular, ground vibrations with human or natural origins leads to a great limitation of the relative sensitivity of our measurement at a few 10^{-5} m/s^2 level. Previous works have addressed this issue by the use of active or passive isolation platform [1] or post signal processing [7]. However, these anti-vibration platforms are not convenient for field operation.

Within MiniAtom, we develop a method to perform a real time vibration compensation based on the post-processing signal method and without any platform. In this method, the atomic phase shift due to vibrations is compensated by a estimated phase shift applied on the Raman reference. In such method, one can site on the center of the fringe, where the sensitivity is the best. An auxiliary DC-coupled low noise mechanical accelerometer continuously monitors the motion of the retro-reflecting mirror. At each cycle, a 24-bits Analog-to-Digital Converter (ADC) acquires this signal during the interrogation in a synchronous manner. The sampled values are real-time processed with the sensitivity function of our instrument [7] by an FPGA board and a resulting atomic phase shift is calculated. This value is then sent to the DDS responsible for producing the frequency chirp of the laser line so that the pre-compensating phase jump is effective just before the third pulse closing the interferometer (less than 1 ms). This method enables to greatly improve the sensitivity of our measurement without any anti-vibration platform (see Fig. 2).

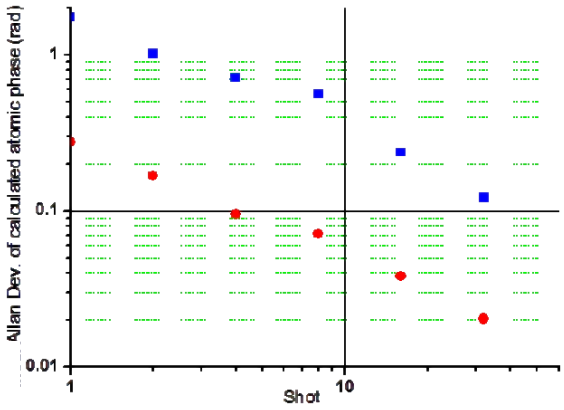

Figure 2. Allan deviation of the atomic phase at the output of the interferometer operating without anti-vibration platform during day-time:
(Blue squares) without real time compensation
(Red dots) with real time correction
Thanks to our method after 15 seconds (30 shots) of integration, the stability goes below the 40 mrad level, which corresponds to a 10^{-6} m/s^2 sensitivity.

IV. CONCLUSION

We target a relative sensitivity to acceleration of gravity below 10^{-7} m/s^2 at one shot in noisy environment like inside a big city [8]. This will allow to monitor time variation of g due to tides and to detect significant mass anomalies and mass displacements. We have shown promising long-term stability with a flicker floor on the 10^{-9} range and up to two day long measurements have been recorded with such architecture [3].

ACKNOWLEDGMENT

We would like to thank Franck Pereira Dos Santos for fruitful discussions and Michel Lours and Laurent Volodimer for the development of the real time vibration compensation module. We also would like to thank the French ANR agency and Région île de France (IFRAF) for funding.

***Abstract*—This paper presents a wafer-level integrated SAW sensor that uses conventional thin-film fabrication for the SAW, and the direct write of a thicker dissimilar metal for the antenna. An automated thermal spray process deposits the antenna conductor onto the SAW substrate, providing ease of fabrication, optimal film thickness, superior adhesion, and application specific materials. Results will highlight the direct printing of thick copper traces onto whole $LiNbO_3$ wafers. The design of a 915 MHz meandered dipole antenna with low mismatch loss and maximized radiation efficiency over a 7 % SAW fractional bandwidth is demonstrated. Experimental performance results of antennas fabricated on standard FR4 and on-wafer by the direct write process are contrasted. Temperature sensors are fabricated on YZ-$LiNbO_3$ and their wireless performance is evaluated.**

I. Introduction

For certain SAW sensor applications the challenge is building a wirelessly interrogatable device with the same lifetime as the SAW substrate. The design of these application intensive sensors is complicated by the degradation of device bond wires, adhesive, and antenna substrate. Previous results demonstrated the feasibility of fabricating an antenna directly onto a SAW substrate, but had a limited interrogation range [1]. For the first time, a direct write process is used to deposit the antenna conductor onto the SAW substrate, eliminating external interconnects. This plasma spray process has the advantage of rapid conformal fabrication without the need for a mask, leaves little waste material, and is automated with a high throughput. The combination of SAW and direct write technology offers a multitude of opportunities for new sensor and communication system embodiments.

The purpose of this paper is to demonstrate the effectiveness of the direct write process in fabricating integrated SAW sensors. A process was developed for writing thick-film copper to lithium niobate wafers that exhibits higher yield and superior adhesion, compared to traditional physical deposition methods. This process uses no adhesion layers and can be adapted to different substrates and metals depending on the application. A meander dipole antenna has been designed for use in conjunction with a 915 MHz RFID SAW sensor on YZ-$LiNbO_3$. Experimental performance results will contrast antennas fabricated using the direct write process to those made traditionally on FR4. Results presented will show an increase in range, compared to previous work, through an improved low loss design and the ability to deposit stable thick antenna traces. Proof of concept temperature sensors show comparable loss and bandwidth to traditionally packaged devices.

This work is partially supported by NASA SBIR contract #NNX11CB86C.

II. Direct Write Fabrication Overview

Several techniques are available for the direct write of patterns onto materials, including ink jet, laser assisted, and plasma spray; each process has its own drawbacks and merits. In this paper a proprietary high-definition plasma spray process is used that is being commercialized and developed by Mesoscribe Technologies. The spray system deposits by injecting material in powder form into a plasma flame and directing the molten material toward the substrate [2]. Dynamic collimation technology allows the line width to be controlled and other process parameters, gas flow and power level, control the density and structure of the deposited film.

A strength of the Mesoscribe process is the ability to conform onto non-planar surfaces while maintaining high throughput production for research or commercial products. A variety of materials can be deposited including dielectrics, metals, or sensor alloys. Materials can be stacked for integrated packaging and electrical isolation, eliminating adhesives. Films are robust and high temperature tolerant. Traces

are typically ≥25 µm in thickness and trace widths are actively controlled at ≥250 µm. The width can also be laser scribed after deposition to a width of 25 µm. Deposition is fully automated and performed by a 6-axis robotic control spray head, as shown in Fig. 1a.

A. Direct Write to SAW Substrate

Using these direct write techniques for SAW sensors, or general microelectronic fabrication, has several unique advantages. Traces are able to write up and over a variety of surfaces and at varying angles; Fig. 1b shows a copper trace written from a circuit board, up the die adhesive, and connecting to a SAW delay line. These films adhere well to substantially thinner dissimilar metals, aluminum in this example. For SAW sensor applications this eliminates bond wires and is a cost effective way to realize high temperature antenna traces and interconnects. The process can also be used to stack traces inside of direct write dielectric layers or inside a trench of the substrate material.

A process has been developed that successfully deposits high quality copper traces onto $LiNbO_3$. Fig. 2a shows an example of a 1 mm wide copper trace written onto a 3 inch diameter wafer. No surface preparation or trenching is required prior to deposition. Copper adheres well without an adhesion layer, passing a simple tape test. The copper is nominally 20 µm thick. Measurement of film thickness by contact profilometer yields an average surface roughness of 2.1 µm, shown in Fig. 2b, which is also evident in the optical image of the copper. These thick copper lines successfully bond to the 80 nm electron beam evaporated aluminum pad. The copper trace has been laser trimmed to provide a taper to the 0.5 mm wide aluminum probe pads of a SAW transducer. Measured sheet resistance is approximately 1.2 mΩ/□. These thick conductors are important in reducing resistive losses of microwave transmission lines because of skin depth effects [3]. A thin conductor, closer to the skin depth, will exhibit higher losses. For the frequency of 915 MHz used throughout this paper, the skin depth is 2.2 µm or 10 % of the total thickness.

(b) A surface scan of the Cu/Al junction on $LiNbO_3$ performed by contact profilometer showing the relative surface heights and roughness. Average step height is approximately 20 µm for the copper and 80 nm for the aluminum.

III. Antenna Design

With a process available for depositing copper onto lithium niobate, an antenna design is required that solves the high loss from previous iterations and exploits the stability of the new metallization. The main considerations when designing an antenna for a SAW sensor is matching the transducer bandwidth, which is a function of device coding and expected temperature variation, and being an efficient radiator. A SAW substrate is not ideal for meeting these requirements due to its high relative permittivity and also the uniaxial anisotropy between the crystal axes.

This work used lithium niobate because of the availability of large wafer sizes, high SAW coupling, and previous delay line SAW design experience. There is a 2:1 difference in permittivity between the X or Y ($\epsilon_{11} = 45.6$) and Z ($\epsilon_{33} = 26.3$) cuts [4]. These properties make the use of a patch antenna difficult due to the high permittivity and thin substrate giving a narrow bandwidth and low efficiency. A loop antenna would be a natural choice for its inductive input impedance; however, for a single loop the efficiency is poor. Therefore, for proof-of-concept a dipole was chosen for an antenna embodiment.

Standard YZ-$LiNbO_3$ wafers come in sizes up to 100 mm, which is too small for a half-wave dipole at the target center frequency of 915 MHz. Typically electrically small antennas are narrowband and the radiation resistance is small, making them inefficient. A meander-line dipole was chosen for miniaturization as the radiation efficiency is acceptable for a small antenna [5] . The example antenna used in this paper is shown schematically in Fig. 3. A fixed straight dipole length is initially chosen and the impedance is determined using Ansys HFSS full-wave simulator. Meander sections are then added, effectively adding shunt capacitive elements to the dipole, to detune the large capactive reactance of the antenna. By increasing the height, h/2, and decreasing the width, w, of each meander will the antenna resonant frequency will decrease [6].

Final design optimizations were then carried out using HFSS with the goal of minimizing the mismatch loss at the SAW/Antenna interface. HFSS allows uniaxial dielectric anisotropy to be incorporated into the simulation. Simulated gain for initial antenna designs had a maximum gain of 1 dBi

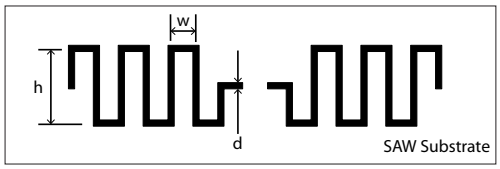

Fig. 3. Schematic representation of the meander line dipole used for this paper.

in a 50 Ω system. In spite of that gain the SAW tag will not be a 50 Ω system and the mismatch loss will need to be determined between the antenna and capacitive transducer impedance. The reflection coefficient at this interface is calculated by

$$\Gamma = \frac{Z_S - Z_A^*}{Z_S + Z_A}, \tag{1}$$

where Z_A is the antenna input impedance given by simulation and Z_S is the input impedance of the SAW found by RF probing. By properly choosing the inductive antenna reactance, the impedance of the antenna at the SAW interface will be purely resistive. Fig. 4 plots the response of the probed SAW transducer of interest and the designed antenna layout onto a Smith chart. The SAW device utilized has a 9 pair transducer, quarter wavelength electrodes, and 100 λ beamwidth. Impedance is adjustable for different transducer configurations and center frequency.

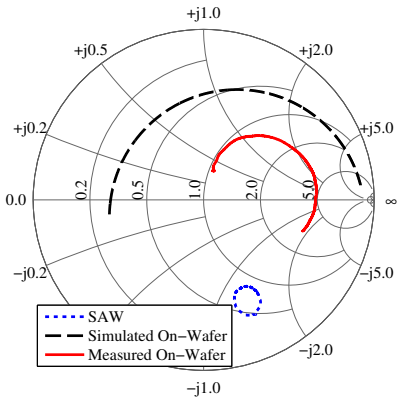

Fig. 4. Impedance Smith chart comparison of the response from an RF probed SAW device, simulated meander dipole antenna, and measured on-wafer antenna.

The calculated mismatch loss of the designed antenna is shown in Fig. 5. The loss at device f_0 is 1.5 dB. Predicted radiation efficiency is 82 %. The final antenna design has a d of 1 mm, h of 11 mm, w of 4 mm, and 10 total bends. The overall length of the antenna is 60 mm, which is short enough to fit 3 antennas onto a 3 inch wafer.

IV. Experimental Results

Several experimental devices were fabricated for testing as integrated sensors and also for experimental verification of the stand-alone antenna. Standard contact photolithography was utilized to define SAW reflective delay line sensors. Minimum

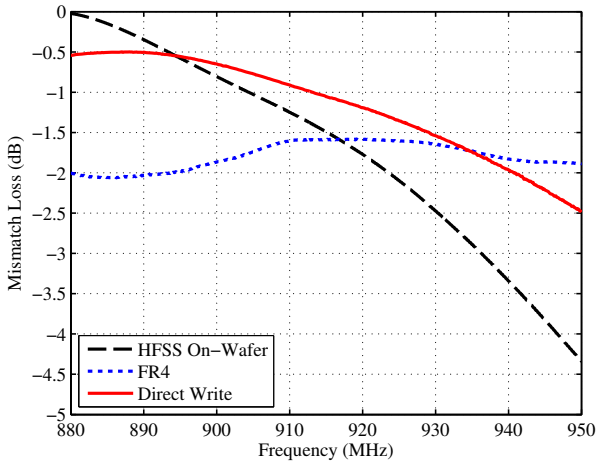

Fig. 5. The predicted and extracted mismatch loss at the SAW/antenna interface found by HFSS simulation and measurement of both a traditionally packaged FR4 device and on-wafer direct write device.

feature size of the SAW device is 0.9 µm, and in order to achieve strong mask contact, fabrication is required prior to antenna deposition. SAW metallization is Ti/Al deposited by electron beam evaporation. A photoresist mask is applied to protect the SAW propagation path from debris generated when depositing and trimming the antenna. Antennas have been written at various thicknesses and levels of corner trimming. However, antennas shown in this paper are only trimmed to taper to the SAW pads and for any over spray on either end, allowing higher throughput. All copper shown is approximately 20 µm in thickness. An example diced SAW/Antenna device is shown in Fig. 6, and compromises the middle third of a 3 inch diameter $LiNbO_3$ wafer.

A. Antenna Characterization

After fabrication, the SAW transducer was removed for stand-alone antenna characterization. Impedance was measured at the input to the antenna, and Fig. 4 shows the results. Measurements obtained follow a similar trend as the simulation.

The measured antenna impedance was used to calculate the mismatch loss at the SAW/Antenna interface. The SAW impedance is determined from RF probed results taken prior to antenna fabrication. Fig. 5 compares the mismatch of the on-wafer antenna to that of a simple dipole fabricated on a traditional FR4 substrate. These results do not consider added

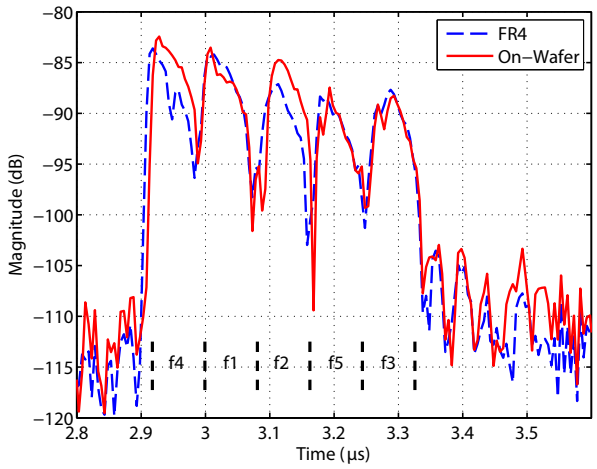

Fig. 7. A time domain comparison of the separate measurement of two SAW sensor configurations, interrogated wirelessly at 20 cm by a vector network analyzer. Each device has approximately 7% fractional bandwidth and the relative center frequencies of each coded reflector is shown.

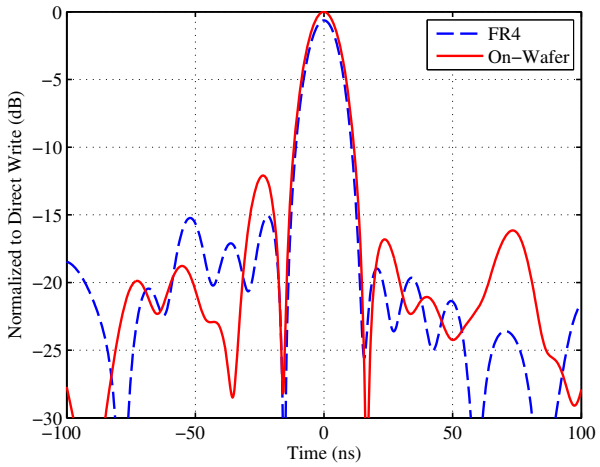

Fig. 8. Matched filter correlation of an integrated on-wafer device and a standard packaged device. Both responses are normalized to the integrated device for comparison. Measurements were taken wirelessly at 20 cm by a vector network analyzer.

parasitics from the device packaging required when mounting to the FR4 antenna.

B. Wireless Sensor Measurements

Fig. 7 compares the wireless measurement of similar wide-band reflective delay line temperature sensors connected to direct write and FR4 antennas. A vector network analyzer was used to wirelessly interrogate each device at a distance of 20 cm. Each device has a coded reflector bank with relative orthogonal reflector frequencies shown. Devices are designed to have 7% fractional bandwidth and a center frequency of 915 MHz [7]. The distributed frequency reflector bank of these devices illustrate the relative bandwidth of each SAW/Antenna combination. Device designs are identical and minimal SAW fabrication differences are assumed. Loss is comparable between the FR4 and integrated devices throughout the band of interest.

An ideal matched filter was generated for the two measured devices. Fig. 8 compares the relative correlation of the matched filter to the data obtained wirelessly at 20 cm. As expected the width of the two correlation peaks are the same. There is a 0.5 dB decrease in correlation amplitude between the FR4 and direct write because of decreased returned SAW signal level because of fabrication differences. Compared to previous published results in [1] loss has decreased approximately 25 dB. These results highlight the ability of the on-wafer antenna to operate in a coded multi-sensor environment without added attenuation.

V. Conclusion

This paper demonstrated a novel SAW sensor structure that integrated a traditional thin-film SAW device and a direct write antenna onto a SAW substrate. For example devices, copper was used for the antenna conductor and lithium niobate for the substrate. A process has been developed that produced reliable, stress free thick film traces that adhere well to the SAW substrate. A meander dipole antenna was designed for use in conjunction with a 915 MHz SAW sensor. Results shown highlight the low antenna loss and also compare well to results from a traditionally packaged and interrogated device. The Mesoscribe direct write process presented is adaptable to different substrates, conductors, and implementations. Direct write technology has many SAW sensor applications, such as high temperature antenna integration and package free strain sensors.

***Abstract*—SAW tags and sensors often operate in 2.45 GHz ISM band using relatively narrow frequency Band = 82.5 MHz available there. The characteristics of these devices can be improved using the ultra wide band (UWB) technology. We have developed prototype devices operating in 200 MHz-400 MHz and 2000 MHz - 2500 MHz UWB frequency ranges. The UWB reader operating in continuous wave radar mode for 2 GHz range was developed and manufactured. The first remote measurements have shown that we get compressed RF pulses of about 2 ns duration, which include unique RF filing of a few sinusoids with amplitude modulation. The precise measurement of the pulse position is possible by correlation methods, avoiding the phase ambiguity problem.The temperature is measured with a precisions of about $0.1\,^{\circ}\mathrm{C}$ degree Celsius. Only 2 reflectors are necessary for such a sensor. The correlation method works even in multi-path environment with strong reflections form metal objects. The short compressed pulses allow measuring a number of sensors simultaneously just separating them in time. For tag application, we measure and identify three different tags at the same time without collision problem, this number can easily be increased. For such limited number of tags there is no "collision" problem.**

I. Introduction

Surface Acoustic Wave (SAW) tags operate on the basis of converting incoming electromagnetic energy into an acoustic propagating wave through piezoelectric effect. As such, they act as truly passive sensors since the acoustic velocity is dependent on the physical environment of the tag. Furthermore, they can be remotely interrogated over large distances ranging up to 10 m thanks to an interrogation reader operating through principles similar to RADAR, radiating less than 100 mW in order to comply with radiofrequency emission regulations [1].

Most sensing applications require that a single reader probes the response of multiple sensors with identification capability. The classical issue of collision lies in the multiple responses recovered simultaneously by the reader as a single interrogation pulse has been emitted [2]: various multiplexing strategies have been implemented including time domain multiplexing (TDMA [3]), spatial domain multiplexing (SDMA [2]), and even spatially separated tags [4]. and frequency domain multiplexing (FDMA [5]). SAW delay lines being intrinsically wideband devices, only the $B = 82.5\ MHz$-wide 2.45 GHz unregulated Industrial, Scientific and Medical (ISM) complies with the required bandwidth. Because of the rather high acoustic propagation loss in this frequency range, about 6 $dB/\mu s$, the possible code signal duration is limited to $T < 3\mu s$. Although the theoretical informative capacity, proportional to $B \cdot T$, is 200 bits, recent practical implementations use 30 bit [6]and the measured devices with 64 Data Bits, and 16 Bit Error Detection were demonstrated [7]. The collision problem is not addressed in these considerations and only allow for a fraction of this information capacity to be used by any single sensor at a given time. An alternative approach consists in using the Ultra-Wide-Band (UWB) strategy [8] is well suitable for SAW-tags and sensor applications [9]. The extended frequency band, ranging up to $B = 500$ MHz around 2.25 GHz, yields significantly increased informative capacity, provinding the entropy needed to prevent collision and allow for tag identification. It will be experimentally shown in this paper that thanks to short compressed signals, $1/B \simeq 2\ ns$, hence including only a few RF signal periods, the phase ambiguity is avoided [10], allowing for precise measuring delay between 2 pulses. The narrow compressed pulse is compatible with an increased number of sensors operating simultaneously, and measurements in an environment with strong reflections and multipath propagation.

II. Low frequency prototype

Due to techological constraints, initial sensor developments were performed in order to operate in the lower frequency range 200 MHz-400 MHz [6] and are discussed here to demonstrate basic principles of UWB readout. A single crystal (YXl)/128° $LiNbO_3$ substrate is patterned with Interdigitated Transducer (IDT) AlCu electrodes along a geometry allowing for Linear Frequency Modulated (LFM) chirp generation (Fig. 1). A bandwidth B close to 200MHz is covered during a dispersive delay $T = 0.5\ \mu$s with a negative rate of the frequency change in order to prevent high frequencies from being scattered by electrodes generating the low frequency signal and bulk wave conversion.

The selected interrogation scheme is based on recording the frequency dependent reflection coefficient S_{11} with a network analyzer. Digital signal post-processing involves multiplying the frequency domain response with the spectrum of the emitted pulse, matched to the electrode pattern, in order to perform pulse-compression. Then, an inverse Fourier transform yields

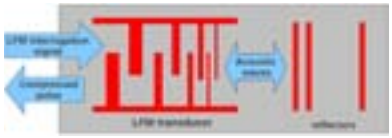

Fig. 1. Sensor layout including a chirped IDT and 3 reflectors.

the time domain response of the resulting dataset, followed by an auto-correlation in order to extract the time duration between successive echoes. In this case the reflected pulses are compressed (Fig. 2) to a duration of about $1/B \simeq 5$ ns associated with a pulse amplitude increase of $B \cdot T = 20$ dB.

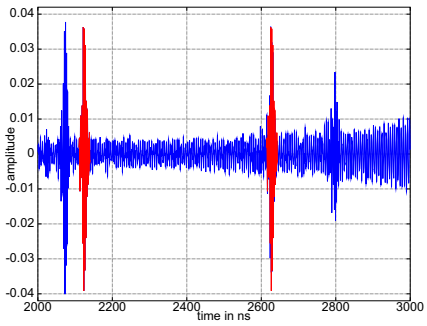

Fig. 2. Compressed responses.

Signal coding by the tag as a chirped returned response provides efficient means of getting rid of enviornmental clutter. The pulse compression gain of 20 dB only affects the signal returned from the sensor and not from reflections on passive reflectors, hence reducing the 1 μs delay usually included in the beginning of the interrogation to allow for clutter to fade out. This signal to noise ratio gain is significant since averaging does not allow to get rid of the passive reflector echoes which are recorded coherently with the emitted pulse in addition to the sensor response.

III. Correlation Measurement of Delays

UWB tags are characterized by the short duration of compressed pulses. As opposed to ISM band SAW-tags with $B = 80$ MHz whose interrogation pulse is at least 30 RF period long, the compressed pulse under investigation here only includes a few oscillations (Fig. 3). All echoes exhibit similar shapes and are well suited for a cross-correlation delay measurement [9], while we observe the lack of phase ambiguity thanks to the few periods included in the compressed pulses.

IV. Temperature Sensor

Acoustic velocity and hence delays between reflections are changed with temperature. The above described low frequency device with reflective delay line has been used for wired temperature measurements. The described signal processing schemes is applied to a sensor located in a temperature controlled oven and cycled from -5°C to +130°C (Fig. 4).

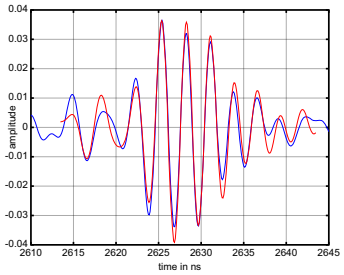

Fig. 3. 2^{nd} (red) and 3^{rd} (blue) pulses from Fig. 2 superimposed.

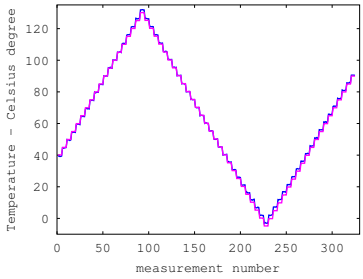

Fig. 4. Temperature calibration: SAW sensor (blue) and Pt100 reference temperature probe (red).

The temperature measurement resolution is estimated $< 0.3\,°C$ by comparing records with a reference Pt100 probe. Hysteresis behaviour attributed to the hard glue used for bond the SAW chip into a ceramic package is also observed.

V. 2.0 GHz - 2.5 GHz Devices

The 2.0 to 2.5 GHz frequency range is attractive for two main reasons: the band is low enough to allow for SAW devices to be mass-produced using optical lithography, and recently introduced US standards allow for increased emission power by the reader associated with increased interrogation range. Therefore, SAW sensors operating in this range were developed and manufactured as discussed here. One such device includes an original design scheme in which 6 transducers with 100 MHz passband are electrically connected in parallel are patterned allong different tracks (Fig. 5).

Fig. 5. Layout of the parallel track architecture.

Such a design was selected since reflectors are adapted to each sub- channel frequency and designed to strongly reflect the acoustic wave, hence providing low losses with a gain of up to 20 dB with respect to the LFM geometry. Simulation of the interrogation strategy is performed by probing (convolution) the sensor with a time-reversed version of its impulse response. The generated compressed signal is about

2 ns long and -11 dB losses are observed by comparing the amplitude of the compressed peak with the amplitude of the interrogation signal. However, strong sidelobes (Fig. 6) around the compressed pulse are a significant hindrance for practical use as they might be misidentified with weaker responses of other devices.

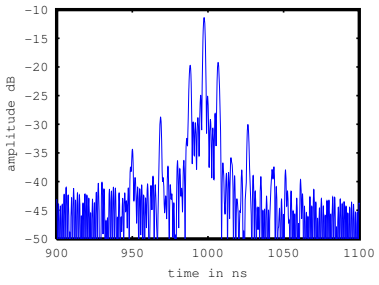

Fig. 6. Compressed pulse - 6 track device interrogated with matched signal

Chirped sensors including LFM transducer have been designed (center frequency 2250 MHz, $B = 500$ MHz, $T = 0.1$ μs). For such devices the efficient number of finger pairs synchronously operating at each given frequency is about $f_c \cdot T/\sqrt{(B \cdot T)} \simeq 32$ is too big for 128 ° $LiNbO_3$ substrate. As a result the waves are very intensively generated at the end of the structure and the generated signal exhibits strongly non-uniform amplitude. Furthermore, its phase deviates too much from the ideal quadratic dependence on time. To reduce these effects, additional electrodes with weighted aperture were added at the beginning and at the end of the chirp transducer (Fig. 7). The transducer is used in both directions, which helps to balance the level between the differents echoes.

Fig. 7. LFM weighted operating in both directions.

Although the response is not uniform, considering SAW-tag as a filter and simulating its interrogation by recording each packaged device transfer function and probing it using ideally matched signal (the time reversed impulse response, but with normalized unit amplitude) we observed compressed pulses with durations of about 2 ns.

Such procedures simulate a wireless reader operation and gives accurate loss levels in compressed pulses with respect to unit amplitude of the interrogation signal at the input of the tag.

VI. Wireless reader

We have used a newly developed interrogation device ("reader") which operates as following the principles of a frequency stepped continuous wave (FSCW) RADAR. For measuring reflected signals at each frequency step, the reader sends a fixed frequency signal during 7 μs.

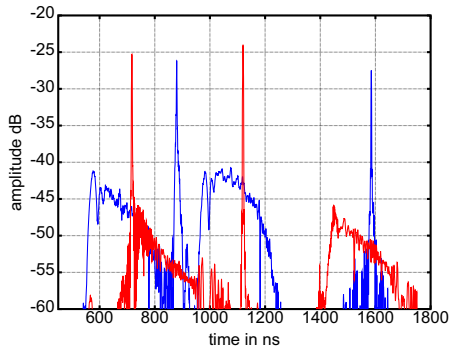

Fig. 8. Compressed pulses for LFM tag, blue curve for transducer operating for low to high frequencies, in red the same transducer in the opposite direction

UWB measuring systems are allowed to radiate power of -41.3 dBm/MHz [8], or about 0.07 μW/MHz, but measured within 1 ms averaging durations. If we measure 1 frequency point every 1 ms, the allowed instantaneous power of the interrogation signal is about $1000/7$ times higher, that is 10 μW or -20 dBm. Datasets provided by the reader are similar to the reflection coefficient S_{11} recorded by a network analyzer but compatible with a wireless readout scheme thanks to the switched emission/reception sequence.

VII. Remote measurements of the UWB sensors

Fig. 9 illustrates the simultaneous wireless measurement of 3 sensors designed along patterns similar to those shown in Fig. 7, with all reflectors on the same side of the transducer.

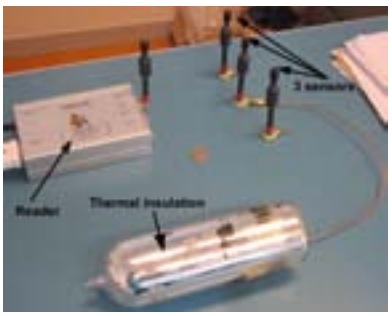

Fig. 9. Remote reading of 3 sensors: one sensor is shielded from room temperature fluctuations in a Dewar bottle.

These 3 acoustic tags are used as sensors for monitoring ambient temperature (Fig. 9). Anticollision is achieved by time multiplexing since all 3 echoes from the 3 sensors are time shifted (Fig. 10).

The temperature is extracted from the delay variations between echoes 1 and 2. No special calibration procedure was applied: the reference temperature point was taken from calibration measurements and assuming a linear delay variation with temperature, using the tabulated CTF_1 coefficient of (YXl)/128 ° $LiNbO_3$ (Fig. 11). The resulting temperature resolution is better than 0.1 ° C, while bias is attributed to the basic processing scheme which does not involve CTF_2.

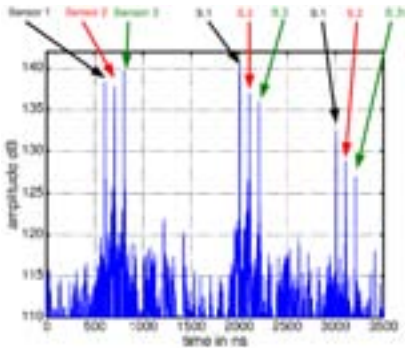

Fig. 10. Remote reading of 3 sensors

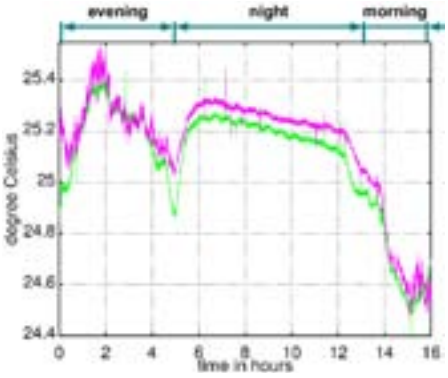

Fig. 11. 16-hour long remote reading of 3 sensors along the setup shown in Fig. 10.

The wireless interrogation range in a free space environment ranges from 1 m for the LFM chirped sensors to 3 m for the parallel track design.

The presence of reflections, possibly stronger than the SAW echoes, typical in industrial applications of SAW tags and sensors, complicates the operation of SAW-tag and SAW-sensor systems. Furthermore, due to multipath propagation, the sensor antenna receives multiple copies of the interrogation signal with different delays. The sensor, being a linear device, processes all of them and the signals returning by different paths to the reader antenna are further spread in time. As a result, instead of one compressed signal of duration $1/B$, a mixture of interfering signals of much longer duration is recorded.

Using the processing techniques discussed above, simultaneous remote temperature measurement of 3 sensors located in a closed oven was performed in the 0 °C to 40 °C range (Fig. 12).

VIII. Conclusion

The main advantage of using the UWB signals for SAW-tags-sensors is the available wide frequency band resulting in a possibility to use very short pulses either directly, or, preferably, after corresponding signal processing procedure. The large informative capacitance $B \cdot T$ can be partly used directly in SAW-tag/sensor and the processing gain of the order of 20 dB can be obtained. The time delay between

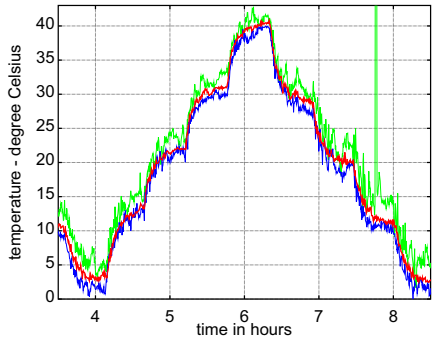

Fig. 12. Temperature recorded from 3 sensors located simultaneously in a closed oven.

the compressed pulses is measured by correlation methods, with the same precision as given by phase measurements, providing a temperature measurement resolution of 0.1 °C. The wideband signals allow measuring responses in strongly reflecting environment, such as inside a metal box.

The perspectives of using UWB technology in truly passive SAW-tag/sensors has been demonstrated, with a proposed solution to anticollision by a time domain multiplexing approach applied to 3 sensors.

***Abstract*- Electric field measurement is not only important for the lift-off of guided missiles, rockets or spacecraft, but is also widely used for safety in urban environments (preventing pollution), super clean labs, oil refineries, bunker stations, explosive plants, wallpaper factories, mining, and in forest fire prevention Various electric field sensors have been developed to monitor electric field intensity on the ground or in the air, to implement effective survey and analysis, to provide reliable methods and basis for meteorological support, and to avoid the destructive effect of a high electric field. This article presents a wireless field sensor system based on a langasite resonator. By using frequency conversion techniques, the system converts the ultrasonic signal of the sensor to a microwave signal, so that it can transmit the signal wirelessly without digitization. The sensor uses passive components which modulate and transmit the full wave form of the ultrasound signal. A high voltage circuit is constructed in order to measure the frequency shifts of the langasite resonator caused by the applied high voltage. A doubly-rotated plano-plano *langasite resonator (YXlw)θ/Φ 45°/85°operating on* its third overtone (6.304844 MHz) was used as the sensor core in the test of wireless transmission system. A network analyzer was used to test wireless system data and compare it with similar wired system data. The comparison shows a good agreement This system has many potential applications and can also be transformed to other types of sensors.**

I. INTRODUCTION

Electric field measurement is critical in many areas of scientific research and engineering technology, especially in electric power systems. Measurements may be performed using an in-situ electric field sensor in the high voltage power system. In the past, many types of electric field sensors have been proposed. Li designed multi-channel fringing electric field sensors for imaging [1]. Vasa has developed an electric field sensor based on the second harmonic generation with electro-optic materials [2]. Roncin proposed an electric field sensor using electrostatic force deflection of a micro-spring supported membrane [3]. Kaplan performed a theoretical analysis for a low-cost DC electric field sensor [4]. Passard used Pockels effect to design and optimize a Low-Frequency electric field Sensor [5]. Bahreyni has analyzed and designed an electric-field sensor that is micromachined [6]. Moreover, Lee integrated an electric field sensor by combining a segmented modulator electrode and a reflective type $LiNbO_3$ Mach-Zehnder modulator [7]. Electric field measurement provides reliable methods and a basis for meteorological support , mitigation of the destructive effect of a high field, and lift-off of spacecraft [8-11].

Langasite is a promising kind of new piezoelectric material combining many advantages of quartz, barium titanate and lithium niobate in having high electromechanical coupling and good frequency-temperature characteristics. In this paper, we use a langasite bulk acoustic wave resonator to make an electric field sensor. A frequency conversion technique which is similar to a recent work [12] is used to convert the ultrasonic signal to a microwave signal so that the signal can be transmitted wirelessly. The sensor uses passive components which modulate and transmit the full waveform to transmit the ultrasound signal. In order to test the sensor's performance, a high voltage circuit is constructed to isolate the destructive effect of a high electrical field. A doubly rotated plano-plano langasite resonator (YXlw)θ/Φ 45°/85°operating on its third overtone (6.304844 MHz) was used as the sensor core in testing the wireless transmission system. A Bode 100 network analyzer was used to test wireless system data and compare it with similar wired system data. The wired and wireless test results both exhibit a good agreement. Many aspects of possible applications and other types of sensors can be achieved by using the wireless langasite resonator electric field sensing system.

II. PRINCIPLE OF OPERATION

A. Electroelastic Effect

The fundamental mechanism for the langasite electric field sensor is based on the electroelastic effect for resonators with circular shape. The electroelastic effect is defined as $\frac{df}{f \cdot E}$, where df is the frequency shift, f is the resonant frequency, and E is the applied DC electric field. A measurement of this effect for several doubly rotated langasite resonators can be found in [13].

B. Design of the langasite Resonator

978-1-4799-0342-9/13/$31.00 ©2013 IEEE

The core of the force sensor is a doubly rotated langasite resonator with gold keyhole electrodes. Table I lists the design parameters for this resonator.

Table I. Design parameters of the langasite resonator.

Cut angle	Diameter (mm)	Thickness (mm)	Fundamental frequency (Hz)	Configuration
YXlw θ/Φ 45°/85°	13.00±0.075	0.65±0.075	2101554±6	Plano-plano

C. The sensing system

Figure 1 shows a diagram of the sensing system. The langasite resonator is clamped in a standard HC-50 resonator holder. A Gamma ES20P-5w high voltage power supply is used to apply the high DC voltage (0-2.5kV) to the resonator. To avoid having the HF oscillations short-circuited by the power supply, a 3.3 MΩ resistor is connected between the sample and the high voltage DC source. Additional resistors are placed to provide a controlled path to ground in the event of a high-voltage DC discharge. A 0.001 μF blocking capacitor is connected between the sample and the network analyzer to isolate the high voltage supply from the frequency measurement system. The electronic circuit and the resonator sample are placed in a plastic electronics enclosure, and the enclosure is covered by a thick insulating glass layer. A Bode 100 network analyzer is used to transmit the excitation signal through a wire and to the langasite resonator and receive the signal from the langasite resonator wirelessly. The wireless transmission system is described in detail in [14].

III. EXPERIMENTAL MEASUREMENT

A. Measurement Procedure

The frequency sweep is generated by using the Bode 100 Network Analyzer whose experimental settings are the same to maintain comparable data in every experimental measurement. The antennas of SDS are mounted to make the receiver transmitter pairs lined up with identical orientations. The distance between the two antennas is 1.98 M. The start and stop frequencies are set to 6.300000 MHz and 6.310000 MHz with a center frequency of 6.305000 MHz and a span of 10 KHz. The sweep mode is set to linear with 1601 data points. The output signal level is set to 13.00 dBm. The attenuator is set to 20 dB for CH1 and 30 dB for CH2 with a receiver bandwidth of 30 Hz. The reference resistance is set to 50.00 Ω. The Gamma ES20P-5w high voltage supply is set from 0 to 1000 V in 100 V increments. The Bode 100 Network Analyzer begins to take measurements once the high voltage device starts to apply the voltage load. The frequency spectrum at each voltage step is recorded and the resonance frequencies are measured. Both wireless and wired transmission tests are performed and compared.

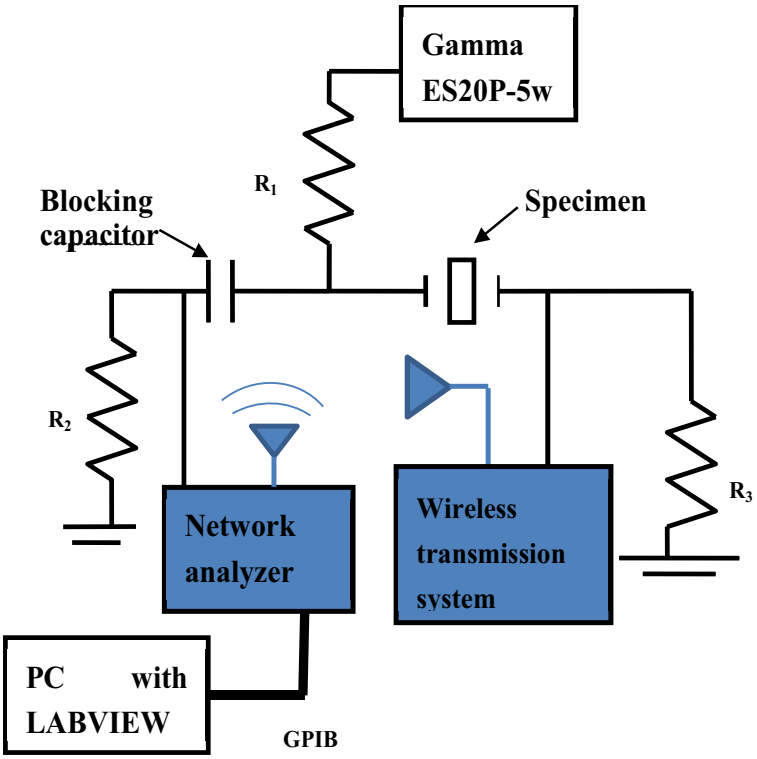

Fig. 1. Schematic diagram of the sensing system. The resistor R_1 is used to prevent an RF short-circuit across the resonator, while resistors R_2 and R_3 act to limit any damage in the event of a high-volatge DC discharge. The blocking capacitor is used to block the DC voltage applied to the specimen from the network analyzer used for the frequency measurements. The network analyzer is used to excite the langasite resonator through a wire and receive the signal from the langasite resonator wirelessly.

B.Experiment Result

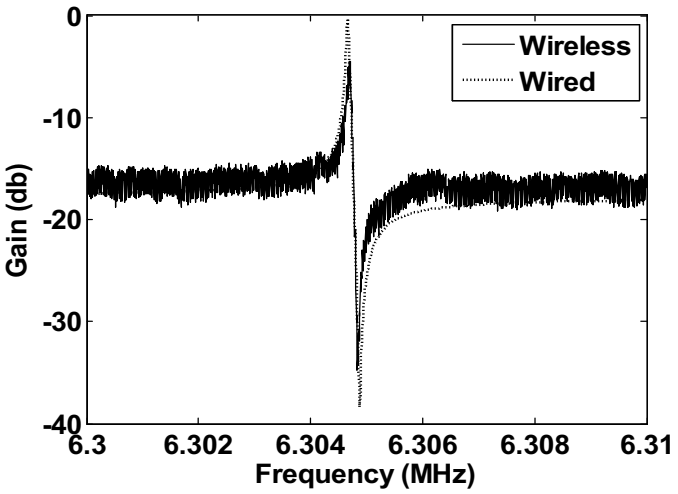

Fig. 2. A comparison between the wired and wireless frequency spectrum at zero voltage.

A comparison between the wired and wireless frequency spectra of the resonator at zero voltage is shown in Figure 2. Figs. 3-4 show the results of voltage-frequency relation. The compared data shows that the frequency spectrum is in good agreement and relationship between a voltage and the resonant frequency is linear as expected. We also found that there is a constant frequency offset of 20~40 Hz in resonant frequencies between wired and wireless data which is most likely arising from electrical loading effects on the crystal by the circuits. This frequency offset can easily be corrected for by a simple calibration, as the data is simply offset by a constant frequency. It is shown in Table II that the sensitivity (frequency vs. voltage slope) for wired and wireless operation is in good agreement.

IV. CONCLUSION

A prototype wireless langasite BAW electric field/voltage sensor was demonstrated experimentally using frequency conversion techniques. Good agreement between wired and wireless measurements can be achieved using a simple frequency offset calibration. The wireless transmission of a signal used in the experiment has the potential to be used in many other applications as well. Future work will be focused on making the system completely wireless and minimizing the components size.

***Abstract*—A novel plate torque transducer based on UHF SAW resonant sensing elements has been developed allowing an easy aftermarket installation of passive wireless torque sensors on large diameter shafts by means of clamping. A design of a large diameter RF rotary coupler for wireless interrogation of the transducer was proposed that had a gap of 20 mm between the stator and the rotor and was insensitive to axial and radial misalignment as well as the rotation angle. The two plate transducers and the RF coupler were installed on a high-speed shaft of a wind turbine gearbox. The torque sensor accuracy achieved after calibration on a test shaft was better than 1% full range within the temperature range from +20°C to +80°C.**

Keywords-torque sensor; SAW resonator; torque transducer; RF rotary coupler; wind turbine gearbox

I. INTRODUCTION

Wind farms are at the moment one of the fastest growing sources of renewable energy. However, the cost of electricity generated by offshore wind turbines is still noticeably higher than that for fossil fuel power plants, and maintenance cost is an important contribution to it. Up to 80% of this cost is associated with unexpected failures of rotating components that could be prevented by predictive and corrective maintenance based on adequate condition monitoring systems. Currently they mainly include vibration, temperature and oil debris sensors [1] but there is also a clear demand for sensing torque. This would allow a more accurate estimation of load on rotating parts, correlation of this load with the data obtained from other sensors and overload protection.
